Sequence variations in mitochondrial DNA have been used to study human evolution, forensic examinations and disease association studies such as Parkinsons and Alzheimers disease. Resequencing of the genome is often carried out using homebrewed methods, while data analysis continue to be a major bottleneck. We present here an integrated solution to resequencing of mitochondrial DNA using Applied Biosystems VariantSEQR Resequencing System and SeqScape Software v2.1.1. This system solution provides researchers the convenience of accurate variant identification with simplified data analysis and reduces the time required for many laborious and repetitive steps. Applied Biosystems SeqScape software v2.1.1 was designed specifically to address the needs of analyzing and identifying sequence variations accurately and reliably, which are critical requirements for resequencing applications such as mutation detection and analysis, SNP discovery and validation, pathogen sub-typing, allele identification, and sequence confirmation. The VariantSEQR Resequencing System includes resequencing sets with predicted confidence values, robust protocols to streamline experimental procedures and a SeqScape Software project template. This project template includes the relevant reference sequence, recommended analysis settings and can be used multiple times. Data analysis using this template can be done with a single click to provide basecalling, sequence assembly, alignment, sequence comparisons and variant identification. We illustrate here analysis of resequencing data from four Coriell DNA Samples for the mitochondrial genome using SeqScape Software v2.1.1. Results could be viewed in comprehensive reports, which contained mapping of each variant in the context of the entire mitochondrial genome and detection of all types of mutations such as insertions, deletions, substitutions and heterozygous indels with quality values. SeqScape Software v2.1.1 resulted in accurate variant identification, less manual data manipulation and shorter turnaround time for the complete analysis of the mitochondrial resequencing project.

The Spectrum of Mitochondrial DNA Mutations in Iranian Patients With Lebers Hereditary Optic Neuropathy.

F. Sharifpanah^{1,2}, M. Houshmand¹, Sh. Lavasani¹, A. Tabasi³, M.H. Sanati¹, M. Vakilian¹. 1) Medical genetics Department, National Research Center for Genetic Engineering and Biotechnology (NRCGEB), Tehran, Iran; 2) Cancer genetics Department, Research Center for Gastroenterology and Liver Diseases (RCGLD), Tehran, Iran; 3) Farabi Eye Hospital, Tehran, Iran.

We studied 14 patients with Leber's hereditary optic neuropathy (LHON) to investigate the mtDNA haplotypes associated with the primary mutation(s). Eleven patients carried the mitochondrial DNA (mtDNA) G11778A mutation, while one had the T14484C mutation; one patient had the G3460A mutation and one the G14459A mutation. The Iranian G11778A LHON mutation was not associated with two mtDNA haplogroups M (0.0% compared with 3.2% in healthy controls) and J (7.7% compared with 10% in healthy controls). Our results showed a similarity in the pattern of LHON primary point mutations between Iranian families with LHON and those of Russian, European, and North American origin. Our results also do not support an association between mtDNA haplogroups J and M with LHON primary point mutations.

The evolutionary history of the dystrophins and dystrobrevins. *R.G. Roberts¹, S. Tan¹, H. Jin¹, M.J. Greener²*. 1) Division of Medical & Molecular Genetics, King's College London, Guy's Hospital, London, United Kingdom; 2) Institut de Génétique Humaine, CNRS - UPR 1142, 34396 Montpellier, France.

The dystrophins and dystrobrevins constitute a family of five proteins in all vertebrates. Members of the dystrophin sub-family (dystrophin, utrophin and DRP2) heterodimerise with members of the dystrobrevin sub-family (- and - dystrobrevin). Both are critical for the assembly and maintenance of dystrophin glycoprotein complexes (DGCs), the absence of which causes Duchenne muscular dystrophy (DMD), a lethal X-linked genetic disorder. The function of the DGC and the mechanism of DMD are essentially still unknown.

By tracing the elaboration of the gene family through evolutionary history, we have found genes encoding a single dystrophin and a single dystrobrevin in all invertebrate organisms hitherto examined, and have continued to search for additional orthologues in organisms which represent critical turning points in evolution. These include the identification of a single common ancestor of dystrophin and utrophin (the two most closely related vertebrate dystrophins) in cyclostomes (lampreys and hagfish), and the pursuit of ever more divergent dystrophins and dystrobrevins in more distantly related metazoans (cnidarians, ctenophora and porifera), converging on extant orthologues of the single last common ancestor of dystrophins and dystrobrevins. It is presumed that this latter molecule, the ur-dystrophin, existed as a homodimer.

The work includes alignments of over 60 dystrophin and dystrobrevin sequences, culled from degenerate RT-PCR of marine biological samples and bioinformatic sources. They are analysed in terms of patterns of conservation (with reference to the crystal structure of the cysteine-rich domain of dystrophin), the order of acquisition or loss of structural features (such as conditional loss of the C-terminal amphipathic helix and modulation of syntrophin stoichiometry by insertion of alternatively spliced exons), and the position of known pathogenic mutations.

Hereditary hemochromatosis in Sao Miguel island (Azores): A population and clinical approach. *L. de Fez, R. Cabral, C.C. Branco, P.R. Pacheco, L. Mota-Vieira.* Molec Genet & Pathol Unit, Hosp Divino Espirito Santo, Azores Islands, and Instituto Gulbenkian de Ciencia, Oeiras, Portugal.

The knowledge of the type, frequency and distribution of recessive mutations is very important in populations living in small geographic areas. Here we studied the hereditary hemochromatosis (HH, OMIM 235200), a recessive and iron overload disease mainly caused by mutations in the *HFE* gene, in the population of Sao Miguel island, the biggest (746.79 km²) and the most populated (131,609 inhabitants) island of the Azores (Portugal). Our approach is based on a screening by a PCR-RFLP of the 3 principal *HFE* mutations (C282Y, H63D and S65C) in a control population of 203 unrelated blood donors, representing the 6 municipalities of the island, and in 14 HH patients with elevated transferrin saturation levels (TS>40%). In the control group, we observed allele frequencies similar to those found in Central Europe: 4.93% for C282Y, 21.67% for H63D, and 1.97% for S65C. Moreover, nine genotypes were identified: wild/wild (50.74%), wild/H63D (31.03%), wild/C282Y (7.88%), H63D/H63D (4.93%), wild/S65C (2.96%), C282Y/H63D (0.99%), and C282Y/C282Y, H63D/S65C, H63D-S65C/H63D all with a frequency of 0.49%. We also investigated the geographic distribution of the mutant alleles within the island. Only for C282Y, the more severe mutation, we observed a statistically significant difference between East (9.3%) and West (3.6%). The molecular analysis of the 14 HH patients revealed no more than 3 subjects with the C282Y mutation: 2 were C282Y homozygotes and 1 was C282Y heterozygote. Of the remaining 11 patients, 1 was H63D/S65C compound heterozygote, 3 were H63D heterozygotes, and 7 have no characteristic *HFE* mutations. In the non-C282Y patient's group, we excluded the presence of a new mutation in this codon by DNA sequencing. In order to investigate the cause of iron overloading in these patients, we are analysing the recessive E60X, M172K and Y250X mutations in the *TFR2* gene, which is involved in iron homeostasis. In conclusion, our data indicate that the molecular basis of hereditary hemochromatosis in Sao Miguel's population is more complex than expected. Funded by DRCT. (lmotavieira@hdes.pt).

Program Nr: 1220 from the 2004 ASHG Annual Meeting

Non-Paternity and Locus Specific Mutation Rates of 36 Y Chromosome STRs. *K. Hadley¹, N.M. Myres¹, J.B. Ekins¹, J.E. Ekins¹, L.A.D. Hutchinson^{1,2}, L. Layton¹, M.L. Lunt¹, S.S. Masek¹, A.A. Nelson¹, M.E. Nelson¹, K.L. Pennington¹, U.A. Perego¹, J.L. Peterson¹, A. Sims¹, T. Tolley¹, A. Welch¹, S. Woodward^{1,3}.* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT; 2) Computer Science, Brigham Young University, Provo, UT; 3) Department of Micro and Molecular Biology, Brigham Young University, Provo, UT.

Mutations and non-paternities are two of the most influential factors that may bias conclusions in Y-chromosome (y-ch) population genetic and lineage studies. Previous studies have determined locus specific mutation rates for 12 y-ch loci. Herein, we characterize mutation rates of 36 STR loci based on 500 individuals separated by between 1-13 meioses, including eight previously reported loci for comparison to published rates. Non-paternity rates have been shown to vary among certain demographics, age groups, and time periods. To account for all of these factors, the present study reports a non-paternity rate for samples collected from over 100 different families that vary in age group, culture, country of origin and the number of meioses separating them.

Sequence variation and haplotype diversity at the *CYP3A* locus. *E.E. Thompson*¹, *H. Kuttab-Boulos*², *D. Witonsky*², *B. Roe*³, *A. Di Rienzo*². 1) Committee on Genetics, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Advanced Center for Genome Technology, University of Oklahoma, Norman, OK.

Members of the cytochrome P450 3A subfamily play important roles in the metabolism and clearance of endogenous substrates, such as bile acids and hormones, environmental compounds, and prescribed drugs. Two enzymes in particular, *CYP3A4* and *CYP3A5*, are involved in substantial first pass drug metabolism due to high expression levels in the liver, kidney and intestine. Both enzymes are characterized by genetic polymorphisms with high inter-ethnic variation, but the observed range of phenotypic response to *CYP3A* substrates is not completely explained by the known genetic data. In addition, few variants have been consistently reported to be associated with specific phenotypes, which may be due in part to large differences in allele frequencies across populations contributing to inconsistent results from association studies. We surveyed sequence variation at *CYP3A4* and *CYP3A5* in three ethnically diverse population samples in order to identify additional polymorphisms, describe patterns of linkage disequilibrium and haplotype structure, and investigate the role of natural selection at the *CYP3A* locus. We used a combination of comparative genomics and computational predictions to identify conserved noncoding sequences (CNS) and clusters of liver-specific transcription factor binding sites. Our results show large allele frequency differences between African and non-African populations, with a defined haplotype structure and strong LD extending across the 150 kb spanned by these two genes. Low levels of nucleotide diversity combined with a high frequency of derived alleles in one haplotype found at high frequency outside Africa are consistent with the effects of a partial selective sweep. Genotyping of a functional allele that defines this common haplotype (*CYP3A5*3*) reveals a highly unusual geographic distribution, again consistent with the action of population-specific selective pressures. The implications of these results for association studies of *CYP3A* variation will also be presented.

3 HAPLOTYPES OF THE α -GLOBIN GENE IN α -CHROMOSOMES OF MEXICAN INDIVIDUALS. *B. Ibarra, M.T. Magaña, F.J. Perea, Z. Ongay.* División de Genética, Centro de Investigación Biomédica de Occidente, Guadalajara Jalisco, México.

α -globin gene family have shown a high polymorphic diversity organized in 5 and 3 haplotypes (5 and 3 Hp). α -chromosomes (α -chr) are in linkage disequilibrium (LD) with 5Hps Bantu, Benin, Senegal, Cameroon and Arab-Indian. In the west coast of Mexico, in Mexican mestizos with African roots, we observed the following 5Hps in α -chr, Bantu (78.8%), Benin (18.2%) and atypical 9 (3.0%). With the purpose to establish the 3Hp, we analyzed 38 DNA polymorphic sites (six by RFLPs and 32 by DNA sequencing) in 33 unrelated α -chr (28 Bantu, four Benin and one atypical 9). The polymorphic sites were structured according to Harding et al (1997) and Lapoumeroulie et al (1992). All Bantu α -chr showed 13A1 3Hp with (AT)₆T₉ repeats (84.9%), a new 3Hp; the Benin were 2B2 (AT)₈T₄ (12.1%) and the atypical 9 4B1 (AT)₈T₅ (3.0%). Because of the high LD observed with Bantu and 13A1 Hps, we expect that if there is a single origin of Bantu α mutation, all of them must show at 3Hp the 13A1 polymorphic DNA sequence. A correlation between 5Hp and 3Hp could be observed with the other α mutations. The atypical 9 was also atypical at 3Hp with the repeats observed with the Cameroon α mutation, however it is different in one position with the typical Lapoumeroulie Cameroon Hp, therefore we can explain this α -chr by different genetic mechanisms or by a new α mutation. We stress the importance to study the DNA polymorphisms at 3Hp, to know the genetic diversity of α -chr as well as its implications in the α -gene expression and its possible effect in the clinical phenotype.

Screening of the single nucleotide polymorphisms in the protamine 1 and 2 genes of infertile men. *H.-S. Lee¹, Y.J. Jeong^{1, 2}, H.W. Choi¹, Y.-S. Park¹, S.Y. Park³, J.T. Seo⁴, M.K. Koong⁵, J.H. Jun¹.* 1) Infertility Research Lab., Samsung Cheil Hospital, Seoul, Korea; 2) Dept. of Animal Sciences, Chunbuk National University, Cheongju, Chungbuk, Korea; 3) Lab. of Medical Genetics, Samsung Cheil Hospital, Seoul, Korea; 4) Dept. of Urology, Samsung Cheil Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea; 5) Dept. of Ob/Gyn, Samsung Cheil Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea.

During spermatogenesis, a marked rearrangement in the sperm nucleus takes place involving the removal of histones and replacement by the highly positively charged protamine 1 and 2 (PRM1 and PRM2). These protamines are the most abundant nuclear proteins in the sperm nucleus packaging the male genome. The male infertility by haploinsufficiency of PRM1 or PRM2 has been reported in mouse model. The aim of this study is to identify the single nucleotide polymorphisms (SNPs) of PRM1 and PRM2 in the infertile men. Genomic DNA was extracted from peripheral bloods of infertile men with oligozoospermia or azoospermia, and analyzed using PCR and direct sequencing. We carried out the direct sequencing analysis of amplified fragments in PRM1 (557 nucleotides from -42 to 515) and PRM2 (599 nucleotides from 49 to 648) genes, respectively. Three SNPs of coding region in the PRM1 gene was found in the analysis of 130 infertile men. However, the SNPs at a133g (aa 96.9%, ag 3.1% and gg 0.0%), c160a (cc 99.2%, ca 0.8% and aa 0.0%) and c321a (cc 56.9%, ca 35.4% and aa 7.7%) coded the same amino acids, in terms of silence phenotypes. On the other hand, as results of the PRM2 gene sequencing in 164 infertile men, only two SNPs, g398c (gg 62.2%, gc 31.1% and ga 6.7%) and a473c (aa 63.4%, ac 29.9% and cc 6.7%), were identified in the intron of the PRM2 gene. We could not detect any SNP, which cause amino acid changes within the PRM1 and PRM2 genes. These results suggest that the PRM1 and PRM2 genes are highly conserved and essential for infertile men as well as normal male. We are trying to elucidate the genetic factors and causative genes, which should be implicated in human male infertility.

Sequence variation and intron 10 mRNA retention at human *NXF1*, an orthologue of a mouse modifier of retrovirus mutations. G. Wen, D. Concepcion, B.A. Hamilton. Dept Medicine/Division of Genetics, Univ California, San Diego, La Jolla, CA.

NXF1 encodes an essential component of the mRNA nuclear export machinery. Our lab has recently shown that a common variant in mouse *Nxf1* acts as a genetic modifier of mutations caused by a class of retrovirus insertions. To ask whether human alleles of *NXF1* might similarly respond to molecular parasites, we have examined sequence and expression polymorphism in *NXF1* and used evolutionary comparisons to predict a potential novel auto-regulatory mechanism. We sequenced conserved regions of *NXF1* from 117 anonymous subjects representing 13 different populations from the NIGMS human diversity collection. Across a 9289 bp footprint, we identified 24 variant sites, but only 5 with minor allele frequencies greater than 5% in this global sample. The nucleotide diversity (π) of *NXF1* is substantially lower than that for other genes in this or similar populations. Standard tests for neutrality, site-frequency spectrum and comparison between human and chimp sequences showed significant departure from neutrality for introns, which contain most of the polymorphic sites. We also examined allelic expression differences in heterozygous cell lines carrying a single SNP in the encoded RNA (cSNP). Using multiple assays, we find haplotype-specific expression differences of up to 60%. Surprisingly, EST data shows an unexpectedly high level of clones that either include part or all of highly conserved intron 10. RT-PCR and northern blots showed that the entire intron 10, but not other introns, is retained in a significant pool of polyadenylated RNA. RNP immunoprecipitation using anti-NXF1 antibodies shows mRNA containing intron 10 binds to export machinery. However, western blots do not show a protein of the predicted size translated from intron 10-containing mRNA. In conclusion, our data show surprisingly little nucleotide variation in human *NXF1*, but significant allelic variation in RNA expression level among common haplotypes. Test of neutrality suggest that *NXF1* might be subject to positive selection. It is likely that intron 10 retention of mRNA plays a role in self-regulation.

X-chromosome Polymorphisms and the Genetic Structure of Amerindian Populations. *S. Bourgeois¹, V. Yotova¹, A. Lovell¹, F. Xiao¹, C. Pich¹, C. Moreau¹, S. Bourthoumieu¹, E. Zietkiewicz¹, R. Michalski², A. Ruiz-Linares³, D. Labuda¹.* 1) Sainte-Justine Hospital, Montreal, PQ, Canada; 2) Victoria Hospital, Prince Albert, SK, Canada; 3) The Galton Laboratory, University College, London, UK.

Genetic data influencing the debate on the peopling of the New World and the place of Native Americans among other populations are essentially limited to these on the non-recombining portion of the Y chromosome and the mitochondrial DNA. There is a lack of similarly extensive studies of neutral nuclear non-Y-chromosome polymorphisms that could broaden the discussion and bring arguments unrestricted by paternal only or maternal only transmission. Toward this goal, we report data on the X-chromosome haplotype consisting of bi-allelic polymorphisms and a microsatellite within an 8 kb segment of the dystrophin gene, for 12 Amerindian populations (n=414 chromosomes) six Asian (n=668), six European (n=463) and three (n=130) of mixed European/Amerindian origin. Among twenty different haplotypes found in Native American populations, four represented 94% of all chromosomes from this continent. Three other haplotypes (representing less than 1%) were specific for Amerindians. Noticeable heterogeneity in haplotype frequencies among Amerindian populations correlates with the geographical localization and distance (Mantel test) but not with the linguistic grouping. Two haplotypes frequent in Eurasia were virtually absent in the Americas, whereas the occurrence of two others was significantly increased in Amerindian populations, consistent with a model of single entry during colonization of these continents. Continental distribution of the haplotypes, also when analyzed by PCA and pairwise FST, indicates a privileged link between the Amerindian, Siberian and Western European populations, rather than between the Amerindian and East-Asian populations. This link is not due to a recent admixture, but rather reflects a common ancestry of these populations. The migration towards the New World could have started in Northern Asia, and subsequently given rise to both NaDene and Amerind speaking people, following diversification of these populations. (Supported by the Canadian Institutes of Health Research MOP-67150).

BAT-25 and BAT-26 microsatellite profile in a sample of individuals of African origin from Rio Grande do Sul, Brazil. *S.L. Cossio*¹, *R.S. Coura*^{2,3}, *M.C. Bortolini*^{2,3}, *P. Ashton-Prolla*^{1,2,3}. 1) Medical Genetics Service, HCPA, Porto Alegre, RS, Brazil; 2) Department of Genetics UFRGS; 3) Post graduation course in genetics and molecular biology UFRGS.

Colorectal cancer (CRC) is one of the six most common cancers and, in Brazil, it is the third in mortality. Several clinical, pathological and morphological parameters are associated with disease prognosis. Molecular markers have also been associated with prognosis, especially in relation to therapeutic response and overall survival rates. Among these, microsatellite instability (MSI) is remarkable. It reflects genomic instability caused by a deficiency in the DNA repair system, which leads to the progressive accumulation of mutations, especially in mono- and dinucleotide microsatellites. Microsatellite stability (MS) status analysis is performed by the comparison between normal and tumoral tissues from the same patient and instability is characterized by the difference in the amplification profile of these tissues. MS status can be evaluated by a panel of five markers: BAT-25, BAT-26, D2S123, D5S346 and D17S250. The last three are polymorphic in several populations, but the former are considered quasi-monomorphic in populations of Caucasian origin. Thus, analysis of BAT25 and BAT 26 status in tumoral tissue only without comparison with the corresponding normal tissue has been considered sufficient for instability detection. One recent study however, showed high frequency of allelic variation for these two markers in a control population of african-american individuals. Our study describes the profile of BAT-25 and BAT-26 in a sample of 116 individuals of African origin from Rio Grande do Sul, Brazil. MSI analysis was performed by PCR and SSCP of 116 samples for BAT-25 and 110 for BAT-26. Allelic variation was 6.9% and 4.5% for BAT-25 and BAT-26, respectively. None of the samples presented simultaneous allelic variation in both markers. These results suggest a polymorphic profile of these markers in the studied sample and reinforce the importance of a comparative study between tumoral and corresponding normal tissue to determine their stability status in CRC. Support: CNPq, CAPES.

Dissecting cis-regulatory variation in the human genome. *E.T. Dermitzakis¹, R. Lyle², M. Forrest¹, S. Deutsch², C. Gehrig², L. Parand², M. Gagnebin², S. Hunt¹, P. Deloukas¹, S.E. Antonarakis².* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Switzerland.

Extensive sequence variation is present in human populations, but only a fraction of this is of functional significance. One way in which sequence variation can be functionally active is by modulating the levels of gene expression. Natural variation in gene expression is suspected to be involved in the etiology of complex disorders, and is likely to serve as useful intermediate markers, providing a more direct link between sequence variation and phenotypic outcomes. We have investigated the extent and pattern of gene expression variation in two different sets of genes. First, we have interrogated by Taqman the expression levels of forty-one chromosome 21 genes, using lymphoblastoid cell lines from the CEPH family collection. We have observed that the majority of genes have significant heritability values and, based on quantitative linkage analysis we infer that about 25% of them harbour cis-regulatory variation. We have now extended our screening of transcript levels using Illumina technology in a larger set of 700 genes from all the ENCODE regions, the whole Hsa21 and a 10 Mb segment of Hsa20. We have observed extensive variation in gene expression in the majority of genes as well cases of significant covariation of genes within the same genomic region, suggesting the presence of functionally variable regulatory regions that regulate the expression of more than one gene. We are currently using SNP genotypes from the Hapmap project as well as new SNP genotypes obtained in our platform to perform association tests between transcript levels and cis nucleotide variation in CEPH lymphoblastoid cell lines in order to identify cis regulatory variants. Preliminary analysis suggests that we are able to identify functionally variable regulatory regions that may serve as good functional candidates for association with quantitative phenotypes and complex disorders in humans.

Estimating allele frequencies and inbreeding coefficients in K-allele models. *S.E. Hodge*^{1,2}, *P. Gorroochurn*². 1) NYSPI, Unit 24, Columbia Univ, New York, NY; 2) Division of Statistical Genetics, Department of Biostatistics, Columbia University, New York, NY.

We examine some of the methods of estimation of allele frequencies and inbreeding coefficients in a K-allele model. Whereas the maximum likelihood estimators of the allele frequencies are equal to their observed (or sample) values under Hardy-Weinberg equilibrium, we show that, surprisingly, this is not the case when Hardy-Weinberg equilibrium does not hold, except in the $K = 2$ allele case. We also present a least-squares way of looking at the estimation problem, which fits observed genotype counts to their expected values. We use simulations to compare the biases and standard deviations of the three estimators (sample, maximum likelihood, and least-squares) in a 3-allele model, and show that the maximum likelihood estimators become more precise than the sample estimators with increasing sample size. Finally, we use probability-generating functions to derive exact expressions for the biases of the sample and Nei's estimators of the inbreeding coefficient in a 2-allele model for any sample size. Although Nei's inbreeding coefficient is usually preferred over the sample inbreeding coefficient since both its numerator and denominator are unbiased, we show that the sample inbreeding coefficient can sometimes be less biased than Nei's.

Alternatives to the Wright-Fisher Model and robustness of Mitochondrial Eve dating. *M. Kimmel*¹, *K. Cyran*². 1) Department of Statistics, Rice University, Houston, TX, USA; 2) Institute of Computer Science, Silesian University of Technology, Gliwice, Poland.

Several models for calculating the distribution of coalescence time exist, however their applicability is limited to a narrow spectrum of population trajectories. Also, they often rely on assumptions about generation to generation sampling scheme, known to be unrealistic for many populations, including the modern human population. We present a simulation-based approach capable of dealing with different population history scenarios, including populations evolving stochastically with environmental impacts variable in time. This approach allows comparing the branching process model of O'Connell with a range of Wright-Fisher type models. We apply our approach to estimate the age of the most recent common female ancestor based on the genetic material from mitochondrial DNA obtained from contemporary humans and extracted from Neanderthal fossils. The results indicate that when Neanderthals are used as an outgroup, the stochastic models based on branching processes provide similar estimates to those obtained with phylogenetic analysis, therefore supporting each other. On the other hand estimates assuming deterministic population growth are considerably higher, indicating that the stochastic demographic effects present in the human population when it was of a relatively small size are not negligible also for inferences dealing with long term history.

Y-chromosomal haplotype variation among the Finns. *P. Lahermo*¹, *S. Koivumäki*^{2, 3}, *P. Sistonen*⁴, *K. Huoponen*³, *M-L. Savontaus*^{2, 3}. 1) Finnish Genome Center, Univ Helsinki, Helsinki, Finland; 2) Department of Biology, Laboratory of Genetics, University of Turku, Finland; 3) Department of Medical Genetics, University of Turku, Finland; 4) Finnish Red Cross Blood Transfusion Service, Helsinki, Finland.

Y chromosomal variation was analyzed in 537 unrelated men from eastern and western Finland. Origins of those men were defined on the basis of their grandparental birthplace. Geographical distribution of the samples and sample sizes were as follows: Western Finland n=231 (consisting of the sub-populations: Southern Ostrobothnia 58, Hame 50, Southwestern Finland 50, Swedish speaking Ostrobothnia 25, and Satakunta 48) and Eastern Finland n=306 (sub-populations: Northern Karelia 22, Southern Karelia 48, Northern Savo 107 and Northern Ostrobothnia 129). Six biallelic and six microsatellite Y-chromosomal markers were studied. Haplotypes were constructed on the basis of five SNP loci (Tat, M9, 92R7, SRY-1532, M17), a Y- chromosome specific Alu-insertion (YAP, DYS287), and six microsatellite loci (DYS19, DYS388, DYS390, DYS391, DYS392 and DYS393). Genetic distances and diversity distributions were calculated using the ARLEQUIN 2.001 software package. Interpopulation variability was estimated for each haplotype and subhaplotype through 2 contingency test. Maximum parsimony networks for SNP haplogroups were constructed and phylogenetic relationships between the microsatellite haplotypes were analyzed with Network 3.0. Principal component analysis was carried out on both SNP and microsatellite data. Both SNP and microsatellite networks showed bifurcated structures reflecting the geographical origins and history of the western and eastern sub-populations. Similar clustering was evident in allelic and haplotype frequencies and genetic distances, giving evidence in support of the theory of two different founder groups for the Finnish population. This study suggests that most of the Y-chromosomal variation found among the Finns originates from the common European gene pool, with some eastern, possibly Finno-Ugric components especially in the eastern sub-population of Finland.

Worldwide polymorphism in classical human major histocompatibility (HLA) genes. *D. Meyer*^{1,2}, *R. Single*^{2,3}, *S.J. Mack*^{4,5}, *A. Lancaster*², *M.P. Nelson*², *H. Erlich*^{4,5}, *M. Fernandez-Viña*⁶, *G. Thomson*². 1) Dept. of Biology, University of So Paulo, Brazil; 2) Dept. of Integrative Biology, University of California, Berkeley, CA; 3) Dept. of Medical Biostatistics, University of Vermont, Burlington, VT; 4) Roche Molecular Systems, Alameda, CA; 5) Childrens Hospital Oakland, Research Institute, Oakland, CA; 6) CW Bill Young/DoD Marrow Donor Program, Naval Medical Research Center, Bethesda, MD.

The classical genes of the human major histocompatibility complex are critical to the adaptive immune response. Various lines of evidence indicate that these genes experience balancing selection. Here we survey data on HLA polymorphism generated by over 30 laboratories that participated in the Anthropology component of the 13th International Histocompatibility Workshop. Our results pertain to the HLA-A, B, C, DRB1, DQB1, DQA1, DPB1, and DPA1 loci. Populations with significant deviations from Hardy-Weinberg proportions were not included in the analyses. We selected 34 populations with at least 40 individuals (median = 94) typed for three sets of loci (class I, DRB1 and DQB1, all class II). We found high values for expected heterozygosity, resulting from many HLA alleles found at intermediate frequencies. Heterozygosity values were highest in African populations, and lowest in indigenous American and Australian populations, consistent with findings for putatively neutral markers, indicating that demographic history has shaped allele frequencies for these selected loci. The interpopulation differentiation at HLA loci has values which are typical of neutral markers, indicating that a simple model of balancing selection acting homogeneously on all populations does not account adequately for the data. Moderate to high LD was observed for all locus pairs, and decayed over chromosomal distance out to approximately 1Mb (after which a consistent effect of distance on LD was not observed). Rankings of world regions based upon LD were consistent with results for neutral markers. These results indicate that the demographic history of these populations along with the effects of balancing selection and drift has shaped variation at these HLA loci.

Gene frequencies of three genetic polymorphisms in malarious patients in south of Iran. *M.B. Mobasheri^{1,2}, P. Amirshahi²*. 1) Medical Genetics Department, School Of Medicine, Tehran University Of Medical Sciences(TUMS), Tehran, Iran; 2) Department Of Human Genetics,School Of Public Health, TUMS, Tehran, Iran.

It is established that several genetic markers specially blood genetic polymorphisms plays critical role in susceptibility to several diseases. Malaria is the most well known natural selective agent in tropical areas which has selected and established some blood genetic markers such as some of the haemoglobins, specially hemoglobin S in sickle cell anemia. Of course gene frequencies of these polymorphic systems in tropical areas is higher than others. To study the association between Malaria and three blood genetic markers, Haptoglobin(HP), Acid phosphatase(ACP) and Esterase-D(ESD) we selected a total of 205 highly susceptible malarious patients and 197 healthy controls from the same ethnic group, inhabited in an malaria endemic area in south of Iran. Using starch gel electrophoresis, the different phenotypes of each systems were determined. The results were analysed using Woolf's test. Significant association were found only in ESD system, in which the ESD2-2 phenotype with frequency of 6.2% in controls and 2% in patients were observed. Gene frequencies of common genes in each system in patients(P) and controls(C) and their relative gene frequencies(RF) are as following: HP1:[P(0.2716), C(0.2775), RF=1.0217], HP2:[P(0.7284), C(0.7225), RF=0.9919], ACP-A:[P(0.3683), C 0.3782), RF=1.0269], ACP-B:[P(0.6268), C(0.6167), RF=0.9839], ACP-C:[P(0.0049), C(0.0051), RF=1.0408], ESD1:[P(0.8308), C(0.7658, RF=0.9218], ESD2:[P(0.1692), C(0.2342), RF=1.3842]. A population under Hardy-Weinberg equilibrium shows no changes in the gene pool. In our study, however the gene ESD-2 showed more resistancy against malaria infection, but the population of origin is under Hardy-Weinberg equilibrium condition. If Genes better able to produce mature offspring than those without them, the frequency of those genes will increase. This is simple expressing Darwin's natural selection. It results from differential mortality and/or differential fecundity. More studies is required to know more about ESD in other populations of tropical areas to know if it has selective advantage against malaria.

DETECTION OF NOVEL SNPs PROVIDES FURTHER INSIGHTS INTO Y CHROMOSOMAL VARIATION IN PAKISTAN. *A. Mohyuddin¹, Q. Ayub¹, S. Firasat¹, P.A. Underhill², C. Tyler-Smith³, S.Q. Mehdi¹.* 1) Biomedical and Genetic Engineering Laboratories, Islamabad, Pakistan; 2) Department of Genetics, Stanford University, Stanford, CA USA; 3) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Biallelic polymorphisms on the Y chromosome have been extensively used to study the history, evolution and migrations patterns of world populations. In this study we screened 8.5 kb of DNA in a panel of 93 Pakistani and 2 African individuals belonging to different haplogroups for new Y-SNPs. Male specific PCR products were mixed with a reference sample and analyzed by DHPLC. Four novel Y SNPs (PK2-5) were identified in the Pakistani samples and one (PK1) in the African sample belonging to haplogroup A of the YCC phylogenetic tree. The ancestral state of each SNP was determined in two chimpanzee samples and various Pakistani ethnic groups using ARMS-PCR or RFLP-PCR. The C to A (PK1) polymorphism found in the haplogroup A sample was also present in four other haplogroup A samples screened. All these samples were derived for the M91 and M6 mutations placing it in the sub clade A2. A T to C (PK2) mutation detected in two Burusho and one Hazara sample belonging to haplogroup C, was present in all haplogroup C-M217 derived Y chromosomes from northern Pakistan and absent in southern Pakistan. The PK3 (T to C) SNP was detected only in haplogroup L Kalash individuals and represents a new branch L/-3 of the phylogenetic tree. The A to T (PK4) mutation was detected in four Pathan samples belonging to clade O. The C to T (PK5) transition found in two Burusho individuals represents a new branch, R1a1/-d, on the M17 background and seems to be a recurrent mutation as it was also detected in the two chimpanzee samples. The detection of several novel Y-SNPs that have been found in the Pakistani ethnic groups enabled us to further investigate extant human Y chromosomal variation within Pakistan. Microsatellite diversity in sub clade L3 in the Kalash population was used to determine the time to the most common recent ancestor (TMRCA) using BATWING. The median TMRCA (95% CI) of 3300 (1500-7900) YBP corresponds to the time of invasion of the Indo-Pak subcontinent by the Indo European-speaking tribes from Central Asia.

Genetic diversity among European settlers of the Gaspé Peninsula (Quebec). *C. Moreau¹, V. Yotova¹, D. Gehl¹, C. Cavier², D. Sinnott¹, P. de Knijff³, H. Vezina², D. Labuda¹.* 1) Research Ctr, St-Justine Hosp, Univ Montreal, Montreal, Quebec, Canada; 2) Dpartement des sciences humaines, Universit du Qubec Chicoutimi; 3) Dept of Human Genetics, Ctr of Human and Clinical Genetics, Leiden University Medical Ctr.

The population of Quebec with its well-documented demographic history is conducive to study the relationship between genetic characteristics and the demographic history of human populations. The Gasp Peninsula, on the south shore of the St-Lawrence river, was colonized in the 18th and 19th centuries. We sampled four groups, namely Acadians, French-Canadians, Loyalists and descendents of settlers from the Channel Islands (Jerseyans), collecting DNA and reconstructing their genealogies. D-loop sequencing (n=368) demonstrated the presence of 112 distinct haplotypes, one of which accounts on 20% of the total sample (from 30% in Acadians to 13% in Jerseyans). Among European lineages we also find haplogroups A, C and D suggesting a significant Amerindian contribution. Y-chromosome lineages are dominated by haplogroups R1 and I, common in Europe, diversified into 132 microsatellite-based haplotypes, mostly singletons, with only few falling into higher frequency classes, especially among Acadians and Jerseyans. In turn, the X-chromosome genotyping reveals two chromosomes carrying Sub-Saharan African specific alleles. Again Acadians appear least varied with haplotype diversity of 0.780, compared to 0.793 for all and 0.814 for French-Canadian group. Two phenomena influenced genetic variability of these recent genetic isolates. The first one was the founder effect: related to the limited number of early settlers, it elevated the frequency of some rare alleles but was not strong enough to significantly change the frequency profile of common variants, which remained characteristic of the original European populations. Secondly, there were subsequent migrations, which, through the contribution of admixed founders of distinct European, or more easily detectable, Amerindian or even Sub-Saharan African origin, exerted a diversifying effect albeit of variable impact, on the populations of Gasp Peninsula. (Supported by NSERC and FRSQ).

Genetic history of Sao Miguel island (Azores): A HLA perspective. *P.R. Pacheco, A. Lismond, L. de Fez, R. Cabral, C.C. Branco, L. Mota-Vieira.* Molecular Genetics & Pathology Unit, Hospital Divino Espirito Santo, Azores Islands and Instituto Gulbenkian de Ciencia, Oeiras, Portugal.

Sao Miguel is the biggest (747 km²) and most populated island (131,609 inhabitants) of the Azores archipelago (Portugal). The island had no native population when the Portuguese first arrived in the XV century. It was peopled by the Portuguese, but Jews, Moorish, African slaves, Flemish, French and Spaniards also contributed to the initial settlement. To improve our knowledge of Sao Miguel population genetic diversity, we investigated the polymorphism of HLA-A, HLA-B and HLA-DRB1 loci. Blood samples were taken, after informed consent, from 106 unrelated blood donors, whose parents were born in Sao Miguel island. HLA typing was carried out using polymerase chain reaction with sequence specific primers (Olerup SSP HLA-A-B-DR SSP Combi Tray kit). Statistical analysis was performed with Arlequin v2.0. At the HLA-A locus, we identified 16 HLA-A alleles, of which A*02 (GF=0.2500), A*01 (GF=0.1509) and A*24 (GF=0.1368) are the most frequent. Of the 24 HLA-B alleles found, B*44 (GF=0.1557), B*08 (GF=0.1368) and B*14 (GF=0.0708) are the most prevalent. At HLA-DRB1 locus we found 13 alleles, of which the most prevalent are DRB1*07 and DRB1*03 (GF=0.1698 and GF=0.1651, respectively) followed by DRB1*13 (GF=0.1462). All genotype frequencies are in Hardy-Weinberg equilibrium. The most frequent haplotype in Sao Miguel is HLA-A*01-B*08-DRB1*03 (HF=0.0802) which is of West European origin. Albeit at lower frequency, we also found the Iberian North African haplotype HLA-A*30-B*18-DRB1*03 (HF=0.0047), the Iberian Berbers haplotype HLA-A*02-B*51-DRB1*13 (HF=0.0047) and two Mongol haplotypes: HLA-A*02-B*50-DRB1*07 (HF=0.0047) and HLA-A*02-B*44-DRB1*04 (HF=0.0142). Moreover, the preliminary interpopulation analysis highlights a strong relatedness with other European populations and input of people from different origins. These findings agree with our previous results on the Y chromosomal heritage of Sao Miguel population, and will be useful for Azorean studies of autoimmune diseases related to HLA genotypes. Funded by DRCT.(paularpacheco@hdes.pt).

FORENSIOMICS: Potential application of Ancestry Informative Markers to Forensics, Pharmacogenomics, and Outcomes Research. *M.F. Seldin¹, N. Yang¹, H. Li¹, L.A. Criswell², P.K. Gregersen³, M.E. Alarcon-Riquelme⁴, R. Kittles⁵, J.W. Belmont⁶.* 1) Univ Calif, Davis, CA; 2) Univ Calif, San Francisco, CA; 3) Univ Uppsala, Uppsala, Sweden; 4) North Shore Univ Hosp, Manhasset, NY; 5) Comp Cancer Cent, Ohio State Univ, Columbus, OH; 6) Baylor College of Medicine, Houston, TX.

We have identified or confirmed several hundred ancestry informative markers (AIMs) with large (>50%) allele frequency differences between different combinations of major ancestral groups including European(EA), West African(AF), East Asian(AS) and Amerindian(AI). A panel of >200 AIMs (optimized for ancestry information and distributed on each chromosome) was used to examine >750 DNA samples including those self identified as EA, AF, AS, AI, African American(AA), Mexican(MX), Mexican American(MA), Puerto Rican(PR) and South Asian(SAS). Analysis using the Bayesian clustering algorithm STRUCTURE 2.1 indicated that these data: 1) best fit a model in which individuals were derived from five major populations (k=5), and 2) showed grouping of individuals with similar ethnic identity without any identifier other than the AIMs genotyping information. In general, the 5 populations corresponded to the self identified ethnicities EA, AF, AS, AI and SAS (e.g.>97% EA had >97% probability of membership in population 1). As expected, other self identified groups showed admixture between the different populations and had distinct profiles (e.g. most MA clearly separated from PR). To further assess the potential of this approach, we used Fishers linear discriminate to examine the ethnic identity of each individual when treated as an unknown. For the majority of samples, the predicted ethnic identity corresponded with the self-identified identity at high probability (p>0.99). However, for some individuals alternative grouping was strongly suggested (e.g. 4 of 73 self described Amerindians were identified as MA at high probability). Overall, this study demonstrates the potential of developing a set of AIMs that can provide a useful adjunct to forensic medicine, pharmacogenomics and disease studies in which major ancestry may be linked to specific outcomes.

Departures from Hardy-Weinberg equilibrium across the human genome. *J.K. Wittke, C. Roe, N.J. Cox.*
Department of Human Genetics, The University of Chicago, Chicago, IL.

Hardy-Weinberg equilibrium (HWE) was first introduced over a century ago (Castle 1903; Hardy 1908; Weinberg 1908) and states that the allele frequencies (p and q , where $p+q=1$) determine the genotype frequencies at a polymorphic locus (e.g. p^2 , $2pq$, q^2), assuming the population is randomly mating and there is no mutation, selection, genetic drift, migration, population structure, or admixture. Departures from HWE in an unselected population sample can be due to violation of any of the underlying assumptions, genotyping error, or chance. We have examined genotypic data for departures from HWE over the human genome at 8,939 single-nucleotide polymorphisms (SNPs) in 150 unrelated Caucasians to characterize regions that show departures from HWE with respect to the extent and direction of departure. We used a χ^2 test with 1 degree of freedom, or Fishers exact test when the HWE-expected genotype counts were less than 5, to assess significance of departures from HWE. We measured linkage disequilibrium (LD) between SNPs across each chromosome using r^2 and D . The estimated genotyping error rate is 0.0004. For any level of significance chosen (0.05, 0.01, 0.001, etc.), we observe a higher proportion of SNPs showing departures from HWE at that significance level than expected by chance. Moreover, we observe a considerable excess of departures even when we create independent bins by clustering SNPs with $r^2 < 0.3$. Departures attributable to genotyping error or non-random patterns of missing data are unlikely to occur in each of several markers in strong LD, whereas departures due to chance or violations of HWE assumptions may be observed in several markers in strong LD. Any violation of the assumptions necessary for HWE must have occurred very recently in this populations history since departures from HWE remain in a population for only one generation, assuming the next generation is randomly mating and no other violation of the assumptions for HWE occurs. Further study is needed in other unrelated, Caucasian samples to better characterize which regions of the human genome show departures from HWE due to chance and which are violating HWE assumptions.

Historical and Genetic Assessment of A Genetic Isolate in North-West Colombia. *G. Bedoya¹, I. Soto-Calderon¹, J. Lopera¹, P. Montoya¹, V. Alvarez², A. Ruiz-Linares^{1,3}.* 1) Grupo de Genetica Molecular, Univ of Antioquia, Medellin, Colombia; 2) Dept. History, Univ of Antioquia, Medellin, Colombia; 3) Galton Laboratory, Univ College London, London, UK.

The Paisa population is a genetic isolate located in the province of Antioquia in North-west Colombia. In the oriental section of the province, the population of Marinilla and the Area of colonization (MAC) seem to have even higher levels of genetic isolation. This region exhibits high frequency of certain surnames and recessive autosomal traits but also had the highest fecundity rate in Colombia during the second half of the 19th century (6,7 children/family). In this research, current and ancient surname lists and records of marriages, as well as uniparental molecular markers of Y-chromosome (YC) and mtDNA were employed to determine the isolation level of MAC and to identify the parental populations.

The percentage of MAC with one of the 15 most frequent surnames was between 39 and 59%. The inbreeding coefficients due to random mating using surnames (ii) were between 0.0040 and 0.0135. The inbreeding calculated with marriages carried out between 1801 and 1850 was 0.0088 (closely equivalent to a union of third by second cousins, 0.0078). The haplotypic diversity of YC was 0.40 and the most predominant lineages were the Europeans (haplogroup A 71.4%, and C 16.9%). Based on STRs of YC, MAC had the shortest distance with Basques, Portugueses and Catalans. It was found a high ratio of Native American mitochondrial lineages A and B, which together account for the 77 to 100% of the localities of MAC. The mitochondrial haplotypic diversity was 0.57 and lower than most of Colombian populations excepting the Embera (Amerind).

These results indicate population growth with genetic isolation levels even higher than other human genetic isolates. Also, the molecular data show admixture in the foundation of MAC provided by females from Amerind populations isolated since Pre-Columbian times and Spaniard males principally of Basque origin. We thank to University of Antioquia (CPT0017) and Banco de la Republica (200212).

Correlation between constitutive skin pigmentation and individual ancestry in admixed populations. *A. Chan¹, M. Vaughn¹, R.A. Kittles², M.D. Shriver³, E.J. Parra¹*. 1) Department of Anthropology, University of Toronto, Mississauga, ON; 2) College of Medicine and Public Health, Ohio State University, Columbus, OH; 3) Department of Anthropology, Penn State University, University Park, PA.

We evaluated the correlation of constitutive pigmentation (melanin content in unexposed areas of the skin) and individual ancestry estimated with ancestry informative genetic markers (AIMs) in five admixed populations showing a wide range of constitutive pigmentation and admixture proportions (African Americans from Washington DC, African Caribbeans living in England, Puerto Ricans from New York, Mexicans from Guerrero and Hispanics from San Luis Valley). We also studied the relationship between pigmentation and individual ancestry by simulation, under several models differing in the presence or absence of admixture stratification (variation of ancestry between the individuals of the admixed sample), the presence or absence of pigmentation differences between the parental populations, and the number of genes determining melanin content. We observed a significant correlation between constitutive pigmentation levels and individual ancestry in each of the admixed samples. However, it is important to note that the strength of the relationship of constitutive pigmentation and ancestry estimated with genetic markers is quite variable. The correlations range from moderately strong (Puerto Rico, $\rho=0.633$) to weak (San Luis Valley, $\rho=0.259$; and Mexico, $\rho=0.212$). The variation observed in the extent of the correlation is presumably a reflection of differences in the degree of admixture stratification present in each population and/or the levels of pigmentation differences between the parental populations and the number of genes involved. Our results emphasize the need to be cautious when using pigmentation as a "marker" of ancestry, or when extrapolating the results observed in one admixed sample to samples from other admixed populations. Finally, we also discuss the implications of these results for population-based association studies and admixture mapping studies in admixed populations.

Performance assessment of methods for selecting haplotype tagging SNPs across four populations. B.V.

Halldorsson¹, F. Hyland², H. Isaac², C. Scafe², S. Istrail¹, F.M. de la Vega². 1) Applied Biosystems, Rockville, MD; 2) Applied Biosystems, Foster City, CA.

The large amount of single nucleotide polymorphisms (SNPs) in the human genome creates a dilemma for geneticists: Do they genotype all available variants, possibly at an excessive cost and risking losing the true association in a sea of noise, or do they choose typing only a subset of the variants and hence possibly not genotyping the causal variation? Algorithms for selecting optimal haplotype tagging SNPs promise a means for dealing with this dilemma by selecting a subset of SNPs that represent all the haplotype variation in the complete set of SNPs. A conundrum of methods has been suggested for selecting tagging SNPs, which creates another dilemma for geneticists: which method should one use? These methods differ mostly in two major aspects: the correlation measure used to measure how well a set of SNPs captures the variance observed in the original dataset, and the algorithm used for the minimization of the final number of tagging SNPs. We evaluate a set of methods suggested based on three criteria: (1) the number of SNPs needed to capture variation in a study data set, (2) the extensibility of the set of tagging SNPs across different populations, and (3) the extensibility of the set of tagging SNPs to samples of the population of different sizes. Our results show that tagging SNPs that perform well in one population will generally perform well even in populations of different ancestry. In closely related populations, sets of tagging SNPs tend to be highly concordant. This reflects the ability of tagging SNP methods to capture common variation. Our results also show that methods considering only pair-wise correlation metrics are highly extensible across populations and sample size but give a larger set of tagging SNPs than multivariate metrics. We conclude that association studies attempting to find common causal variants in any population can be vastly simplified due to the background distribution of common variation, even if that background variation is ascertained in distantly related populations.

Direct determination of mutation characteristics of Y chromosome STR loci. L.A.D. Hutchison^{1,2}, N.M. Myres², J.E. Ekins², U.A. Perego², J.B. Ekins², K. Hadley², L. Layton², M.L. Lunt², S.S. Masek², A.A. Nelson², M.E. Nelson², K.L. Pennington², J.L. Peterson², A. Sims², T. Tolley², A. Welch², S.R. Woodward^{2,3}. 1) Department of Computer Science, Brigham Young University, Provo, UT, USA; 2) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT, USA; 3) Department of Micro and Molecular Biology, Brigham Young University, Provo, UT, USA.

We present new analysis methods for haploid STR loci, which provide significant insight into per-locus mutation models and rates, as well as population substructure. These methods do not require knowledge of genealogical relationships between individuals, but are based on all-pairs comparisons between the individuals in a dataset (as employed by "mismatch distributions"). We formulate the *mutation model curve (MMC)* as the probability of matching at a specific locus, given that n out of N_L loci match in total between a pair of individuals; this function shows how quickly or slowly a locus mutates away from its original value, and the degree of back-mutation that occurs. We also present a method for quantification of population substructure in the data, and for calculation of per-locus mutation rates. The mutation model curve and the calculated mutation rate are given for each of 36 Y STR loci in a predominantly European dataset of 7976 individuals. The calculated mutation rates are shown to be comparable to rates obtained by observational studies. The mutation rates for many of the 36 loci in our study have not previously been determined by observation, yet mutation rates may be predicted for these loci by calibration to loci with known rates. These analysis techniques yield additional useful information about mutation characteristics of the loci, such as by inferring conditions under which identical-by-state matches are expected, and by demonstrating evidence in support of a stepwise mutation model.

A Nonparametric Approach for Population Structure Inference Using Multilocus Genotypes. *N. Liu*¹, *H. Zhao*^{1,2}.

1) Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT; 2) Department of Genetics, Yale University School of Medicine, New Haven, CT.

In genetic studies, characterizations of the population structure of species are very useful in a variety of contexts. Such as in evolution studies, much effort has been devoted for the estimation of the degree of population differentiation in order to investigate the evolutionary relationship of modern populations. In other situations, the presence of population structure poses a practical nuisance. Such as in genetic association studies using unrelated individuals, the presence of population stratification may lead to false-positive findings if it is not properly considered. We describe a two-stage approach in inferring population structure using multilocus genotype data. In the first stage we use dimension reduction methods such as singular value decomposition to reduce the dimension of the data (and noise), and in the second stage, we use clustering methods on the reduced data to identify population structures. The approach has the ability to identify population structure, make correct inference of the number of subpopulations, and assign individuals to its corresponding subpopulation. Our approach does not have any population genetics assumptions (such as Hardy-Weinberg equilibrium and complete linkage equilibrium between loci within populations) and can be used with any genotype data. We present results applying the approach to a mixture of two American populations. Compared to the most popular method (STRUCTURE, Pritchard et al. 2000; Falush et al. 2003), our approach has comparable performance and is faster and more efficient in inferring the number of clusters.

Genetic Structure of a Culturally Conserved Afro-Colombian Population. *I. Soto-Calderon¹, J. Lopera¹, MC. Mondragon¹, Y. Caicedo¹, L. Caraballo², G. Bedoya¹, A. Ruiz-Linares^{1,3}.* 1) Grupo de Genetica Molecular, Univ Antioquia, Medellin, Colombia; 2) Univ. de Cartagena, Cartagena, Colombia; 3) Galton Laboratory, Univ. College London, London, UK.

In 1774, the population of San Basilio de Palenque (PSB) was settled near Cartagena de Indias, the most important harbor of African slaves in the New World. This population kept in isolation until late 19th century, propelling the conservation of ancestral African costumes and the formation of a new tongue with Bantu influence.

Molecular data were used to determine the admixture level and to ascertain the predominant parental populations involved in the settlement of PSB. The markers used encompass 6 STRs and 4 biallelic loci in non-recombinant section of the Y-chromosome (YC), 6 biallelic loci in mtDNA, 4 autosomal loci with population specific alleles (PSA) and 6 sites located in the α -globin gene cluster.

It was found 83% of African (haplogroup E) or potentially African YC haplotypes (C, D) in PSB, which is consistent with high levels of African ancestry identified with the PSA (90%). Other YC haplotypes found in PSB indicate 4% of Amerindian lineages (haplogroup B) and 13% European. The average gene diversity calculated with 6 STRs in YC was 0.50.

In mtDNA, it was found 69% of lineages proceeding from Sub-Saharan Africa (haplogroup L), 8.4% Amerindian (A-D) and 22.6% non-Amerindian, whose origin remains to be established. Also, the haplotypic diversity (0.58) was lower than that reported for other admixed and Amerind Colombian populations.

The allelic frequency of the ^s mutation (E6V) in the gene was 8.8%. 84% of the haplotypes linked to E6V in PSB have been previously reported in African populations exhibiting 52% of Benin, 28% of Cameroon and 4% of one haplotype found in Central African Republic and Senegal. As the origin of the E6V mutation has been traced to Africa and regarding the high degree of African ancestry in PSB, it can be suggested recombination between 5' and the gene .

Genetic contribution of Acadian founders to the contemporary Quebec population. *M. Tremblay, J. Bergeron, L. Houde, H. Vézina.* Univ Quebec, Chicoutimi, PQ, Canada.

The year 2004 marks the 400th anniversary of the arrival of the first French settlers in the Acadian peninsula. The present Acadian population of North America is descended from these early 17th century French immigrants who settled in an area located in the province of Nova Scotia (Eastern Canada). In 1713, this French territory was yielded to the British Crown through the signature of the Utrecht Treaty. Forty-two years later, the British authorities ordered the deportation of the Acadians who were dispersed in the British colonies of America. Some of the deportees settled in Canada, which became a British colony in 1763 (Treaty of Paris). It is estimated that between 2000 and 3000 Acadians have settled in the territory of what is now the province of Quebec, during the second half of the 18th century. In Quebec, some parishes were founded and populated almost exclusively by Acadians, while others received a considerable number of Acadian migrants. The goal of this study is to evaluate and characterize the impact of the Acadian migratory input on the Quebec gene pool by measuring and comparing its demographic and genetic contributions to the various regions of Quebec. Analyses are based on genealogical data contained in a corpus of 2340 ascending genealogies (BALSAC-RETRO database). These genealogies cover the entire Quebec territory and go back to the beginning of the 17th century, with a maximum lineage depth of 16 generations. Acadian founders were identified, and their period of marriage, frequency of occurrences in the genealogies and genetic contributions to the regional populations of Quebec were analyzed. Although Acadian founders can be found in most genealogies, results point toward an important variability of the Acadian imprint on Quebec's regional gene pools.

Genetic analysis of caste and tribal populations of south India. *W.S. Watkins¹, B. Mowry², T.N. Srinivasan³, R. Thara³, B.V.R. Prasad⁴, J.M. Naidu⁴, B.B. Rao⁴, M.J. Bamshad^{5,1}, L.B. Jorde¹.* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT 84112; 2) Queensland Centre for Mental Health Research, Wacol, Brisbane, Australia 4076; 3) Schizophrenia Research Foundation India, Chennai, Tamil Nadu, India; 4) Department of Anthropology, Andhra University, Visakhapatam, India; 5) Department of Pediatrics, University of Utah, Salt Lake City, UT 84112.

The diverse populations of the Indian subcontinent provide an opportunity to examine human evolution and population affinities influenced by well-defined social customs. To test hypotheses of population differentiation, we genotyped 43 unlinked short tandem repeats (STRs) in 179 individuals from 4 castes of varying social rank (2 Brahmin (upper), Mudaliar (middle), Harijan (lower)) from the state of Tamil Nadu and 152 individuals from 8 tribal groups (Chenchu, Irula, Kattunaicken, Khonda Dora, Maria Gond, Santal, Siddi, Yanadi) from south India. STR heterozygosity is similar between caste groups (mean = 0.683, range 0.665 - 0.697). In contrast, tribal populations vary substantially for STR heterozygosity (mean = 0.665, range 0.731 - 0.538), suggesting that substantial genetic drift has occurred in these isolated populations. R_{ST} estimates are low for Tamil castes (0.007), Andhra castes (0.010), and between Tamil and Andhra groups (0.002). The R_{ST} estimate for tribal populations (0.042, Siddi excluded) is more than 4 times greater than that for all south Indian castes (0.010) and, interestingly, greater than the value for 7 sub-Saharan African populations ($R_{ST} = 0.026$). For the 3 Tamil speaking castes, genetic distance estimates (dsw method) followed caste status (Brahmin/Mudaliar = 0.0011, Brahmin/Harijan = 0.0021, Mudaliar/Harijan = 0.0015) showing a positive, although non-significant, correlation ($r = 0.92$, $p > 0.32$). Caste populations from Andhra Pradesh show a similar pattern. The trend was not observed when the non-Tamil speaking Brahmin group was included, possibly reflecting the effects of language on mating patterns.

The use of Short Tandem Repeats Loci to study the genetic structure of several populations from Zulia State, Venezuela. *W. Zabala¹, L. Pineda¹, L. Borjas¹, E. Fernández¹, MG. Portillo¹, MA. Sanchez¹, A. Aranguren², W. Delgado¹, JA. Chacín¹.* 1) Medical Genetic Unit, Univ Zulia, Maracaibo, Venezuela; 2) Department of Genetics, Faculty of Veterinary, Univ Zulia, Maracaibo, Venezuela.

Short Tandem Repeats (STR), is a group of highly polymorphic markers used mainly as markers of genetic individuality in criminalistic and paternity testing. However, the distribution of allelic frequencies has shown significant differences when comparing them between ethnic groups, suggesting that these systems can be used to detect genetic differences between populations and sub-populations. The aim of this study is to evaluate the utility of autosomal STR loci to define the genetic structure of five populations in Zulia. The sample consisted of unrelated individuals from Maracaibo, Isla de Toas, San Jose de Heras (SJH), Bari and Yukpa. DNA was extracted and seven autosomal STR loci were amplified (CSF1PO, TPOX, TH01, VWA, D7S820, D13S317 and D5S818). PCR products were characterized by PAGE 5%, and stained with silver nitrate. The allelic frequencies, HW-Eq, Obs and Expect Heterozygosity, the Wrights F-statistic, were determined. It was constructed a pair-wise distance matrix between populations using the coefficient of gene differentiation or F_{ST} . A dendogram with the algorithm UPGMA using the Nei's D_A distance was used to compare the zulian populations with others in the world, and also the principal components analysis was used to depict the genetic distances in three dimensions. It may be observed that there are differences in the distribution of the allelic frequencies for each population, allowing identification of their own characteristics, probably related to the origin of each one. The major genetic diversity was found in SJH. It was also proved the existence of a general tendency of not random crosses that causes a departure from panmixia in the studied population. The dendogram clustered the zulian populations with those groups that have greater affinity. These results are supported with the estimation of the percentage of ethnic admixture and the historic evolution of the region emphasizing the importance of considering history for a suitable interpretation of genetics data.

The DRD2 A1 allele Contributes to the Severity of opium-dependence in the Iranian Population. M.

Shahmoradgoli N.^{1, 2}, M. Ohadi¹, MT. Joghataie¹, F. Valaie¹, Y. Riazalhosseini¹, H. Najmabadi¹. 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Tehran, Iran; 2) Young Researchers Club, Science and Research Department, Islamic Azad University, Tehran, Iran.

Dopaminergic mechanisms are thought to play an important role in the pathogenesis of certain neuropsychiatric disorders including drug abuse. Little attention has been focused on the molecular genetic factors that might influence the prognosis and severity of opiate-dependence. We studied the allelic association between DRD2 Taq A1 polymorphism and daily drug usage in 100 opium-dependent Iranian patients and 130 unrelated controls. A 310 bp region surrounding Taq I site at the DRD2 locus was amplified by polymerase chain reaction (PCR) and the PCR product was digested with Taq I restriction enzyme. The A1 allele remained intact while the A2 allele was cut. Significant association was observed between the A1 allele and the average use of opium (g/day) in opium-dependent patients; the A1A1 genotype correlated with higher daily usage comparing with the A1A2 or A2A2 genotypes ($P=0.0001$). Our results support a role for DRD2 in the severity of opium addiction in the Iranian population.

Program Nr: 1248 from the 2004 ASHG Annual Meeting

Intronic Regions Involved in Splicing Show Less Polymorphism. *B. A. Salisbury, C. Harris-Kerr, J. C. Stephens.*
Genaisance Pharmaceuticals, Inc., 5 Science Park, New Haven, CT 06511.

Variation found in introns may have phenotypic relevance either through regulatory or splicing effects. We analyzed the distribution of intronic SNPs discovered in the course of resequencing over 5000 genes. We discovered a clear pattern of greatly reduced variability in the splice donor and acceptor regions of introns. The detailed patterns we observed correspond well with what is known about the recognition of splicing elements by components of the spliceosome. Furthermore, the SNP pattern is consistent with the patterns reported by others of nucleotide variation among introns; i.e., sites that have a limited nucleotide variability among introns have limited polymorphism within introns. We observed about 90% fewer SNPs in the two 5'-most and two 3'-most nucleotide positions relative to the most SNP-dense positions. A stretch of significantly reduced SNP density was also observed in the poly-pyrimidine tract near the acceptor splice site. Certain other positions also showed significant differences in SNP density. Finally, differences in SNP density correlate strongly with differences in allele frequencies for the SNPs that exist; at positions with fewer SNPs, the SNPs that are found tend to have low minor allele frequencies. We have additionally considered the spectrum of nucleotide changes reflecting allele status as common or rare and ancestral or derived relative to chimpanzee sequence.

L1-mediated mobilization of trans-spliced and chimeric transcripts: a mechanism to increase genomic diversity.

*D.V. Babushok*¹, *E.M. Ostertag*^{1,2}, *K. Ohshima*³, *J.M. Choi*¹, *N. Okada*⁴, *H.H. Kazazian, Jr*¹. 1) Dept Genet, UPenn; 2) Dept Path Lab Med, HUP, Philadelphia, PA; 3) Nagahama Inst Bio-Sci Tech, Nagahama; 4) Grad Sch Biosci Biotech, Tokyo Inst Tech, Yokohama, Japan.

LINEs are thought to have contributed to more than 40% of the human genome through direct insertion, by trans-mobilization of Alus, SVAs, and processed pseudogenes, and by providing substrates for chromosomal rearrangements. L1s have the potential for exon-shuffling by carrying along 5'-transduced sequences when transcribed from a fortuitously-located upstream promoter, or 3'-transduced sequences by forgoing their own polyadenylation signal for a stronger downstream one. Here we report a novel mechanism of L1-mediated exon-shufflingretrotransposition of trans-spliced RNAs. We previously described an active L1 tagged with a bi-directional splice acceptor gene-trap. We now demonstrate precise splicing of the gene-trap cassette to the upstream splice donor when integrated into an intron. Using TAIL-PCR we have characterized genomic locations of 36 insertions. One insertion landed into intron 1 of the PKIA gene on 8q21 and had all the hallmarks of a bone fide retrotransposition event. Unexpectedly, the inserted sequence was a chimera formed by two trans-spliced RNAs the 3'-most 119 bp of exon 1 of the heterologous transcript FLJ23285 was spliced precisely to the 5' splice acceptor of the gene-trap cassette. Using RT-PCR we ruled out the occurrence of a prior insertion into FLJ23285, followed by a 5'-transduction event, splicing and integration of the transcript into 8q21. To assess the extent of such events, we examined 10,000 human processed pseudogenes for evidence of retrotransposed fused exonic sequences. One such chimera was detected on chr. 17, in which 5 exons of HMG-4 gene from chr. X were fused 3' to 3 exons of ATP synthase gene on chr.11, all flanked by TSDs characteristic of L1-mediated retrotransposition. The fusion site was most consistent with this being a product of template switching during the TPRT reaction. Thus, we demonstrate the potential of L1s to mobilize trans-spliced and otherwise fused transcripts, contributing to exon and domain shuffling and increasing genomic diversity.

Unexpectedly high allelic variation found in a locus of young and active L1 elements. *C.N. Talchai, M.dC. Seleme, H.H. Kazazian.* Dept. of Genetics, School of Medicine, University of Pennsylvania, Philadelphia, PA.

L1 retrotransposons are the only family of active transposable elements in the human genome as indicated by multiple cases of *de novo* insertions, cell culture assays, retrotransposition in transgenic mice and database analyses. The overall L1 family comprises about 17% of our genome, but only a small proportion of elements (<0.2%) retain open reading frames and are potentially active. Among these intact L1 elements, 38 of 86 (44%) are polymorphic as to their presence or absence in human populations. The isolation of the first active element (L1.2) revealed that L1 elements present alleles just as regular cellular genes do. Recently it was shown that two alleles (L1.2A and L1.2B) of this element display a 16-fold difference in retrotransposition capacity, suggesting that allelic heterogeneity can influence the potential mutational load of an individual genome. Here, we further investigated the allelic status of a highly active and polymorphic L1 (A1512428). We isolated the full-length L1s from heterozygous individuals of diverse ethnic origins and compared their sequences. By direct sequencing, we verified that no PCR errors were introduced during the 6kb amplification. The copies of the element tested from five different individuals were very variable, with two alleles almost identical to the database reference sequence and two others identical to each other, but with 6 nucleotide changes from the reference. Some changes were shared among different alleles. Intriguingly, the fifth allele contained 9 changes from the reference element: among the 4 private ones, 2 introduced stop codons into ORF1. This is the first example of allelic differences in a young L1 locus that features both mutated (likely dead) and active alleles, adding an important level of complexity to our understanding of individual genome dynamics. We hypothesize that other polymorphic L1 loci contain such allelic variability, and are further investigating allelic variation and retrotransposition activity of these polymorphic L1s.

Prevalence of the FMR1 mutation in Taiwan assessed by large-scale screening of newborn boys and analysis of DXS548-FRAXAC1 haplotype. *C.C. Tzeng¹, L.P. Tsai², W.L. Hwu³, S.J. Lin⁴, M.C. Chao⁵, Y.J. Jong⁵, S.Y. Chu⁶, W.C. Chao¹, C.L. Lu⁷.* 1) Department of Pathology, Chi Mei Medical Center, Tainan; 2) Department of Pediatrics, Taipei Municipal Womens and Childrens Hospital, Taipei; 3) Department of Pediatrics and Medical Genetics, National Taiwan University Hospital, Taipei; 4) Bureau of Health Promotion, Department of Health, Taipei; 5) Departments of Pediatrics and Medical Genetics, Kaohsiung Medical University, Kaohsiung; 6) Departments of Pediatrics, Buddhist Tzu Chi Hospital, Hualien; 7) Department of Medical Research, Chi Mei Medical Center, Tainan, Taiwan.

If carrier women could be identified in time and take appropriate measures, fragile X syndrome can be prevented. Wide screening of women to be or in their early pregnancy was considered a good approach to identify carriers without misdetection. Nevertheless, we argued against the cost-effectiveness of implementing such a screening program in Taiwan, due to the lower carrier rate found in our pilot study. To reliably estimate the prevalence of mutant FMR1 gene in Taiwan, we anonymously screened 10,046 newborn boys using bloodspot PCR. Among them, 5 had Z (61-200 CGG repeats) or L (full mutation) allele, revealing a prevalence of one per 2,009 X chromosomes, which is significantly lower than a prevalence of one per 462-482 X chromosomes in Caucasians (p 0.05). The prevalence of S (41-60 CGG repeats) allele was one per 50 X chromosomes (201/10,046), also significantly lower than one per 33-35 X chromosomes in Caucasians (p 0.05). Furthermore, when comparing analyses of the distribution of alleles at the two most often investigated microsatellite loci, DXS548 and FRAXAC1, between 100 control and 28 unrelated fragile X chromosomes, we found no apparent founder haplotype prevalent among the fragile X patients. Because a few founder haplotypes were reportedly prevalent in two thirds of fragile X alleles in Caucasians and Chinese in central China, we thus suggested that lack of founder fragile X chromosomes might result in a relatively low prevalence of mutant FMR1 gene in a population, as observed in Taiwan.

Comparative analysis of human and chimpanzee duplicated regions, located in an unstable loci in distal Xq28. *R. Bandyopadhyay, D.L. Nelson.* Baylor College of Medicine, Department of Molecular and Human Genetics, Houston, TX.

Analysis of the human genome sequence shows that 5% of the human chromosome is composed of intra and inter chromosomal duplications. Segmental duplications play significant roles in human disease. Segmental duplications on sex chromosomes constitute an important proportion of recent duplications. Incontinentia Pigmenti (IP) is a X-linked, male lethal disorder characterized by abnormal skin pigmentation, retinal detachment, alopecia, and mental retardation. The majority of the IP cases have an identical deletion in the NEMO gene that eliminates exons 4 to 10. The gene is located on Xq28, immediately distal to G6PD. A 35.5kb region containing the majority of the NEMO gene is duplicated, and the inverted copy found about 22 kb distal is more than 99% identical in sequence. Comparative studies in closely related species is one approach to understand the origin and maintenance of these duplicated sequences; this duplication is found in both chimpanzee and gorilla. We analyzed the sequence divergence of the orthologous chimpanzee locus (NEMO-duplications) for both the flanking and the duplicated regions. The result showed reduced divergence of the duplicated sequence compared to the flanking sequence. The overall nucleotide substitution level in aligned regions between PTR-NEMO dup and HSA-NEMO dup is about 1% (excluding indels), which is significantly lower than the reported estimates of divergence, ranging from 1.23% to 1.44%. We identified 38 indels in total. The overall divergence between the two sequences is ~ 2%, counting the indels, which is again lower compared to 5%, when indels are counted. The longest indel identified in this region is 91bp and it is within an Alu sequence in the noncoding region. Other segmental duplicated regions present in Xq28 were also analyzed. All these regions show high sequence conservation between the PTR and HSA. The high sequence similarity between the duplicated regions may be due to frequent gene conversion and possibly a directional bias in gene conversion is responsible for the lack of drift within each sequence.

A New Technique for the Rapid and Inexpensive Genotyping of Y Haplogroups. *L.R. Harrell¹, L. Zhou², L. Jorde¹.*
1) Human Genetics, University of Utah, Salt Lake City, UT; 2) Pathology, University of Utah, Salt Lake City, UT.

We present the application of a new method for performing inexpensive and rapid genotyping of the Y chromosome. This method amalgamates a few straightforward techniques into a formidable genotyping system. The first step is the asymmetric PCR of the region immediately surrounding the SNP (or small insertion/deletion) which generates an excess of one of the template strands. The PCR product is then combined with a dye that binds double-stranded DNA (LC Green I) and a 3-blocked oligonucleotide whose sequence straddles the SNP, mimicking the template strand that was depleted in the PCR reaction. The mixture is then completely denatured, cooled, and slowly reheated on either a LightCycler (for a single sample) or a LightTyper (for 96- or 384-well plates of samples), generating a melting curve for the duplex. Due to the nature of the oligo, two scenarios are possible; either the oligo will be a perfect match to the SNP or it will contain a 1bp mismatch because the oligo doesn't match template at the location of the SNP. The difference between these two possibilities shifts the melting curve of the duplex sufficiently to be diagnostic of the allelic state of the SNP. Additional benefits, such as the lack of a need to eliminate mispriming events and our ability to multiplex the PCR reactions, make this method both efficient and cost effective. We have used this new method to design a genotyping panel for the Y chromosome that is able to assign individuals into 1 of 38 haplogroups (A1 through R2) based on the Y Chromosome Consortium tree. We have used this panel to genotype nearly 1000 individuals with a special focus on populations from southern India. Population substructure and migration histories were examined and compared to previous findings for Y chromosome and mtDNA HVS I sequences.

What Can Environmental Genome Project Data Tell Us About Gene Haplotype Structure? *R.W. Morris¹, P.D. Terry², L. Li³, N.L. Kaplan³, J.A. Taylor^{2,4}*. 1) Dept of Anesthesiology, Duke Univ Medical Ctr, Durham, NC; 2) Epidemiology Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC; 3) Biostatistics Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC; 4) Laboratory of Molecular Carcinogenesis, National Institute of Environmental Health Sciences, Research Triangle Park, NC.

The Environmental Genome Project (EGP) is a publicly available data set of resequenced DNA repair and cell cycle control genes in a sample of 90 people of diverse ethnicity. We characterized genotype structure in 106 genes using 2058 common SNPs (minor allele sample frequency > 0.1). 381 different observed ensembles of minor alleles were directly observed in individuals homozygous for either the major or minor allele at each SNP. Forty additional inferred ensembles of SNPs were identified where pair-wise genotype correlation coefficients exceeded 0.80. On average, there were 19 common SNPs representing 4 ensembles per gene. These ensembles often consist of unique sets of minor alleles and are thus "orthogonal" to one another. Observed and inferred ensembles together can be used to explain 97% of the SNP genotype variation in the EGP sample. How well can these ensembles explain SNP genotype variation in other data? To answer this question, we used data from the HapMap project. For SNPs present in both data sets, the ensembles from the EGP data matched haplotypes inferred from HapMap genotypes of CEPH families. Many of the ensembles from the EGP could not be evaluated because of the paucity of HapMap SNPs within the relevant genes. In addition, although the ethnicity data for the EGP data has been destroyed, we have used Cancer500 data to confirm that common EGP SNPs are multi-ethnic. We conclude from these comparisons that SNP ensembles found in the EGP data accurately represent haplotype variation found in HapMap CEPH families, but that, because of low SNP density, HapMap currently fails to sample many additional common gene haplotypes that can be found using resequencing data. In addition, common SNPs from EGP are pan-ethnic, suggesting that the resulting haplotypes are also pan-ethnic.

Hearing impairment associated with DFNA5 is caused by an unusual mechanism where skipping of one specific exon leads to disease, that is not caused by other mutations in this gene. *G. Van Camp¹, K. Vrijens¹, M. Pfister², S. Thys¹, M. Mueller², V. Van Tendeloo³, L. Umans⁴, L. Serneels⁴, F. Kooy¹, R. Smith⁵, D. Van Bockstaele³, F. Van Leuven³, J.-P. Timmermans⁶, L. Van Laer¹.* 1) Dept. of Medical Genetics, University of Antwerp, Belgium; 2) Hals-Nasen-Ohrenklinik, University of Tübingen, Germany; 3) Laboratory of Experimental Haematology, University of Antwerp, Belgium; 4) Experimental Genetics Group, University of Leuven, Belgium; 5) Molecular Otolaryngology Research Laboratories, University of Iowa; 6) Laboratory of Cell Biology and Histology, University of Antwerp, Belgium.

Three mutations have been described in the DFNA5 gene in 3 families with autosomal dominant non-syndromic hearing impairment. Although different at the genomic DNA level, these mutations all lead to skipping of exon 8 at mRNA level. DFNA5^{-/-} mice were generated through deletion of exon 8 by targeted recombination, simultaneously mimicking the human mutation. To test the hearing, frequency-specific ABR (Auditory-evoked Brainstem Response) measurements were performed. Transfection experiments in mammalian cell lines (HEK293T; COS-1) using GFP-tagged wild-type and mutant DFNA5 were performed and cell death was analysed using flow cytometry and fluorescence microscopy. ABR tests could not demonstrate significant differences between DFNA5^{-/-} mice and their wild-type littermates. After transfection with mutant DFNA5-GFP, cell death approximately doubled when compared with transfection with wild-type DFNA5-GFP. The fact that DFNA5^{-/-} mice have normal hearing, in combination with the fact that only mutations that lead to exon 8 skipping have been described for human hearing loss, led to the hypothesis that hearing impairment associated with DFNA5 is caused by a highly unusual mechanism where skipping of one specific exon leads to disease, that is not caused by other mutations in this gene. We hypothesize that this represents a gain-of-function mutation, with the truncated protein exerting a deleterious new function. This hypothesis was supported by the fact that transfection with mutant DFNA5-GFP significantly increased cell death.

Spectrum and functional analysis of inactivating mutations in the epidermis-type lipoxygenase genes in autosomal recessive congenital ichthyosis (ARCI). *K.M. Eckl¹, P. Krieg², W. Küster³, H. Traupe⁴, F. André¹, N. Wittstruck¹, G. Fürstenberger², H.C. Hennies¹.* 1) Molecular Genetics and Gene Mapping Center, Max Delbrück Center, Berlin, Germany; 2) Eicosanoids and Tumor Development, German Cancer Research Center, Heidelberg, Germany; 3) Tomesa Fachklinik, Bad Salzschlirf, Germany; 4) Dermatology, University of Münster, Germany.

Autosomal recessive congenital ichthyosis (ARCI) forms a clinically and genetically heterogeneous group of severe inherited keratinization disorders characterized by intense scaling of the skin, different in color and shape, and often associated with erythema. Mutations in *ALOX12B* and *ALOXE3* on chromosome 17p13, coding for epidermal lipoxygenases 12R-LOX and eLOX-3 preferentially synthesized in the skin, were previously found in patients with ichthyosiform erythroderma. 12R-LOX and eLOX-3 are subsequent members of the same pathway, which converts arachidonic acid to an epoxyalcohol. In a large group of 150 families with ARCI, we identified 20 novel and one previously described point mutations in *ALOXE3* and *ALOX12B* in 20 families from various ethnic backgrounds. We found only few mutations repeatedly in different families but no founder effects as demonstrated by microsatellite analysis. We further analyzed the expression of the mutant genes and developed an in vitro assay in order to determine the enzyme activity using the genuine substrates. Analysis of reaction products by reversed-phase HPLC demonstrated that all missense mutations but one depleted the enzymatic activity of recombinant enzymes. Moreover, we intend to study subsequent changes in the expression of further interacting proteins of keratinocytes. All patients were clinically characterized in detail. We observed that mutations in epidermal lipoxygenase genes resulted in a mild phenotype of ARCI with light scales, normal hair, mild or absent palmoplantar hyperkeratosis, and hypohidrosis. We did not see dark brown scales on the face and/or adherent scales on the trunk. This is the first time that genetic findings in patients with ARCI could be correlated with the phenotype, whereas mutations in the gene *TGM1* were seen with the whole spectrum of mild to very severe forms of ARCI.

Single-stranded DNA fragments isolated from plasma of healthy subjects. *J.J. Jonsson^{1,2}, A. Alfredsson², J. Johannsdottir^{1,2}, G.H. Gunnarsson^{2,3}, M. Konradsson^{1,2}, S. Kristjansdottir², J. Asmussen².* 1) Dept Genetics/Molecular Med, Landspítali-Univ Hosp, Reykjavik, Iceland; 2) Dept. of Biochemistry and Molecular Biology, Faculty of Medicine, Univ. of Iceland; 3) BioCule, Reykjavik, Iceland.

Aims: DNA is present in low concentration in plasma. Limited information is available on its characteristics and function in health and disease. We developed four assays for plasma DNA concentration and structure and analysed samples from healthy adult subjects. **Methods:** DNA was isolated from plasma samples collected from 20 healthy individuals (21-33 yrs.) using High Pure Viral Acid Kit (Roche Diagnostics). DNA concentration was measured with an ultrasensitive LightCycler qPCR assay amplifying an 169 bp segment from Alu repeats with real-time SYBRGreen I fluorescence and a direct PicoGreen fluorometric assay for dsDNA. Size of dsDNA fragments was determined with PAGE and size and fraction of dsDNA and ssDNA fragments with 2D strandness-dependent electrophoresis (2D-SDE) and fluoroimaging. **Results:** We developed two quantitative methods based on different analytical principles since no standard for plasma DNA is available. Average concentration of plasma DNA was 4,7 g/L (range 1,77,8) according to the qPCR-Alu method and 3,1 g/L (range 1,06,0) with the direct dsDNA fluorometric assay. Correlation coefficient between the two methods was only 0.7. dsDNA in plasma DNA of healthy individuals was between 150 to 300 bp in length on electrophoresis. 2D-SDE revealed that the majority of plasma DNA was single stranded, explaining the bias and relatively poor correlation between the two quantitative methods. **Conclusions:** We have developed four sensitive assays to characterize plasma DNA in normals and various disease states. Surprisingly, the majority of plasma DNA isolated from normals was single stranded and corresponded to 1-2 nucleosomes in length. In contrast, current models of apoptotic and necrotic cellular release of DNA favor double-stranded fragments. Future studies should address to what extend strandness of plasma DNA fragments is dependent on methods of isolation and poorly characterized biological factors.

Characterization of human homologs of yeast ubiquitin-conjugating enzyme Ubc6p: Phosphorylation of hsUbc6e. *R.S. Oh^{1,2}, X. Bai¹, J.M. Rommens^{1,2}*. 1) Genet & Genom Biol, The Hospital for Sick Children, Toronto, ON, Canada; 2) Mol & Med Genet, U of Toronto, Toronto, ON, Canada.

Mutant membrane proteins that are associated with human disease are frequently targeted for degradation from the endoplasmic reticulum (ER). Nascent terminally misfolded or misassembled membrane proteins are subject to retrotranslocation from the lumen of the ER to the cytosol where ubiquitination machinery localized at the cytosolic face of the ER targets them for the proteasome. Ubiquitin-conjugating enzyme Ubc6p, a tail-anchored protein which is localized to the cytoplasmic face of the ER membrane, has been implicated in the degradation of several misfolded membrane proteins in yeast including mutant ABC transporters Ste6p and Pdr5*, and also heterologously expressed CFTR. We have undertaken characterization studies of two human homologs of Ubc6p, hsUbc6 and hsUbc6e. Both display high conservation to the yeast protein in their catalytic domain and possess a tail-anchored membrane protein motif. Both are functional ubiquitin-conjugating enzymes as determined by in vitro thiol-ester assay. Both also displayed induction by unfolded protein response, a feature of many ER-associated degradation (ERAD) components. Post-translational modification of hsUbc6e was observed and identified as phosphorylation at Ser184, which resides within the uncharacterized region linking the highly conserved catalytic core and the carboxyl terminal transmembrane domain. The modification was evident soon after translation, was stable over time in pulse-chase metabolic labeling experiments, and required membrane localization. Assays of hsUbc6e mutants S184D and S184E, which mimic the phosphorylated state, suggest that phosphorylation may reduce capacity for formation of ubiquitin-enzyme thiol esters. The occurrence of two distinct Ubc6p homologs in vertebrates, including one with phosphorylation modification, emphasizes diversity in function via modulation of thiol ester formation and possibly substrate recognition in ERAD processes. Further studies will be aimed at elucidating these distinctions as well as involvement of these human homologs in the degradation of wild-type and mutant CFTR.

Combined bioinformatic and biochemical analysis discriminates between neutral and clinically significant genetic variation in ABCA1. *L.R. Brunham¹, R.R. Singaraja¹, P.D. Thomas², M.R. Hayden¹.* 1) Dept Medical Genetics, CMMT, Univ British Columbia, Vancouver, BC, Canada; 2) Applied Biosystems, San Francisco, CA, USA.

ABCA1 is the key regulator of cellular cholesterol efflux. Many mutations and SNPs have been described in the ABCA1 gene, which result in a broad spectrum of clinical phenotypes of HDL-C levels and susceptibility to atherosclerosis. A major challenge remains the assignment of function to these genetic changes. We used data from PANTHER, a bioinformatics tool, to predict the functional consequences of each SNP and mutation in ABCA1, and validated these predictions through biochemical assays of function. PANTHER consists of a collection of protein families and subfamilies that allows us to ask the question, how likely is a given amino acid to occur at a given position in related proteins from the same and other organisms? By comparing the probabilities of the wildtype amino acid and its substitution, we can calculate a score to predict the functional consequence of a given substitution. Compared to mutations (n=15), SNPs (n=9) score much closer to zero (mean -1.57 1.04 vs. -5.32 1.68, Mann-Whitney $P < 0.0001$), indicating that SNPs are predicted to result in much milder effects on ABCA1 function compared to mutations. The two mutations with the most neutral subPSEC scores, D1289N and P2150L, both scored in the range observed for most SNPs. We tested the ability of proteins harbouring these mutations to elicit cholesterol efflux and found no significant change relative to wildtype ABCA1, suggesting that these mutations are in fact functionally neutral. Conversely, the mutations with the most negative subPSEC scores (N935H, N935S and Q597R) uniformly result in severe phenotypes in vivo. We tested the ability of two of these mutations to elicit lipid efflux. Relative to wildtype, these mutations resulted in significantly reduced cholesterol efflux (N935S: 29.31% 13.0; Q597R: 17.73% 13.77), underlying the severe clinical phenotype observed in patients with these mutations. These results validate the use of PANTHER in making predictions of the functional consequences of genetic variation.

Bioinformatic identification of regulatory regions within *RBI* introns. *S. Lithwick*^{1,2}, *V.D. Brown*², *W.W. Wasserman*³, *T.W.Y. Wang*², *B.L. Gallie*^{1,2}. 1) Department of Molecular & Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Department of Cancer Informatics, Princess Margaret Hospital, Toronto, Ontario, Canada; 3) Centre for Molecular Medicine & Therapeutics, Vancouver, British Columbia, Canada.

Retinoblastoma is a rare childhood retinal cancer, resulting from mutations within the *RBI* tumor suppressor gene. Coding mutations are implicated in 89%, and promoter mutations in 5% of probands. No *RBI* mutation has been identified in 6% of probands. Regulatory domains additional to the promoter have been identified within introns using cross-species comparisons; functionally significant sequences are maintained while surrounding sequences diverge. We hypothesize that some of the probands in whom no *RBI* mutation is yet identified have mutations within non-coding regions that regulate *RBI* gene expression. We used phylogenetic footprinting to identify *RBI* promoter and intronic regions that are conserved between species. Conserved regions were analyzed using a suite of in-silico motif prediction and sequence analysis programs. Bioinformatic predictions were evaluated using electromobility shift assays (EMSA), chromatin immunoprecipitation (ChIP), and luciferase transcription assays. Transcription factor binding sites (TFBSs) were predicted within the *RBI* core promoter and a 5' portion of intron 1 conserved between human, mouse, and rat. All functionally implicated sequences were independent of simple genomic repeats, and did not resemble either snoRNAs or microRNAs. All of the conserved sequences were biased for GC basepairs. EMSA assays suggested that proteins interact with each of the conserved regions, and ChIPs indicated that one protein interactor may be E2F. Non-coding sequence regions conserved among *RBI* orthologs may play an important role in the regulation of gene expression at discrete stages of mammalian development. These conserved regions are candidate sequences in which to search for mutations that predispose to retinoblastoma.

SCA1 pathogenesis: An alteration in ROR mediated gene expression. *H. Serra*¹, *J. Lande*^{1,3}, *H.Y. Zoghbi*², *H.T. Orr*¹. 1) Lab Medicine & Pathology, Institute of Human Genetics, Univ Minnesota, Minneapolis, MN; 2) Howard Hughes Medical Institute, Dept Molecular and Human Genetics, Baylor College of Medicine, Houston TX; 3) Dept of Medicine, Univ Minnesota, Minneapolis, MN.

Spinocerebellar ataxia type 1 (SCA1) is an autosomal dominant neurodegenerative disease caused by the expansion of a polyglutamine repeat within the disease protein, ataxin-1. We used microarray analysis to better understand the pathophysiology of SCA1. Initially we identified a set of downregulated genes related to glutamate signaling in the cerebellum. With further analyses we detected a decrease in the retinoid-related orphan receptor-mediated (*ROR*) gene expression in the line carrying mutant ataxin-1 when compared to the non-ataxic line. In the mutant line a decreased expression of genes related to synaptic calcium signaling as well as to glutamate signaling were observed. Most of these genes are known to have their expression controlled by ROR. To examine the relationship between ROR and ataxin-1 we performed coimmunoprecipitations using cerebellar extracts from a wild type mouse to demonstrate that ROR and ataxin-1 interact in vivo. The interaction between ROR and ataxin-1 is under further investigation. Together with other data these results point to a direction where ataxin-1 participates in a nuclear complex involving gene transcription and RNA regulation.

A systematic approach for functional annotation of human KAO-NASHI (Face-less) genes. *N. Shimizu¹, A. Shimizu¹, T. Sasaki¹, M. Furutani-Seiki², H. Kondoh², S. Asakawa¹*. 1) Dept Molecular Biol, Keio Univ Sch Medicine, Tokyo, Japan; 2) Kondoh Research Group, SORST, JST, Japan.

The Human Genome Project has provided the DNA sequences of 3 billion base pairs and identified over 30,000 protein-coding genes in the human genome. However, many of these protein-coding genes are not fully proven by experimental evidences. In general, proteins with known motifs are readily classified, but substantial numbers of protein have no obvious motifs in their sequences. We designated these genes/proteins without obvious motifs as KAO-NASHI (Face-less) and initiated a project to unveil their face (kao) by comparative genomics and knockdown analysis using Medaka (a small teleost fish) as animal model.

First, we made a list of human genes/proteins, and analyzed whether they have known motifs using HMMER program and Pfam database or trivial or nave names of obvious function. All genes/proteins were filtered by motif names or gene names and about 4,000 genes remained after this filtration. Genomic structures and open reading frames were carefully inspected to remove non-coding RNA genes and single exon genes. Next, the homology search by BLAST was performed against nr for finding the orthologs in different species. Finally, we deduced complete gene structure using comparative genomic analysis and removed some genes with known motifs in the novel coding sequence. This series of analysis provided with a list of 1,600 KAO-NASHI genes.

In order to unveil these KAO-NASHI genes, we decided to use Medaka (*Orzias latipes*) as a model animal because it is easy to obtain embryos and to observe the organs or anatomical structure. The gene knockdown method using morpholino-antisense-oligonucleotides (MO) is especially effective for Medaka embryos. We have so far identified medaka orthologs for over 60% of human KAO-NASHI genes using the medaka EST and whole genome shotgun sequence databases. We will present the data regarding expression profiles of these KAO-NASHI genes at different developmental stages and phenotypes generated by knockdown analysis.

Effects of C-propeptide Mutations in Type I Collagen on Extracellular Matrix Deposition and Fibrillogenesis.

A.M. Barnes¹, S.A. Milgrom¹, E. Moriarty¹, W.A. Cabral¹, J.P. Cassella², J. Pace³, J.C. Marini¹. 1) BEMB, NICHD/NIH, Bethesda, MD, USA; 2) CEASR, Univ. of Derby, Derby, England, UK; 3) Dept. of Pathology, Univ. of Washington, Seattle, WA, USA.

Mutations in the C-propeptide region of Type I collagen have been found in patients with Type II-IV Osteogenesis Imperfecta (OI). We identified four novel C-propeptide mutations by RT-PCR and direct sequencing of COL1A1 cDNA. Three involved substitutions at conserved residues, including W1097C (nt 15408) in Type III OI, and T1120I (nt 15476) and P1266H (nt 16331) in Type IV OI. The fourth proband, with Type II OI, had a six nt deletion at the E51/I51 junction that caused the in-frame insertion of all but two nt of I51 in cDNA and the loss of the 7th C-propeptide cysteine. We compared proband fibroblasts with normal control cells, a proband with a C-terminal helical mutation (Type III OI, 1(I) G997S) and a published lethal C-propeptide mutation (D1263Y, nt 16321; Pace, J Med Gen 2002; 39:23). All mutant collagens, including G997S, showed broad backstreaking of 1(I) on SDS-Urea-PAGE of steady state collagen, suggesting delayed chain incorporation. Incorporation of pro-1 chains with single amino acid substitutions was 2-3 times longer than in control cells (~20 minutes). D1263Y and helical G997S procollagen required 4 times longer to incorporate 1 chains than control, and pro-1 chains with an intronic insertion were only 1/3 incorporated at 120 minutes. A processing assay suggested delayed C-propeptide removal from secreted collagens containing substitutions in the C-propeptide or at the end of the helix. Overmodified collagens are incorporated into fibroblast matrix in culture and form mature cross-links. Skin and bone fibrils from two probands (T1120I and P1266H) were examined by electron microscopy (EM). Proband dermal fibrils are approximately 10-15% larger than control fibrils. SEM revealed increased disorganization of bone fibrils, compared to an OI proband with a mid-helical mutation. The data show that alterations in the C-propeptide or in interacting regions lead to delayed procollagen processing, incorporation of overmodified collagen into fibrils, and altered fibril organization.

Genetic interaction of TRPS1 and RUNX2 during skeletal development identified by SNP analysis of the RUNX2 promoter. *D. Napierala*¹, *R. Morello*², *G. Zhou*², *Q. Zheng*², *T. Bertin*², *R. Shivdasani*³, *B. Lee*^{1,2}. 1) HHMI, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA.

TRPS1 and *RUNX2* are transcription factors important in skeletal development. Mutations in *TRPS1* cause tricho-rhino-phalangeal syndrome (TRPS), while loss of function mutations of *RUNX2* lead to cleidocranial dysplasia (CCD). Both TRPS and CCD patients exhibit short stature, brachydactyly and cone-shaped epiphyses suggesting that TRPS1 and RUNX2 may play critical roles during chondrocyte differentiation. RUNX2 is a master transcriptional regulator of osteoblast differentiation and chondrocyte maturation. Its expression, however, must be downregulated in mesenchymal condensations during endochondral ossification. Until now, transcriptional repressors of Runx2 *in vivo* have yet to be identified. By combining SNP analysis of control and CCD subjects and cross species sequence analysis, we have identified conserved GATA domain binding sites in the RUNX2 promoter. Because TRPS1 is the only GATA domain transcription factor known to function in skeletogenesis, we analyzed its expression pattern during mouse embryonic development. Interestingly, *Trps1* is expressed in skeletal regions where *Runx2* needs to be turned off, including all mesenchymal condensations destined for chondrogenic lineages. Moreover, TRPS1 specifically binds to the GATA cis elements found in the RUNX2 promoter. In transfection studies, *Trps1* strongly represses the *Runx2* promoter as well as the Runx2 proteins transactivation of its target promoters. Deletion analysis suggests that the interaction is mediated by the RUNT domain. Finally, transgenic mice overexpressing *Trps1* exhibit lengthened growth plates. Together, our data suggest that *Trps1* can inhibit expression of the *Runx2* gene as well as *Runx2* protein function both early during cell fate commitment of mesenchymal condensations and later during chondrocyte maturation. This genetic and biochemical interaction explains some of the clinical features found common in TRPS and CCD.

Activation of Phospholipase D in Angiomyolipomas from Tuberous Sclerosis Complex (TSC) Patients. *K.-S. Au, R. Zhu, H. Northrup.* Dept Pediatrics, Univ Texas Medical Sch, Houston, TX.

Tuberous sclerosis complex (TSC) is a dominantly inherited disease in humans affecting 1:6700 live births. Affected patients are at risk to develop hamartomas in many tissues and organ systems. The greatest morbidity is caused by renal and CNS complications. Renal angiomyolipomas (AMLs) and cysts are common occurring in >80% of patients. The disease is caused by mutations in one of two genes (TSC1 and TSC2) that code for the tumor suppressing proteins hamartin and tuberlin, respectively. Functions of hamartin and tuberlin in normal cells have been actively studied over the last decade concluding that the hamartin/tuberlin complex functions as a GTPase activating protein (GAP) modulating signals from small GTPase (i.e. Rheb, Rap1A, Rab5) to regulate protein translation, vesicle trafficking, cell survival, migration, and proliferation events. The functions involve several cell-signaling pathways including but not limited to PI3K/Akt, Wnt/GSK3, Rho/ERK. Through comparative gene expression microarray studies using mRNAs isolated from three kidney AMLs of a TSC patient with a known germline TSC2 mutation, we observed elevated expression of G-protein coupled receptors and phospholipase D (PLD). The finding was observed in all three samples. The tumors studied were previously reported to have loss of heterozygosity of the TSC2 gene suggesting that a new signaling event in these tumors was activated with the absence of functional tuberlin. Immunoblotting studies demonstrated elevated PLD proteins present in two of the tumor lysates that showed the most elevated PLD1 mRNA by microarray studies. Elevated PLDs have been observed in many tissues studied from human cancers. Of particular importance, elevated PLDs were correlated with reduced sensitivity to rapamycin treatments in breast cancer patients. Rapamycin is currently under study in a clinical trial to treat kidney AMLs in TSC patients. PLD activity in TSC patients may be important in determining their response to rapamycin efficacy for treatment of TSC tumors. Genetic variants leading to higher PLD activity may modify the disease phenotype and tumor treatment outcome for TSC patients.

Pcp4: construction and validation of a transgenic mouse model. *G.M. Barlow¹, J.M. Vesa¹, M. Brennan², D. Patterson², J.I. Morgan³, J.R. Korenberg¹*. 1) Med Genetics Institute, Cedars-Sinai & UCLA, Los Angeles, CA; 2) Eleanor Roosevelt Institute, Denver, CO; 3) St Judes Childrens Hospital, Memphis, TN.

Pcp4 is a calmodulin-binding IQ motif peptide that modulates apoptosis and the activity of CaMKinase II, which is important for long-term potentiation (LTP), learning and memory. It is expressed in neuronal subpopulations of the cortex, dentate gyrus granule cells, hippocampal pyramidal CA2 neurons, cerebellar Purkinje cells, thalamus, caudate putamen and septal nuclei. In vitro, cells transfected with Pcp4 exhibit reduced UV-induced apoptosis and neuronal populations expressing Pcp4, including dentate gyrus granule cells and cerebellar Purkinje cells, can exhibit resistance to degeneration. The Pcp4 gene maps to 21q22.2, which contributes the neurocognitive features of Down syndrome (DS). Further, whilst DS individuals exhibit an increased risk of Alzheimers disease, it is unclear whether they exhibit the dementia expected from their neuropathology. Overexpression of Pcp4 may ameliorate the neural features of DS. We now report generation and validation of a transgenic mouse model for Pcp4, using a human BAC spanning the Pcp4 coding region and 84 kb upstream of the transcriptional start. Two independent lines of mice were shown to express the human Pcp4 mRNA. We then validated the model at the RNA, protein and histological levels as a test of neuron-specific DS features. Using Quantitative Real-time PCR with human and mouse gene-specific primers vs GAPDH controls, we found human Pcp4 mRNA levels 1.4 X those of the native mouse gene for Line 1, and 50-65 X for Line 2 (3 transgenics & 3 wildtypes for each of 2 litters/line). Western blot analyses of adult brain protein confirmed increased Pcp4 levels in Tgs vs wts. Using IHC, we demonstrated that adult neuronal distributions of Pcp4 in the Tg were similar to those seen in the wildtype. This mouse model will be useful for studying the potentially neuroprotective effects of increased Pcp4 expression and its effects on hippocampal learning and memory in DS.

Analysis of *BDNF* expression in rats treated with Semax and PGP under the brain experimental ischemia. L. Dergunova¹, V. Stavchanskii¹, A. Botsina², I. Platonova², T. Tvorogova², E. Shaykhutdinova¹, V. Skvortsova², S. Limborska¹. 1) Dept Human Molecular Genetics, Inst Molecular Genetics, Moscow, Russian Federation; 2) Dept of Basic and Clinical Neurology and Neurosurgery, Russian State Medical University, Moscow, Russian Federation.

Brain-derived neurotrophic factor (BDNF) is a natural neuroprotector involved in proliferation, differentiation and survival of neuronal and glial cells. It was revealed that *BDNF* expression was increased in rat cultured glial cells under treatment by the neuroprotector Semax (synthetic polypeptide Met-Glu-His-Phe-Pro-Gly-Pro; its N-terminus represents a fragment of adrenocorticotrophic hormone. We have analyzed the effect of Semax and its C-terminal fragment Pro-Gly-Pro (PGP) upon *BDNF* expression within cerebellum and forebrain cortex of the rats subjected to global brain ischemia. After 15 minutes of irreversible bilateral common carotid artery occlusion the animals were subjected to intraperitoneal injection of Semax, PGP or 0,9% NaCl. Animals were decapitated 30 minutes / 1 hour / 2 hours after the operation. Within the last group (2 hours) the animals were injected for the second time 1 hour after the occlusion. Sham-operated animals were used as a control. *BDNF* mRNA expression level was assessed by semi-quantitative PCR. *BDNF* PCR signals were normalized to the corresponding RT product GAPDH signal. BDNF and GAPDH PCR signals were analyzed for two cDNA samples of each rat. Under experimental conditions, the sham-operated and ischemized rats treated with 0,9% NaCl did not demonstrate the difference between *BDNF* expression levels within investigated brain regions. *BDNF* expression within the cerebellum of the ischemized rats also was not influenced by Semax and PGP. At the same time, comparing to the ischemized animals treated with 0,9% NaCl, expression level of *BDNF* within forebrain cortex of the animals treated with Semax and PGP was increased. Within the forebrain cortex of the animals treated with Semax and PGP *BDNF* expression level was found to be maximal 30 minutes after occlusion. Possibly, therapeutic effect of Semax is mediated by the increased production of *BDNF* within brain cells.

Polyalanine tracts of the ARX homeobox gene, mutation, conservation and function. *J. Gecz^{1,2}, O. McKenzie¹, M. Finnis¹, T. Fullston¹, C. Shoubridge¹, D. Cloosterman^{1,2}, M. Mangelsdorf^{1,2}*. 1) Dept of Genetic Medicine, Women's Department of Genetic Medicine, Womens & Childrens Hospital, Adelaide, Australia; 2) Department of Paediatrics, University of Adelaide, Adelaide, Australia.

Aristaless related homeobox gene, ARX is mutated in various forms of intellectual disability with or without additional features including infantile spasms, dystonia, lissencephaly, autism, dysarthria, etc. Results of our screening (>500 samples) indicate that mutations of ARX are found in virtually all families with non-syndromic mental retardation (NSXLMR) mapping across the ARX gene (8 out of 8 tested, 3 not tested yet; ~11% of published NSXLMR) and ~3.4% of putative XLMR (include brother pairs, trios, uncle-nephew pairs, cousin pairs and small unmapped families). So far the most frequent and the most pleiotropic ARX mutation is a duplication of 24bp (428-451dup24bp), which accounts for ~30% of known ARX mutations. It causes expansion of one of four polyalanine tracts of the ARX gene from 12 to 20 alanines. The function of polyalanine tracts, which are frequently found in transcription factors, is not known. We have studied various full-length and truncated, normal and mutated ARX constructs in transcription repression studies. Our results show that ARX is a strong repressor. We mapped this activity within one, highly conserved, invariable polyalanine tract, tract 4, which has not yet been found mutated in patients. The transcription repression activity of ARX is also affected by the 428-451dup24bp (tract 2) and (GCG)₁₀₊₇ (tract 1) polyalanine tract expansion mutations, which were tested individually or in the context of the full length ARX. There is a correlation between the number of extra alanine residues and the resulting transcription repression. Deletions within alanine tracts 1 and 2 have little effect on the repression activity. Stably transfected PC12 cells (tet-on) with normal and 428-451dup24bp ARX full-length cDNAs do not show signs of aggregation of ARX. In summary, the dup24bp mutation is the most prevalent and the most pleiotropic ARX mutation, which likely exerts its pathogenic effect via elevated repression activity of the mutated ARX protein.

Connexin 32 promoter P2 mutations highlight a common mechanism of demyelination. *M. Girard*¹, *H. Houlden*², *C. Cockerell*^{3,4}, *D. Ingram*³, *NW. Wood*², *M. Goossens*¹, *RWH. Walker*^{3,4}, *MM. Reilly*². 1) Genetique Moleculaire et Physiopathologie, INSERM U468, Hopital Henri Mondor, France; 2) Department of Molecular Neurosciences, Institute of Neurology, The National Hospital for Neurology and Neurosurgery, London, UK; 3) St Bartholomews Hospital and The Royal London Hospital, London, UK; 4) Princess Alexandra Hospital, Harlow, Essex, UK.

Charcot-Marie Tooth disease (CMT) is the most common hereditary disorder of the peripheral nervous system. The X-linked form of CMT is mainly caused by mutations in the GJB1 gene, encoding the gap-junction protein Connexin 32 (Cx32). The number of different mutations reported in the coding region of this gene is now over 250, however only two mutations have been identified in the non-coding regions of Cx32. Here, we identified a large family from Essex in the UK with CMT. Sequencing of the Cx32 promoter region revealed a novel mutation at position -526bp in the P2 region, which segregated with the disease and was not present in controls. To prove pathogenicity, linkage analysis was carried out using high-density markers on the X-chromosome. This revealed highly significant genetic linkage to the Cx32 (Xq13.1) region with no recombination between marker DXS993 and DXS990. The Connexin 32 P2 promoter region was sequenced in a number of different species and the region of interest was conserved throughout. This mutation is located in a highly conserved SOX10 binding site, and functional studies carried out on the mutant Cx32 promoter revealed that this mutation reduced the activity of the Cx32 promoter and the affinity for SOX10 binding. These data and previous observations suggest that mutations in this region of the Cx32 gene are part of a complex mechanism of Schwann cell dysfunction involving SOX10 and EGR2 and leading to demyelination. Progress in the understanding of how mutant genes lead to the development of different types of neuropathy is likely to be critical to understanding the pathogenesis of CMT.

In vivo inhibition of caspase-6 cleavage of expanded huntingtin protects against neurodegeneration. RK.

Graham¹, Y. Deng¹, E. Slow¹, B. Haigh¹, N. Bissada¹, G. Lu¹, R. Oh¹, L. Bertram¹, K. Vaid¹, S. Roy², DW. Nicholson², BR. Leavitt¹, CL. Wellington¹, MR. Hayden¹. 1) CMMT, UBC, Vancouver, BC, Canada; 2) Merck-Frosst, Montreal, PQ, Canada.

Huntington disease is a neuropsychiatric disease caused by expansion of a trinucleotide repeat in the HD gene, huntingtin. Proteolytic cleavage of huntingtin by caspases with concomitant generation of toxic huntingtin fragments has been well characterized in vitro, and caspase-mediated fragments of huntingtin are present in HD brain prior to clinical onset of HD. These observations provide strong support for the toxic fragment hypothesis which proposes that huntingtin cleavage is a crucial determinant of pathology in HD and furthermore suggest that caspase-resistant (CR) huntingtin may delay or prevent the onset or progression of HD in vivo. To test this hypothesis using the YAC animal model of HD, we used homologous recombination to mutate both caspase 3 and 6 cleavage sites within full length genomic huntingtin with 15 and 128CAG. Neuropathological analysis revealed that complete inhibition of caspase cleavage of expanded htt protects against the neurodegeneration observed in the YAC 128 model. We then sought to determine whether caspase 3 or caspase 6 is the key player in generating the selective toxicity observed in the striatum. Analysis of 128C3R and 128C6R lines demonstrated that while 128C3R did not provide protection, selective mutagenesis of the caspase-6 site provided significant protection from neurodegeneration in vivo. In two independent 128C6R lines, brain weights and striatal volumes are indistinguishable from wild-type. In contrast, brain weights and striatal volumes in caspase cleavable YAC128 mice are decreased by 10 (*p<0.05) and 16% (**p<0.0003) respectively. These results suggest that caspase-6 cleavage of huntingtin may play an important role in the generation of specific toxic fragments resulting in selective neurodegeneration in HD and that preventing caspase-6 cleavage of huntingtin may be a promising therapeutic strategy.

ALS2 gene product expression pattern in mouse tissues. *F. Gros-Louis¹, R. Devon², P. Orban², J. Laganier¹, P. Hince¹, M.R. Hayden², G.A. Rouleau¹.* 1) McGill University Health Centre, Montreal General Hospital, Montreal, Quebec, Canada; 2) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, Canada.

Amyotrophic lateral sclerosis (ALS) is a devastating disorder that has an incidence of between 0.5 and 3 per 100,000. ALS is characterized by the degeneration and death of motor neurons in the cerebral cortex, brainstem and spinal cord, resulting in progressive muscle weakness, atrophy and death from respiratory paralysis. Recently, the gene responsible for a juvenile onset autosomal-recessive form of ALS, ALS2 was identified. The ability to detect the ALS2 gene product (alsin) with an antibody will be an important resource for the to study tissues expression pattern in mouse and molecular pathways that lead to motor neuron degeneration in ALS. Six oligopeptides (20mers) have been generated that are specific to either or to both the published splice variants. The peptides have been designed against specific regions that are meant to be antigenic according to the hydrophilicity plot . All our antibodies have been generated in rabbits using standard methods. Immunohistochemistry and western blotting were performed using standard methods. We demonstrated that alsin is widely expressed during development at low levels when compared to adult mouse. The protein is present in the cell bodies of various tissues, including neurons of the cortex, brain stem and spinal cord. Surprisingly, the highest level of expression was in the cytoplasm of the cerebellar Purkinje cells and in the inferior olivary nucleus of the brain stem, regions not previously known to be affected in ALS2. The selective loss of motor neurons, in the face of a widespread expression, suggests that alsin may have a pivotal role in maintaining the integrity of this cell population. These data also suggest that alsin may have different functions during development and adulthood. It is not clear whether or not the cerebellum is involve in the pathology of ALS as motor neuron degeneration may mask any cerebellar phenotype but an understanding of cerebellar involvement may lead to important new insights in the molecular pathogenesis of ALS.

Functional analysis of hamartin and tuberin using yeast-two-hybrid screening. *S. Khare, A. Kumar.* MRDG, Indian Institute Of Science, Bangalore, Karnataka, India.

Tuberous sclerosis complex is an autosomal dominant genetic disorder characterized by the presence of benign tumors called hamartomas in multiple organ systems, particularly in brain, skin, lungs, heart and kidneys. TSC is caused by mutations in two distinct genes: TSC1 located on chromosome 9q34 and TSC2 located on chromosome 16p13.3. TSC1 encodes a protein hamartin of 130-kDa, which contains a putative transmembrane domain and two putative coiled-coil domains (CCDs). A stretch of 133 amino acids (from a.a. 145-278) close to the potential transmembrane domain is conserved in human, mouse, rat and *Drosophila*, suggesting an unknown functional role for this stretch. TSC2 encodes tuberin, a 180-kDa protein (1,807 amino acids), which contains two coiled-coil domains, two transactivation domains, a calmodulin binding domain and a GAP domain. It has been shown that tuberin and hamartin interact with each other and form a complex *in vivo*. This interaction is mediated by N-terminal CCD (N-CCD) of tuberin and C-terminal CCD of hamartin. However, the function of C-terminal CCD of tuberin is not known. We have used yeast-two-hybrid system to identify the interacting proteins for the 133 amino acids long stretch of hamartin as well as C-CCD of tuberin. For this purpose, the 133 amino acids long stretch of hamartin and the C-CCD of tuberin were cloned separately in Gal4 DNA binding domain (DNA-BD) vector pGBT9 and used as baits to screen a fetal mouse brain cDNA library cloned in Gal4 activation domain (AD) vector, pACT2. Yeast-two-hybrid library screening was carried out using 1×10^6 independent cDNA clones for each bait. After the screening, the transformants were assayed for interaction using nutritional selections, - and -galactosidase assays. Following screening, we have identified putative interacting proteins for the 133 amino acids long stretch of hamartin as well as C-CCD of tuberin. We are in the process of performing co-immunoprecipitation to confirm the interactions. (Financial support from the CSIR, New Delhi is gratefully acknowledged).

Subnuclear localization of ATRX with PML and DAXX: identification of domains and effect of mutations. M.

Mangelsdorf¹, N.G. Bérubé^{1,3}, J. Healy¹, T. Hodgson¹, M. Jagla¹, D.J. Picketts^{1,2}. 1) Molecular Medicine Program, Ottawa Health Research Institute, Ottawa, Ontario, Canada; 2) Department of Medicine and Biochemistry, Microbiology, and Immunology, University of Ottawa, Ontario, Canada; 3) Current Address: Biochemistry and Paediatrics, University of Western Ontario, Canada.

ATRX encodes a SNF2-like chromatin remodeling protein, mutations in which cause X-linked mental retardation (XLMR). Although most mutations lie within the chromatin interaction domains little is known about how these contribute to *ATRX* function and normal CNS development. Recent studies have shown that *ATRX* forms a complex with DAXX and associates with PML oncogenic domains (PODs) suggesting that it may regulate the formation of nuclear domains or the expression of target genes. We define *ATRX* domains essential for subnuclear localization and assess how patient mutations or loss of *ATRX* impinge on the formation of such domains. Full-length *ATRX* and a panel of deletion constructs were fused to GFP to identify regions responsible for the correct localization of the protein. The full length protein maintains the endogenous pattern characterized by speckles amongst diffuse nuclear staining. *ATRX* fragments highlighted two regions responsible for speckle formation; L2 (amino acids 924-1651) and L19 (1965-2492). L19 but not L2 colocalized with PML and DAXX suggesting that the C-terminal region directs *ATRX* to PODs. Mutations in L19 attenuated the association of *ATRX* with PODs and also reduced their number. To explore this *in vivo* we examined the localization of DAXX in a forebrain-specific *ATRX* knockout mouse model. We show by immunohistochemistry that DAXX also co-localizes with *ATRX* in mouse. However in the forebrain of the *ATRX* knockout animals, DAXX was mislocalized and speckles were no longer observed. Our results have identified regions of *ATRX* that are important for its localization to PODs and mutations alter this association. Moreover, an absence of *ATRX* similarly effects the localization of DAXX. Taken together these results suggest that altered subnuclear localization of *ATRX* may contribute to the XLMR phenotype.

Defining new genes in Xq28 distal region as candidates for linked SNC diseases. *M.G. Miano¹, J. Monfregola¹, C. Laperuta¹, S. Crispi², D. Esibizione¹, N. Silva¹, M. D'Urso¹, M.V. Ursini¹.* 1) Institute of Genetics and Biophysics Adriano Buzzati Traverso, CNR, Naples, Italy; 2) BioGeM, Ariano Irpino, Italy.

The human Xq28 region contains several disease loci whose causative gene is still unknown. However, the difficulty to isolate new disease genes is remarkable because of the paucity of polymorphic markers available for linkage study. Our aim was to refine critical regions for SNC diseases mapping in Xq28 such as MRX72, PMGX, and Waisman syndrome. Starting from the nucleotide sequence, partially performed in our laboratory, we have selected new DNA markers. We identified several new STRs that have high allele frequencies in Caucasian population for which we have established the index of heterozygosity and consequently their power in linkage studies. Those STRs are in use to narrow down disease loci for SNC diseases in affected families identified by us in collaboration with clinical geneticists. Accordingly, this strategy is in use to define the linkage interval for another X-linked mental retardation (MRX81) that was recently identified and mapped by our group. Among the Xq28 disease genes, we focalized on few genes with a putative role in the SNC development. Briefly, we identified a novel gene closed to F8c, in tight linkage with MRX72 locus, which encodes an evolutionary conserved protein containing three putative transmembrane motifs, appearing to be a novel member of a large family of proteins. In the second instance, we studied the gene encoding for a key enzyme of the carnitine biosynthetic whose physiological relevance in neuronal survival and differentiation is documented. Finally, the third gene of interest for our group is located less than 10 kb from the telomere associated repeat of the X chromosome which from bioinformatic and functional analysis resulted to be a G-actin binding protein which has a clear well documented role cytoskeleton organization and in neuronal cell migration. Functional, structural and evolutionary data for all of them will be illustrated in more details according with an approach to understand gene function and to correlate in human diseases.

NIPA1, mutated in spastic paraplegia type 6 (SPG6), is a putative neuronal endosomal transporter. *R.D. Nicholls, K. Talbot, Q-C. Yu, J-H. Chai.* University of Pennsylvania, Philadelphia, PA.

SPG6 is a hereditary spastic paraplegia characterized by corticospinal tract degeneration and progressive lower-extremity spasticity. In this disorder, we previously found a dominant-negative mutation in *NIPA1*, a novel gene from human chromosome 15q11.2 (AJHG 73:898-925, 967-71). Two mechanisms may account for brain-enriched *Nipa1* expression, transcriptional regulation of the *Nipa1* promoter and/or a non-coding antisense transcript (*Nipa1as*) that overlaps *Nipa1*. *Nipa1as* is alternatively spliced and initiates from a bidirectional promoter shared with the adjacent *Nipa2* gene, but has much lower expression levels and could serve to regulate levels of *Nipa1* in brain or other tissues. To investigate the function of NIPA1, which encodes a putative transporter with 9 predicted transmembrane (TM) domains, we generated antisera against peptides from the TM4-TM5 loop and the C-terminus, then examined the expression and subcellular localization of NIPA1. Western blot studies of total and membrane protein fractions from mouse tissues and *Nipa1-EGFP* transfected HeLa cells show that both endogenous NIPA1 and NIPA1-EGFP fusion protein are enriched in the TM fractions. Interestingly, a short isoform of NIPA1 is identified only in the brain, suggesting brain-specific processing. Immunohistochemical studies demonstrate that NIPA1 is widely expressed in the cytoplasm and dendrites of neurons in many regions of the human and mouse nervous system, such as the cerebral cortex, hippocampal formation, cerebellum, midbrain, pons and medulla. NIPA1 is also expressed in oligodendrocytes of the cerebral cortex and corpus callosum, as well as in Schwann cells of peripheral nerves. Although a NIPA1-EGFP fusion protein overexpressed in HeLa cells is present in cytoplasmic vesicles co-localized with -Lamp1, a late endosomal/lysosome marker, electron microscopy on mouse cerebellar Purkinje cells shows that NIPA1 *in vivo* is present in clusters along the endoplasmic reticulum and adjacent vesicles possibly representing early endosomes. Further studies will examine co-localization with endosomal markers and the potential transport function of NIPA1 in regulating vesicular trafficking.

Identification of distal elements regulating *Smn* gene expression. C. Rochette¹, A. Semionov¹, N.L. Germain¹, F. Vigneault², R. Drouin², L.R. Simard¹. 1) Centre de recherche de l'Hôpital Sainte-Justine, Université de Montréal, Montréal, QC, Canada; 2) Centre de recherche CHUS, Sherbrooke, QC, Canada.

There exist two survival motor neuron (*SMN*) genes in humans, the result of a 500-kb duplication that occurred after the divergence of lineages leading to humans and mice. Mutations in the *SMN1* gene are responsible for childhood spinal muscular atrophy (SMA) while ablation of the single mouse *Smn* gene causes early embryonic lethality. Up-regulation of the human *SMN2* gene is an important target for the treatment of SMA. We have previously characterized the minimal *SMN*/*Smn* promoters and have now screened the entire *Smn* gene, which is half the size of its human counterpart, for distal elements regulating transcription. We performed an inter-species sequence comparison using PIPMaker, generated a series of reporter gene constructs spanning the entire gene and conducted *in vivo* genomic footprinting experiments to screen for DNA-protein interactions within specific genomic segments. Sequence conservation between the 30 kb human *SMN* and 14 kb mouse *Smn* genes was very sparse outside the coding regions. Only two segments displayed 75 identity of 100 bp, the minimal promoter region and within the 5'-most portion of intron 1. An additional segment in intron 5 showed 70 identity of 100 bp. While two genomic fragments exerted a small effect on TK promoter activity, only one of these was found to regulate the *Smn* promoter *in vitro*. Various reporter-gene constructs that contained the minimal *Smn* promoter and increasingly larger fragments of intron 1 displayed an incremental silencer effect. Inclusion of 520 nt of intron 1 caused a 16-fold decrease in *Smn* promoter activity in transient transfection assays of P19 cells. This effect was orientation independent and was replicated in differentiated P19, NSC34, SK-N-SH and HepG2 cells. *In vivo* DNA footprinting of P19RA cells using 3 different DNA modifying agents failed to reveal any convincing DNA-protein interactions involving this region. We are currently testing the hypothesis that the observed silencer effect is most likely mediated via a mechanism involving secondary structures within *Smn* intron 1. *Funded by CIHR.*

Program Nr: 1277 from the 2004 ASHG Annual Meeting

Human spastin (SPG4): Functional characterization of potential nuclear export sequences. *J. Schickel, C. Beetz, T. Deufel.* Institut fuer Klinische Chemie und Laboratoriumsdiagnostik, Klinikum der Friedrich-Schiller Universitaet Jena, Erlanger Allee 101, 07740 Jena, Germany.

Mutations in the human spastin gene (SPG4) cause the most prevalent form of autosomal dominant hereditary spastic paraplegia (HSP), a neurodegenerative disorder characterised by progressive weakness and spasticity of the lower limbs. In a recent study using polyclonal antibodies against the N-terminal spastin sequence we have shown that the native protein is localised in both the perinuclear cytoplasm and the nucleus. Furthermore, using a reporter system based on four in-frame fused copies of green fluorescent protein we demonstrate that spastin carries two nuclear localisation sequences both independently functional in mediating nuclear entry. We suggest a dual function for the spastin protein. Involvement in cytoplasmic trafficking and a still unknown function in the nucleus. Precise lokalisation may be a regulated process involving import into the nucleus as well as export back into the cytoplasm. Supporting this notion, two potential nuclear export sequences are found within the spastin amino acid sequence. Our study was aimed at characterizing domains in the N-terminal part of spastin impeding nuclear entry of transiently expressed spastin in cultured cells. First results identified a short sequence motif of approximately 25 amino acids in size to be responsible to retard spastin in the cytoplasm of the cell.

Neural intranuclear inclusions in FMR1 premutation carriers affected by fragile X-associated tremor/ataxia syndrome (FXTAS) contain FMR1 mRNA. *F. Tassone, C. Iwahashi, P.J. Hagerman.* Department of Biochemistry and Molecular Medicine.

We have recently identified a neurological disorder among male carriers of the fragile X premutation, characterized by tremor and/or ataxia, cognitive deficits, parkinsonism, and autonomic dysfunction. The disorder, named fragile X-associated tremor/ataxia syndrome (FXTAS) has been observed almost exclusively in older adult premutation males. Our studies have indicated that at least 30% of male carriers over 50 years of age will develop neurological symptoms of FXTAS. Post-mortem studies of the brains of individuals who had FXTAS have identified ubiquitin-positive intranuclear inclusions in both neurons and astrocytes throughout the cerebrum and brainstem of all cases examined to date (n = 11). Although neuronal inclusions have been observed in other trinucleotide repeat disorders including Huntingtons disease, Kennedys disease, and a number of the spinocerebellar ataxias, the presence of inclusions in FXTAS is puzzling, since the FMR1 protein is structurally normal, and present in near-normal levels, in premutation carriers. Because premutation carriers possess elevated levels of FMR1 mRNA, we have hypothesized that FXTAS might result from a toxic gain of function of the FMR1 mRNA itself. The mechanism by which increased FMR1 mRNA levels lead FXTAS and to inclusion formation is not fully understood at present. By analogy to the RNA gain-of-function model in myotonic dystrophy, the abnormal FMR1 mRNA could trigger inclusion formation by sequestering CGG binding proteins, which may result in loss of their normal functions. This hypothesized sequestration may also lead to the neuropathology and clinical features of FXTAS. Here, we report that the FMR1 mRNA is present within the intranuclear inclusions supporting the direct involvement of the FMR1 mRNA in the inclusion formation observed in FXTAS.

***MOB* is a gene encoding human sphingomyelin synthase 1.** I. Vladychenskaya, L. Dergunova, V. Dmitrieva, S. Limborska. Dept Human Genetics, Inst Molecular Genetics, Moscow.

Prior investigation of human brain cDNA libraries revealed an evolutionarily conserved gene *MOB* that has been cloned in silico on chromosome 10. Analysing hypothetical primary structure of the transmembrane peptide product proposed for the *MOB* major transcript we have found it to be identical with the primary structure of human sphingomyelin synthase 1 (SMS1); now we consider *MOB* as a gene encoding SMS1. In human, two yet uncharacterized genes paralogous to *MOB* (*SMS1*) were revealed. These genes termed p1 *MOB* and p2 *MOB* are localized on chromosomes 4 and 10, respectively; together, they represent a novel gene family. *MOB*, p1 *MOB* and p2 *MOB* orthologs of conserved genomic structure were found in warm-blooded animals; orthologs of p2 *MOB* were also found in *D. melanogaster* and *C. elegans*. We have examined *MOB* (*SMS1*) transcription activity; expression levels of the major *MOB* transcript (transcript encoding SMS1) were assessed among different human tissues by means of semi-quantitative RT-PCR. Comparing to the maximal expression level detected within the brain tissues, transcript abundance within kidney is one and a half times less, within lung and liver - two times less, within spleen and lymphatic node - seven times less. We have also analysed the expression pattern of the alternative *MOB* transcript lacking the longest coding exon VII and found it to be similar with that of the major transcript.

Molecular characterization of the mammalian ISWI gene, *SNF2L*, and its assessment as an X-linked Mental Retardation (XLMR) candidate gene. *D.J. Yip^{1, 2}, A.C. De Maria¹, M.A. Lazzaro¹, P. Lavigne¹, D. Vallée¹, D.J. Picketts^{1, 2}.* 1) Molecular Medicine Program, Ottawa Health Research Institute, Ottawa, Ontario, Canada; 2) Department of Biochemistry, Microbiology and Immunology, University of Ottawa, Ottawa, Ontario, Canada.

Chromatin remodeling is an ATP-dependent process performed by an assortment of multi-protein complexes each of which contains a SWI/SNF-like catalytic subunit. Mutations that have been observed in genes encoding chromatin-remodeling proteins have been linked to developmental disorders. Moreover, mutations in SWI/SNF homologs, such as ATRX, have been shown to cause X-linked mental retardation (XLMR), as a result chromatin-remodeling factors represent strong XLMR candidates. In *Drosophila*, ISWI functions as the ATP-hydrolysing component in chromatin modulating complexes important as regulatory mechanisms for developmental gene expression. The two mammalian ISWI orthologs, *SNF2H* and *SNF2L* present differential expression patterns suggesting that they possess distinct developmental roles. In order to assess these genes as candidates for human disorders we have characterized *SNF2L* as a brain-enriched transcript with increased expression upon differentiation, suggesting a role in maturing neuronal cell populations. We have shown an increase in *SNF2L* expression across a 96-hour differentiation timecourse in mouse NIE115 and human SH-SH5Y neuroblastoma cells by RT-PCR and indirect immunofluorescence. The *SNF2L* gene spans 77 kb and is encoded by 25 exons that undergo alternative splicing. Isoforms are generated by the alternate use of exons 1 and 13, and by alternate donor splice sites within exon 24. Interestingly, alternative splicing within exon 24 removes the nuclear localization signal and alters the subcellular distribution of *SNF2L*. *SNF2L* localizes to Xq25-26, a 7cM region of the X chromosome where several mental retardation disorders overlap. We identified 3 non-coding nucleotide polymorphisms in the *SNF2L* gene after screening 12 XLMR families for which the disease gene was localized to this genomic interval. Despite the absence of a pathogenic mutation, *SNF2L* remains a prime candidate for XLMR localized at Xq25-26.

Identification of genes involved in the pathogenesis of haemangiomas using suppression subtractive

hybridization. *A.J Scott¹, K. Robertson², R. Crawford¹, A. Smith³, D. Marchuk⁴, P. North⁵, J. Pearson⁶, R. Roberts¹, J.N. Berg^{1,2}.* 1) Department of Medical and Molecular Genetics, Kings College London, Guy's Hospital, UK; 2) Department of Molecular and Cellular Pathology, Ninewells Hospital and Medical School, Dundee, UK; 3) Department of Academic Surgery, Kings College London, St Thomas's Hospital, UK; 4) Department of genetics and microbiology, Duke University Medical Centre, Durham, NC; 5) Arkansas Childrens Hospital, Little Rock, AR; 6) Centre for Cardiovascular Biology and Medicine, Kings College London, UK.

Infantile haemangiomas are benign tumours of vascular endothelial cells. They grow rapidly after birth and proliferate to form a network of blood capillaries, followed by apoptosis of endothelial cells and involution. Haemangiomas have been shown to be monoclonal and are thought to arise following somatic mutation in endothelial cells. Haemangiomas also provide a model of angiogenesis. Previous gene expression studies in haemangiomas have focused on a pre-selected group of genes. Through suppression subtractive hybridisation, an unbiased technique, this project has identified a number of genes that may be involved in infantile haemangioma formation. Real-time quantitative PCR has confirmed differential expression of these genes in infantile haemangioma tissue compared to that of normal endothelial cells in culture. Expression profiles show up-regulation of Decorin and Ribonuclease 1 and down-regulation of chemokine (CXC) receptor 4 and connective tissue growth factor receptor. These proteins are known to be expressed by endothelial cells or to affect angiogenesis in culture but have not before been implicated in the pathogenesis of infantile haemangioma. Immunohistochemistry has confirmed the expression of ribonuclease 1 in haemangioma endothelial cells in a proportion of infantile haemangiomas. For Decorin and CXCR4, staining showed high levels of protein expression in connective tissue, but less prominent staining around haemangioma endothelial cells. Our data suggest that the role of these genes in both the control of endothelial cell function and in haemangioma formation merits further investigation.

TAZ mRNAs in Barth Syndrome subjects, alternative splicing and exon evolution. *I. Gonzalez.* Dept Res, Sr Res Scientist, DuPont Hosp for Children, Wilmington, DE.

Barth syndrome (MIM 302060) is an X-linked condition that includes dilated cardiomyopathy, neutropenia, failure to thrive, abnormal mitochondria, 3-methylglutaconic aciduria. The mutated gene, TAZ, was first described in 1996 and was reported to produce a large set of alternatively-spliced mRNAs with initiations of transcription upstream of exons 1 and 3. Since then, disease-causing mutations had been found in all exons except exon 5. Because of the initially-described 2nd initiation of transcription in intron 2, with in-frame initiation of translation in exon 3, we hypothesized that subjects with mutations in exons 1 and 2 would produce normal "short products" which might attenuate their phenotype. Moreover, it was of interest to determine which splice variants were functional, as exon 5 is not present in yeast and rodent TAZ genes and the variant lacking this exon is the most abundant in humans. We characterized TAZ mRNAs from a set of Barth syndrome subjects and of healthy controls. TAZ genes and mRNAs of primates were also included to determine the origin of exon 5. Our findings include: [1] There is only one site for initiation of transcription upstream of exon 1. [2] The alternatively-spliced assortment is more limited than previously thought. Our results suggest that only 2 functional protein variants exist, 5 and full length, in agreement with results of others who have tested functionality of TAZ minigenes. [3] There are two alternative splice sites within introns 1 and 2 which could potentially produce an in-frame product; their functionality has not yet been tested. [4] Although the exon 5 sequence is present in Old and New World monkeys, it lacks one of the splicing signals. It evolved into splicing-competent "exonhood" in the hominoid lineage, after the split from Old World monkeys. Its true exonic status is confirmed by the recent finding of an affected child with an exon 5 mutation.

Program Nr: 1283 from the 2004 ASHG Annual Meeting

Analysis of emerin deficient mouse. *Y. Hayashi, R. Ozawa, M. Ogawa, I. Nishino.* Dept Neuromuscular Research, Natl Inst Neuroscience, NCNP, Tokyo, Japan.

Emery-Dreifuss muscular dystrophy is an inherited muscular disorder characterized by the triad of progressive weakness in humero-peroneal muscles, early contractures and cardiomyopathy with conduction block. We produced emerin lacking mice as a model of X-linked Emery-Dreifuss muscular dystrophy by insertion of a neomycin resistance gene into exon 6 of the gene including a transmembrane domain. Tissues from the mutant mice lacked normal mRNA and protein of emerin. However, the emerin deficient mice displayed normal growth rate indistinguishable from their littermates and fertile. The mutant mice did not show any joint contractures and gait abnormality. No muscle weakness or atrophy was observed, and they can survive more than 100 weeks. Histological analysis of cardiac and skeletal muscle from the mutant mice showed no dystrophic changes. Lamin A, lamin C, lamin B2 and LAP2 localized at nuclear membrane and showed no difference from heterozygous and wild type. This result suggests only deficiency of emerin did not cause muscular dystrophy in mice.

Haplotype-analysis of TNF and TNF polymorphisms and its relation to TNF expression *in vivo*. S. Schulz^{1,2}, T. Suess^{1,2}, D. Rehfeld^{1,2}, U. Schagdarsurengin², I. Hansmann², K. Werdan¹, U. Mueller-Werdan¹, C. Glaeser². 1) Dep Intern Med, Univ Halle, Halle, Germany; 2) Inst Human Genetics, Univ Halle, Halle, Germany.

TNF and TNF are important cytokines in the complex signalling pathway involved in the development of CAD. **Methods:** We studied the influence of two polymorphisms (PM) of TNF (c.-238G>A) and TNF (T60N) on the *in vivo* TNF-expression (RT-PCR: monocytes; ELISA: plasma) in the context of CAD. In this clinical study 176 age matched patients with angiographically confirmed diagnosis were included: 88 patients with severe CAD and 88 patients without any coronary symptoms as controls. **Results:** We could show that the c.-238G>A-PM is influencing TNF mRNA-expression significantly in the whole patient group (GG: 6.2±5.9ag/cell; AG: 8.8±6.2ag/cell; p=0.019). This influence is mainly due to variation in the CAD-patients (p=0.013). Furthermore, we could prove a significant effect of the T60N PM on TNF gene expression in the whole patient group (AA: 4.3±4; AC: 7.7±6.7; CC: 5.7±5.4ag/cell; p=0.007). However, this regulation was more pronounced in the control group (p=0.011) than in the CAD-group (p=0.079). A haplotype-analysis revealed that the c.-238G>A PM is a stronger predictor for an elevated TNF mRNA-expression. The heterozygous variant AC-AG (T60N-c.-238G>A) causes the highest expression (9±7.6ag/cell) followed by the variant CC-AG (8.4±2.8ag/cell). All other combinations showed significant lower expression rates (AC-GG: 7.5±6.6; CC-GG: 5.5±5.5; AA-GG: 4.3±4ag/cell; p=0.002). On translational level only the T60N-PM, could be referred as a predictor of TNF protein-expression in the group of CAD-patients but not in the whole patient group: A-allele carriers showed a significantly increased TNF protein-expression (p=0.045). **Conclusions:** genomic variants in both TNF and TNF gene are proven to affect *in vivo* TNF- gene-expression. Especially in CAD, an effect of the TNF-PM c.-238G>A and the TNF-PM T60N on gene and protein expression, respectively, could be proven. These results emphasize the importance of the genomic background on the regulation of TNF expression not only in the development of CAD.

Regional absence of mitochondria causing energy depletion in the failing myocardium of the MLP knockout mouse. *B. Bosch van den*¹, *C. Burg van den*¹, *K. Schoonderwoerd*², *P. Lindsey*¹, *H. Scholte*², *I. DeCoo*², *E. Rooij van*¹, *A. Wijngaard van den*³, *H. Rockman*³, *P. Doevendans*⁴, *H. Smeets*¹. 1) Genetics and Cell Biology, University Maastricht, Maastricht, Netherlands; 2) Depts. of Clinical Genetics, Biochemistry and Child Neurology, Erasmus MC Rotterdam, The Netherlands; 3) Dept. of Medicine, Duke University Medical Center, Durham NC; 4) Dept. of Cardiology of the Heart Lung Centre Utrecht (UMCU), The Netherlands.

Defects in myocardial mitochondrial structure and function have been associated with heart failure in humans and animal models. However, the exact role for mitochondrial dysfunction in different stages of cardiac disease remains to be elucidated. Mice lacking the muscle LIM protein (MLP) develop morphological and clinical signs resembling human DCM and heart failure. We tested the hypothesis that defects in the cytoskeleton lead to DCM and heart failure through mitochondrial dysfunction in the MLP mouse model. Our results demonstrate a 35% decrease in overall mitochondrial OXPHOS activity and citrate synthase (CS) activity in the failing hearts. However, activity per amount of CS, a measure for mitochondrial density, was normal, indicating a decreased number of mitochondria in the knockouts. Light and electron microscopy revealed regional absence of mitochondria and a decreased overall mitochondrial size. Mitochondrial and nuclear-encoded transcripts were decreased to 60% of the controls, most likely resulting in decreased mitochondrial biogenesis. Peroxisome proliferator activated receptor gamma co-activator 1 (PGC-1), a key regulator of this process, was decreased to 67% of the controls and corroborates these findings. MtDNA copy number (ratio mtDNA/nuclear DNA) was slightly increased in the knockouts. Our results show that the absence of MLP causes a local loss of mitochondria, leading to energy depletion. This is likely caused by a disturbed interaction between cytoskeleton and mitochondria, which interferes with energy sensing and energy transfer. Recovery of energy depletion by stimulating mitochondrial biogenesis might be a useful therapeutic strategy for improving the energy imbalance in heart failure.

Two novel TNNI3 mutations in restrictive cardiomyopathy. *A. van den Wijngaard¹, D. Merckx¹, C. Marcelis⁴, E. Rubio^{1, 2}, I. de Coo³, C. de Die¹, R. Jongbloed¹, H. Smeets¹.* 1) Clinical Genetics, Academic Hospital Maastricht, Maastricht, Netherlands; 2) Pediatrics, Academic Hospital Maastricht, Maastricht, The Netherlands; 3) Child Neurology, Erasmus MC, Rotterdam, The Netherlands; 4) Clinical Genetics, Radboud Hospital Nijmegen, Nijmegen, The Netherlands.

Troponine I (TNNI3) is a sarcomeric protein expressed in the human ventricular myocardium. The protein is essential for the coupling between the myosin heavy chain globular head and actin during contraction of the cardiac fibers. Occasionally mutations in TNNI3 are found in families with hypertrophic cardiomyopathy (HCM). Recently, also some mutations were reported in patients with restrictive cardiomyopathy. Restrictive cardiomyopathy is a rare cardiomyopathic disorder characterized by impaired ventricular filling with reduced volume, ultimately leading to heart failure. Especially in young children the prognosis is poor compared to adults where the clinical course is more variable. In this study we screened two exons of TNNI3, known to contain the majority of previously identified mutations, in 69 HCM families for mutations by DHPLC. In addition, the complete TNNI3 gene was analyzed by direct sequence analysis in four families with idiopathic restrictive cardiomyopathy. No mutations were identified in the HCM families. However, in two of the four unrelated probands with restrictive cardiomyopathy we found three mutations. In proband 1 we found a novel splice site mutation (IVS7+2delT) and in proband 2 we found a known mutation (R145Q) together with a novel mutation (Arg192Cys). In both families the probands were young girls (age 0.5 and 9 years respectively). The disease manifestation is more severe in proband 1, which might be explained by the difference in the underlying genetic defect. These data indicates that TNNI3 should be analyzed completely when restrictive cardiomyopathy is diagnosed especially in young patients.

RNA interference against a parasitic infection. *V.D.B. Pascoal*¹, *T. Campos-Pereira*¹, *I.G. Maia*², *L.A. Magalhães*³, *E.M. Zanotti-Magalhães*³, *I. Lopes-Cendes*¹. 1) Med.Genet., UNICAMP/FAC. CIENCIAS MED., Campinas, SP, Brazil; 2) Inst. Biocincias, Dept. de Genet., UNESP/Botucatu, SP, Brazil; 3) Dept. de Parasitologia, IB/UNICAMP, Campinas, SP, Brazil.

Approximately two hundred million people are infected with *Schistosoma mansoni* worldwide, demonstrating its high medical importance. *S. mansoni* is unable to synthesize purines *de novo*; therefore, it uses precursors obtained from the host blood, using the essential gene hypoxanthine-guanine phosphoribosyltransferase (HGPRTase), a long-dated potential drug target. RNA interference (RNAi) is a technology that promotes potent and specific gene silencing. It is based on the introduction of small interfering RNAs (siRNAs) that guide target RNA degradation. Its therapeutic use was demonstrated against viruses *in vitro* and *in vivo*. These reports prompted us to investigate the *in vivo* efficiency of this technique against a parasitic disease, by silencing *S. mansoni* encoded HGPRTase gene in infected mice. We chose three target sequences in the *S. mansoni* encoded HGPRTase coding region and produced siRNAs by *in vitro* transcription. Sixty mice were infected with one hundred cercariae each. Seventy days later, animals were either mock-inoculated (PBS buffer) or inoculated with siRNAs (five micrograms diluted in PBS per animal). Six days after the injection, the animals were sacrificed and the number of parasites was counted in the liver and in the porta and mesenteric veins. Overall, the total number of parasites per mouse was reduced by approximately 24% after treatment with siRNAs. The mean number of parasites in the untreated group (n=25) was 39 (median = 40) as compared to a mean of 29 parasites (median = 28) in the treated group (n=23; P = 0.0023, Kruskal-Wallis). It was not possible to determine HGPRTase mRNA reduction in this system; thus we began *in vitro* studies to confirm knock down through RT-PCR. Here we show the successful use of RNAi against *S. mansoni in vivo*. This new approach opens new avenues of research. Our work now expands RNAi therapeutic range to combat parasites, promising a general revolution in disease treatment.

***EFHC1* gene product interacts with Hsp70 and caspase 3.** K. Aguan¹, T. Suzuki¹, A.V. Delgado-Escueta², K. Yamakawa¹. 1) Neuropathology, Brain Science Institute, RIKEN, Wako-shi, saitama, Japan; 2) Center for Integrative Bioscience, Genetics/Genomics Laboratories, Comprehensive Epilepsy Program, David Geffen School of Medicine at UCLA and VA GLAHS-West Los Angeles, Los Angeles, USA.

Juvenile myoclonic epilepsy (JME) is one of the most frequent hereditary grand mal epilepsies. Recently, we have mapped and cloned a JME gene, *EFHC1*, on chromosome 6p12-p11 (Bai et al. Am J Med Genet 113:268-274, 2002; Suzuki et al., in press). *EFHC1* encodes a non-ion channel protein with a single EF-hand motif, interacts with a calcium channel protein, and induces apoptosis in primary culture neurons. As most of the epilepsy genes encode ion channels, conceptually it has been a challenge how *EFHC1* would be involved in epilepsy. In protein array screenings, we identified Hsp70 and caspase 3 as *EFHC1*-interacting proteins. These observations suggests that *EFHC1* is a multifunctional protein that may induce cell death by co-interacting with ion-channel and apoptosis initiating factor, and at the same time possibly regulating the cellular survival response by interacting with Hsp70.

Alternative splicing of *TRIM37*. R. Hämäläinen, T. Joensuu, A-E. Lehesjoki. Folkhälsan Institute of Genetics, Department of Medical Genetics and Neuroscience Center, Biomedicum Helsinki, University of Helsinki, Finland.

The *TRIM37* gene encodes a peroxisomal member of the TRIPartite Motif (TRIM), also known as RING-B-box-coiled-coil (RBCC), protein family. The function of *TRIM37* is yet unknown. *TRIM37* was first identified as the gene underlying Mulibrey nanism, a rare autosomal recessively inherited disorder, characterized by prenatal-onset growth retardation, typical facial features and pericardial constriction with hepatomegaly and an increased risk of developing ovarian tumors and Wilms tumor. To date eleven mutations in *TRIM37* have been associated with Mulibrey nanism. The *TRIM37* gene has 4111 bp of known mRNA transcribed from 24 exons and predicting a protein of 964 amino acids. In northern blot analysis a strong transcript of approximately 4 kb is present in testis, in addition to the 4.5 kb transcript present in all tissues. We have identified and characterized *TRIM37* transcripts using bioinformatics, RT-PCR, real-time quantitative RT-PCR and Northern blotting. *In silico* analysis of *TRIM37* specific EST:s suggests the existence of several alternative *TRIM37* transcripts, that were confirmed by RT-PCR in human testis and lymphoblastoid cell mRNA. One of these novel transcripts corresponds to the 4 kb transcript seen in northern analysis of testis tissue. This transcript has an additional exon 3' to exon 24. It encodes a 964 amino acid protein identical in sequence with the protein encoded by the 24 exon transcript, but an alternative termination codon and 3' untranslated region. In quantitative real time PCR analysis the 24 and 25 exon transcripts have equal expression levels in testis, whereas in other tissues the 24 exon transcript is expressed 6 to 30-fold higher than the 25 exon transcript. Our data suggest that alternative splicing of *TRIM37* is a frequent event, the physiological significance of which remains to be determined.

The interaction between FRG1P and PABPN1 implies a common molecular pathway for the muscular dystrophies FSHD and OPMD. *S.M. van der Maarel¹, S. van Koningsbruggen¹, K.R. Straasheijm¹, H. Dauwerse¹, J.M. Cowan², P.G. Wheeler², H. ter Laak³, B.G. van Engelen⁴, G.W. Padberg⁴, R.R. Frants¹.* 1) Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Division of Genetics, Department of Pediatrics, Tufts-New England Medical Center, Boston, MA; 3) Department of Pathology, University Medical Center Nijmegen, Nijmegen, Netherlands; 4) Department of Neurology, University Medical Center Nijmegen, Nijmegen, Netherlands.

FRG1 is considered a candidate gene for facioscapulohumeral muscular dystrophy (FSHD) based on its location at chromosome 4qter and the apparent upregulation of its gene product in FSHD muscle. The FRG1 protein (FRG1P) is localized in nucleoli, Cajal bodies and nuclear speckles after stable and transient transfections, which are all structures involved in RNA processing. A putative role of FRG1P in RNA processing is further supported by its nuclear redistribution upon transcription inhibition and its presence in the human spliceosome and in a *C. elegans* cluster of co-regulated proteins involved in ribosomal and mRNA biogenesis. We here show that transient expression of VSV-FRG1 redistributes endogenous PABPN1, the protein mutated in oculopharyngeal muscular dystrophy (OPMD), from the speckles to nucleolar aggregate-like structures. These aggregates are composed of PABPN1, ubiquitin, proteasomes and poly(A) RNA and are resistant to proteinase K treatment, similar to the nuclear aggregates found in OPMD myonuclei. Co-immunoprecipitation experiments with tagged FRG1 and PABPN1 proteins confirmed the interaction. Further evidence for a common molecular pathway in both muscular dystrophies comes from our observation of a FSHD family with possible digenic inheritance involving the FSHD and OPMD locus and from a OPMD patient with a large terminal deletion of 4q including the FSHD locus but without PABPN1 mutation.

Pendred Syndrome and Enlarged Vestibular Aqueduct Syndrome: Identification of six novel mutations in the gene (SLC26A4/PDS). *R. Birkenhäger, A. Aschendorff, T. Klenzner, R. Laszig, J. Schipper.* Department of Otorhinolaryngology and Head and Neck Surgery, University Hospital Freiburg, Killianstrasse 5, D-79106 Freiburg.

Pendred syndrome (PDS), an autosomal-recessive disorder is characterized by sensorineural deafness and goiter [1]. This syndrome is one of the most common forms of syndromic deafness. Hearing loss is prelingual in the majority of the cases, only a subset of patients have a progressive hearing loss later in life. The deafness is associated with temporal bone abnormalities that range from isolated enlargement of the vestibular aqueduct (EVA, LAV) to Mondini dysplasia, a more complex malformation that also includes cochlear hypoplasia. Both, LAV and Mondini dysplasia are easily recognized by computer tomography. PDS is caused by mutations in the SLC26A4 gene, it is located on Chromosome 7q31 and is composed of 21 exons that encode a 780 amino acid protein. This gene product, a transmembrane protein, is called pendrin. Pendrin is expressed in the non-sensory epithelia of the inner ear, renal cortical collecting ducts and proximal tubule of the kidney. Functional studies in *Xenopus laevis* oocytes and Sf9 cells have demonstrated that pendrin is a transporter of iodide and chloride [2]. In this study we analyzed several multiplex families with LAV and hearing loss to distinguish between the Pendred- and LAV-Syndrome. Individual exons and intron transitions of the SLC26A4/PDS gene of patients were PCR amplified. Direct automatic sequencing of variant fragments was performed with the same primers, on an automatic genetic analyser or alternatively after RNA isolation and cDNA synthesis. In our project we describe the mutation analysis of the SLC26A4 gene and identified 13 mutations, 6 of these mutations are novel. In 25 % of our patients we could not identify any mutation. These patients carry potential mutations in regulatory domains such as promotor regions, or the alternative possibility of a distinct locus for a gene of autosomal recessive deafness with enlarged vestibular aqueduct. 1 Everett LA et al. Nat Genet. 1997 Dec;17(4):411-222 Scott DA, et al. Nat Genet. 1999 Apr;21(4):440-3.

Loss of Ubr2 gene function compromises genome stability and double strand break repair mediated by homology recombination. *Y. Ouyang*¹, *Y.T. Kwon*², *A. Varshavsky*³, *Y. Marahrens*¹. 1) Dept Human Genetics, Univ California, Los Angeles, CA; 2) Center for Pharmacogenetics and Department of Pharmaceutical Sciences, School of Pharmacy, University of Pittsburgh, Pittsburgh, Pennsylvania; 3) 152612, and Division of Biology, California Institute of Technology, Pasadena, California 911253.

Ubr2 is an E3 ubiquitin ligase that functions in the N-end rule pathway for ubiquitin-targeted proteolysis. Previous work showed that deletion of the Ubr2 gene in mouse cells exhibit defects in N-end rule pathway, which leads to *ubr2*^{-/-} female embryonic lethality and male sterility. The male *ubr2*^{-/-} mice have meiotic cells arrested in pachytene stage where homologous chromosomes fail to recombine and this results in massive apoptosis. If Ubr2 mediates homology recombination (HR) in meiosis, we suspect that Ubr2 might also mediate HR in somatic cells. In somatic cells, HR plays a major part in faithful DNA repair when double strand break (DSB) occurs. To test our hypothesis, we use an HR assay developed by Jasins lab which quantifies HR mediated repair and we find that HR mediated repair is much lower in *ubr2*^{-/-} mouse embryonic fibroblasts (MEFs) than in wild type MEFs. Further we find that mitotic spreads made from *ubr2*^{-/-} MEFs have higher frequency of chromosomal breaks. Besides, *ubr2*^{-/-} MEFs display different viability to DNA damaging agents. From all these observations, we conclude that Ubr2 ubiquitin ligase maintains genome integrity and participates in HR mediated double strand break repairs.

The DNA replication profile at the human myotonic dystrophy locus: Determinants of repeat instability. *J.D. Cleary*^{1,2}, *K. Nichol Edamura*¹, *C.E. Pearson*^{1,2}. 1) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto, Ontario, Canada.

The expansion of gene-specific trinucleotide repeats is a form of mutation responsible for at least 15 human diseases, including myotonic dystrophy type 1 (DM1). The cellular processes of DNA replication and/or repair are believed to contribute to repeat instability. Instability of CAG/CTG repeats was mediated by DNA replication in an SV40-primate model system, such that the position of the repeat tract within the advancing replication fork appeared to alter repeat instability. Furthermore, in humans DNA replication may also contribute to repeat instability, as proliferation was required for instability in cultured human DM1 patient-derived fibroblasts. Taken together, these results suggest that the location of replication initiations (origins) and/or their utilization relative to the repeat tract may be an important factor in determining repeat instability. Alternatively, replication fork progression through the repeat tract may contribute to repeat instability.

The replication profile at the DM1 chromosomal locus was determined in DM1 patient cells that were actively undergoing expansions. This analysis suggests that the DM1 locus is located within a region of abundant replication activity, with proximal replication origins located both upstream and downstream of the repeat tract. Within this profile, the repeat tract is located within an inflection point of replication activity. Interestingly, the inflection point also includes both upstream and downstream binding sites for the zinc-finger protein CTCF, implicated as an insulator element at the DM1 locus. These results highlight the possible role of *cis*-elements flanking the repeat tract, including but not limited to CTCF binding sites, in affecting the progress of the replication fork through the DM1 repeat tract and thereby contributing to repeat instability in humans.

Novel alternative transcripts of the oral-facial-digital syndrome type 1 (OFD1) gene in lymphocytes. T.

Morisawa¹, M. Yagi², A. Surono¹, N. Yokoyama¹, M. Matsuo¹. 1) Pediatrics, Kobe University Graduate School of Medicine, kobe, Hyogo, Japan; 2) Clinical Evaluation of Pharmacotherapy, Kobe University Graduate School of Medicine, kobe, Hyogo, Japan.

Oral-facial-digital syndrome type 1 (OFD1) is an X-linked dominant disease characterized by malformations of the face, oral cavity, and digits. The OFD1 gene has an open reading frame of 3,033 bp over 23 exons, but the function of the OFD1 protein has been unknown yet. Thus far, one alternative transcript of OFD1 using cryptic splice acceptor site in intron 9 were reported in human embryo, retina, and teratocarcinoma other than lymphocyte. We disclose here novel alternative transcripts of OFD1 mRNA extracted from lymphocytes during the process of identification of the OFD1 gene mutation. The proband was the first female child of healthy unrelated parents. She was diagnosed with OFD1 at the age of six months. RT-nested PCR amplification of normal OFD1 mRNA extracted from lymphocytes successfully revealed novel alternative splicing products, including skipping of single exons (10, 11, or 19), two consecutive exons (3 and 4), multiple exons (10 to 12), and the combination of exons (8, 10, 11, and 12). In the index case, novel double deletion mutations were revealed from identification of four novel transcripts, which included three alternative transcripts (skipping of 10, 10 to 11, and 10 to 12). The alternative transcript previously reported was not detected in this analysis. Therefore, alternative splicings of the OFD1 pre-mRNA might be regulated in a tissue-specific manner. The OFD1 protein has five coiled-coil domains and LisH motif. Alternatively spliced exons encode coiled-coil domains or LisH domain, and further study is needed to disclose the role of these novel alternative transcripts.

The Identification of Novel Sarcoglycan-Interacting Proteins. *J. Chen*¹, *M. Skinner*², *A. Wildeman*², *Y-M. Chan*¹. 1) The Henry Hood Research Program, Sigfried and Janet Weis Center for Research, The Geisinger Clinic, Danville, PA 17822; 2) Department of Molecular Biology and Genetics, University of Guelph, Guelph, Ontario, Canada.

Sarcoglycans are a group of single-passed transmembrane proteins predominantly expressed in skeletal and cardiac muscle. They form a specific complex on the muscle membrane via a discrete stepwise assembly pathway and consist of four subunits (alpha, beta, gamma and delta-sarcoglycan). Mutations in sarcoglycans often disrupt the sarcoglycan complex by affecting specific stages in the assembly process and have been shown to cause autosomal-recessive limb-girdle muscular dystrophy (LGMD) as well as dilated cardiomyopathy. Currently, the function of the sarcoglycans or their role in LGMD is not well understood. Using yeast two-hybrid system and database searching, we have identified several novel proteins associated with the sarcoglycans. One of them is a 16kDa subunit of the vacuolar ATPase. Immunohistochemical analysis of muscle biopsy suggests that the 16kDa subunit is predominantly localized in cytoplasm but sarcolemmal staining is also detected. In expression studies, this protein specifically interacts with delta-sarcoglycan but not with the highly homologous gamma-sarcoglycan. In addition, a 16kD deletion mutant lacking the last transmembrane segment was shown to disrupt its interaction with delta-sarcoglycan in overexpression studies. This mutant has previously been shown to disrupt its binding to beta-1-integrin and alter the morphology of L6 myoblasts. The characterization of these proteins and their interactions with the sarcoglycans in muscle should provide important information regarding the function of the sarcoglycans.

MODY locus on 8p23: mutation screening and identification of alternative 5 UTRs in the transcription factor *GATA4* gene. W.M. Mlynarski^{1,2}, M. Borowiec^{1,2}, C. Powers¹, A. Doria^{1,2}. 1) Department of Genetics & Epidemiology, Joslin Diabetes Center, Boston, MA; 2) Harvard Medical School, Boston, MA.

The *GATA4* gene (NM_002052) encodes a member of the GATA family of zinc-finger transcription factors. Mutations in this gene have been associated with cardiac septal defects. The gene is located within the critical region of the maturity-onset diabetes of the young (MODY) locus that we recently described at 8p23 (Kim *et al.*, 2004). In this study, we examined whether sequence differences in this gene underlie this MODY locus. We resequenced the seven known exons and 2 Kb of the promoter region in probands of families showing evidence of linkage at 8p23. This revealed 13 single nucleotide polymorphisms (SNPs), including two missense variations in exon 5 at positions +48754 A/G (Ser377Gly) and +48763 G/A (Val380Met) from the ATG start codon. However, none of these sequence differences segregated with diabetes in our MODY families. Further in silico evaluation of the gene structure showed that there are at least three *GATA4* transcripts with different 5UTRs (ESTs: BI826615, AK097060, BU194442). We confirmed these finding by RT-PCR, RACE and direct sequencing of the cDNAs. Compared to the reference sequence, in which the first exon is located 4.1 Kb upstream from the start codon, two alternative first exons exist, at about 15.9 and 31.0 Kb upstream. Both of these forms have in common a second non-coding exon (271 bp), which is attached directly to the first coding exon of the *GATA4* transcript. These alternative transcripts show a tissue specific pattern of expression. In conclusion, our data exclude mutations in the *GATA4* coding sequence as a cause of MODY. However, our findings of a complex? transcriptional regulation of this gene indicate that the mutation screening must be extended to additional 5 regions before *GATA4* can be excluded as the MODY gene at 8p23.

MyoD-inducible lysosomal sialidase (neu1) is differentially regulated during myogenic differentiation of C2C12 cells. *M. Champigny*¹, *R. Perry*¹, *S.A. Igdoura*^{1, 2}. 1) Department of Biology; 2) Department of Pathology, McMaster University, Hamilton, ON, Canada.

Lysosomal sialidase, encoded by *neu1*, is required for the removal of terminal sialic acid residues from a variety of sialoglycoconjugates. In humans, deficiency of this enzyme results in the inborn error of metabolism Sialidosis, characterized by the accumulation of sialoglycoconjugates within the nervous system and in peripheral organs. A subset of sialidosis patients present with symptoms of profound muscle dysfunction, including progressive muscular atrophy. We have previously shown that the 5 regulatory region of murine *neu1* is typical of skeletal muscle-specific genes due to the presence of several E boxes and its responsiveness to stimulation by muscle regulatory factors (MRFs) such as MyoD. Here we report that sialidase activity is increased by 6-fold during the first 24 hrs of differentiation of C2C12 myoblasts followed by an attenuation to pre-differentiation levels by 48 hrs. We demonstrate that the lysosomal sialidase promoter is highly upregulated by MyoD through a mechanism that is dependent on the MyoD chromatin remodelling domain. We also show that the sialidase promoter is repressed by activated MEK. Inappropriate over-expression of sialidase 48 hrs after the onset of differentiation results in down regulation of myogenin as well as myosin heavy chain expression, and in a halt of the differentiation cascade. This study indicates that lysosomal sialidase is a potent regulator of the early stages of myogenesis.

LMX1B promoter characterization and search for kidney specific regulatory elements. S. Endeke, S. Richter, A. Winterpacht. Inst Human Genetics, Erlangen, Germany.

The Nail-Patella Syndrome (NPS) is a rare autosomal-dominant disorder characterized by dysplastic nails, absent or hypoplastic patellae, dysplasia of the elbows, exostoses of the ilia and, in some cases (~50%), nephropathy. Nephropathy is the most serious aspect of NPS and, in most cases, manifests only by chronic benign proteinuria. In approximately 15% of cases, however, the disease develops towards end-stage renal disease. NPS is caused by heterozygous loss of function mutations in the *LMX1B* gene, encoding a member of the LIM homeodomain protein family. Interestingly, only 30-60% of NPS patients develop nephropathy in spite of identical or similar *LMX1B*-mutations. In addition, incomplete penetrance and a strong intrafamilial variable expressivity has been observed. It is suggested that yet unknown genetic modifiers in the mixed genetic background may influence the renal phenotype of NPS patients. In an attempt to identify modifying factors of *LMX1B* action, we started to characterize the promoter region of the human *LMX1B* gene and to search for kidney specific regulatory regions. Extensive computer based analysis and interspecies sequence comparison using the available genomic sequences of human, mouse, chicken and fish revealed several conserved regions upstream of exon 1 and within intron 2. From EST-data, RT-PCRs and expression studies we conclude that some of these upstream regions most probably correspond to a novel gene adjacent to *LMX1B* in antisense orientation. To further characterize possible regulatory regions, we mapped the transcription start point of *LMX1B* by RACE, primer extension analysis and RPA. Different start sites were mapped, but by comparison between RNA from human kidney and skeletal muscle no kidney specific transcription start site could be identified. In silico analysis of the predicted promoter region using the genomatix software correspond quite well with the experimental data. Interestingly, a comparison of the *LMX1B* promoter with known kidney specific promoters revealed a common framework of transcription factor binding sites. These binding sites and their kidney specificity is currently under detailed investigation.

siRNA knockdown of striated muscle -actinins alters muscle fiber-type differentiation in C2C12 cells. L.A.

Frieden, A.H. Beggs. Genomics Program & Division of Genetics, Children's Hospital, Harvard Medical School, Boston, MA.

Many congenital myopathies are characterized by breakdown of the sarcomere and aberrant localization of skeletal muscle Z line proteins. The Z lines maintain sarcomeric structure by anchoring actin-containing thin filaments and linking adjacent myofibrils. Two key components of the Z line are slow/cardiac -actinin-2 (*Actn2*) and the fast fiber isoform, -actinin-3 (*Actn3*). To investigate whether these two isoforms differentially affect muscle development and function, we used siRNA knockdown (KD) technology to specifically ablate either *Actn2* or *Actn3* expression in cultured mouse C2C12 myoblasts. A selectable retroviral vector system was used to generate stable C2C12 cell lines that express various short hairpin RNAs under the control of the U6 RNA polymerase III promoter. After testing several alternate siRNAs for each gene, stably transfected *Actn2* KD, *Actn3* KD, and negative control nonsense siRNA-KD cell lines were generated in triplicate. Quantitative rtPCR assays confirmed that both *Actn2* and *Actn3* mRNA levels were specifically reduced to 5% or less of control mRNA levels. Western blot analyses indicated that protein expression was also significantly and specifically reduced. Both *Actn2* and *Actn3* KD cell lines differentiate into contracting myofibers. Interestingly, *Actn2* KD C2C12 cell lines differentiated into particularly large contracting myotubes more rapidly than *Actn3* KD or control cell lines. Furthermore, indirect immunofluorescence and western blot analyses demonstrated decreased levels of slow muscle myosin heavy chain protein in the *Actn2* KD cells. Conversely, *Actn3* KD cells had decreased levels of fast muscle myosin heavy chain. These data suggest that fast and slow muscle fiber development may be impacted by the presence of *Actn2* and *Actn3* transcripts and/or proteins. To further study differences between the *Actn2* and *Actn3* KD cell lines, we are performing gene expression profiling of these KD and control cell lines. This will enable us to analyze expression changes for multiple fiber-type specific genes as well as detect other fundamental differences between *Actn2* and *Actn3* KD cell lines.

Synthesis and processing of mutant JAGGED1 proteins *in vitro*. M. Meunier-Rotival¹, J. Boyer¹, C. Crosnier^{1,2}, C. Driancourt¹, N. Raynaud¹, M. Hadchouel^{1,3}. 1) Cholestases genetiques, INSERM E00-20, Kremlin-Bicetre, France; 2) Vertebrate Dev. Lab., Cancer Res. UK, London, UK; 3) Hopital de Bicetre, France.

Introduction : Heterozygous mutations in JAGGED1 (JAG1), encoding a single-pass transmembrane ligand for Notch receptors, are responsible for Alagille syndrome (AGS). These mutations map to the extracellular and transmembrane domains of JAG1, and 70% of them give rise to a premature termination codon (PTC). The effects of only 3 JAG1 mutations have been studied *in vitro*: in all cases, missense mutations cause an abnormal glycosylation pattern and an abnormal intracellular transport of the defective protein. To gain insight into the possible synthesis and processing of other abnormal JAG1 proteins with missense or PTC mutations, we performed *in vitro* studies in cell culture. **Methods:** Wild-type *JAG1* cDNA or *JAG1* cDNAs with AGS mutations (1 missense, 2 PTC) were cloned in the pcDNA3.1 expression vector and transfected in COS7 cells. Synthesis, processing and localization of JAG1 were studied by western blots and immunohistochemistry. **Results:** Transient transfection experiments showed that wild-type JAG1 protein and JAG1 with a missense mutation located in EGF2 were both synthesized in COS7 cells, and cleaved at the level of the transmembrane domain. In both cases, only the extracellular domain was found in the culture medium. The truncated proteins resulting from PTC in EGF5 or cysteine-rich domain were synthesized, addressed to the membrane and were recovered in the culture medium. **Conclusion:** We have shown that mutant JAG1 proteins can be synthesized *in vitro* and released in the culture medium. These results suggest that mutant proteins could signal outside of the cell (if mutant transcripts escape nonsense mediated mRNA decay) and support a dominant negative effect of mutant JAG1 proteins in the molecular mechanisms of Alagille syndrome.

Cellular homolog of the poxviral p28/N1R RING virulence factor. *T.A. Gray¹, P.J. Fortin¹, R.D. Nicholls²*. 1) Genomics Inst, Wadsworth Ctr, New York State Dept Health, Troy, NY; 2) Ctr for Neurobiology and Behavior, Dept of Psychiatry, University of Pennsylvania, Philadelphia, PA.

Many non-essential poxvirus genes are derived from captured host cDNAs and usually encode products that act in the same host pathways as their cellular homologs. The poxviral p28/N1R virulence factor features a prominent C₃HC₄ RING zinc-finger in its C-terminus. Orthologs of this factor are found in all vertebrate poxviruses, but are mutated in several less virulent vaccinia virus strains. This RING zinc-finger is 44% identical and 60% similar to the RING zinc-finger of the cellular Makorin protein family. Makorin proteins are characterized by multiple C₃H zinc-fingers, the RING zinc-finger, and a distinct, conserved, cysteine-histidine motif that may represent a novel zinc-finger. In addition to the RING zinc-finger, fowlpox and canarypox homologs also encode a Makorin-like C₃H zinc-finger and the distinct cysteine-histidine motif, firmly establishing a homologous link between the cellular and viral genes. Elucidating the function of the cellular Makorin proteins may provide insight into the pro-virulent function of the poxvirus factors. To that end, we are characterizing a mouse *Mkrn1* insertional mutant line to examine the role of *Mkrn1* in mouse development and to evaluate these mice for changes in poxvirus susceptibility. Homozygous *Mkrn1*^{-/-} mice, with less than 0.3% of wildtype *Mkrn1* transcript levels, are born at expected ratios and have no overt developmental phenotype. Importantly, our mice lacked the severe kidney and skeletal dysmorphic features of a recently reported mouse model that were attributed to a partial down regulation of *Mkrn1*. The reported mouse model resulted from a transgenic insertion/deletion near a *Mkrn1* pseudogene (*Mkrn1-p1*), and a paradigm-shifting conclusion was drawn stating that pseudogenes can regulate their source genes. Our mouse line and supporting molecular data clearly refute this unconventional molecular mechanism, and suggest that another mechanism must cause the kidney and bone phenotype observed in the reported mouse model. We are currently evaluating our *Mkrn1* mutant mice for more subtle phenotypes relevant to poxvirus virulence.

Gene duplication at the AZFc region on the human Y chromosome caused by sister chromatid exchange. Y.W. Lin^{1, 2}, P.L. Kuo³, C.C. Hsu⁴, W. Schempp⁵, D.A. Doan Thi⁵, P.H. Yen^{1, 6}. 1) Institute of Biomedical Sciences, Academia Sinica, Taiwan; 2) Graduate Institute of Life Sciences, National Defense Medical Center, Taiwan; 3) Department of Obstetrics and Gynecology, National Cheng Kung University, Taiwan; 4) Department of Obstetrics & Gynecology, China Medical University, Taiwan; 5) Institute of Human Genetics and Anthropology, University of Freiburg, Germany; 6) Department of Pediatrics, Harbor-UCLA Medical Center, Torrance, CA, U.S.A.

The human Y chromosome plays a major role in spermatogenesis. It contains several genes/gene families that are expressed specifically in the testis. About 10% of subfertile men with idiopathic azoospermia or severe oligospermia have microdeletions on their Y chromosome, frequently in the AZFc region. Most men have four *Deleted in Azoospermia (DAZ)* genes within AZFc. These genes contain 1-3 copies of RNA binding motifs and 7-24 copies of DAZ repeats. Recently a polymorphism for a 1.6 Mb deletion at the AZFc region was reported. The so-called gr/gr deletion, present in about 2% of the male population, removes two of the four DAZ genes and is a significant risk factor for spermatogenic failure. One of the possible mechanisms underlying the deletion is nonallelic homologous recombination between sister chromatids, which would generate a reciprocal recombination Y chromosome containing 6 DAZ genes. We designed a novel DNA blot hybridization strategy to analyze the DAZ genes in genomic DNA samples. We found that 5 of the 82 samples we studied had 6 DAZ genes. The presence of 6 DAZ genes in three of the 5 cases was confirmed by interphase FISH analysis. Further studies of the DAZ repeat regions within the DAZ genes identified additional polymorphisms that could have been generated only through sister chromatid exchange (SCE). The results provide strong evidence that SCE in germ cells plays a significant role in the genesis of deletions, duplications and polymorphisms of the human Y chromosome. Our hybridization protocol also serves as a new tool for identifying novel Y chromosome variants and for tracing human migration in the context of Y chromosome evolution.

Program Nr: 1303 from the 2004 ASHG Annual Meeting

Apparent instability in the normal range at the *FMRI* locus: clinically significant or red herring? *D.J. Allingham-Hawkins, T. Ashfield, J. Guo, D. Kennedy, D. Ramadeen, R. Rezaie, M. Shama, M. Skuterud, C. Stanley, J. Steer.*
Genetics Program, North York General Hospital, Toronto, ON, Canada.

We previously reported apparent instability in the normal range at the *FMRI* locus in a series of 9 patients with developmental delay (Tzountzouris *et al.*, 2000, *Genet Test* 4(3):235). We have now detected this apparent instability in 26 patients and/or their parents referred to the laboratory for testing for fragile X syndrome. Of the 26 subjects, 19 (73%) were male and 6 (27%) were female. The majority of subjects were referred because of symptoms of developmental delay (17/26 or 65%) but 7 subjects (27%) were referred because of a family history of developmental delay and 2 subjects (8%) were referred because of apparently unstable alleles in their children. All 19 males were found to have two alleles by PCR but a single band at 2.8 kb by Southern blot indicating the presence of a single X chromosome. The presence of Y chromosome sequences was confirmed by PCR for all male subjects. Of the 6 females, 5 had 3 alleles by PCR while the remaining female had 4 alleles by PCR. All 6 female subjects had a normal female pattern (2.8 and 5.2 Kb) by Southern blot. Other extensive studies in several of the patients including paternity testing, karyotyping, FISH and haplotyping indicated that there was no obvious explanation (non-paternity, sex chromosome mosaicism, chimerism) other than instability for the results. There were two "familial" instances of instability - one in a mother/daughter and one in a father/son. One might envision the transmission of the same unstable allele from mother to daughter but this is not the case in the father to son "transmission" suggesting there may be another mechanism - perhaps autosomal - to explain this instability. These findings represent a dilemma in the clinical lab because the clinical significance, if any, is unclear. A study looking for the presence of unstable alleles in the general population (no developmental delay or family history of such) at the same frequency as seen in our fragile X referrals (approximately 1%) may help to differentiate whether this is a true phenomenon or simply a polymorphism with no clinical significance.

Alterations in the length of the c-terminal alanine tract in Zic2 modulate both DNA binding and transactivation activity. *S. Brown, M. Paraso, L. Brown.* Dept OB/GYN, Columbia Univ, New York, NY.

Alanine tract expansion mutations in transcription factors, including ZIC2, have been shown to cause at least 8 different malformation syndromes, suggesting the possibility of a common pathogenic mechanism. However, the role alanine tracts in determining protein structure and function is unknown. In some cases, alanine tract expansion has resulted in loss of function and in other cases, gain of function. With this in mind, we have constructed cDNA clones in which the normal 15 alanine tract of Zic2 has been expanded to 25, mimicking a recurrent human mutation. In addition, we have created alleles containing an expansion to 35 alanines as well as a 13 alanine deletion. Luciferase assays using a promoter element from the apolipoprotein E gene show that the 25 alanine expansion results in near complete loss of transactivation whereas the shorter alanine tract allele results in increased activity compared to the wild-type protein. In contrast, luciferase assays using the SV-40 promoter show that alanine tract expansion has much less effect on transactivation activity, indicating that the effects of alanine expansion are promoter dependent. Competition experiments indicate that the 25A allele can only partially suppress the activity of the wild type allele even when in 10 fold molar excess, suggesting diminished DNA binding. To test this hypothesis, we have used electrophoretic gel shift mobility assays (EMSA) to determine the relative DNA binding of these alleles. Surprisingly, EMSA, using sequences from the apolipoprotein E gene show that DNA binding is reduced by alanine tract expansion. On the other hand, deletion of the alanine tract results in a five fold increase in DNA binding, a result that is in keeping with its increased transactivation activity. Thus, the Zic2 alanine tract apparently modulates DNA binding as well as transactivation activity. This result opens the possibility that alanine tracts may have a similar role in other transcription factors.

Different Processes of Trinucleotide Repeat Instability Occur in Cultured Fibroblasts of DM1, HD & FRAXA Patients. *R. Lau¹, Z. Yang¹, K. Nichol Edamura¹, D. Chitayat², C.E. Pearson^{1,3}.* 1) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) University Health Network; 3) Department of Molecular & Medical Genetics, University of Toronto, Toronto, Canada.

Somatic instability of the DMPK CTG tract is high in multiple tissues of Myotonic Dystrophy (DM1) patients. In contrast, the Huntington's disease (HD) CAG tract and the Fragile X (FRAXA) CGG repeat display low levels of instability. Using primary fibroblasts derived from DM1 patients we observed spontaneous and synchronous expansions of the (CTG)₂₁₆ DM1 tract in proliferating but not in quiescent cells. However, the (CAG)₁₈₀ HD tract in proliferating primary fibroblasts of HD patients was stable, and unaffected by induced quiescence. The (CGG)₆₆₂ FRAXA tract in proliferating primary fibroblasts of a FRAXA patient did not show any changes detectable by Southern blotting.

Cells were also treated with agents known to alter DNA synthesis but not directly damage DNA; mimosine blocks the initiation of replication; emetine blocks lagging strand synthesis at replication forks; and the DNA polymerase inhibitor aphidicolin blocks both leading and lagging strands. In DM1 cells, the magnitude of expansions was significantly enhanced by exposure to aphidicolin or emetine. The effects were specific to the expanded disease allele. Mimosine treatment had no effect upon DM1 CTG instability. Treatment of HD cells differed dramatically; mimosine or emetine resulted in small contractions of the expanded HD CAG tract, while aphidicolin had no effect. This tendency towards contraction was not evident in the HD cell line containing (CAG)₄₅, a size more representative of typical HD. Treatment of FRAXA cells also differed; aphidicolin treatment resulted in small contractions of the expanded FRAXA CGG tract, while length alterations could not be detected following either mimosine or emetine treatments.

The different patterns of instability and the differential effects of various replication inhibitors on expanded CTG/CAG tracts of similar lengths in DM1 and HD cells suggests that different processes are regulating the instability at these genetic loci.

Repair of slipped-strand DNAs formed by disease-associated CTG/CAG repeats. *G.B. Panigrahi, R. Lau, M.R. Blondin, C.E. Pearson.* Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada.

CTG/CAG instability is the cause of 14 diseases including myotonic dystrophy (DM1) and Huntingtons disease (HD). In humans repeat instability can occur in proliferating and quiescent cells. Depending upon the disease, the tissue or developmental stage the instability manifests as either an expansion-bias, deletion-bias or stable maintenance of the repeat tract. The majority of proposed mechanisms for repeat instability involve slipped-strand DNA structures formed by the repeats either in breaks at non-replicating DNA or at replication forks. In both cases, slip-outs of the nicked or continuous strands represent intermediates of expansion or deletion events, respectively. Processing of these intermediates, either independent of and/or in conjunction with DNA replication, may be one of the underlying processes responsible for repeat instability (or stability).

Repeat instability can be perturbed in model organisms that are deficient in various repair processes. However, DM1 and HD patients that display repeat instabilities are not known to be deficient in any repair activity. Thus, repeats from these patients can be expanded, deleted or stably maintained in cells that are repair-proficient. To date, there is no direct experimental evidence of how repair, in a repair-proficient state may contribute to the various kinds of repeat instability.

We established an in vitro assay to determine the fidelity of slipped-DNA processing by human cell extracts that are functional in many DNA metabolic processes. As substrates, we used structurally defined slipped-DNAs containing an excess of CTG or CAG repeats and a single nick. Our results indicate that a variety of repair outcomes can arise. Importantly, the choice of repair path depends critically upon the biophysical features of the slipped-DNAs. The formation of specific DNA intermediates and their distinct repair outcomes may explain the different mutation patterns occurring at each of the various genetic loci or between tissues.

Heterogeneity of Class I insulin VNTR alleles and insulin secretion. *S. LE FUR, C. AUFRAY, C. LE STUNFF, P. BOUGNERES.* Dpt of Pediatric Endocrinology & U561 INSERM, Hôpital Saint-Vincent de Paul, Paris, France.

The polymorphism of the INS VNTR locus is associated with variations of insulin gene transcription and is also a susceptibility locus for Type 1 diabetes (T1D) known as IDDM2. As a group, "short" Class I alleles of the VNTR are associated with increased circulating insulin (Le Stunff, *Nat Genet* 2000, 26: 444-446), and with predisposition to T1D. Since all Class I alleles do not equally predispose to T1D (Stead, *Hum Mol Genet* 2000, 9: 2929-2935), we examined the effect of Class I allele genomic structure on insulin secretion in obese children. Class I VNTR alleles were classified according to the presence of a multi four "A" repeat (3 x 4A) motif in the VNTR part located close to the insulin gene. "A" repeat is ACAGGGGTGTGGGG. Four "A" sequences have been associated in vitro with an increase of insulin gene transcription (Kennedy, *Nat Genet* 1995, 9: 293-298). We compared the values of the insulinogenic index in the different Class I genotypic groups, using the Fisher PLSD test. The insulinogenic index was 107.125 (SD) in obese children with two VNTR alleles encompassing the 3 x 4A motif (N = 32) versus those with only one of such alleles (71.55, p = 0.02, N = 179) or those who do not have this motif (78.53, p = 0.005, N = 256). These data suggest that the functional Class I VNTR alleles may be more heterogeneous than previously thought and may depend on the presence of this 3 x 4A motif.

Searching the target genes for human single-minded 2 (SIM2) transcription factor. *Y. Shimizu*¹, *A. Yamaki*¹, *S. Asai*¹, *J. Kudoh*², *N. Shimizu*². 1) Dept Medical Genetics, Kyorin Univ Sch Health Sci, Hachioji, Tokyo, Japan; 2) (2) Department of Molecular Biology, Keio University School of Medicine, Shinjuku-ku, Tokyo, JAPAN.

Human SIM2 gene, located on chromosome 21q22.2, is a homolog of *Drosophila* single-minded gene which plays a key role in the midline cell lineage of a central nervous system. SIM2 interacts with ARNT2 and these two proteins belong to the basic helix-loop-helix/PAS (Per-Arnt-Sim) transcription factors. SIM2 and ARNT2 form heterodimers but the downstream target genes are not known. To find the target genes of SIM2/ARNT2, we have established the stable cell lines which express continuously SIM2 or SIM2/ARNT2. We made the constructs of pIRES-puro GFP vector, pIRES-puro-SIM2 GFP and pIRES2-hyg-HA ECFP ARNT2, transfected into HeLa cells and selected the transfectants in the presence of puromycin or puromycin/hygromycin. Then, we have performed the differential display analysis using RNA from these four cell lines (parental HeLa, HeLa-mock, HeLa-SIM2 and HeLa-SIM2/ARNT2). After cDNAs were synthesized from RNA, the PCR reactions were done using 5 different downstream primers and 24 upstream primers. We have purified the bands showing different patterns among the cell lines in polyacrylamide gel electrophoresis and cloned into pT7 Blue-3Blunt vector. Sequencing analysis and homology search identified 26 potential target genes of SIM2 and SIM2/ARNT2. Among these holocarboxylase synthetase which can link biotins to histone, was inhibited and hyaluronan synthase 2 was stimulated by overexpression of SIM2 and SIM2/ARNT2. Further analysis of the expressions of these target genes may provide new insight into the molecular function of SIM2 and SIM2/ARNT2 in Down syndrome phenotype.

Identification and characterization of a new serpin-like gene in the 14q serpin cluster. *G. Macintyre, C. Singh, B. Cavilla, D.W. Cox.* Dept. Medical Genetics, University of Alberta, Edmonton, AB, Canada.

Serine protease inhibitors, serpins, are involved in various processes, including coagulation, prevention of tissue degradation, inflammation and tumorigenesis. Human 1-antitrypsin (AAT), a serpin, is synthesized in the liver and transported to the lung, where it is the major inhibitor of neutrophil elastase. AAT deficiency can result in chronic obstructive pulmonary disease and emphysema, but can also affect other tissues and is linked to a number of diseases, including liver disease. 1 antichymotrypsin has also been associated with liver and lung disease. The AAT gene is located at 14q32.1, within a gene cluster containing related serpin genes that have apparently arisen by gene duplication. The cluster includes PI (*SERPINA1*, the AAT gene), a PI pseudogene, and genes encoding alpha1-antichymotrypsin, corticosteroid-binding globulin, protein C inhibitor, kallistatin and *SERPINA10*. Recently, two more serpin-like genes have been identified in the cluster, *OL-64* and *GCET1*. We have re-examined the serpin cluster, in the search for new genes that may be disease related. Our *in silico* analysis revealed at least three additional genes in the cluster, including *OL-64* and *GCET1*, with similarities to the other serpins, suggesting that these encode previously unknown proteins possessing serpin-like activity. EST information and RT-PCR analyses of liver cDNAs indicates that these genes are expressed in liver cells. Other groups have since shown that *GCET1* is expressed in germinal B-cell centres and *OL-64* in visceral adipocyte tissue. The third gene, newly identified in our study, putatively named, *SERPINA14*, is specifically expressed in liver tissue. The tissue-specific gene expression of other cluster members, considered to have predominant expression in the liver, has revealed additional expression elsewhere, including respiratory tissues. The potential role of the 14q cluster serpins in disease needs to be explored.

Expression analysis of netrins-G1 and -G2: Human netrin-G1 isoforms show evidence of differential expression.

J. Meerabux¹, H. Ohba¹, M. Fukasawa¹, Y. Suto², M. Aoki¹, S. Itohara³, Y. Yoshikawa¹. 1) Laboratory for Molecular Psychiatry, RIKEN, BSI, 2-1 Hirosawa, Wako 351-0198, Japan; 2) Laboratory of Human Evolution, Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa 277-8562, Japan; 3) Laboratory for Behavioral Genetics, RIKEN BSI, 2-1 Hirosawa, Wako 351-0198, Japan.

Netrins-G1 and -G2 form a distinct subgroup within the UNC-6/netrin gene family of molecules that have been shown to guide cell growth cone migrations. These recently identified genes differ from classical netrins by three main features: the presence of a glycosyl phosphatidyl-inositol lipid site for membrane anchorage, the generation of multiple isoforms and a non-responsiveness to receptors for classical netrins. In this study we examined the mRNA expression patterns of human netrin-G1 and -G2 and found that whilst both genes show limited non-neuronal expression, there is wide expression in the brain, particularly of netrin-G2. Using a semi quantitative PCR assay, we set out to identify human mRNA isoforms based on the prevalence of variants in the mouse. We identified a total of nine isoforms, three of which were highly expressed in the brain and three isoforms, one of which was highly expressed in the kidney. All variants were derived from the alternative splicing of five exons that code for the unknown domain and three EGF like domains. This data suggests that netrin-G1 isoforms are differentially expressed between the two tissues and that this mechanism may provide further specificity of function. No human isoforms of netrin-G2 were detected in this study. Additionally, we mapped the genomic layout of the human netrin-G1 and -G2 genes and confirmed their chromosomal localization at 1p13.3 and 9q34. In conclusion, our data suggests that the function of netrin-G1 may be fine tuned by the expression of multiple isoforms.

Comparative sequence analysis reveals the presence of bacterial sulfatase operons and a common evolutionary origin between sulfatases and pyrophosphatases. *M. Sardiello*¹, *A. Ballabio*^{1,2}. 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Medical Genetics, Department of Pediatrics, Federico II University, Naples, Italy.

Sulfatases perform important roles in many biological processes, including the turnover and degradation of sulfated compounds. Several human genetic diseases are due to deficiency of specific sulfatase activities. We and others recently identified the gene responsible for Multiple Sulfatase Deficiency (MSD), an intriguing human disease in which all sulfatase activities are simultaneously defective. This gene, named Sulfatase Modifying Factor 1 (SUMF1), is involved in the post-translational modification of a cysteine residue into C-formylglycine at the active site of sulfatases a key step for catalytic activity of sulfatases in most living organisms, with the exception of some bacteria that have sulfatases carrying a serine (instead of a cysteine) that gets modified into formylglycine by a different modifying factor (AslB). An exhaustive search for genes encoding sulfatases and sulfatase modifying factors in all sequenced organisms revealed that: 1) In many instances modifying factor genes are physically associated to sulfatase genes in prokaryotes, indicating the presence of sulfatase operons. SUMF1 bacterial genes flank cys-type sulfatase genes in 70% of the cases, while AslB genes flank both ser-type and cys-type sulfatase genes, strongly suggesting that AslB can modify both types of sulfatases. 2) The domain containing the sulfatase active site shows intra-species sequence convergence, likely due to the evolutionary pressure for the active site to meet precise requirements of the modifying factor in each species. 3) Sulfatases show significant sequence similarities with a subgroup of pyrophosphatases (PPases) and the structures of PPases and sulfatase active sites are similar. Most likely, sulfatases evolved from PPases after the appearance of the post-translational modification. Finally, we completed the catalog of human sulfatases with the identification of four novel genes, leading to a total of 17 genes. These data will be useful for both functional and disease association studies.

***NOS3AS*, the overlapping antisense transcript with endothelial nitric oxide synthase (*NOS3*), encodes a putative mammalian autophagy protein highly expressed in placenta.** *T. Yamada*¹, *A.R. Carson*¹, *G.B. Robb*², *I. Caniggia*³, *T. Yoshimori*⁴, *P.A. Marsden*², *K. Nakabayashi*¹, *S.W. Scherer*¹. 1) Dpt. of Genet., The Hosp. for Sick Children, Toronto, ON; 2) Dpt. of Medicine, Univ. of Toronto, Toronto, ON; 3) Samuel Lunenfeld Res. Inst, Mt. Sinai Hosp., Toronto, ON; 4) Dpt. of Cell Genet, Nat. Inst. for Genet., Japan.

The human *NOS3* gene mapped on 7q36 encodes a nitric oxide synthase. Some DNA polymorphisms in the gene are reported to be associated with cardiovascular diseases and preeclampsia. We have identified *NOS3AS* as an overlapping antisense transcript with *NOS3*, and have shown that it participates in the post-transcriptional regulation of *NOS3*. Further analyses revealed that *NOS3AS* encodes a 924 amino-acid protein that contains 25% sequence identity with the yeast autophagy gene 9 (*APG9/ATG9*). Autophagy is an intracellular degradation process highly conserved from yeast to higher eukaryotes. Yeast *APG9* encodes a transmembrane domain-containing protein shown to be indispensable for autophagic vesicle formation. Sequence analysis identified two *APG9*-like genes in the human genome: *APG9L1* on 2q35 and *APG9L2* (*NOS3AS*) on 7q36. Northern and RT-PCR analyses revealed that *APG9L1* is ubiquitously expressed, while *APG9L2* is expressed in a tissue-specific manner (pituitary gland and placenta). Phylogenetic analysis for *APG9*-like genes from multiple species revealed that chicken and lower eukaryotic species have only one *APG9*-like gene, which is closer to *APG9L1* than *L2*. Moreover, species higher than chicken have two *APG9*-like genes (*L1* and *L2*), indicating that *APG9L2* is a mammalian-specific gene. However, subcellular localizations by the transient expression of the GFP-tagged protein in COS7 cells determined *APG9L1* and *APG9L2*s distribution to be indistinguishable. Taken together, our data suggest that both *APG9L1* and *APG9L2* are likely to be functionally orthologous to yeast *APG9*, but *APG9L2* may be critical for autophagy in mammalian specific developmental events. Experiments are underway to determine if *APG9L1/L2* are functional in the mammalian autophagy pathway and to examine the possible roles of *APG9L2* in placental development and disease.

Isolation and characterization of human TRUB1 encoding the cytoplasmic and mitochondrial pseudouridine-55 synthase. *J.L. Peters*^{1,2}, *Q. Yan*², *M.X. Guan*^{1,2}. 1) Graduate program of Molecular and Developmental Biology, Cincinnati Children's Hospital, University of Cincinnati, Cincinnati, OH; 2) Division of Human Genetics, Cincinnati Children's Hospital, Cincinnati, OH.

Modified nucleotides of cytoplasmic and mitochondrial tRNA are crucial for tRNA structure and function. This posttranscriptional modification of tRNA is a complicated process catalyzed by enzyme complexes. In particular, bacterial Trub protein catalyzes the formation of pseudouridine (Ψ) at the conventional position 55 in tRNA, a modification highly conserved among all tRNA. The A8344G mutation in corresponding position of human mitochondrial tRNA^{Lys} is associated with MERRF syndrome, a classic mitochondrial disorder. Here, we have cloned and characterized the human counterpart TRUB1. TRUB1 is comprised of 8 exons on chromosome 10 spanning roughly 40kb. The gene encodes a predicted protein of 37,252 daltons. This protein is highly conserved from bacteria and yeast to human, particularly in the central activity domain. Previous studies showed that the TRUB1 gene is ubiquitously expressed across 12 different tissues. Immunofluorescence analysis of human 143B cells revealed that Trub1 co-localized, although not exclusively, with the mitochondrial protein COX1. This result suggests that Trub1 localizes in mitochondria and the cytoplasm. Thus, we propose that Trub1 catalyzes the -55 modification in both cytoplasmic and mitochondrial tRNA and therefore plays a role in modulating the phenotypic manifestation of disease-associated mitochondrial tRNA mutations.

Efficient Transgenesis and Sustained Muscle-Specific Expression of a *Myogenin-EGFP Tol2* Transposon

Construct in Zebrafish. A. Rashid¹, M.J. Ng¹, J. Ben², F.S.H. Cheah², A. Koga³, E.W. Jabs⁴, C.G.L. Lee⁵, C.H. Phang¹, S.S. Chong^{2,4}. 1) Life Sciences & Chemical Technology, Ngee Ann Polytechnic, SINGAPORE; 2) Pediatrics, Ob/Gyn, Lab Medicine, Nat'l Univ Singapore & Hospital, SINGAPORE; 3) Biological Sciences, Nagoya Univ Graduate School of Science, JAPAN; 4) Pediatrics, Institute of Genetic Medicine, Johns Hopkins Medicine, USA; 5) Biochemistry, Nat'l Univ Singapore, SINGAPORE.

Molecularly reconstructed and naturally occurring vertebrate transposons have numerous potential scientific and clinical applications, including insertional mutagenesis, gene trapping, gene transfer, and gene therapy. *Tol2* is a vertebrate transposon occurring naturally in the medaka fish *Oryzias latipes* that encodes its own fully functional transposase. We wished to evaluate the application of *Tol2*-mediated transgenesis to the analysis of gene expression in the living zebrafish. An enhanced green fluorescent protein (*EGFP*) reporter gene driven by a 2.5kb *myogenin* (*myog/myf4*) promoter was cloned into a *Tol2* transposon vector. The recombinant clone was co-injected with *Tol2* transposase mRNA into fertilized zebrafish embryos. EGFP expression was monitored using a fluorescent stereomicroscope. Muscle-specific expression of EGFP was observed as early as 24 hpf in all microinjected embryos. After 13 weeks (3 months), all surviving fish continued to exhibit a mosaic pattern of EGFP expression in the skeletal muscles of the trunk. Of these, 35% showed strong EGFP fluorescence, 29% had moderate EGFP expression, while the remaining 35% showed only isolated patches of EGFP expression. After more than 4 months, 14 of 15 remaining fish continued to express EGFP in a tissue specific manner, EGFP being undetectable in only one of the previously low expressing fish. In marked contrast, EGFP expression in fish injected with a non-transposon plasmid construct carrying the same expression cassette was transient and declined rapidly, with a majority of fish losing expression by 5 days. Outcrossings of founder mosaic transgenic fish will be performed to determine the degree of germline integration and to analyze EGFP expression patterns in constitutive transgenic F1 progeny.

Lgl2 regulates nuclear import of the glucocorticoid receptor and downstream effects on cytokine synthesis in airway epithelial cells. *F. Kaplan*^{1,2,3}, *J. Lan*², *R. Hache*⁴, *T. Tao*^{1,2,5}. 1) Dept of Human Genet., McGill Univ., Montreal, QC, CA; 2) Montreal Child. Hosp. Res. Inst, Montreal, QC, CA; 3) Dept of Pediatr., McGill Univ., QC, CA; 4) Ottawa Health Res. Inst and Dept of Med. and Biochem., Univ. of Ottawa, ON, CA; 5) Key Laboratory of the Ministry of Education for Cell Biology, Xiamen University, Xiamen, China.

Anti-inflammatory effects of glucocorticoids (GC) are critical to treatment of airway inflammation in such common disorders as asthma and COPD. There is a considerable variation in responsiveness to GC and prolonged exposure to GC can result in GC resistance. We reported the cloning of LGL2, a GC inducible gene in fetal rat lung cell culture. Comparison with sequences in the genome database identified lgl2 as a member of the importin- family of nuclear import receptors. We described the functional characterization of lgl2 as an importin- protein and demonstrated developmental regulation of its nucleocytoplasmic shuttling in fetal lung. We now report on the identification of the GC receptor (GR) as a primary cargo substrate for lgl2. To our knowledge this is the first identification of a nuclear transport carrier for a specific hormone receptor. We show that C-terminal lgl2 (which includes the ligand-binding domain) competitively inhibits nuclear entry of GR in HeLa cells. To investigate the potential role of lgl2 in modulating GC-GR regulated events in the lung, we studied lgl2 regulated GR transport in airway epithelial cells. The pro-inflammatory cytokine TNF- potently stimulates airway epithelial cells to produce cellular inflammatory cytokines including IL-8, an effect inhibited by GC. We show that an LGL2 siRNA that inhibits lgl2 synthesis in A549 lung epithelial cells prevented nuclear translocation of GR. Moreover, silencing of lgl2 in siRNA treated cells abrogated the ability of cortisol to inhibit synthesis and secretion of IL-8 following stimulation with TNF-. Our findings support a role for lgl2 in regulation of GC anti-inflammatory effects mediated by GR. We speculate that variation in both cellular levels of lgl2 and intracellular lgl2 shuttling rates may contribute to GC resistance.

Localization of regulatory elements of the human LMX1B gene with transgenic mice. *L. Liu, J.A. Dunston, C. Tran, I. McIntosh.* Inst Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Nail Patella Syndrome (NPS) is an autosomal dominant, pleiotropic condition affecting the nails, patellae, skeletal system, kidneys, and eyes. NPS is caused by mutations in the LIM homeodomain transcription factor LMX1B. To identify sequences responsible for the spatio-temporal expression of LMX1B gene, transgenic mouse lines were established using two overlapping bacterial artificial chromosomes (BACs), 123K19 and 265A2, containing varying distances upstream and downstream of the gene. Each BAC was digested with *NruI* or *SalI* (named as 19S, 19N, 2N, respectively), and then injected into fertilized mouse eggs. F1 transgenic embryos were analyzed by *in situ* hybridization mid-gestation. Consistent with the published data, the expression of mouse *lmx1b* gene was observed in the limb, spinal cord, mammary gland and midbrain-hindbrain junction. The segments defined by the BAC clones revealed expression of the transgenic LMX1B gene in distinct anatomical locations comparable to mouse *lmx1b* except for the limb. The 19N transgenic embryos showed gene expression in the dorsal part of both the forelimb and hindlimb, while the expression of transgene in 19S and 2N was restricted to the shoulder and pelvic girdles. This preliminary data suggests that regulatory elements 25-65kb upstream of the LMX1B gene regulate its expression in dorsal limb. Local alignments of genomic sequences were determined for the LMX1B genes from human, mouse, rat and chick with the MultiPipMaker or AdvancePipMaker program. Within this 40-kb region upstream of LMX1B gene, 5 regions longer than 100 bp with greater than 80% identity were found to be conserved between mammals. Only two of them were also conserved in chick and were analyzed for a common framework of transcription factors.

The TRPS1 transcription factor is associated with promyelocytic leukemia (PML) nuclear bodies through the interaction with the Topoisomerase I binding RS protein (TOPORS). *H.-J. Lüdecke¹, S. Weger², B. Horsthemke¹, F.J. Kaiser¹.* 1) Inst. for Human Genetics, University Clinic, Essen, Germany; 2) Dept. of Virology, Free University, Berlin, Germany.

The TRPS1 gene on human chromosome 8q24.1, which is mutated in the tricho-rhino-phalangeal syndrome, encodes a repressor of GATA mediated transcription. To identify co-factors of TRPS1, we performed a yeast two-hybrid screen with the C-terminal 647 amino acids (aa) of TRPS1 as a bait. Among 23 yeast clones obtained, two encode aa 930-1006 of the 1045 aa topoisomerase I binding RS protein (TOPORS). Using a yeast *in vivo* -galactosidase assay, we narrowed down the TOPORS-binding region of TRPS1 to the C-terminal 100 aa (1181-1281). We verified the interaction of endogenous and ectopically expressed TRPS1 and TOPORS in T47D and COS-7 cells by immunochemical precipitation experiments. TOPORS also interacts with Topoisomerase I and the p53 tumor suppressor, and it has been suspected that it functions as a negative regulator of cell growth and possibly as a tumor suppressor itself (Saleem et al., 2004, *Oncogene*, in press). TOPORS interacts with SUMO-1 and the SUMO-1 conjugating E2 enzyme UBC9 and is localized in promyelocytic leukemia (PML) nuclear bodies, which play a role in a variety of transcriptional regulation processes. Weger et al. (2003, *Exp Cell Res* 290, 13-27) have speculated that TOPORS might function as a SUMO-1 E3 ligase. Interestingly, we found that in human primary fibroblasts TRPS1 is almost completely SUMOylated. The endogenous TRPS1 is located in dot-like nuclear structures, some of which also contain PML protein. Whereas ectopically expressed TRPS1 is homogeneously distributed throughout the nucleus of COS-7 cells, it is only found in the dot-like structures when co-expressed with TOPORS. This indicates that TOPORS is involved in the TRPS1-PML association. In a luciferase reporter assay, we could exclude a direct effect of TOPORS on the repression function of TRPS1. We speculate that TOPORS acts as a SUMO-1 E3 ligase on TRPS1 in PML nuclear bodies and thereby modulates the function of TRPS1. (Supported by the Deutsche Forschungsgemeinschaft).

Wnt-4 inhibits the canonical Wnt pathway by redirecting β -catenin to the cytoplasmic membrane. *P. Bernard, A. Lacombe, A. Fleming, E. Vilain.* David Geffen School of Medicine at UCLA, Departments of Human Genetics, Pediatrics and Urology, Los Angeles, CA.

Wnt-4 is a signaling molecule essential for kidney, adrenal and gonadal development. Wnt-4 deletion results in the masculinization of XX mouse pups, and we have previously shown that overexpression of Wnt-4 dramatically reduces testosterone levels in XY mice, suggesting that Wnt-4 acts as an anti-male factor. We have investigated the molecular mechanisms of action of Wnt-4 and shown that it utilizes a novel signaling pathway. Using transient transfections, we have shown that Wnt-4 inhibits TCF and SF1 responsive genes. Specifically, Wnt-4 disrupts the synergistic interaction between SF1 and β -catenin on the promoter of target genes such as the Steroidogenic Acute Regulatory Protein (StAR). However, instead of promoting β -catenin degradation as it has been previously described for inhibitory Wnt genes, Wnt-4 stabilizes β -catenin. In addition, β -catenin accumulates at the cytoplasmic membrane as shown by indirect immunofluorescence assay on cells stably expressing Wnt-4. We confirmed this finding by co-immunoprecipitation with E-cadherin, a membrane-bound protein that binds β -catenin. In the presence of Wnt-4, larger amounts of β -catenin co-precipitate with E-cadherin compared to control. Increased interaction between β -catenin and E-cadherin also promotes E-cadherin-mediated cell-cell adhesion, ultimately leading to decreased cell migration. The latter observation is consistent with previous observations that the lack of Wnt-4 correlates with an increase of steroidogenic cell precursors migrating into the female gonad. Altogether these results demonstrate that Wnt-4 acts through a novel signaling pathway that prevents β -catenin action in the nucleus by redirecting it to the cytoplasmic membrane.

Interspersed 3 AGG interruption in the CGG repeat sequence in the FMR1 gene in mentally retarded patients of unspecified cause. *P.M.K. Poon¹, K.Y.C. Lai², Q.L. Chen², C.K. Wong², C.P. Pang³.* 1) Chemical Pathology, Chinese Univ Hong Kong, Hong Kong, China; 2) Psychiatry, Chinese Univ Hong Kong, Hong Kong, China; 3) Ophthalmology & Visual Sciences, Chinese Univ Hong Kong, Hong Kong, China.

We have shown that the CGG repeat pattern of the FMR1 gene is different in mentally retarded patients from the normal population. Haplotypes involving polymorphic markers flanking the FMR1 gene, CGG-FRAXAC2 and FRAXAC2-DXS548, also distributed differently. Since 3 AGG interruption in the FMR1 CGG repeat sequence affects stability of CGG stability, we investigated the link between AGG interspersion pattern and mental status. We determined the FMR1 CGG substructure in 104 normal healthy male subjects and 232 unrelated male patients with mental retardation of unspecified cause. All the study subjects had less than 53 CGG repeats and therefore did not have fragile X syndrome of mental retardation. There is a significant difference ($p < 0.006$) in the AGG interspersion pattern between the normal controls and the mentally retarded patients. Although the majority of both groups of subjects have 2 interspersed AGG, the mentally retarded patients have proportionally less 2 and 3 AGG but more 0 and 1 AGG than the normal controls. They also have a lower frequency of (CGG)10AGG(CGG)10AGG(CGG)9 but a higher frequency of (CGG)10AGG(CGG)19 alleles. Their pure CGG repeat at the 3 position is longer and their CGG internal configuration is less variable. Our results show that the AGG interspersion pattern is associated with mental retardation prior to or independent of the mutational events leading to the development of FRAXA mental retardation.

Functional Genomics of the Human Catecholamine Storage Vesicle Protein Chromogranin B (CHGB). *R.M.*

Salem¹, J. Wessel², F. Rao^{1,3}, S.K. Mahata^{1,3}, N. Mahapatra^{1,3}, V. Mahboubi⁴, P.E. Cadman^{1,3}, G. Wen¹, M.T. Robinson¹, D.W. Smith⁴, B.A. Hamilton¹, M. Stridsberg¹, B.K. Rana⁴, N.J. Schork², D.T. O'Connor^{1,3}. 1) Department of Medicine, UCSD, La Jolla, CA; 2) Department of Psychiatry, UCSD, La Jolla, CA; 3) VASDHS, San Diego, CA; 4) Department of Biology, UCSD, LA Jolla, CA.

Chromogranin B (CHGB) is a member of the chromogranin-secretogranin protein family, comprised of acidic, soluble proteins that are stored in secretory granules with hormones, transmitters, and neuropeptides throughout the endocrine and nervous systems. Interest in CHGB has increased as recent studies suggest that CHGB plays a critical role in intracellular catecholamine compartmentalization and release. To improve the understanding of mechanisms of catecholamine release, and the role that dysfunction may have on development of complex human diseases, we undertook systematic variant discovery by resequencing this locus in 160 ethnically diverse human subjects. We resequenced all 5 exons and adjacent intron regions, ~1 kb upstream of the 5 promoter, 2 conserved promoter regions up to ~4 kb upstream, and 1 intronic conserved regions. A total of 52 SNPs and a single base (C) insertion/deletion were identified. Of these, 19 were common (minor allele >5%) in our sample. Remarkably, 10 SNPs were identified in exon 4, 9 of which encoded amino acid substitutions. A subset of 11 of the identified CHGB SNPs was genotyped in additional phenotyped subjects. 9 of the 11 SNPs predicted CHGB expression in vivo (plasma peptide fragment CgB439-451 level). In 150 twin pairs, 3 of the 11 SNPs [Glu348Glu ($p=0.014$), and His397Arg ($p=0.032$) in exon 4, and C13612A ($p=0.035$) in intron 4] predicted heritable, stress-induced blood pressure increments. In a male population sample with extreme blood pressures (300 high/300 low), systolic blood pressure was elevated in association with the C allele of the T10501C SNP ($F=3.52$, $p=0.024$). We conclude that common allelic variation at the CHGB locus has functional consequences for expression of the gene in vivo, as well as for stress susceptibility of blood pressure variation, and finally for development of hypertension.

Studying RNA instability mutations via a novel model using a BAC clone. A. Eeds¹, R. Wade-Martins³, D. Mortlock¹, D. Piston¹, L. Hall², A. Putnam², T. Nalls², M. Summar^{1,2}, *The Urea Cycle Disorders Consortium*. 1) Center for Human Genetic Research, Dept Molec Physiology, Vanderbilt Univ, Nashville, TN; 2) Dept Pediatrics/Div Medical Genetics, Vanderbilt Univ, Nashville, TN; 3) The Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Carbamyl phosphate synthetase I (CPSI) is the liver specific enzyme that catalyzes the rate-determining step of the urea cycle. We have found mutations in patients with CPSI Deficiency that may cause RNA instability. We hypothesize that these mutations result in the instability of that RNA message due to splicing defects and premature termination codon formation leading to nonsense-mediated decay and that these mutations can be studied using a BAC clone. Because CPSI is liver specific, patient fibroblast cell lines cannot be used for RNA assays. Also, these mutations are spread throughout the gene, which is composed of 38 exons that span over 120 kb of genomic sequence. Therefore, our focus is to find a way to re-create and test each of these mutations using one construct that can be efficiently manipulated. A BAC clone containing the CPSI genomic sequence was modified to contain a gene for GFP to assay for transfection efficiency, hygromycin resistance for selection in eukaryotic cells, and EBNA-1, a viral gene to aid in episomal retention of the BAC following transfection in eukaryotic cells. We also engineered CPSI to be driven by the CMV promoter for more ubiquitous expression. Putative RNA instability mutations will be rapidly engineered into this construct using homologous recombination with oligos that contain the mutation in question. Following transfection of the BAC construct into eukaryotic cell cultures, the resulting RNA species can be assayed to determine the precise mechanism of the mutation using conventional RNA assays. This model system will allow rapid determination of the mechanisms that the mutations responsible for CPSID employ to cause RNA instability. We anticipate this model system will be widely applicable for studying heterogeneous mutations responsible for genetic disorders as well as for determining if a mutation has an effect on RNA when there is no patient source available.

Analyses of splicing patterns and variations of transcription start sites using human full-length cDNAs constructed by oligo-capping method. *T. Isogai¹, A. Wakamatsu¹, K. Kimura², J. Yamamoto¹, J. Uechi², T. Nishikawa^{1,2}, S. Sugano³, N. Nomura⁴.* 1) Reverse Proteomics Res Inst, Kisarazu, Chiba, Japan; 2) Central Research Laboratory, Hitachi Ltd., Tokyo, Japan; 3) Department of Medical Genome Sciences, Graduate school of Frontier Sciences, University of Tokyo, Tokyo, Japan; 4) Biological Information Research Center, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan.

Full-length cDNA clones are important materials for experimental elucidation of gene function. About 30 thousand of human full-length cDNAs were sequenced by our NEDO human cDNA sequencing project, and were deposited to DDBJ/GenBank/EMBL. From the analysis of human genome sequences, the number of human genes is predicted to be approximately 30K-40K. And the number of mRNA transcribed from the human genome is predicted to be approximately 80K-110K. From these results, a lot of variant cDNAs including splicing and transcription start site variations could be obtained. In order to search splicing variant cDNA efficiently, 29,789 full-length cDNAs of our project and 42,821 cDNAs of other cDNA projects and RefSeq eliminated same sequences as cDNA projects were mapped to 27,803 loci of human genome. For this we found that 12,002 loci consisted of two or more splicing patterns had 41,021 of splicing patterns. Then the variations of the splicing patterns based on ORFs were analyzed. We are analyzing and cloning of variant cDNAs including splicing and transcription start site variations from about 1.4 million cDNAs of about 100 kinds of cDNA libraries consist of human tissues and cells constructed by oligo-capping method. About 500 bp of all 5-end of the cDNAs were obtained by our NEDO human cDNA sequencing project. The full-length rate of 5-end of those was about 90%. We mapped those to human genome for cloning of variant cDNAs based on ORF variations, and then obtained not only splicing variant cDNAs, but transcription start site variations. Some of them had tissue specific expression profiles. This work was supported by a grant from New Energy and Industrial Technology Developmental Organization (NEDO) project of the Ministry of Economy, Trade and Industry of Japan.

DNA Palindromes: The role of DNA repair functions. *J.H. Appleby*^{1,2}, *S.M. Lewis*^{1,2}. 1) Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada.

DNA palindromes consist of pairs of inversely repeated sequences having central symmetry that are able to form intra-strand hairpin and cruciform structures. The formation of these structures poses a special threat to the genome as they can block replication and are postulated to lead to gross chromosomal rearrangements such as deletions, translocations, gene amplification and repeat expansion. How palindromes mediate such rearrangement is undetermined. Based upon a murine model, a unique mechanism for dealing with palindromes has been proposed, termed the Center-Break Model. Extrusion of a cruciform occurs from a perfect palindrome, and each of the hairpin tips are nicked, creating a double strand break at the center of symmetry. This break is then repaired by the NHEJ pathway, often resulting in deletion of sequence that creates a central asymmetry.

Two complementary assays are being used in a candidate gene approach to determine which DNA repair functions are involved in palindrome processing. The first assay uses the Line 78 mouse that bears a perfect 15.4kb palindrome on chromosome 17 and in a wild-type background rearranges at a rate of 0.5% per generation. Rates of rearrangements for this chromosomally located palindrome are being determined by crossing the Line 78 mouse with mice deficient for the candidate gene. The Werners syndrome protein, DNA-Pkcs, Ku70, and Artemis are currently being tested for roles in palindrome processing. The second transient assay uses a 15.6kb palindromic circular dimer that is transfected into Abelson cell lines deficient for the candidate gene. The dimeric molecule undergoes rearrangement consistent with the center-break model, and is recovered as a monomer. The number and structure of recovered monomers reveals any deviation in palindrome processing from wild-type.

Sense-antisense RNA transcription and methylation of D4Z4 repeat array in Facioscapulohumeral muscular dystrophy. *L. Felicetti*^{1,2}, *A. Cellini*¹, *M. Rossi*¹, *P. Venditti*¹, *G. Galluzzi*², *L. Colantoni*², *R. Frusciante*¹, *B. Merico*¹, *P. Tonali*¹, *E. Ricci*¹. 1) Institute of Neurology, Catholic University, Rome, Italy; 2) UILDM, Rome.

Linkage and physical mapping strategies have localized the FSHD gene to the subtelomeric region of chromosome 4q, a polymorphic locus containing an array of KpnI repeat units (D4Z4). A decrease in the number of these repeats below the threshold of 10 units is associated with the disease. Despite the presence of an open reading frame containing two homeodomains and a putative promoter region, no protein coding transcripts derived from the D4Z4 locus have been so far identified in vivo (Hewitt et al, 1994). To further investigate RNA transcription from KpnI repeats in FSHD, we searched for D4Z4-derived RNA species that are not limited to the open reading frame sequences present in the region. Using a RNase protection assay and Northern blot analysis with probes positioned across the KpnI sequence, we show that transcription occurs on both DNA strands in muscle biopsies derived from FSHD patients, giving rise to RNAs that may play an essential role in the chain of events leading to the disease. Since we do not find such transcription in muscles obtained from normal subjects, it is conceivable that it represents an inappropriate activity of the KpnI repeat units present on the contracted D4Z4 locus. Consistent with a transcriptional up-regulation of the contracted D4Z4 array, a marked hypomethylation of this region was recently found on both alleles in FSHD patients (van Overveld et al, 2003). Using bisulfite genomic sequencing technique we have analysed the methylation status of two regions within the KpnI units at 4q35. While the first region analysed, showed a marked hypomethylation on both 4q alleles in FSHD patients, as previously described, the second region, showed the same methylation status on 4q alleles in healthy and affected subjects. According to these results the methylation status is not uniformly spread on the entire KpnI unit, underscoring the complexity of the locus where specific subregions could play different roles in the molecular mechanism of the disease.

Identification of a CYP2E1 gene duplication in African American and Caucasian populations using TaqMan Real-Time PCR. *L.Y. Wong, M. Lin, S.-N. Liew, J. Stevens, K.J. Livak, K.D. Lazaruk.* Applied Biosystems, Foster City, CA.

CYP2E1 is a cytochrome P450 enzyme that catalyzes the bioactivation of environmental carcinogens such as N-nitrosamines. A wide range in CYP2E1 expression and activity between individuals has been previously reported. Interindividual variation is thought to be partly influenced by genetic factors. However, no clear large-scale associations between genetic polymorphisms and phenotypes have been established. In this study, we determined that individuals may carry a duplication of the CYP2E1 gene. TaqMan allelic discrimination assays were used to genotype single nucleotide polymorphisms (SNPs) at positions -352A>G, -333T>A, -71G>T, and 4768G>A of the CYP2E1 gene in African Americans and Caucasians. Atypical results were observed for 7 out of 90 individuals when signal intensities from the two allele-specific fluorogenic probes were graphed on a plot. TaqMan real-time quantitative PCR assays were used to determine the dosage of the CYP2E1 5 regulatory region, exon 4, intron 6, and exon 9. The results indicated that the atypical individuals carried 3 copies of each CYP2E1 region assayed while all other individuals carried 2 copies. Dosage data from a CEPH family in which the father carried the CYP2E1 duplication demonstrated that the duplication was inheritable and stable. The prevalences of the duplication in African Americans and Caucasians were estimated at 5% and 11%, respectively. These findings may partially account for interindividual variation in CYP2E1 expression and activity. Further characterization of the duplication will be required to determine whether the duplication is an active gene.

SNP Haplotype at the *MDR1* Promoter affect its activity under ultraviolet irradiation stress. C.G. Lee^{1,2}, S.M. Ngoi². 1) Department of Biochemistry, National University of Singapore, SINGAPORE; 2) Div Medical Sci, National Cancer Ctr, SINGAPORE.

The *MDR1* multidrug transporter plays an important role in shielding the individual against xenobiotic toxicity. Single nucleotide polymorphisms (SNPs) and SNP haplotypes within the *MDR1* gene have been shown to account for variability in *MDR1* expression and function, drug response as well as disease susceptibility. However, the effect of SNPs on *MDR1* promoter activity is not well characterized. Through sequencing of 1.5 kb of sequences at the *MDR1* promoter region in 70 individuals of Chinese ethnic origin, we identified only three SNPs, intron-1 -41A>G, exon1 -145C>G and exon1 -129T>C. These three SNPs have been previously reported. SNPs intron-1 -41A>G and exon1 -145C>G reside in the predicted NF-Y and ETS binding sites, respectively. These SNPs were genotyped in approximately 96 individuals from each of five ethnic populations, Chinese, Malays, Indians, Caucasians and African Americans. All three SNPs were found to occur at frequencies of less than 10% in all populations with SNP exon1 -145C>G being Chinese-specific and SNP intron-1 -41A>G being monomorphic in Indians and of very low frequencies in the Caucasians and African Americans (0.5% minor allele frequency). Of 8 possible haplotypes, 5 haplotypes were observed in the Chinese, 4 in the Malays, 3 in the Caucasians and African American and 2 in the Indians. *In vitro* promoter assays revealed that none of the observed haplotypes significantly affected *MDR1* promoter activity in KB3-1 or N2a cell-lines. However, one haplotype which was not observed in any of the ethnic group examined affected promoter activity significantly under ultraviolet (UV) irradiation stress in KB3-1 but not N2a cell-lines. It is possible that this haplotype occur at a frequency that is lower than what was examined. In summary, our results suggest that SNP haplotypes at the *MDR1* promoter may influence its activity in specific cell-types and/or under specific external stress.

Toward the Evaluation of Function in Genetic Variability: Characterizing Human SNP Frequencies and Establishing BAC-Transgenic Mice Carrying the Human CYP1A1_CYP1A2 Locus. Z. Jiang¹, T.P. Dalton¹, L. Jin¹, B. Wang¹, Y. Tsuneoka², H.G. Shertzer¹, R. DeKa¹, D.W. Nebert¹. 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Yokohama Hospital, Yokohama Midoriku Terayamachou, Japan.

Inter-individual differences in human CYP1A1 and CYP1A2 expression are believed to be associated with variability in risk toward various types of environmental toxicity and cancer caused by polycyclic aromatic hydrocarbons and aromatic amines present in combustion products. These two genes are oriented head-to-head on human chromosome 15; the 23.3-kb spacer region might contain distinct regulatory regions for CYP1A1 and distinct regulatory regions for CYP1A2, or regulatory regions for the two genes might overlap one another. From the five major geographically isolated human subgroups, we performed SNP-discovery in 24 unrelated subjects by DNA resequencing of both genes (all exons and all introns) plus some 3 flanking sequences and the entire spacer region (39.6 kb total); 85 SNPs were found, 49 of which were not currently in the NCBI database. Of the 57 double-hit SNPs, we carried out SNP-typing in 94 Africans, 96 Asians, and 83 Caucasians and found striking ethnic differences in SNP frequencies and haplotype evolution. Four BAC-transgenic mouse lines, carrying the human CYP1A2 and much of the spacer region (except 8,115 bases closest to the CYP1A1 gene), expressed only negligible basal CYP1A2 mRNA, which was not inducible by dioxin. A fifth BAC-transgenic mouse line, carrying both the human CYP1A1 and CYP1A2 genes and ample amounts of 3 flanking sequences, plus all of the spacer region in the absence of the mouse *Cyp1a1* or *Cyp1a2* genes expressed the human CYP1A1 and CYP1A2 mRNA, protein and enzyme activities in liver and various nonhepatic tissues very similar to that of the mouse. Comparison of this hCYP1A1_1A2 transgenic line with hCYP1A1_1A2 lines carrying other common human haplotypes will enable us to evaluate function in human CYP1A1_CYP1A2 locus variability, with regard to polycyclic aromatic hydrocarbon- and aromatic amine-induced toxicity and cancer.

Establishment and characterization of *Aire*-expressing thymic cell lines. *Y. Yamaguchi*¹, *J. Kudoh*¹, *K. Tani*¹, *K. Sakai*¹, *S. Noda*², *A. Takayanagi*¹, *N. Shimizu*¹. 1) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 2) Department of Nursing, School of Health Science, Tokai University, Kanagawa, Japan.

Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED: OMIM 240300) caused by mutation in autoimmune regulator (AIRE) gene is an organ-specific autoimmune disease with monogenic autosomal recessive inheritance. Recently, aberrant or promiscuous expression of a broad range of peripheral tissue-restricted genes by thymic medullary epithelial cells has been implicated in the essential process of establishing self-tolerance and AIRE in thymic epithelial cells has been demonstrated, by experiments using knockout mice, to control this promiscuous gene expression. Since AIRE is expressed only in a few epithelial cells of thymus and not expressed in established thymic epithelial cell lines, biochemical analysis of AIRE function in thymic epithelial cells is very difficult, and thus little is known about AIRE function associated with the mechanism regulating the transcription of peripheral tissue-restricted genes in thymic medullary epithelial cells, although AIRE protein has been reported to have both transcriptional activator and E3 ubiquitin ligase activities. To establish permanent lines derived from thymic medullary epithelial cells which express AIRE gene, we produced transgenic mice expressing SV40 T-antigens driven by mouse *Aire* gene promoter. Gross abnormality was found only in thymus of transgenic mice, namely they developed gigantic thymus about 40 days after birth. RT-PCR analysis revealed that SV40 T-antigen mRNA is expressed in the gigantic thymus but not in any other tissues examined. Cells dissociated from the gigantic thymus were cultured and three cell lines were cloned by limited dilution. These established cell lines (*Aire* cell) expressed *Aire*, SV40 T-antigen, and some peripheral tissue-restricted genes against which antibodies were produced in the APECED patient. *Aire* cell lines will be invaluable for the biochemical analysis of *Aire* gene function in relation to the promiscuous gene expression in thymic epithelial cells.

Regulation of Hermansky Pudlak Syndromes genes in human lymphoblastoid cell lines. A. Rivera, C. Carmona-Rivera, C.L. Cadilla. Department of Biochemistry, University of Puerto Rico School of Medicine, San Juan, PR.

The Hermansky Pudlak Syndrome (HPS)[MIM#203300] is the major cause of albinism cases in Puerto Rico. HPS is caused by defects in many genes, seven of them have been identified in humans. *HPS2* codes for the 3A subunit of the AP3 adaptor complex and *HPS7* codes for dysbindin, a component of the dystrophin associated protein complex (DPC), the rest of the human genes are novel and show no sequence similarity to other proteins and have few known functional domains. The HPS gene products are frequently undetectable in cells or tissues derived from both human patients and mouse models of HPS. The expression of the *HPS1*, *HPS2*, *HPS3*, *HPS4*, *pallidin* and *muted* genes in lymphoblast cell lines was examined by RT-PCR. The mRNA^{HPS1} was detectable in cells derived from a patient with HPS-1. Expression of the *HPS1*, *HPS2*, *HPS3*, *HPS4*, *pallidin* and *muted* genes was detectable by RT-PCR in both normal and HPS-1 human lymphoblast cell lines. Analysis of the 5-flanking DNA of several HPS genes using the TESS software showed potential response elements for glucocorticoid hormones, cAMP and Phorbol esters. Preliminary RT-PCR analysis of serum-starved cells treated with dexamethasone (DEX), PMA, cAMP, and Insulin for 8 hours showed an enhancement in the expression of almost all HPS genes. Real time RT-PCR analysis confirmed the inductive effect of these agents on the expression of HPS genes, with the exception of the *HPS3* gene, whose mRNA levels were decreased by cAMP treatment. Northern blot analysis shows an inductive effect of Dexamethasone, cAMP and Insulin on the expression of *HPS2*. However, treatment with PMA caused a decrease in the mRNA^{HPS2} levels. Western Blot analysis of lymphoblasts treated with PMA indicated a slight reduction in the expression of HPS1 and HPS4 proteins in normal human lymphoblasts. Further studies on the regulation of HPS genes are necessary to fully understand the cellular pathways affected in HPS. Grants from NIGMS S06GM08224 and R25GM61838 and NCRRG12RR03051 supported this study.

FMRP binds mainly to mRNAs relevant to neurodevelopment: Use of a yeast tri-hybrid approach to analyze protein-mRNA binding. *N. Zhong*^{1,2}, *K. Zo*², *A. Wronska*¹, *W. Ju*¹, *J. Shen*¹, *W.T. Brown*¹, *Y. Shen*². 1) Department of Human Genetics, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 2) National Key Laboratory of Molecular Medical Biology, China Academy of Medical Sciences/Peking Union Medical College, Beijing, China.

Lack of FMRP, the FMR-1 encoded protein, clinically results in the fragile X syndrome. FMRP has been characterized as having intrinsic mRNA-binding activity. To isolate and characterize FMRP-bound mRNA molecules, we employed a yeast tri-hybrid system. An RNA-expressing cDNA library was constructed in the pRH5 plasmid using human brain tissue. A full-length human FMR1 cDNA, that expresses FMRP in-frame, was subcloned into pYES3. Library screening was carried out by filter assay on selective medium with 3-AT. Of more than 50 mRNA molecules isolated, the majority was relevant to neuron development, including NEDD5, ROBO1, GDF11, and calmodulin 2. In addition, there were four categories of RNAs involved either in regulating cellular transcription and translation, or ribosomal transcripts, or RNA-binding protein transcription, as well as transcripts with uncharacterized functions. Characterization of these RNAs expression profiles in *fmr-1* knockout mouse brain by quantitative PCR and in situ hybridization are currently being undertaken. This approach has the potential to open new avenues to explore the pathogenic mechanism underlying the fragile X syndrome. It may also contribute new therapeutic targets for treatment of the syndrome.

Comparative genomics identifies a flagellar and basal body proteome that includes the *BBS5* human disease gene. *J.M. Gerdes*¹, *J.B. Li*³, *C.J. Haycraft*⁴, *Y. Fan*⁵, *T.M. Teslovich*¹, *H. May-Simera*⁶, *H. Li*⁷, *O.E. Blacque*⁵, *C.C. Leitch*¹, *R.A. Lewis*⁸, *J.S. Green*⁹, *P.S. Parfrey*⁹, *M.R. Leroux*⁵, *W.S. Davidson*⁵, *P.L. Beales*⁶, *L.M. Guay-Woodford*⁷, *B.K. Yoder*⁴, *G.D. Stormo*³, *S.K. Dutcher*³, *N. Katsanis*^{1,2}. 1) McKusick-Nathans Institute of Genetic Medicine; 2) Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD; 3) Department of Genetics, Washington University School of Medicine, St. Louis, MS 63110; 4) Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL 35294; 5) Department of Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC V5A 1S6, Canada; 6) Molecular Medicine Unit, Institute of Child Health, University College London, London WC1N 1EH, UK; 7) Division of Genetic and Translational Medicine, Departments of Medicine, Pediatrics, and Genetics, University of Alabama at Birmingham, Birmingham, AL 35294; 8) Departments of Molecular and Human Genetics, Ophthalmology, Pediatrics, and Medicine, Baylor College of Medicine, Houston, TX 77030; 9) Departments of Medical Genetics and Clinical Epidemiology, Memorial University, St. John's Newfoundland, Canada.

Cilia and flagella are microtubule-based structures nucleated by modified centrioles termed basal bodies. These biochemically complex organelles have more than 250 and 150 polypeptides, respectively. To identify the proteins involved in ciliary and basal body biogenesis and function, we undertook a comparative genomics approach that subtracted the nonflagellated proteome of *Arabidopsis* from the shared proteome of the ciliated/flagellated organisms *Chlamydomonas* and human. We identified 688 genes that are present exclusively in organisms with flagella and basal bodies and validated these data through a series of *in silico*, *in vitro*, and *in vivo* studies. We then applied this resource to the study of human ciliation disorders and have identified *BBS5*, a novel gene for Bardet-Biedl syndrome. We show that this novel protein localizes to basal bodies in mouse and *C. elegans*, is under the regulatory control of *daf-19*, and is necessary for the generation of both cilia and flagella.

Investigating NAD kinase as a mitochondrial mutator. *K.V. Shianna*¹, *M.K. Strand*², *D.A. Marchuk*¹. 1) Dept Mol Genetics/Microbiol, Duke Univ Medical Ctr, Durham, NC; 2) Laboratory of Molecular Genetics, National Institute of Environmental Health Sciences, Research Triangle Park, NC.

The aging process, along with many neurodegenerative disorders, results in an increase in the mitochondrial mutation frequency. The molecular mechanisms behind this are not fully understood. We have previously shown that insertional inactivation of the yeast mitochondrial NADH kinase (*POS5*) leads to a 50-fold increase in the mitochondrial mutation rate. Expression analysis on the *pos5* demonstrated increased expression of most of the iron transport genes. This expression pattern is very similar to the yeast frataxin homolog knockout, a model for the neurodegenerative disease Friedreich's ataxia. In addition, the *pos5* showed decreased expression for many of the enzymes involved in electron transport. We have demonstrated that the *utr1* (cytoplasmic NAD kinase) *pos5* double knockout is synthetically lethal in yeast, and that this lethality can be rescued by the human NAD kinase cDNA. Since the NAD/H kinase proteins are highly conserved, we hypothesized that mutations in a mammalian homolog could lead to an increased mitochondrial mutation rate. Recently, we have established an NAD kinase mouse model. The homozygote is embryonic lethal. The F1 and F2 heterozygotes appear to be healthy at six months of age. We are currently measuring the frequencies of mitochondrial deletions and point mutations. Crosses are also being performed to determine if the heterozygote state has an effect on the mouse after several generations of maternal mitochondrial inheritance. Also, the heterozygote is being coupled with other knockouts that affect responses to reactive oxygen species.

Complementation Studies of Shwachman-Diamond Syndrome Protein Homologues in Yeast. *G.R.B. Boocock*^{1,2}, *M.R. Marit*¹, *C. Shamma*³, *A.J. Warren*³, *J.M. Rommens*^{1,2}. 1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada; 3) MRC Laboratory of Molecular Biology, Cambridge, UK.

Shwachman-Diamond syndrome (SDS) is a recessive, multisystem disorder affecting the bone marrow, exocrine pancreas, and skeleton. The gene that is mutated in SDS (*SBDS*) encodes a soluble protein with highly conserved counterparts in all eukaryotic and archaeal genomes. The structure of the *Archaeoglobus fulgidus* homologue has recently been solved and revealed a three-domain arrangement, with a novel amino-terminal domain, a central domain composed of three α -helices, and a carboxyl-terminal domain that occurs in a number of proteins of diverse function. *YLR022c*, the *Saccharomyces cerevisiae* homologue of *SBDS*, is an essential gene. We have developed a complementation assay in yeast based on a plasmid shuffle system. When 17 disease-relevant missense mutations were generated in *YLR022c*, all but two over-expressed variants supported yeast growth, indicating that most mutations do not abrogate protein function. This is in agreement with the absence of homozygosity for common, early truncation mutations in a large patient collection, indicating that SDS arises due to hypomorphic alleles of *SBDS*, and that complete loss of *SBDS* function is incompatible with life. We have determined that *SBDS* itself cannot functionally substitute for *YLR022c*. However, chimeras containing *SBDS* sequence corresponding to domain-1 or domain-3 were capable of complementation. A chimera with the carboxyl-terminus of *Arabidopsis thaliana*, including domain-3 and an extended segment with a putative zinc finger, was also capable of complementation. Functional complementation did not extend to the Archaea, as neither domain-1 nor domain-3 from *Solfolobus solfataricus* could substitute for homologous yeast sequences. Taken together, these results suggest that domain-2 imparts a species-specific functionality, while domains 1 and 3 are interchangeable amongst eukaryotes. Study of *YLR022c* will therefore yield direct insights into the function of *SBDS*.

The Diamond Blackfan Anemia gene product, ribosomal protein S19, interacts with the Pim-1 oncoprotein. I.

Dianzani¹, A. Chiocchetti¹, L. Gibello¹, A. Carando², P. Secco¹, A. Biava¹, A. Aspesi¹, U. Dianzani¹, U. Ramenghi², C. Santoro¹. 1) Dept of Medical Sciences, Univ. Piemonte Orientale, Novara, Italy; 2) Dept of Pediatric Sciences, Univ. Torino, Italy.

Diamond Blackfan Anaemia (DBA) (MIM 205900) is a congenital disease characterized by defective erythroid progenitor maturation. The bone marrow progenitors from patients do not respond in vitro and in vivo to exposure to erythropoietic growth factors, such as EPO, IL-3, TPO. Mutations in the gene encoding for ribosomal protein (rp) S19 account for 25% of patients. The link between defective erythropoiesis and rps19 is still unclear. Two hypotheses, not mutually exclusive, have been proposed: one considers that the cause of the defective erythropoiesis resides in a decreased protein synthesis, whereas the second invokes the loss of a possible extraribosomal function. In recent years several ribosomal proteins have been shown to have a second function besides their structural role in the ribosome. To identify a possible second role for rps19 we performed the Yeast Two Hybrid System, using rps19 as the bait to screen a cDNA library obtained from human liver at the 19-24th week of gestation, a period in which hepatic erythropoiesis is active. In our hypothesis the nature of the interactor could have suggested a second role for rps19. Our screening identified a cDNA clone, present in three different versions, which encoded for the Pim-1 oncoprotein. PIM-1 is widely expressed in erythropoiesis after induction by erythropoietic growth factors, such as EPO, IL-3 and TPO. The interaction between Pim-1 and rps19 was demonstrated both in vitro and vivo, by a pulldown and a coimmunoprecipitation assay. Our data also show that both the N-terminal and C-terminal regions of rps19 are critical for this interaction and thus suggest a conformation site. The nature of this interaction and its functional role in hemopoiesis still need to be elucidated. In conclusion, a link between erythropoietic growth factor signaling and rps19 has been for the first time identified: these data suggest a new biological role for rps19.

Spastin shows association with the centrosome: implications for the pathogenesis of Hereditary Spastic

Paraplegia. *M.T. Kloos¹, I.K. Svenson¹, A.C. Horton², A.A. Ashley-Koch³, M.A. Pericak-Vance³, M.D. Ehlers², D.A. Marchuk¹.* 1) Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC; 2) Department of Neurobiology, Duke University Medical Center, Durham, NC; 3) Center for Human Genetics, Duke University Medical Center, Durham, NC.

Hereditary Spastic Paraplegias (HSPs) represent a group of genetically heterogeneous neurodegenerative disorders characterized primarily by hyperreflexia and progressive spasticity of the lower limbs. The common pathology is neuronal degeneration that is maximal at the distal ends of the longest axons of the central nervous system. Mutations in the *SPG4* gene, encoding spastin, result in the most common form of autosomal dominant HSPs. To gain insight into the normal function of spastin and its role in HSP pathogenesis we have developed a peptide antibody to investigate the subcellular localization of endogenous spastin. The peptide antibody was designed for maximum specificity to all spastin isoforms. The epitope is located outside of the highly conserved AAA domain, outside the less conserved MIT domain, and not encoded by alternatively spliced exons 4, 8 or 15. Our data suggest that endogenous spastin in several cell types is localized to the centrosome, the site of microtubule nucleation and organization. A location at the microtubule organizing center (centrosome) is consistent with published reports showing that mutant spastin associates with and reorganizes microtubules in transient transfection experiments. Taken together, our findings are consistent with a proposed cytoplasmic role for spastin in regulation of microtubule dynamics. These findings are also consistent with the proposed axonal transport theme for HSP pathogenesis, as the microtubules form the molecular rail system for axoplasmic flow.

Biological and Clinical Consequences Of Sarcoglycan Gene Mutations. *M. Hegde¹, Y.M. Chan², B. Chong¹, S.V. Khadilkar⁴, W. Shi², M. Farber², V. Wong³, P. Ip³, Z. Simmons⁵, C.S. Richards⁶, D.R. Love⁷.* 1) Medical Genetics Laboratories, Baylor Col Medicine, Houston, TX; 2) The Henry Hood Research Program, Sigfried and Janet Weis Center for Research, The Geisinger Clinic, Danville, PA 17822; 3) Division of Child Neurology, Department of Pediatrics and Adolescent Medicine, Queen Mary Hospital, University of Hong Kong, Hong Kong SAR, China; 4) Department of Neurology, Bombay Hospital, Bombay, India; 5) Department of Neurology, Penn State College of Medicine, Milton S. Hershey Medical Center, Hershey, PA 17033; 6) OHSU DNA Diagnostic Lab OHSU3181 SW Sam Jackson Park Road, MP-350 Portland, OR 97239; 7) School of Biological Sciences, University of Auckland, Private Bag 92019, Auckland, New Zealand.

Mutations in sarcoglycans have been shown to cause the autosomal recessive Limb-girdle Muscular Dystrophy (AR-LGMD). Sarcoglycans consist of four transmembrane proteins (a-SG, b-SG, g-SG and d-SG) and form a specific complex in sarcolemma. We have evaluated 100 clinically defined LGMD patients from US, New Zealand, Hong Kong and India. To screen for all the sarcoglycan genes involved in LGMD, a mutation scanning strategy using dHPLC and/or sequencing of the coding region, with immunohistochemical analysis of muscle biopsies was used. We identified mutations in 40 patients, of which 21 are missense mutations, 10 are nonsense mutations and 9 are frame-shift mutations. Earlier we have demonstrated that assembly of the sarcoglycan complex follows a pathway that is dependent on the interaction between b-SG and d-SG. In co-expression studies using truncated deletions in d-SG, the extreme C-terminal was shown to be critical for interaction with b-SG. This domain consists of conserved EGF-like repeat that forms intramolecular di-sulfide bond as well as a highly conserved sequence of 8 amino acids. We predict that these sarcoglycan mutations produce deleterious effects on muscle function by disrupting the formation of a functional b/d-SG core during assembly process. The analysis of truncated deletions in sarcoglycans will help further elucidate the functional role of different domains of sarcoglycans and better understand the phenotypic variation in LGMD.

Regulation of Wilms Tumor Gene 1(WT1) in desmoid tumors. *S. Amini Nik¹, P. Hohenstein², A. Jadidizadeh¹, K. Van Dam¹, A. Bastidas¹, R. Berry³, C. Patek³, B. Van der Schueren¹, J. Cassiman¹, S. Tejpar¹.* 1) Department of Human Genetics, University of Leuven, Leuven, Belgium; 2) Comparative and Developmental Genetics, MRC Human Genetics Unit, Western General Hospital, Crewe Road, Edinburgh, EH4 2XU, UK; 3) Cancer Research UK Laboratories, Molecular Medicine Centre, Western General Hospital, Crewe Road, Edinburgh EH4 2XU, UK.

Desmoid tumors (aggressive fibromatosis) are locally invasive soft tissue tumors in which b-Catenin/TCF3 mediated Wnt signaling is activated. More than 80% of desmoid tumors contain activating mutations in b-Catenin. It has been shown that the Wnt signaling pathway interacts with WT1 in normal kidney development and plays a role in the genesis of some Wilms tumors. About 15% of Wilms tumors contain WT1 mutations and of these, about 50% contain b-Catenin mutations. This overlap in mutation pattern of WT1 and b-Catenin in Wilms tumor suggests that these two genes may collaborate in the genesis of a subset of Wilms tumors. To investigate whether this hypothesis could be extended to other Wnt-dependent tumor types, we searched for WT1 mutations and studied WT1 expression in b-Catenin mutant desmoid tumors. We investigated the expression of WT1 mRNA and protein in desmoid tumors. Medium to high abundant levels of WT1 mRNA were detected by TaqMan quantitative PCR in all tested desmoids cells, while adjacent normal fibroblasts showed less expression of WT1. Western blot analysis and immunohistochemistry confirmed this overexpression at the protein level. A mutational screen of the WT1 zinc-finger region by sequence analysis did not identify any mutations. Finally, we investigated a possible role of b-Catenin on WT1 regulation and vice versa. Overexpression of different b-Catenin mutants in the HEK293T cell line did not modulate WT1 promoter activity and WT1 did not affect b-Catenin /TCF transcriptional activity in this cell line. These results show that the wild-type WT1 gene is strongly overexpressed in b-Catenin mutant desmoid tumors and may play a role in tumorigenesis of desmoid tumors, similar to what has been suggested in some epithelial malignancies.

A yeast based mutation screen to uncover new insights into frataxin function. *G.L. Dalgliesh, S.M. Purandare, K.G. Marichal, J.M. Brown, S.I. Bidichandani.* Depts of Biochemistry & Mol. Biol. & Pediatrics. Univ of Oklahoma Hlth Sci Ctr, 975 NE 10th St, Oklahoma City, OK 73104, USA.

The inherited neurodegenerative disease Friedreich ataxia (FRDA) is caused by loss of frataxin function due to either a GAA triplet repeat expansion in intron 1 of the *FRDA* gene or, very rarely, a point mutation in the coding sequence. Little is known about the functionally important residues of this highly conserved protein, despite the gene sequence and protein structure of frataxin being known. We exploited this high degree of conservation by constructing a chimeric yeast-human frataxin (*cYHF*) allowing mutations in the human *FRDA* sequence to be analyzed in a yeast model system. Mutation libraries were generated by amplifying *cYHF* using two error prone polymerases providing a comprehensive spectrum of mutations. PCR conditions were adjusted so the majority of mutant clones had a single base substitution. To determine the effect of these mutations on frataxin function, a yeast based genetic screen was developed using a heterozygous yeast frataxin knockout. This heterozygote has a normal phenotype, but when sporulated, the haploid knockouts are respiratory deficient. The knockout was used to screen both mutation libraries for functionally important mutations based on the inability of the library plasmid to rescue the respiratory deficient phenotype. We have screened 4,000 clones to uncover thirteen novel missense mutations. These mutations were found to be in a similar region of the protein as patient mutations i.e. on either the beta sheets or second alpha helix of frataxin, encoded by exons 4&5. Notably, five of the mutations are in the final carboxy tail of frataxin, an area which has not previously been implicated in frataxin function through patient mutations. The effects of these novel mutations on frataxin expression and yeast sensitivity to oxidative stress have also been measured. These measurements indicate that all mutations result in greater sensitivity to oxidative stress. The discovery and functional analysis of these mutations has yielded insight into functionally important regions of human frataxin, including a region not previously recognized.

Improved quantitative PCR-based gene dose analysis for the clinical laboratory: Assay design parameters and quality assurance metrics. *B.C. Hendrickson, T. Judkins, A. Kouzmine, J. Tazelaar, K. Eliason, D. Gonzales, B.E. Ward, T. Scholl.* Myriad Genetics, Salt Lake City, UT.

Gene dosage analysis is important in clinical genetic testing for detection of duplication and deletion events that impair the structural integrity of genes. For many clinical laboratories, quantitative PCR approaches are preferred due to simplicity of specimen isolation and assay implementation. However, quantitative measurements by PCR are a demanding application of this technology.

A number of quantitative PCR approaches, including real-time and single point analysis of multiplexed reactions, have been proposed for rearrangement detection. Presented are comparative data on several available technologies. Also, the benefits to assay performance by employing various design parameters relating to amplicon and primer design, and redundancy of analysis are demonstrated in a model system that involved a comprehensive assay for gene-dosage analysis of *BRCA1* and *BRCA2*. When compared to quantitative methods currently in use, assay robustness was increased by applying the following improvements. All regions were represented by at least two unique amplicons, each in separate multiplexed reactions. Adjacent exons were integrated into different multiplexes. Within multiplexes, amplicons for both genes were interleaved along with control genes selected from haplo- and duplolethal regions of the genome. Also, a likelihood based approach rather than naïve dosage quotients or visual inspection was demonstrated to be superior for data analysis. Using historical data, patient results for each multiplex are normalized to every possible mutation scenario and the mutation status is returned with a statistical level of confidence. Finally, application of this model system to 500 anonymous high risk breast/ovarian cancer patients negative by sequence analysis demonstrated that 6% had large rearrangements. The application of these methods permits quantitative PCR assays with increased robustness and quantitative measures of performance that improve application of this technology to clinical genetic testing.

Both in vivo and in vitro evidence of inactivation of splice donor site by G to A nucleotide change at 5th nucleotide of intron 32 of the dystrophin gene. *T.Thi. Hoai Thu*¹, *A. Surono*¹, *M. Yagi*¹, *Y. Takeshima*¹, *H. Wada*², *M. Matsuo*¹. 1) Department of Pediatrics, Kobe University Graduate School of Medicine, Japan; 2) Department of Pediatrics, Sakura Ryoikuen Hospital, Sanda, Japan.

Maturation of pre-mRNA having a single nucleotide change within consensus sequences of splice donor site is controversial. A single nucleotide change at 5th nucleotide of intron 32 of the dystrophin gene (GIVS32+5A) has been reported either a polymorphism or a mutation identified in DMD. Here we show both in vivo and in vitro evidence that GIVS32+5A inactivate an authentic splice donor site and instead activate cryptic splice donor sites. In a Japanese DMD case dystrophin mRNA in lymphocytes was found to have two novel mRNAs; one had 98nt deletion of exon 32 and the other had 28 nt insertion between exons 32 and 33. However, only one nucleotide change of G to A conversion at 5th nucleotide of intron 32 of the dystrophin gene (GIVS32+5A) was disclosed from genomic DNA analysis. In order to exemplify inactivation of splice donor site by GIVS32+5A splicing products from mini-dystrophin genes with either normal or mutant intron 32 sequence in Hela cells were analyzed by reverse-transcription PCR amplification. Remarkably 98bp deletion of exon 32 was identified in mutant mini-gene transcript, while full of exon 32 sequence was present in the mini-gene transcript with normal intron 32 sequences. Our results indicated clearly that GIVS32+5A inactivated the authentic splice donor site and activated the cryptic splice donor site. In addition, it was shown that 23 mer RNA probe corresponding to the consensus and its neighboring sequences of splice donor site was shown to bind nuclear protein stronger than the RNA probe with the mutant sequence. It was concluded that GIVS32+5A was a cause of inactivation of splice donor site and produce two out-of-frame dystrophin mRNAs responsible DMD phenotype though GIVS32+5A was once reported as a polymorphism. This report shows that in vitro splicing reaction can be used for identification of a disease causing mutation.

Identification of PXR/RXR transcriptional targets by *in vitro* competition with DNA binding sites predicted by information theory. C. West¹, C. Bi^{1,2}, P.K. Rogan^{1,2}. 1) Children's Mercy Hospital, Schools of Medicine and; 2) Computer Science and Engineering, University of Missouri-Kansas City.

PXR/RXR is a generalized chemosensor that induces expression of metabolic and transporter proteins by regulating their corresponding gene promoters. The affinity (ie. individual information content, R_i) of PXR/RXR for cognate enhancer elements (PXREs) can be predicted by information theory-based DNA binding site models. We previously refined a model of PXRE sequences by iteratively cycling information theory-based prediction and validation using published and predicted binding sites. Here, we use a novel microtiter plate assay to specifically detect binding sites with defined information contents from putative PXR/RXR transcriptional targets. The amount of PXR/RXR bound to a solid-phase, reference nucleic acid binding site (eg. CYP3A4 proximal PXRE [$R_i=16.5$ bits]) is determined for varying concentrations of a test competitor sequence in solution. Protein bound to the reference sequence is detected with an enzyme-linked, secondary antibody that recognizes a primary antibody to RXR. To identify sites with a broad range of binding affinities, the assay is performed with a series of reference and competitor oligonucleotides with comparable R_i values. Published (n=4) and predicted (n=4) binding sites used to develop the refined model were confirmed with this assay. Lower concentrations of stronger competitor sequences can sequester PXR/RXR, decreasing the amount of protein bound to the reference sequence. Controls included no competitor, multiple concentrations of a homopolymer negative control sequence, and the consensus binding site predicted by information theory. The assay was validated with a set of 15 PXREs from rifampin-inducible genes that were not included in the original model. Finally, we evaluated 12 strong binding sites detected in information theory-based scans of known human gene promoters, and demonstrated that each of these sites compete with the reference site for binding to PXR/RXR. Most of the loci associated with these sites are novel targets and are not related to genes known to be involved in xenobiotic metabolism or transport.

Quantitative studies of *AGTR1* mRNA haplotypes and metabolic syndrome traits. *M.R. Abdollahi, R. Lewis, T.R. Gaunt, S. Rodriguez, H.E. Syddall, C. Cooper, D.I.W. Phillips, I.T. Cameron, I.N.M. Day.* Human Genetics Division (MP808), Southampton General Hospital, Southampton, Tremona Rd, SO16 6YD, United Kingdom.

Introduction: angiotensin II type I receptor (*AGTR1*) is the main receptor through which angiotensin II, the most important component of the renin angiotensin pathway, influences cardiovascular tone, cell growth, fluid and electrolyte balance. *AGTR1* is expressed in blood vessel walls, heart and many other organs. *AGTR1* A1166C, in the 3' UTR, has been reported to associate with hypertension and myocardial infarction. **Purpose:** to study the association of the *AGTR1* polymorphisms with cardiovascular and metabolic traits and investigate transcript expression. **Methods:** we used Phase and STATA to examine haplotypes of *AGTR1* constituted of A1166C, L191L, A-153G and C-521T in relation to anthropometric and metabolic syndrome phenotypes in the North and East Hertfordshire UK populations. Ratiometric analyses (based on quantitative-gel image analysis of restriction digests of cDNA) were developed for the transcribed SNPs A1166C and L191L in order to determine relative allelic expression from haplotypes. Additional to these within-individual-between-allele assays, between-individual comparisons were made using TaqMan assays applied to both homozygous and heterozygous genotypes and haplotypes, analysed by Phase, SPSS and HTR. **Results:** 1) CC genotype of *AGTR1* A1166C (and L191L) are significantly associated with protective anthropometric and metabolic syndrome trait values. 2) C-521T and A-153G did not reflect these associations. 3) There are two haplotype blocks in the *AGTR1* gene. 4) In the quantitative mRNA assays, there was no significant difference for alleles of L191L, but 1166C and haplotypes carrying it marked low *AGTR1* mRNA level. Effect was much greater in CC homozygotes than in heterozygotes. **Conclusion:** *AGTR1* 1166C marks anthropometric and metabolic effects and also marks low *AGTR1* mRNA levels. All effects were much more prominent in homozygotes, possibly reflecting interallelic interaction through feedback loops of mRNA regulation.

Functional polymorphisms in the regulatory region of genes implicated in G1/S checkpoint. *H. Belanger, P. Beaulieu, M. Lariviere, C. Moreau, S. Langlois, D. Labuda, D. Sinnett.* Division of Hematology-Oncology, Sainte-Justine Hospital Research Center, University of Montreal, Montreal, QC, Canada.

Cell cycle checkpoints mediate quality control of the cell cycle, particularly the fidelity of replication. Following abnormalities, these checkpoint mechanisms will stop the cell cycle progression and activate repair processes or cell death by apoptosis. We propose that functional polymorphisms in candidate genes could bring variability in the mechanisms that regulate the cell cycle which could give rise to differences in the risk of developing complex diseases such as cancer. The main objectives are to identify and validate functional polymorphisms in targeted regulatory regions, arbitrary defined as a 2kb genomic segment upstream of exon 1. Mutation analysis was carried out on 17 genes involved in the G1/S checkpoint. Polymorphisms were detected using denaturing HPLC in a population panel of 40 individuals from different ethnic backgrounds. A total of 136 regulatory SNPs (rSNPs) were identified. In this study we selected 13 rSNPs that were predicted using *in silico* tool, to lead to gains of binding sites for transcription factors. Electrophoretic mobility shift assays showed that nuclear proteins from different cell lines (HeLa, Caco2, Jeg-3, HepG2) exhibited differences in the binding affinity for 12 of the rSNPs tested. Expression analyses were performed by cloning 2kb haplotypes corresponding to different construction of the selected rSNPs into a luciferase reporter gene vector (pGL3) and were tested for differences in their ability to drive transcription in HeLa, Jeg-3 and HepG2 cells. Differences in expression greater than 1.5-fold were detected between haplotypes of TGF1, E2F1, CDC25a and HDAC1. However, no significant differences were found between haplotypes for p21, p27 and RB1. The detection and validation of polymorphisms in the regulatory regions of genes implicated in cell cycle checkpoints will provide a better understanding of their involvement in susceptibility to complex diseases. This work is supported by genome-Quebec/Canada.

Program Nr: 1344 from the 2004 ASHG Annual Meeting

In-vitro studies of natural mutations in PK-M2 isozyme. *M.K. Akhtar, A. Dhir, R. Bamezai.* NCAHG, SLS, Jawaharlal Nehru University, New Delhi, Delhi, India.

No natural mutations in Pyruvate kinase (PK)-M2 gene have been implicated in any disease. For the first time natural mutations were reported from our laboratory in PK-M2 gene in Bloom Syndrome cell lines and the Lymphocytes of a Bloom Syndrome patient from India. Two different missense mutations, H391Y and K421R were found in the region of Inter Subunit Contact Domain, which down regulates the enzyme activity to different extents. However, the biological significance of these mutations is not yet clear. Transcriptional and translational regulation of PK-M2 gene were assessed by Real time PCR and enzyme activity in PHA-stimulated Lymphocytes from normal volunteers at different time points. The RNA level increased many fold at 12hr and decreased at 24hr when compared to 0hr, and the specific activity decreased at 12hr, which increased again at 24hr to a level similar to 0hr. Normal PK-M2 cDNA and its mutants were expressed in bacteria and found that the specific activity of H391Y mutant decreased by about 50% and in K421R mutant, decreased by about 70% as compared to normal PK-M2. Further these were sub-cloned in EGFP expression vector, transfected into HepG2 cell line. Confocal analysis revealed that EGFP vector alone could go both in cytosol and in nucleus, while EGFP-PK-M2 remained in cytosol around the cell periphery. The H391Y and K421R mutants localised both in cytosol and in the nucleus. Transcriptional and translational studies showed that there is certain time lag between the appearance of PK-M2 transcript and functionally active PK-M2 molecules. The two different point mutations changed the normal structure of PK-M2, which not only decreased the activity of the enzyme to different levels but also affected the property of localization within a normal cell as observed in Confocal studies. It will be interesting to know if the mutant PK-M2 proteins enter into the nucleus due to a loss of identity or any structural change made the protein to interact with any other partner protein which facilitated its entry into the nucleus.

Identification of potential downstream genes of Trps1 by cDNA microarray analysis of mouse embryonic limbs.

*P. Brega*¹, *C. Kosan*², *T. Möröy*², *R. Shivdasani*³, *B. Horsthemke*¹, *H.-J. Lüdecke*¹. 1) Institute of Human Genetics, Universitaetsklinikum, Essen, Germany; 2) Institute of Cell Biology, Universitaetsklinikum, Essen, Germany; 3) Department of Medical Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts.

Mutations in the TRPS1 gene cause the tricho-rhino-phalangeal syndrome, which is characterized by craniofacial and skeletal abnormalities. The gene encodes a transcription factor that has a GATA-binding zinc finger and represses GATA-regulated gene expression. During development, the gene is highly expressed in the cartilage condensations of the limbs and in other structures (Kunath *et al.* Gene Expression Patterns 2002). The phenotype of Trps1 knockout mice that are heterozygous for an in frame deletion of the GATA-zinc finger coding exon is comparable to but milder than the human TRPS I. Homozygous knockout mice die shortly after birth (Malik *et al.* MCB 2002). To identify genes affected by the Trps1 knockout, we used the MOE430A Affymetrix microarrays to determine the expression profiles of E11.5 limbs from normal and mutant mice. We compared the expression profiles of 3 wild type, 2 heterozygous and 3 homozygous knockout mice from the same litter. Genes were considered as differentially expressed when showing at least a 1.5-fold difference in the mean expression level between wild type and mutant embryos with a standard deviation of less than 25%. Between heterozygous and wild type embryos we found 329 differentially expressed genes: 211 overexpressed in the mutants and 118 in the wild type. When comparing homozygous and wild type mice, we found 177 differentially expressed genes: 75 overexpressed in the mutants and 102 in the wild type. Thirty-four genes were conspicuous in both comparisons. Among the differentially expressed genes were genes for transcription factors, growth factors and extracellular matrix components that are known to play important roles in mouse embryonic limb development. Our results provide a first insight into the complex role that Trps1 plays in mouse limb development.

Cross-species sequence comparison of alpha-fetoprotein gene regulation. *J.N. Davidson, M. Glenn, L. Long, A.A. Wells, B.T. Spears.* Microbiology, Immunology and Molecular Genetics, University of Kentucky, Lexington, KY.

The alpha-fetoprotein (AFP) gene is expressed at high levels in the fetal liver but is dramatically repressed at birth. The gene is normally silent in the adult liver but can be reactivated in hepatocellular carcinomas and during liver regeneration following liver damage. Three upstream enhancers, E1, E2 and E3, regulate transcription of the AFP gene both in mouse and rat. Sequence analysis indicates that E1 and E2 are more closely related to each other than either is to E3, suggesting that E1 and E2 arose from duplication of a primordial enhancer. The purpose of this study was to compare DNA sequence data for the upstream region of the AFP genes from a variety of mammals. Data originated from genomic databases as well as from our own sequencing results for horse. Sequences were then aligned and analyzed. In primates, dog and horse, we found a deletion within E1 that eliminates nearly the entire enhancer, and the human E1 is inactive. E2 is the most conserved of the three enhancers. The E3 sequence is dramatically different across all species studied. Moreover, human and mouse E3 bind different transacting factors. These results indicate species-specific differences in AFP regulation. Data will also be presented that describes a novel hexanucleotide repeat (CTATAT) that is present in humans, chimpanzees and gorillas but absent in mice and rats. Among humans repeat length and surrounding sequences are highly polymorphic. Supported by NIH grant DK51600.

The mouse dystrophin muscle enhancer-1 imparts skeletal muscle, but not cardiac muscle, expression onto the dystrophin Purkinje promoter in transgenic mice. *Y. De Repentigny¹, P. Marshall¹, R.G. Worton^{1,2,4}, R.*

Kothary^{1,3,4}. 1) Molecular Medicine Program, Ottawa Health Research Inst, Ottawa, Ontario, Canada; 2) Department of Biochemistry, Microbiology and Immunology, University of Ottawa, Ottawa, Ontario, Canada; 3) Department of Cellular and Molecular Medicine, University of Ottawa, Ottawa, Ontario, Canada; 4) Department of Medicine, University of Ottawa, Ottawa, Ontario, Canada.

A subset of patients harboring mutations in the dystrophin gene suffer from X-linked dilated cardiomyopathy (XLCM), a familial heart disease that is not accompanied by any clinical signs of skeletal muscle myopathy. Since the muscle (M) isoform of dystrophin is not expressed in these patients, the absence of skeletal muscle myopathy has been attributed to expression of the brain (B) and cerebellar Purkinje (CP) isoforms of dystrophin in skeletal, but not cardiac, muscles of XLCM patients. The compensatory mechanism of B and CP promoter upregulation is not known but it has been suggested that the dystrophin muscle enhancer from intron 1, DME-1, may be important in this activity. Previous studies have shown that the presence of the DME-1 is essential for a significant increase in B and CP promoter activity in skeletal muscle cells in culture. Here, we demonstrate that the mouse dystrophin CP promoter drives expression of a *lacZ* reporter gene specifically to the cerebellar Purkinje cell layer but not to skeletal or cardiac muscle of transgenic mice. However, if the mouse counterpart of DME-1 is present in the transgene construct, the CP promoter is now activated in skeletal muscle, but not in cardiac muscle. Our findings provide *in vivo* evidence for the importance of the dystrophin muscle enhancer sequences in activating the dystrophin CP promoter in skeletal muscle. Furthermore, they strengthen the model in which the DME-1 sequence activates the dystrophin B and CP promoters in the skeletal muscle of XLCM patients whereas the cardiac tissue remains refractory to this action.

Isoform repertoire and regulation of ectodysplasin (EDA) gene function. *T. Hashimoto, CY. Cui, M.C. Durmowicz, R. Nagaraja, D. Schlessinger.* Laboratory of Genetics, National Institutes of Health/National Institute on Aging, Baltimore, MD.

The EDA gene is mutated in anhidrotic ectodermal dysplasia in humans and in the Tabby mouse, resulting in the absence of sweat glands and several types of hair, as well as rudimentary teeth. The gene encodes a series of isoforms, but the complete catalogue of isoforms and their functional significance has remained unknown. Furthermore, a 2 kb DNA fragment just upstream of the transcription start site is sufficient to drive high level transcription of the gene in transfected cells in vitro, but the level of the mRNA is paradoxically very low in most cells in vivo, and might be related to differential formation or stability of various isoforms. To infer a more complete repertoire of EDA transcripts, we have derived cloned cDNAs from keratinocyte cells in which transcription is unusually high. The transcripts include a total of 9 species. In addition to the long EDA-A1 and -A2 forms, which jointly account for 77% of the transcripts, and 2 other previously reported transcripts (EDA-A3 and EDA-A4), five new transcripts were found including two that account for 7% and 2%, respectively. Isoform functions are largely unanalyzed, but we have shown that one of the longest species, EDA-A1, is able to correct some but not all of the EDA defects; and other species interact with EDA-A1, at least in the case of formation of one class of hair follicles. Finally, the possibility that mRNA stability might be linked to the level of expression of different isoforms was further hinted by the presence of AU-rich elements in the 3UTR that have been associated with instability of short-lived mRNA species. However, the half-life of cellular EDA is about 2 hr for all transcripts that have 4, 2, or no AU-rich elements; and this relative level of instability cannot explain the low expression of the gene in vivo compared to the strength of transfected promoter DNA. Instead, regulation appears to be at transcription for the entire range of isoform transcripts, through repressor action in most cells.

Program Nr: 1349 from the 2004 ASHG Annual Meeting

Analysis of the 5 distal regulatory region of the human tyrosinase gene. *R.A King, J.P. Fryer, W.S. Oetting.* Dept. of Medicine and Institute of Human Genetics, Univ Minnesota, Minneapolis, MN.

BACKGROUND: Oculocutaneous albinism type 1 (OCA1) results from mutations of the tyrosinase gene. Most affected individuals are compound heterozygotes, and more than 150 different mutations of this gene have been described. Approximately 15% of OCA1 alleles have no detectable mutation with sequence analysis of the coding, adjacent intron, and proximal promoter regions of the gene suggesting that mutations in other regulatory regions of the gene may be responsible. A distal enhancer region of the tyrosinase gene has been identified (NCBI accession AY367052) (*Pigment Cell Res* 16:679, 2003). We have now extended our initial studies to identify additional components of this distal regulatory region and have identified a potential mutation in OCA1 that has functional effects on a reporter assay. **METHODS:** Constructs containing sequential additions or deletions of sequence from the original enhancer sequence (EPP2) were developed and analyzed in a luciferase expression system. Site directed mutagenesis was used to create specific base changes in the regulatory region sequence. **RESULTS:** Constructs with sequential deletion of the 5' end of the original EPP2 enhancer sequence produced a loss of enhancer activity, while the addition of contiguous sequence to the 5' end of EPP2 resulted in a significant increase in enhancer activity. Additional sequences further revealed a 5' negative regulatory element. Sequence analysis of the tyrosinase gene in individuals with OCA1 showed a single base substitution (c.-9322G>A), not found in 100 chromosomes from normally pigmented individuals with no history of OCA1. Expression analysis of the enhancer sequence containing this substitution resulted in a marked reduction in enhanced expression when compared to the wild type sequence. **CONCLUSION:** This work reveals the complexity of the tyrosinase distal regulatory region with enhancer and suppressor function, and identifies the first potential regulatory mutation of the tyrosinase gene that may be associated with the development of OCA1.

Program Nr: 1350 from the 2004 ASHG Annual Meeting

The miscarriage-associated HLA-G -725G is associated with increased expression: Is too much of a good thing bad? *S.A. Kuldanek, C.M. Billstrand, K.A. Vigh, L.A. Weiss, C. Ober.* Human Genetics, The University of Chicago, Chicago, IL.

HLA-G is primarily expressed in trophoblast cells at the maternal-fetal interface, where it plays an immunomodulatory role in pregnancy. We previously identified in the Hutterites 18 SNPs, defining 8 unique haplotypes, in the 1300 bp upstream of exon 1, which contains all the known regulatory elements (Ober et al., 2003; *AJHG* 72:1425). One SNP, -725C/G, was associated with miscarriage (odds ratio in couples in which both partners carried a -725G allele = 2.76; $p=0.035$). To explore the hypothesis that -725G influences transcription rates, we subcloned the promoter region of 4 unique haplotypes (2 with -725G; 2 with -725C) into pGL3 vectors with a firefly luciferase gene, and transfected the vectors into a choriocarcinoma (trophoblast) cell line, JEG3. Assays of luciferase expression were run in triplicate in 8 independent experiments. Expression levels were significantly different between -725G and -725C haplotypes ($p=1.74 \times 10^{-6}$); median expression was 85% higher for haplotypes with -725G. Transferring by site-directed mutagenesis a G at -725 to a haplotype with -725C resulted in a significant change in expression ($p=1.22 \times 10^{-3}$), with median expression increasing 36% on the mutated haplotype. These studies indicate that the presence of a G at -725 results in significantly increased transcription, regardless of the haplotype background, and that overexpression of HLA-G in pregnancy may be a risk factor for miscarriage. Supported by HD21244.

THE TREACHER COLLINS SYNDROME GENE (TCOF1) PROMOTER CHARACTERIZATION. C.

Masotti¹, L.M. Armelin-Correa¹, A. Splendore², A. Barbosa³, C.J. Lin³, S. Brochado⁴, T.M. Félix⁵, M. Sogayar⁴, M.R. Passos-Bueno¹. 1) CEGH/IBUSP Brazil; 2) INCA/RJ Brazil; 3) HCFM/USP Brazil; 4) IQ/USP Brazil; 5) HCPA/RS Brazil.

Treacher Collins syndrome (TCS) is an autosomal dominant craniofacial malformation, with an incidence of 1:50.000. The gene associated with this syndrome, *TCOF1*(5q31-33), encodes a nucleolar protein called treacle. The hypothesis for clinical manifestation is haploinsufficiency of treacle during embryonic development. TCS has high inter and intra familial clinical variability, ranging from mild malar hypoplasia to perinatal death due to airway collapse. More than 100 pathogenic mutations were described in *TCOF1* - most of them insertions or deletions causing a premature stop codon and no genotype/phenotype correlation has been observed. We have hypothesized that mutations in the promoter region of the gene in trans with pathogenic mutation can modulate the phenotype. Therefore, the aims of the present work are to characterize the *TCOF1* genes core promoter and to identify mutations in this region that could contribute to the phenotypic variation of this syndrome. We analyzed 1,2 Kb from the *TCOF1* 5' upstream sequence in 25 patients and in 50 normal controls through SSCP and DHPLC, followed by direct sequencing of the identified alterations. We detected 4 polymorphisms: -106AC, -332TC, -948GA, -1025GC. The first two changes were identified only in normal population, both with a frequency lower than 2%; the latter two mutations had a frequency higher than 10% in affected patients and in normal controls, with no difference between the groups. In order to delimitate the minimal promoter region, two fragments, -1200 pb and -600 pb, were cloned in a vector with the luciferase reporter gene. Both were transfected in two human cells lineages, HepG2 and 293T, and were able to promote luciferases gene transcription. The 600 pb vector presented higher activity than 1200 pb vector, indicating that the region between -1200 pb and -600 pb comprises an inhibitor element and that the 600 pb contains the core promoter. We are currently doing functional studies with the regions containing the polymorphisms -948GA, -1025GC as well as with the putative core promoter region. FAPESP/CEPID/CNPq.

A distal regulatory element controls expression of the transcription factor p63. *C. Missero¹, D. Antonini¹, B. Rossi¹, S. Banfi¹, J. Brissette², R. Han², S. Zannini³, T. Di Palma³.* 1) TIGEM, Napoli, Italy; 2) Massachusetts General Hospital, Boston, USA; 3) Federico II University, Napoli, Italy.

The transcription factor p63, a member of the p53 family, is essential for the development of various ectodermal structures, including the epidermis and the hair follicle. Specific mutations of the p63 gene cause five distinct human malformation syndromes that are characterized primarily by limb abnormalities, ectodermal dysplasia, facial cleft, and absence of mammary glands. p63 is a complex gene encoding at least six isoforms with two main transcription start sites, TA and DeltaN, and is primarily expressed in epithelia including the proliferative compartments of the skin. Given its crucial role in skin development and its relevance in some epithelia abnormalities, we set up to identify regulatory genomic regions responsible for the specific expression of the p63 gene in skin. As an initial effort, we cloned and tested the activity of 4kb genomic portions upstream the transcription start site of the TA and DeltaN isoforms. Although these regions displayed promoter activity, comparable activity was obtained in mouse primary keratinocytes as well as in non-expressing cell types. We thus carried out a systematic genomic sequence comparison between human and mouse to search for conserved regions that would act as a skin-specific enhancer for p63. We selected and tested conserved sequences in the p63 genomic locus of at least 100bp in length and 75% identical with a low probability (>1/1000) to be conserved by chance. Out of forty conserved sequences tested four displayed strong enhancer activity. Interestingly, one of them conferred keratinocyte specific expression to a reporter gene, when placed in front of a TK minimal promoter or in front of the DeltaNp63 promoter. The ability of this sequence to recapitulate p63 gene expression was tested by generating transgenic mice, in which the genomic sequence was placed in front of a globin promoter driving LacZ. Functional characterization of the enhancer by mutation analysis, chromatin immunoprecipitation, and siRNA for specific transcription factors binding to it, revealed a previously unsuspected regulation of the p63 gene.

Identification of the regulatory elements controlling expression of the *Chx10* human microphthalmia gene in the retina. L. Weaving, H. Kim, A. Sertie, J. Horsford, R. Abboud, R.R. McInnes. Programs in Developmental Biology and Genetics, The Hospital for Sick Children, Toronto, ON, Canada.

Chx10 is a highly conserved homeodomain transcription factor required for normal eye development. *Chx10* loss-of-function mutations in both human and mouse result in blindness and microphthalmia. *Chx10* is expressed in both retinal progenitor cells and adult bipolar interneurons, the major interneurons of the retina. In the *Chx10^{or-J/or-J}* mutant mouse, there is a substantial decrease in neuroretinal progenitor cell proliferation, and a specific lack of bipolar cells. To understand the role of *Chx10* in eye development, we have begun to identify the enhancers that regulate *Chx10* expression. We have characterised a microphthalmia mouse model designated *Chx10^{or-2J/or-2J}* which has no retinal expression of *Chx10* due to an inversion of ~750 kb. The 5 breakpoint occurs ~18 kb upstream of the *Chx10* start site, disrupting a conserved 2 kb putative regulatory element. To test if this region encompasses a *Chx10* retinal enhancer, we linked the wild-type 2 kb fragment to the 5.3 kb *Chx10* promoter region and a lac Z reporter in transgenic mice. Although expression was observed in adult bipolar cells, there was no expression in retinal progenitor cells. These results indicated that an element within this 7.3 kb fragment is necessary for *Chx10* expression in mature bipolar cells, but not in neuroretinal progenitor cells. To identify other *Chx10* enhancers, we performed sequence alignments among human, mouse and pufferfish, and identified five elements 29 to 50 kb upstream of murine *Chx10*, that are conserved across all three species. We are using both a candidate approach, taking the conserved elements as putative enhancers, and constructing a deletion series of a *Chx10* BAC, in an attempt to identify the progenitor enhancer/s. Identification of these enhancers is the first step in dissecting the regulatory cascade of genes controlling *Chx10* expression.

Identification of the tissue-specific enhancer element responsible for mouse type X collagen gene expression *in vivo*. Q. Zheng¹, B. Keller¹, G. Zhou¹, D. Napierala^{1,2}, Y. Chen¹, A. Parker³, B. Lee^{1,2}. 1) Mole. & Hum. Genetics, Baylor Coll. Med., Houston, TX; 2) Howard Hughes Med. Inst; 3) Respiratory and Inflammation Res. Area, AstraZeneca, Cheshire U.K.

Type X collagen (*Col10a1*) gene is specifically expressed in hypertrophic chondrocytes during endochondral ossification. Its deficiency in human causes Schmid metaphyseal chondrodysplasia (SMCD). Multiple regulatory elements within human, murine and chicken *Col10a1* promoter regions have been reported to direct *Col10a1* expression at different levels by *in vitro* transfection studies. Our previous studies showed that 4kb *Col10a1* promoter containing Runx2 elements can specifically drive weak reporter gene (*LacZ*) expression in the lower hypertrophic zone of transgenic mice. However, *cis* elements directing its high level hypertrophic chondrocyte-specific expression *in vivo* have not yet been described. In this study, we report identification of the tissue-specific enhancer element responsible for high level mouse *Col10a1* expression by generating additional transgenic mouse lines harboring various *Col10a1* promoter and intronic fragments driving *LacZ* as reporter. An 8kb *Col10a1* regulatory region encompassing the same 4kb promoter and second intron can direct reporter gene expression throughout the hypertrophy zone, albeit at low level. In another transgenic mouse line containing a 10kb regulatory element, high level tissue-specific expression throughout the hypertrophic zone was observed. These *in vivo* data suggest the presence of enhancer elements in both *Col10a1* distal promoter and second intron that cooperate with the Runx2 binding elements in the proximal promoter to specify its tissue-specific expression. *In silico* cross species analysis of *Col10a1* shows highly conserved elements within both the *Col10a1* distal promoter and second intron. These elements contain putative AP-1 and Cdx binding sites respectively. We found that transgenic mice using the 6kb and 4.6kb *Col10a1* element could direct *LacZ* expression within the hypertrophic zone. This suggests that the conserved *Col10a1* distal promoter element (-4.6 to -3.9kb) acts as a critical tissue-specific enhancer for *Col10a1* (reporter) expression *in vivo*.

Identification of an evolutionary conserved, putative intronic splicing enhancer in the CFTR gene: a general 5splice site recognition mechanism? *I. Aznarez^{1,2}, G. Deng¹, J. Parkinson^{1,2}, J. Cheung¹, J. Zielenski¹, B.J. Blencowe², L.-C. Tsui^{1,2,3}*. 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Canada; 2) University of Toronto, Canada; 3) University of Hong Kong.

Cystic fibrosis is an autosomal, recessive disease caused by mutations in the cystic fibrosis transmembrane-conductance regulator (CFTR) gene. Proper splicing of the CFTR gene requires accurate selection of splice sites (ss) promoted by elements that are bound by splicing factors. In order to identify intronic splicing elements we performed multi-species alignments of CFTR genomic sequences. Conserved regions downstream of 5ss, spanning 20-40 bp, and located in 12 of the 26 CFTR introns, were considered as candidate splicing elements. We screened for motifs among the conserved sequences by scanning for random hexamer. The scanning analysis identified 2 over-represented motifs present in 9 of the 12 conserved human CFTR 5ss-adjacent intronic sequences. Conversely, the motifs were found in only 2 of the 14 non-conserved sequences ($p=0.004$). Neither motif was found downstream of pseudo 5ss ($n=76$) in the CFTR gene suggesting they could be intronic splicing enhancers (ISE). To assess whether the putative ISEs (pISEs) were present in other genes, we scanned 26,555 protein-coding, intron-containing genes. Results showed that 6,000 genes contained one of the pISEs within 30 bp downstream of the 5ss (3-fold increase over a control screen based on intronic nucleotide content, $p=0.015$). This pISE has a similar consensus sequence to the binding site for TIA-1, a splicing factor known to aid the recognition of 5ss. TIA-1s function is evolutionary conserved which agrees with the identification of the pISE in conserved regions. We are assessing whether TIA-1 mediates recognition of CFTR 5ss through the pISE. Phylogenetic and conservation analyses are being performed for the other pISE-containing 6000 genes. We are also assessing whether the pISE is more often present downstream of constitutive or alternative exons and the optimal distance of the pISE from 5ss to promote splicing. These results will provide insights into the mechanism of 5ss recognition in CFTR and other genes.

Distribution and characterization of lamin A/C mutations: a role for silent variations? *S. Benedetti¹, I. Menditto¹, C. Rodolico², P. Carrera³, D. Toniolo⁴, M. Ferrari^{1,3}*. 1) Dept Molecular Biology, Diagnostica e Ricerca HSR, Milano, Italy; 2) Neuroscience Department, University of Messina, Messina, Italy; 3) Unit of Genomics for Human Disease Diagnosis, IRCCS San Raffaele, Milano, Italy; 4) DIBIT, IRCCS San Raffaele, Milano, Italy.

Lamin A/C mutations have been associated to a variety of pathologies affecting mainly muscular, nervous and adipous tissues. More than 100 mutations scattered along the gene have been described to date and, although no clear genotype-phenotype correlation could be established, some clustering has been recognized. The analysis of 110 patients with different lamin-associated disorders highlighted 14 mutations, 9 of which had not been previously described. The distribution of these variations, mostly missense substitutions, confirms preferential clustering of muscular disorders-associated mutations in exons 4, 6 and 7. In addition, three conservative substitutions were identified and analysed at the RNA level: c.357C>T (R119R) in exon 2, c.1146C>T (G382G) in exon 6 and c.1551G>A (Q517Q) in exon 9. The importance of exonic splicing enhancers and silencers as modulators of the splicing process is increasingly recognised and softwares have been designed to predict gain or loss of interactions with splicing regulatory proteins (serine/arginine-rich, SR). The analysis performed with the ESEfinder software (<http://exon.cshl.org/ESE/>) predicted an increase of the affinity for two SR proteins in the case of the exon 6 substitution, a decrease for the exon 9 variant and no difference for the exon 2 one. mRNA analysis by RT-PCR and sequencing of the c.1146C>T variant revealed the activation of a cryptic exonic splice site leading to deletion of the last 13 bp of exon 6 and consequent frameshift, while no obvious change was observed in the other two variants. These observations suggest that particular attention should be paid when evaluating the pathogenicity of apparently silent substitutions. The use of prediction softwares, although providing useful hints, needs always to be integrated by experimental data.

The effects of temperature and other variables on illegitimate splicing in leukocyte-derived mRNA. A.

Carmichael^{1,2}, *J.A. Stuart*², *P.J. Ainsworth*^{1,2}. 1) Biochemistry, University of Western Ontario, London, Ontario, Canada; 2) Molecular Diagnostic Laboratory, London Health Sciences Centre, Ontario, Canada.

The central dogma of molecular biology posits a flow of genetic information from DNA to RNA to protein. mRNA splicing is central to this process and involves, in eukaryotic cells, a spliceosome composed of upwards of 300 distinct proteins and multiple untranslated RNAs. The specificity of this intricate macromolecular splicing complex is conferred by the interactions of acceptor, donor, and branch site sequences as well as exon splice enhancer elements, with the components of the spliceosome. Errors of splicing, termed illegitimate splicing, can and do occur. These typically involve the insertion or deletion of exons and/or introns which may lead to abnormal transcripts giving rise to truncated or irregular proteins. The inaccurate processing of RNA transcripts may interfere with the diagnostic detection of gene mutations, especially when using approaches such as the protein truncation test (PTT). We have used a model system involving the illegitimate insertion of exon20a into the BRCA2 gene transcript derived from peripheral blood leukocytes (PBLs) to test the effect of a series of variables that may alter the fidelity of splicing. These variables include, aging of the sample, temperature variation, or the introduction of a protein synthesis inhibitor or a mitogen. We have shown that PBL-derived mRNA from a freshly drawn blood sample, even when held at room temperature for a relatively short time, could exhibit illegitimate spliceforms, and that this problem increases with sample aging. Maintenance of stored samples in a heated environment (37C) immediately following venepuncture reduces the occurrence of illegitimate splicing. Culturing PBLs from samples stored at room temperature (25C) for up to 72 hours also resulted in a marked reduction in the proportion of the aberrant isoform. The presence or absence of phytohemagglutinin (PHA) did not appear to affect this process. It was concluded that an effective approach to reducing the problem of illegitimate spliceforms in shipped blood samples was to routinely culture PBLs derived from these samples prior to RNA isolation.

Exon-identity determinants and splicing-based therapeutic strategies in spinal muscular atrophy. *A.R. Krainer¹, L. Cartegni^{1,2}, M. Hastings¹*. 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) Memorial Sloan Kettering Cancer Center, New York, NY.

Spinal muscular atrophy (SMA) is a severe autosomal recessive neurodegenerative disorder caused by mutations in *SMN1*. An *SMN1* paralog, *SMN2*, expresses enough functional SMN protein for viability, but not enough to prevent degeneration of spinal-cord motor neurons. *SMN1* and *SMN2* differ by a translationally silent C to T transition at position +6 of exon 7, which causes predominantly skipping of this exon in spliced *SMN2* transcripts in all cells, producing mostly inactive SMN protein. A low level of *SMN2* exon 7 inclusion gives fully functional protein. If inclusion of *SMN2* exon 7 could be improved, the resulting elevation of SMN protein levels may prevent motor neuron degeneration and SMA. We have previously shown that an SF2/ASF-dependent exonic splicing enhancer (ESE) in exon 7 is inactivated by the C to T transition, causing exon skipping. It has been suggested that this transition might instead create an hnRNP-A1-dependent exonic splicing silencer element. We are systematically addressing whether C6T is a loss-of-function or gain-of-function mutation. Our results support the ESE loss-of-function model, and demonstrate that the effect of hnRNP A/B proteins is independent of the C to T transition and reflects their general inhibitory effect on inclusion of alternative exons. These findings are relevant for SMA therapy development, and have mechanistic implications for exon skipping due to exonic mutations, which are common in many genetic diseases. We are pursuing a rational-design therapeutic strategy involving synthetic chimeric antisense/peptide molecules that promote exon inclusion. In addition, small molecules that promote *SMN2* exon 7 inclusion in cultured cells were previously identified, but their mechanism of action remains unclear. We are using a cell-free splicing assay that recapitulates the difference between *SMN1* and *SMN2*, to determine whether these compounds act directly on the splicing machinery, and if so, to determine their precise mechanism of action and specificity.

Up-regulation of CRELD2 expression by a heart defect-associated mutation that interferes with unproductive splicing. C.L. Maslen, D. Babcock, M.A. Jones, B. Ross. Oregon Health & Science University, Portland, OR.

Regulation of protein expression at the level of transcription via unproductive splicing coupled with nonsense-mediated mRNA decay (NMD) is an underappreciated mechanism by which protein abundance can be reduced. Unproductive splicing occurs through alternative exon usage that shifts the reading frame and introduces a premature termination codon (PTC). NMD is triggered when a PTC is detected by mRNA quality surveillance machinery. This requires a pilot round of transcription, hence the acronym RUST (Regulation by Unproductive Splicing and Translation). Gene expression data for *CRELD2*, a candidate gene for cardiac atrioventricular septal defects (AVSD), shows that skipping of exon 2 results in the introduction of a PTC, producing a mRNA species that is subject to NMD. This indicates that *CRELD2* expression is regulated by RUST via exon 2 skipping. In studying the potential association between *CRELD2* mutations and AVSD, we identified a heterozygous 3 bp insertion (132insTTC) at the 5' donor splice site of intron 1 in DNA from a subject with sporadic isolated AVSD. The insertion was not detected in over 400 race-relevant normal chromosomes indicating that this is a disease-associated mutation. The insertion is at the +3 position of intron 1, disrupting the 5' donor splice site consensus sequence. *In vivo* splicing assays were used to determine the consequences of the mutation. As expected, two species of RNA were transcribed from the wild type construct, one with exons 1, 2 and 3 appropriately spliced, the second transcript with exon 2 skipped. However, the insertion mutation construct produced only appropriately spliced product, and did not make transcripts that skip exon 2. Hence, the mutation up-regulates *CRELD2* expression by interfering with exon 2-mediated RUST. This is consistent with our premise that *CRELD2* is a competitive inhibitor of *CRELD1*. Our previous work showed that dominant negative mutations of *CRELD1* are associated with AVSD. Up-regulation of *CRELD2* expression by this mutation may ultimately interfere with *CRELD1* function, thereby increasing susceptibility to AVSD. This defines a new disease mechanism whereby a mutation interferes with RUST.

A new alternative splice variant in BRCA1 generating an additional inframe exon. *A-M. Moisan^{1,2}, J. Fortin^{1,2}, Y. Labrie¹, F. Durocher¹, INHERIT BRCA^s¹, J. Simard¹.* 1) Cancer Genomics Lab, CHUL Research Ctr, Quebec, PQ, Canada; 2) Authors contributed equally to this work and should be considered as equal first author.

Germline mutations in the tumour suppressor gene BRCA1 predispose individuals mainly to breast and ovarian cancer. The BRCA1 gene consists of 24 exons encoding a protein of 1863 amino acids interacting with multiple protein complexes involved in several cellular mechanisms, such as DNA repair, transcription, homologous recombination and cell cycle regulation. Several known BRCA1 splice variants changing the coding region have been reported. They are caused by a series of relatively large deletions as well as the addition/deletion of one or two amino acids due to a usage of leaky splice sites and their regulation and possible cellular function(s) remains under investigation. We report for the first time a novel BRCA1 splice variant caused by an inframe insertion. This transcript, designated exon 13A, is generated by an insertion of 66 nucleotides between exon 13 and 14, due to an alternative splicing of parts of intron 13 (IVS13-2786_-2720). No sequence variants has been detected by direct genomic sequencing of exon13A in 760 individuals originating from 225 French Canadian high risk breast/ovarian cancer families. The exon 13A transcript was detectable in twelve tested total RNA samples from normal tissues and from both ER+ and ER_ breast cancer cell lines as well as several other cancer cell lines. As revealed by real-time PCR analysis, the abundancy of the exon 13A transcript correspond to 20 to 25 % of the total BRCA1 mRNA expression levels in fresh leukocytes, brain and cerebellum tissues, whereas its relative level of expression is about 5% in other samples. It is of interest to note that this novel alternative transcript adds 22 amino acids after residue 1452, thus modifying the primary structure of the trans-activation domain 1 (AD1) as well as the protein-protein interacting domain of BRCA1 with BRCA2, the nuclear androgen receptor, the transcriptional co-activator p300/CBP and the mismatch repair protein hMSH2.

Improving exon inclusion in a human splicing disease: cis acting sequences and the effect of kinetin. S.

Slaughaupt^{1,2}, *M. Hims*^{1,2}, *E. Ibrahim*², *J. Mull*¹, *M. Leyne*¹, *S. Gill*¹, *J. Poskin*¹, *R. Reed*². 1) Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA.

Familial dysautonomia (FD) is a progressive degenerative disorder of the sensory and autonomic nervous system. The major FD mutation is at base pair 6 of intron 20 (IVS20+6 T>C) in the *IKBKAP* gene. This mutation results in a decrease in splicing efficiency that leads to variable, tissue-specific skipping of exon 20. We have developed an *in vivo* minigene splicing system that models the aberrant splicing in FD. Additionally, we have found that the plant cytokinin kinetin dramatically increases exon 20 inclusion in both FD patient cell lines and in our *IKBKAP* minigene system, and this small molecule is currently being evaluated as a potential therapy for FD. The effect of kinetin on *IKBKAP* exon 20 inclusion is at least partially sequence specific since we see no increase in exon inclusion in other genes tested to date. In this study, we aimed to determine the sequence elements involved in *IKBKAP* exon 20 skipping and to identify the specific sequences that are crucial for the action of kinetin. In our *IKBKAP* minigene model, we created a series of sequence changes to cis-acting elements within the exon, within the intronic sequences, and to the 3' and 5' splice sites. We identified numerous sequence changes that improve, reduce or completely disrupt exon 20 inclusion. We then tested all of the altered minigene sequences following kinetin treatment to determine if any sequence changes disrupt or enhance the action of kinetin. We found that with the exception of those sequence alterations that completely disrupt splicing, kinetin had the same overall effect of improving exon inclusion. In order to further investigate the mechanism by which kinetin alters splicing in human cells, we are using microarray studies and testing treated FD cell lines for changes in gene expression. Our findings using the minigene system provide valuable insight into the cis-acting sequence elements required for accurate mRNA splicing. Further, our microarray studies will likely yield downstream targets of kinetin, which may provide additional routes toward therapy for this devastating disease.

Silencing of *MeCP2* in adult mice through RNA interference. *T. Campos-Pereira*¹, *I.G. Maia*², *M. Grippo*¹, *R. Gilioli*³, *I. Lopes-Cendes*¹. 1) Dpto of Medical Genetics, State University of Campinas, Campinas, São Paulo, Brasil; 2) Dpto of Genetics, IBB, Unesp - Botucatu, São Paulo, Brasil; 3) Centro de Bioterismo, Unicamp - Campinas, São Paulo, Brasil.

RNA interference (RNAi) is a recent technology that promotes potent and specific gene silencing through double-stranded RNA molecules such as 21bp small interfering RNAs (siRNAs). This technique has recently been applied to adult mice with success. Rett syndrome (RS) is a neurodevelopmental disorder that affects 1/15000 women, characterized by ataxia, autistic behavior, loss of language skills and stereotyped hand movements. Most cases of RS is associated with mutations in the gene encoding Methyl-CpG-binding protein (*MeCP2*).

We used RNAi in adult mice in order to silence *MeCP2* *in vivo*. For this purpose, we synthesized siRNAs *in vitro* and injected in the tail vein (2 g of siRNA per mouse with PBS). Control groups were injected with either PBS only, irrelevant siRNA or mutated siRNA. Forty-eight hours latter animals were sacrificed and protein samples from liver, kidney, lung, spleen, heart and brain were extracted for analyses. Animals were treated according to the Ethics Commission in Animal Experimentation guidelines for animal care of State University at Campinas.

Western blot analyses confirmed successful knocking down of *MeCP2* in mice kidneys. These animals showed no classical stereotyped forelimb movements, evidencing a brain-selective disfunction of *MeCP2* as the primary cause of RS.

There are three animal models for RS, all of them originated from genomic DNA modification and resembling RS features. Here we report the first animal model using *MeCP2* disruption by RNAi, and the only one with selective silenced of *MeCP2* in visceral organs, but not in the brain. Such approach may shed some light on *MeCP2* function on visceral organs and its contribution to RS.

Identification of interactions of the Shwachman-Diamond syndrome protein (SBDS). *D.W. Ellenor*^{1,2}, *J.M. Rommens*^{1,2}. 1) Department of Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada.

Shwachman-Diamond syndrome (SDS) is an autosomal recessive disorder characterized by exocrine pancreatic insufficiency, hematological dysfunction and skeletal abnormalities. Mutations in the *SBDS* gene have been associated with SDS. The gene product, SBDS, is a member of a highly conserved protein family of unknown function, with orthologs identified in eukaryotes and archaea. Indirect evidence suggests that the homologs may be involved in RNA metabolism or ribosome biogenesis. In order to investigate the role of the SBDS in mammalian cells, approaches aimed toward the identification of molecules that interact with SBDS were attempted. Exhaustive screens with yeast two-hybrid methodology, using human SBDS and cDNA libraries prepared from human pancreas, bone marrow or liver RNA, did not reveal any direct interactors. Methods that detect only strong binary interactions may not provide suitable approaches, as SBDS may be involved in transient or multi-protein or RNA/protein complexes. Modified interaction detection schemes have been devised using human fibroblasts to identify both protein and nucleic acid interactors. Gentle lysis and mild denaturing conditions are being used for the generation of extracts, together with mass spectrometry techniques (for proteins) or PCR-based recovery schemes (for nucleic acids). To date, SBDS-specific interacting protein bands have been detected and reproduced on Coomassie-stained polyacrylamide gels. The identification of the obtained interactors will provide insight into the function of SBDS and aid in the elucidation of the nature of any associated complexes.

Functional analysis of mutations at EGF2 domain of Factor IX gene. *A.R. Jaloma Cruz¹, J. Mantilla¹, N. Enjolras², J.L. Plantier², C. Vinciguerra³, C. Negrier².* 1) Division de Genetica, CIBO-IMMS, Guadalajara, Mexico; 2) Faculte du Medicine RTH LAENNEC, Francia; 3) Hopital Edouard Herriot, Francia.

Once a candidate mutation has been identified in patients with hemophilia, it is important to determine the impact of the mutated residues in synthesis and functional activity of factor IX (FIX). We studied three mutations at the same codon of FIX gene (C88G, C88Y and C88F) located in the EGF2 domain, which induced different aminoacid changes and distinct clinical behavior of the hemophilia B patients. **METHODS.** The FIX mutants were cloned in an expression vector following in vitro directed mutagenesis. mRNA expression, intracellular production, intracellular trafficking, and secretion were studied in Cos-1 cell line. Kinetics and half-life were measured by pulse chase and biochemical properties were evaluated from purified products. **RESULTS.** The mRNA expression of the 3 mutants was similar to the wild-type FIX (FIXwt). Conversely, the intracellular ER accumulation and the corresponding decrease in secretion (10-15 fold) were shown for the mutants in comparison with FIXwt. Cystein protease inhibitors did not exhibit a significant effect as compared with previously published results for other cysteine mutations located in EGF domain (C71Y and C109Y). Pulse-chase studies demonstrated an increased concentration in culture supernatant at 21h as compared with FIXwt, although the absolute amount was significantly lower, suggesting a secretion defect. Since these different missense mutations were not shown to significantly affect intracellular trafficking or cellular secretion, the hemophilia B phenotype is likely due to additional differences at the biochemical level. **CONCLUSIONS** This study revealed further aspects of factor IX processing that were correlated with the phenotypic characteristics of hemophilia B patients.

Interaction of the familial Mediterranean fever protein with 14.3.3 in an isoform-specific and phosphorylation-dependent manner regulates its translocation to the nucleus. *I. Jeru¹, S. Papin¹, S. L'Hoste², P. Duquesnoy¹, C. Cazeneuve¹, J. Camonis², S. Amselem¹.* 1) INSERM U.468, Hopital H. Mondor, Creteil, France; 2) INSERM U.528, Institut Curie, Paris, France.

Familial Mediterranean fever (FMF), an inherited disorder characterized by recurrent episodes of fever and serosal inflammation, is associated with mutations in the MEFV gene. The corresponding protein, called pyrin or marenostrin, exists in at least two isoforms, the functions of which are largely unknown: a cytoplasmic full-length isoform (pyrin.fl) and a predominantly nuclear isoform generated by in-frame splicing of exon 2 (pyrin.DEx2), raising the question of the mechanisms underlying such different localization patterns. Here, we have identified two members of the 14.3.3 protein family as pyrin-binding partners. Although pyrin.fl interacts with 14.3.3t and 14.3.3e, pyrin.DEx2 does not. We also show that pyrin.fl is phosphorylated and that this posttranslational modification mediated 14.3.3 binding. As shown by co-immunoprecipitation experiments, this interaction is provided by the domain encoded by MEFV exon 2. Further mapping of the region involved in this interaction identified two unconventional 14.3.3 binding sites located in this domain, with serine 208 and serine 209 (site 1) and serine 242 (site 2) acting as critical residues. Using a S208/S209/S242A pyrin.fl triple mutant or wild-type pyrin.fl in the presence of an inhibitor of 14.3.3:ligand interactions, we show that 14.3.3 binding promotes the cytoplasmic retention of pyrin. Taken together, these data indicate that the phosphorylation- and isoform-dependent interaction of pyrin with 14.3.3, which may modulate so-far unknown functions of pyrin, plays a critical role in regulating the translocation of pyrin to the nucleus.

Program Nr: 1366 from the 2004 ASHG Annual Meeting

Investigation of the subcellular localisation of spartin, mutated in a complicated form of HSP, in neuronal cell lines NSC34 and SH-SY5Y. *H. Patel, A.H. Crosby.* Medical Genetics Unit, St George's Hospital Medical School, London, United Kingdom.

The hereditary spastic paraplegias (HSPs) are a complex group of neurodegenerative disorders characterised by lower limb spasticity and weakness. We have shown that mutations in spartin underlie an autosomal recessive variant of HSP (Troyer syndrome, SPG20) present at high frequency amongst the Old Order Amish. Using a spartin antibody, which has been tested against a panel of human tissues and protein extracts from three cell lines (NSC34, SH-SY5Y and CHO), a single band of ~85kDa was identified on a Western blot. We have performed immunofluorescent staining of endogenous spartin to evaluate its subcellular localisation in the human and mouse neuronal cell lines SH-SY5Y and NSC34, respectively. Green fluorescent protein-tagged spartin shows a pattern of expression that is throughout the cytosol and punctate in NSC34 cells. Endogenous spartin also shows a punctate pattern. However, we often observe intense fluorescence at cell process termini and some immunostaining in the nucleus. The pattern of endogenous spartin in differentiated (retinoic acid) SH-SY5Y cells differs from that in NSC34 cells; it is again nuclear and also found throughout the cytosol, however cells often show an intense region of fluorescence adjacent to the nucleus, and a punctate pattern is also clearly visible in cell processes. The intense fluorescence at the cell termini in NSC34 cells is not replicated in SH-SY5Y cells.

Molecular characterisation of interacting proteins with lamin A encoded by LMNA and disrupted by in the laminopathies. *S. Shackleton¹, D. Smallwood¹, A. Fry², R. Trembath¹*. 1) Dept of Genetics, University of Leicester, Leicester, United Kingdom; 2) Dept of Biochemistry University of Leicester, Leicester, United Kingdom.

In a yeast two-hybrid interaction screen using the C-terminal domain of lamin A as bait, we previously isolated the adipocyte differentiation factor, sterol response element binding protein 1 (SREBP1). In the same screen, we identified murine SUN1 (mSUN1) as a lamin A interacting protein. Software algorithms predict mSUN1 to conform to the typical SUN protein structure with an NTD and a CTD separated by 4 transmembrane domains. Using antibodies raised against the CTD of mSUN1 (residues 1-355) is responsible for lamin binding and NE localisation. To investigate the topology of mSUN1 in the NE, digitonin permeabilisation experiments were performed on NIH 3T3 cells labelled with our anti-mSUN1 antibodies and, surprisingly, these studies suggested that the CTD of mSUN1 lies on the outer face of the NE, exposed to the cytoplasm. These findings were confirmed by immunogold scanning electron microscopy of the outer face of the NE. Together, our data suggest that mSUN1 adopts a novel topology, spanning both membranes of the NE, with the NTD responsible for NE localisation by binding to the nuclear lamina at the inner face of the NE, whilst the CTD lies on the outer face of the NE. Like *C. elegans* SUN-1/matefin, mSUN1 may be involved in microtubule dependent nuclear positioning through nuclear-centrosomal attachment, and identifies a further mechanism by which mutations of LMNA, may contribute to the dystrophic processes observed in the laminopathies.

Molecular and cellular characterization of the Down Syndrome Critical Region Protein 2 (DSCR2). *J. Vesa, Y. Brown, D. Greenfield.* Dept Ped, Medical Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA.

Down Syndrome (DS) is the most prevalent cause of mental retardation affecting approximately one in 700 newborns. Cytogenetic and clinical studies have demonstrated that DS is caused by complete or partial trisomy of chromosome 21. To elucidate the pathways underlying the abnormalities of the DS brain, we have characterized genes that are associated with cognitive defects of DS. Of these, the DSCR2 gene encodes a novel 288 amino acid protein with 85% homology to the corresponding mouse protein. Computational prediction programs suggest a molecular weight of 32.9 kDa for the human protein with one potential N-glycosylation site at amino acid position 129 and two transmembrane domains at positions 72-90 and 208-243. Near the N-terminus, the polypeptide has a low complexity region encompassing amino acids 17-36, where the mouse protein has one additional amino acid. The lack of a predicted signal peptide suggests that DSCR2 is targeted to a cytoplasmic compartment. To test if these predictions hold true, we analyzed transiently transfected HEK-293 and COS-1 cells, using N- and C-terminally FLAG-tagged cDNA constructs. Our expression studies propose that DSCR2 is synthesized as a 44 kDa precursor protein that is trimmed at the N-terminus resulting in a 42 kDa polypeptide. In vitro mutagenesis assays revealed that the difference between predicted and observed molecular weights is not due to a differential glycosylation status of the protein but is more likely caused by other co-/post-translational modifications. Membrane fractionation and subcellular localization studies of the same cell lines imply that DSCR2 is not associated with membranes but is targeted to the cytoplasmic compartment as a soluble form. To determine the expression pattern of DSCR2 in adult mouse brain, we performed immunohistochemical stainings of cryosections with the DSCR2 specific antibody. The results obtained from these experiments showed positive immunoreactivity mainly in the corpus callosum and brainstem. Future co-localization studies with cell-specific antibodies will reveal the cell types and structures where DSCR2 is expressed in the brain.

Role of N-glycosylation in lysosomal neuraminidase. *D. Wang, E. Bonten, A. d'Azzo.* Department of Genetics and Tumor Cell Biology, St Jude Children's Research Hospital, Memphis, TN.

Mammalian lysosomal neuraminidase (NEU1) is crucial for the maintenance of cellular homeostasis because it is responsible for the removal of terminal sialic acid residues on sialo-glycoconjugates. The interaction with PPCA is essential for its intracellular localization and catalytic activation. Loss of NEU1 function is associated with two lysosomal storage disorders: sialidosis and galactosialidosis (GS). NEU1 contains three (human) or four (mouse) potential N-glycosylation sites. The N-glycosylation sites in the murine Neu1 are: Asn180, Asn337, Asn346 and Asn372. Our previous studies showed that both mammalian and insect cell-expressed recombinant Neu1 occurred in at least two differentially glycosylated forms. Eliminating all 4 N-glycans of Neu1 expressed in insect cells made the enzyme unstable and inactive. To better understand the role of the glycan in Neu1, we generated four mutants (Mut1-4), each carrying an Asn to Asp amino acid substitution at 1 of the 4 N-glycosylation sites. We then assessed the biochemical properties of Mut1-4 by expressing them in insect cells and Neu1 deficient mouse lung fibroblasts. Our data revealed that Mut1 was less stable but retained some residual activity in both expression systems. It could be partially transported to the lysosome in cultured fibroblasts. Mut2 and Mut3 purified from insect cells, albeit recovered in fewer amounts, were catalytically active and appeared less heterogeneous on SDS-PAGE. In contrast, deficient fibroblasts transduced with MSCV-based retroviral vectors expressing either Mut2 or Mut3 had somehow reduced enzyme activities. But the activity of Mut2 was rescued by co-expression of PPCA, while that of Mut3 was not. These data suggest that the Asn346 glycosylation site is likely important for the association of Neu1 with PPCA. So far our results indicate that the glycosylation sites in Neu1 have a synergistic effect on the proteins stability and activity. We are currently verifying this hypothesis and in addition we are testing whether the individual glycosylation mutants are effective in the correction of the phenotype in *Neu1*^{-/-} mice. (Supported in part by NIH grant GM060950).

The Valine274Isoleucine allele does not affect transactivation by IRF6 in a cell culture assay. *S. Kondo*¹, *N. Rorick*², *Z. Abrerra*², *A. Russo*³, *B.C. Schutte*¹. 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Genetics PhD Program, Univ Iowa, Iowa City, IA; 3) Dept. Physiology and Biophysics, Univ Iowa, Iowa City, IA.

Interferon regulatory factor 6 (IRF6) is a member of the Interferon Regulatory Factor family of transcription factors and is expressed in the fusing palate, tooth buds, skin and external genitalia during development. The IRF6 gene encodes a protein of 467 amino acids (aa) that consists of four domains, DNA binding (aa13~aa113), Proline-rich (aa114~aa225), protein binding (aa226~aa412), and Ser/Thr-rich (aa413~aa467). Recently, we reported that mutations in IRF6 cause two orofacial clefting disorders, Van der Woude and Popliteal Pterygium syndromes (VWS; OMIM 119300 and PPS; OMIM 119500, respectively) and that the SNP resulting in a missense change Valine to Isoleucine (V274I) is significantly associated with isolated cleft lip and palate. However, the function of IRF6 and the potential effect of V274I are unknown. In this study, we performed cell culture transactivation assays to determine the functional domain(s) of IRF6 and to measure the effects of mutations on its activity. We demonstrate that IRF6 is a strong activator of transcription, that the main transactivation domain of IRF6 is located in the Proline-rich domain, that the Ser/Thr-rich domain acts in an autoinhibitory manner, that mutations that cause either VWS or PPS reduce the transactivation function of IRF6, and that the V274I allele has no significant effect. Similar results were obtained in two different epithelial cell lines. These results contribute to the understanding of IRF6 structure/function and etiology of VWS and PPS. They are also consistent with the hypothesis that V274I is not a functional polymorphism, although additional studies are necessary.

ATRX shows sequence-specific DNA binding activity. P. Tang¹, A. Argentaro³, D. Higgs³, M. Familiar¹, J.M. Graves¹, V.R. Harley². 1) Department of Zoology, The University of Melbourne, Victoria, Australia; 2) Human Molecular Genetics, Prince Henry's Institute, Victoria, Australia; 3) Institute of Molecular Medicine, Oxford, UK.

Human *ATRX* mutations lead to a condition known as α -thalassaemia mental retardation X-linked (*ATRX*) syndrome, associated with urogenital abnormalities in 80% of cases, ranging from cryptorchidism to male pseudohermaphroditism [1-2].

While the biochemical role of *ATRX* is unknown, a role in gene regulation via chromatin remodelling is speculated [2]. The *ATRX* protein contains a C2-C2 zinc finger (ZF) adjacent to a plant homeodomain (PHD)-like ZF to which 60% of *ATRX* mutations cluster, highlighting the importance of this domain [2].

The *ATRX* protein binds double-stranded DNA homopolymers *in vitro* through its ZF/PHD domain [3]. Using an EMSA-based random DNA oligonucleotide selection assay [4] we observed that recombinant ZF/PHD domain enriches DNA sequences from the random DNA pool over successive rounds. *ATRX*-selected DNAs have been sequenced and show increased binding affinity when compared to the unselected pool.

Using transfected mammalian cells, we show that *ATRX* represses SV40-mediated transcription of luciferase from the pGL3-Control vector without additional cloned sequences. This repression is dose-dependant and the ZF/PHD domain alone is sufficient for repression. We are currently attempting to identify the DNA elements mediating this repression. Our observations suggest a model for *ATRX* function in gene repression involving binding to regulatory regions of specific genes.

Progressive Myofibrillar Pathology in a Transgenic Mouse Model of LGMD1A. *S.M. Garvey¹, S.E. Miller², M.A. Pericak-Vance¹, M.A. Hauser¹.* 1) Center for Human Genetics; 2) Department of Pathology, Duke University Medical Center, Durham, NC.

Limb-Girdle Muscular Dystrophy Type 1A (LGMD1A) is an autosomal dominant, progressive disorder with onset in the third decade. Two independent missense mutations in the *myotilin* gene cause LGMD1A. Recently, three additional *myotilin* missense mutations were found in patients with myofibrillar myopathy (MFM), a disease similar to LGMD1A. The amino acid substitutions resulting from these mutations occur at the N-terminus of myotilin, a domain with unknown function. Myotilin protein is expressed in skeletal and cardiac muscle, localizes to the myofiber Z-disc, and interacts with α -actinin, α -filamin, and F-actin.

To explore the effects of the LGMD1A mutations on myotilin and muscle function, we generated transgenic mice expressing the thr57ile *myotilin* mutation specifically in skeletal muscle under the control of the human skeletal actin promoter. The transgene includes the human *myotilin* cDNA and an N-terminal c-myc epitope tag. We have generated five expressing lines, and skeletal muscle from two lines have been characterized by light and electron microscopy. Both lines exhibit a progressive myofibrillar phenotype not seen in littermate controls. Masson trichrome-stained cross-sections and longitudinal sections of quadriceps and tibialis muscle suggest discrete disruption of myofibrils. Analysis of 2-, 4-, 5-, 6-, 7-, and 11-month transgenic mice shows an age-dependent increase in both the size and number of myofibrillar lesions. Ultrastructural analysis of an 11-month old transgenic mouse reveals central nuclei, rimmed vacuoles, Z-disc streaming, and large patches of myofibrillar disarray recapitulating that seen in LGMD1A and MFM patients. Muscle from a control transgenic line expressing the wild-type *myotilin* cDNA displays no histopathology. We have also generated a founder mouse positive for the integration of a *myotilin* transgene containing a deletion that removes the N-terminal 79 amino acids. Grip-strength analysis, muscle morphometry, and immunolocalization of sarcomeric proteins will also be discussed.

Unconventional translation of a human retrotransposon. *J.L. Garcia-Perez, R. Alisch, J. Moran.* Human Genetics, Univ. Michigan Medical School, Ann Arbor, MI.

Long Interspersed Element-1 (LINE-1) is an abundant retrotransposon that comprises ~17% of human DNA. The average human genome contains ~100 retrotransposition-competent LINE-1 elements. These LINE-1s contain two non-overlapping open reading frames (ORF1 and ORF2), which are separated by a 63 nucleotide intergenic sequence that contains two in-frame stop codons. ORF1 encodes a RNA binding protein (ORF1p), whereas ORF2 encodes a protein (ORF2p) with endonuclease and reverse transcriptase activities. Both proteins are required for efficient retrotransposition in cultured human cells; however, how ORF2p is translated has been a long-standing mystery.

We previously showed that the LINE-1 encoded proteins preferentially retrotranspose their encoding transcript by a process termed *cis*-preference. Thus, it is likely that ORF2p expression is tightly regulated. Here, we have used a cultured cell LINE-1 retrotransposition assay in conjunction with molecular biological approaches to determine how ORF2p is translated. Our results demonstrate the following: 1) the intergenic sequence is dispensable for LINE-1 retrotransposition; 2) the putative ORF2 AUG initiation codon can be mutated to any other amino acid without drastically affecting LINE-1 retrotransposition (i.e., the resultant constructs retrotranspose between 10-70% wild type levels); however, when the AUG codon is mutated to a stop codon (TAA, TAG, or TGA), retrotransposition is reduced to 2% wild type levels; 3) the synthesis of a functional ORF1p is not required for ORF2p translation; 4) finally, the putative ORF2 AUG initiation codon in a synthetic mouse LINE-1 element also is dispensable for retrotransposition. Taken together, these data suggest that ORF2p can be synthesized in the absence of an AUG codon and that its translation occurs by an unusual mechanism such as ribosome shunting or is facilitated by an unconventional internal ribosome entry sequence.

The leucine zipper domain of ORF1p is required for L1 retrotransposition. *A.E. Hulme, J.N. Athanikar, J.V. Moran.* Department of Human Genetics, University of Michigan, Ann Arbor, MI.

The non-LTR retrotransposon LINE-1 (L1) comprises ~17% of the human genome. Retrotransposition-competent L1s are composed of a 5' UTR, two non-overlapping open reading frames (ORF1 and ORF2), and a 3' UTR that ends in a poly (A) tail. The exact function of the ORF1 encoded protein (ORF1p) remains unknown; however, ORF1p co-localizes with L1 RNA in cytoplasmic ribonucleoprotein particles, which are proposed retrotransposition intermediates. Residues in the C-terminus of ORF1p are needed for RNA binding, while the N-terminus mediates ORF1p multimer formation. Although the sequence of the amino terminus of ORF1p is poorly conserved, a predicted coiled coil domain is conserved among mammalian L1s. Human ORF1p contains a putative leucine zipper (LZ) in this domain, which lies within the region required for ORF1 multimer formation. As this LZ domain is absent from rat, mouse, and rabbit L1s, it is uncertain whether it is required for retrotransposition.

In order to investigate the necessity of the LZ domain for retrotransposition we mutated the 4 leucine residues of the LZ domain to valine residues. These mutations abolished the ability of L1 to retrotranspose in cultured human cells. We hypothesized that this defect was due to the inability of the LZ mutants to form multimers. To investigate this possibility, we conducted GST pulldown and glutaraldehyde cross-linking assays. Unexpectedly, our data demonstrated that the LZ mutant protein could interact under the same conditions as wild type ORF1p in both assays. These results were confirmed using a yeast two-hybrid screen. In addition, LZ mutant protein was found to localize to RNPs, like wildtype ORF1p. Therefore, we conclude that mutations in the LZ domain abolish retrotransposition, but still allow ORF1-ORF1 protein interaction. These paradoxical findings indicate that multimer formation of ORF1 protein is not sufficient for retrotransposition, and suggest that the LZ domain has another role in retrotransposition.

***In vivo* identification of individual active L1 retrotransposons.** *M.dC. Seleme, H.H. Kazazian, Jr.* Dept Genetics, Univ of Pennsylvania, Philadelphia, PA.

Two basic premises must apply for an autonomous transposon to be active *in vivo* : I) The element must have open reading frames and all its key structural sequences intact, II) The element has to be located in a favorable (permissive) genomic environment so that it can be expressed. Cases of human diseases caused by *de novo* mobilization of a closely related group of L1 retrotransposons (Ta-subgroup) indicate that this is a family of autonomous elements in which at least some members definitely comply with the above-cited premises for mobilization. Analyzing the human genome sequence, we have identified 90 L1 elements complying with the first premise. Our *ex vivo* L1-mobilization assay showed that 49% of them are transposition-competent. Based on these data and on the allelic frequency of these L1s, we estimated that an average human carries between 80 to 100 transposition-competent L1s. Because the cultured cells assay tests the transposition capacity of cloned L1s isolated from their genomic environment, our current estimates of active L1s in the human genome do not necessarily reveal their activity potential in their original genomic location. To assess the validity of these estimates *in vivo*, here we investigate whether these L1 elements, active *ex vivo*, are actually expressed in human tissues. Since L1s move through the obligatory synthesis of a full-length RNA intermediate, the presence of these transcripts in tissues can be used as a molecular indication of L1s sitting in permissive genomic locations and can provide a better estimate of the actual number of active L1s *in vivo*. Taking advantage of available L1 sequence data and using an RNA circularization-RT-PCR technique, we have worked out experimental conditions for the individual detection of full-length elements being expressed in human carcinoma cell lines. For example, we were able to identify a full-length transcript, the 5' and 3' ends of which correspond to those of element A1162431 (active on our retrotransposition assay). We have now a useful experimental tool to identify individual L1 elements expressing transcripts relevant for retrotransposition in cells derived from testicular, ovarian and other human tissues susceptible of L1 mobilization.

L1 retrotransposon-mediated stable gene silencing in human cell line. *N. Yang*¹, *L. Zhang*², *H.H. Kazazian Jr*¹. 1) Dept of Genetics; 2) Center for Research on Reproduction and Women's Health and Abramson Family Cancer Research Institute, University of Pennsylvania, Philadelphia, PA.

RNA interference (RNAi) is an evolutionally conserved mechanism of sequence-specific, post-transcriptional gene silencing initiated by small interfering RNA (siRNA) homologous to the gene being suppressed. It is now established as a general method to silence gene expression in a variety of organisms, including mammals. The short-hairpin RNA (shRNA) structure produced by an RNA polymerase III (polIII) promoter has been reported to generate gene-specific siRNA *in vivo*. Both plasmid and viral based vector systems have been used to deliver shRNA into mammalian cells. However, the current systems suffer from limitations including transient effect, demanding viral handling and/or potential insertional mutations. Here we describe a simple plasmid-based system using human L1 (L1Hs) retrotransposon for stable expression of siRNA in cultured HeLa cells. A ~160bp RNAi cassette containing H1 polIII promoter and shRNA sequence targeting a specific gene was inserted downstream of the *neo*-cassette tagged L1Hs in a plasmid. Transfection of such a plasmid into wild-type HeLa cells and subsequent application of G418 led to selection of cell clones in which the RNAi cassette had been stably integrated into the host genome upon L1Hs retrotransposition. Using this system, the mRNA and protein expression of an exogenous gene, GFP, was reduced by up to ~90% as revealed by real-time RT-PCR, western blot and FACS analysis. In addition, expression of an endogenous gene, GAPDH, was successfully reduced at both the mRNA and protein levels as shown by real-time RT-PCR, western blot and immunohistochemistry. Further characterization indicated that L1Hs retrotransposition occurred within 3-8 days post transfection, most transfected cells had no more than one retrotransposition event occurred, and only one integrated RNAi cassette was sufficient to elicit a strong RNAi effect. Our plasmid-based L1 retrotransposon-mediated RNAi system provides a novel strategy for stable gene silencing in cultured cells in a very easy and efficient manner and may have potential applications for *in vivo* molecular therapy.

Program Nr: 1377 from the 2004 ASHG Annual Meeting

Effect of the CTG expanded repeats on the transcriptome of PC12 neuronal cells. *M.A. Bermudez de Leon, P. Gomez-Islas, P. Velazquez-Bernardino, B. Cisneros.* Department of Genetics and Molecular Biology, CINVESTAV-IPN, 07360 Mexico city, Mexico.

Myotonic dystrophy (DM1) is a multisystemic disorder caused by a CTG repeat expansion within the 3'-untranslated region of the myotonic dystrophy protein kinase (DMPK) gene. Recent studies have demonstrated that the disease mechanism involves a dominant gain-of-function conferred upon mutant transcripts by expanded repeats. Although DM1-associated mental retardation suggests that neuronal functions are disturbed by the expansion mutation, the effect of this alteration in neuronal cells has not been approached. To address this issue, we previously characterized PC12 stable clones expressing the 3'-UTR of the DMPK gene with 5, 30 and 90 CTG repeats. Interestingly, we found that expression of 90 CTG repeats inhibits the PC12 neuronal differentiation. A detail characterization of the effects of CTG expanded repeats on the PC12 cell transcriptome would identify genes associated with the differentiated phenotype that are potential targets of the CTG mutation. For this purpose, wild type and CTG90 PC12 clones were treated with NGF for 6 days and total RNA samples were collected from them. The cDNAs of these clones were labeled and hybridized to a high-density cDNA microarray containing 5 thousand different rat genes. We found approximately 786 genes showing an altered regulation in response to the CTG mutation; from this total number, 73% were down-regulated and 27% up-regulated. Among the affected genes, it could be noticed genes involved in cell proliferation, cell survival, adhesion/motility and neuronal differentiation of PC12 cells. This study is supported by the Muscular Dystrophy Association, Inc. Grant No. MDA-3693.

HUMAN ATAXIN-3 STRUCTURAL ANALYSIS: PRELIMINARY DATA. *M.C.C. Garcia*¹, *C.E. Bendetti*², *C.L.P. Oliveira*³, *P.R. Kuser*⁴, *G. Neshich*⁴, *I.C. Torriani*³, *I. Lopes-Cendes*¹. 1) Med. Genet., UNICAMP/FAC. CIENCIAS MED., CAMPINAS, SP, Brazil; 2) LNLS - CAMPINAS, SP, Brazil; 3) UNICAMP/IFGW - CAMPINAS, SP, Brazil; 4) EMBRAPA/BIOINF. - CAMPINAS, SP, Brazil.

We are applying structural and computational methods to study ataxin-3, a protein that when mutated causes Machado-Joseph disease (MJD). Several neurodegenerative diseases are caused by expansion of a polyQ domain within the respective proteins forming aggregates within neurons, possibly due to misfolding. The physiological and biochemical functions of ataxin-3 remain unknown. In this way the small-angle X-ray scattering (SAXS) technique is a very useful tool since it can be performed with proteins in solution, in conditions close to the native state. Recombinant human ataxin-3 (ATX-3N-Q18) was expressed in *E.coli* and purified by affinity chromatography. SAXS measurements were performed in samples containing 10mg/mL of protein. Search of a structural model was retrieved from the SWISS-PROT/TrEMBL database. We applied BLAST/PSI-BLAST to search for homologous proteins in several sequence databases. The multiple sequence alignment was constructed by CLUSTALW. To predict the secondary structure of the proteins we used the PSIPRED prediction server. An initial model of ataxin-3 was analyzed with Sting Millennium suite. From the SAXS experiments we obtained a value for the molecular weight close to the expected for this protein, increasing the reliability of the data. Also, the analysis indicated an elongated conformation and presence of loose parts in the structure. *Ab initio* calculations allowed the construction of low-resolution 3D models. The secondary structure prediction suggests that the protein mainly consists of α -helices. Further studies are being performed to model the structure of ataxin-3. The development of several technologies now proves it feasible to perform mass screening of proteins and the field of proteomics is rapidly progressing. A comprehensive computational analysis of ataxin-3 together with experimental data from the SAXS experiments can contribute to elucidate important features and may serve as guidelines for future experiments.

Effect of CAT or AGG interruptions and CpG methylation on nucleosome assembly on the (CAG)_n and (CGG)_n tracts of SCA1 and FRAXA. *K.A. Hagerman¹, D.J. Mulvihill², K. Nichol Edamura¹, C.E. Pearson¹, Y.-H. Wang².* 1) Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Robert Wood Johnson Medical School, Piscataway, NJ.

Chromatin packaging and nucleosome assembly can regulate many aspects of DNA metabolism. CAT or AGG interruptions within the (CAG)_n or (CGG)_n tracts of spinocerebellar ataxia type 1 (SCA1) or fragile X mental retardation (FRAXA), respectively, confer increased genetic stability to the repeats. We report the formation of nucleosomes on sequences containing pure and interrupted SCA1 and FRAXA repeats having lengths above the genetic stability threshold ($n > 34$). Increased lengths of pure repeats led to increased and decreased propensities for nucleosome assembly on the SCA1 repeats and FRAXA repeats, respectively. CpG methylation of the CGG repeat further reduced assembly. CAT interruptions in (CAG)_n tracts decreased nucleosome assembly. In contrast AGG interruptions in (CGG)_n tracts did not affect nucleosome assembly by hypoacetylated histones. The latter observation was unaltered by CpG methylation of the repeats. Nucleosome assembly by hyperacetylated histones on interrupted CGG tracts was increased relative to pure tracts and this effect was abolished by CpG methylation. Thus, CAT or AGG interruptions can modulate the ability of (CAG)_n and (CGG)_n tracts to assemble into chromatin, the effect of the AGG interruptions is dependent upon both the methylation status of the DNA and the acetylation status of the histones.

Replication mediated instability of the GAA triplet repeat mutation in Friedreich ataxia. *L.M. Hern¹, R. Sharma¹, M. Gómez¹, S. Shah¹, M.B. Delatycki^{2,3}, L. Pianese⁴, A. Monticelli^{4,5}, B.J.B. Keats⁶, S.I. Bidichandani¹.* 1) Depts. Biochemistry & Molec Biol & Pediatrics, Univ Oklahoma Health Science Center, Oklahoma City, OK; 2) Murdoch Children's Research Institute; 3) Univ of Melbourne, Australia; 4) Dept Molec & Cell Biol & Pathology; 5) IEOS-CNR, Federico II Univ., Naples, Italy; 6) Dept Genetics, Louisiana St. Univ., New Orleans, LA.

Friedreich ataxia is caused by expansion of a GAA triplet repeat sequence in the *FRDA* gene. The triplet repeat is polymorphic and unstable, but the mechanisms underlying its instability are poorly understood. Replication of (GAATTC)_n sequences [9-105 triplets] in plasmids propagated in *E. coli* displayed length- and orientation-dependent instability. In addition to short sequence variation upon replication in both directions, large contractions were frequently seen when the "GAA" strand was the template for lagging strand synthesis. DNA replication was also significantly slower in this orientation. To evaluate the physiological relevance of our findings we analyzed repeats of similar length [8-107 triplets] within human leukocytes *in vivo*. Analysis of 9400 somatic *FRDA* molecules using small-pool PCR revealed a similar mutational spectrum, including large contractions. A (GAA)₃₉ allele, which had previously undergone hyperexpansion during intergenerational transmission, was completely stable in somatic cells, indicating that the threshold lengths, and perhaps the underlying mechanisms of repeat instability, are different in somatic and germ cells. Consistent with the stabilization of premutations by interruptions, somatic instability was abrogated by (GAGGAA)_n hexanucleotide interruptions. Our data demonstrate that the GAA triplet repeat mutation in Friedreich ataxia is destabilized during DNA replication, perhaps during lagging strand synthesis, and indicate that this mutation can be reversed.

Program Nr: 1381 from the 2004 ASHG Annual Meeting

Effect of the CTG expanded repeats on the Tau protein phosphorylation in the PC12 cell line. *O. Hernandez-Hernandez, P. Velazquez-Bernardino, L. Quintero-Mora, P. Gomez-Islas, V. Tapia-Ramirez, B. Cisneros.* Department of Genetics and Molecular Biology, CINVESTAV-IPN, Mexico city, Mexico.

Myotonic dystrophy 1 (DM1) is one of the most prevalent human inherited neuromuscular disorders; classical DM1 onset develops during early adulthood and is characterized primarily by myotonia, muscle weakness and progressive muscle wasting; whereas congenital myotonic dystrophy (CMD), the most severe form of the disorder, is characterized by profound hypotonia, mental retardation and developmental abnormalities. The DM1 mutation has been identified as an expanded CTG trinucleotide repeat tract in the 3'untranslated region (3'UTR) of the DM protein kinase gene (MtPK). Although mental retardation suffered by CMD patients indicates that normal neural functions are disturbed by the CTG expansion, the effect of this alteration on neural cells has been poorly approached. We previously established stable transfectans of PC12 neural cell line expressing the reporter gene CAT alone or fused to the MtPK 3-UTR with 90 CTG repeats (CTG90 clone). We found that CTG90 clone did not response to NGF-induced differentiation and the gene regulation of the late differentiation marker MAP2 was disturbed. Recently, intraneural aggregates of hyperphosphorylated tau protein, a brain microtubule associated protein, have been found in brain areas of DM1 patients and transgenic DM mouse. Additionally, a disruption in the normal expression pattern of tau splicing isoforms has been also observed in those patients. These results suggest that alteration of the expression of tau could account for the mental retardation observed in DM patients, however the mechanism underlying such alteration remains unknown. Hence, taking advantage of our neuronal cell model, we investigated the expression and phosphorylation status of tau protein in the wild type and CTG90 PC12 clones. Our results indicated that levels and phosphorylation stage of the tau protein are altered in the PC12 clone expressing 90 CTG repeats. This study is supported by the Muscular Dystrophy Association, Inc. Grant No. MDA-3693.

***EPM1* VNTR-mediated transcriptional repression reversed by SP3 and an LKLF-Gal4 fusion protein.** L. Hsu, G. Manthey, A. Bailis, T. Krontiris. Divisions of Molecular Medicine and Molecular Biology, Beckman Research Institute of the City of Hope, Duarte, CA.

Expansion mutations of gene-associated variable number of tandem repeats (VNTR) are responsible for several human diseases, including myoclonus epilepsy (*EPM1*). The *EPM1* VNTR contains a 12 bp repeat unit that is 100% G+C; the minisatellite is located about 70 nucleotides upstream of the transcription start site of the cystatin B (*CSTB*) gene. The expanded allele reduces the activity of the *CSTB* promoter in certain cells. For insight into the mechanism underlying VNTR-mediated transcriptional repression, we have generated a knock-in yeast strain that survives only when the reporter gene for cycloheximide sensitivity, *CYH2^s*, is down-regulated. Insertion of the expanded *EPM1* VNTR sequence at the 5' end of the *CYH2^s* promoter inhibited its promoter activity, allowing selection of cycloheximide resistant colonies, whereas insertions of the normal (two-repeat-unit) VNTR allele did not alter promoter function and cycloheximide sensitivity. Using a yeast one-hybrid system, we have identified and characterized two potential human *EPM1* VNTR binding proteins, Sp3 and LKLF, and have shown that they are capable of suppressing minisatellite transcriptional repression. Transcriptional down-regulation of the *CYH2^s* gene in our knock-in strain by an expanded *EPM1* VNTR was reversed by transformation of Sp3 cDNA, indicating that Sp3-*EPM1* VNTR interaction regulates gene transcription. The other binding protein of GC-rich DNA we identified using the one-hybrid screen, LKLF, when fused to a Gal4 activation domain and expressed in the *CYH2^s* knock-in, also suppressed the effect of the expanded VNTR allele. (The LKLF clone we obtained in the one-hybrid screen lacked its native activation domain.) Gel mobility shift analyses indicated the specific binding of both these proteins to the *EPM1* VNTR repeat unit. We are now probing chromatin structure near the *CYH2^s* promoter to determine what effects are conferred by the presence of the expanded minisatellite and how expression of Sp3 and LKLF might affect transcriptional repression by the VNTR.

Program Nr: 1383 from the 2004 ASHG Annual Meeting

Molecular genetic study of CAG repeat instability in Drosophila. *J. Jung, N. Bonini.* Dept Biol, HHMI, Univ Pennsylvania, Philadelphia, PA.

Huntingtons disease (HD) and Machado-Joseph Disease (also known as Spinocerebellar ataxia type 3; MJD/SCA3) are among a class of hereditary neurodegenerative diseases due to an expanded CAG repeat within the open reading frame of the gene. One of the key features of these diseases is the instability of the CAG triplet repeat. Strikingly, CAG repeats tend to expand in successive generations, resulting in earlier and more severe disease phenotypes. Somatic instability may also contribute to the severity of the disease. Therefore, it is of interest to understand the molecular mechanisms of triplet repeat instability, in order to understand both germ line and somatic changes in the repeats. Drosophila models have provided valuable insights into the mechanisms of expanded polyglutamine toxicity, suppression, and candidate therapeutic reagents. We have examined CAG repeat instability in a fly model for polyglutamine disease. Our current data suggest that expanded CAG repeats are unstable in Drosophila, and have a strong tendency for further expansion. Understanding the mechanisms underlying repeat instability may provide new avenues for therapeutics.

PABPN1 overexpression leads to upregulation of genes encoding nuclear proteins that are sequestered in oculopharyngeal muscular dystrophy nuclear inclusions. *A.F. Klein¹, L-P. Corbeil-Girard¹, A.M.J. Sasseville^{1,2}, M.J. Dicaire¹, A. Saint-Denis¹, M. Page¹, G. Karpati³, G.A. Rouleau³, B. Massie⁴, Y. Langelier², B. Brais¹.* 1) neurogenetique, CHUM-Hopital Notre-Dame, Montreal, Quebec, Canada; 2) centre de recherche CHUM-Hopital Notre-Dame, Montreal, Quebec, Canada; 3) McGill Health center, McGill university, Montreal, Quebec, Canada; 4) Institut de recherche en biotechnologie, CNRC, Montreal, Quebec, Canada.

Autosomal dominant oculopharyngeal muscular dystrophy (OPMD) is an adult-onset disease with a worldwide distribution. Intranuclear inclusions (INIs) in skeletal muscle fibers are its pathological hallmark. The dominant OPMD mutations consist in expanded (GCN)₈₋₁₃ stretches in the poly(A) binding protein nuclear 1 gene (PABPN1). The (GCN) repeat codes for a polyaniline tract at the N-terminus of the protein. The INIs are known to contain PABPN1, molecular chaperones, ubiquitin, proteasomal subunits and poly(A)-mRNAs. We describe an adenoviral model of PABPN1 expression that produces INIs in most cells. Microarray analyses using the Affymetrix human HG-U133A GeneChip show that PABPN1 overexpression induces a reproducible change in the expression of 202 genes. The majority of the 103 upregulated genes encodes nuclear proteins, many of which with RNA or DNA binding activities. Immunofluorescence microscopy studies reveal that all tested nuclear proteins encoded by eight upregulated genes colocalize with PABPN1 in the INIs: CUGBP1, SFRS3, FKBP1A, HMG2, HNRPA1, PRC1, S100P and HSP70. Moreover, we show that CUGBP1, SFRS3 and FKBP1A are also present in OPMD muscle INIs. Our results demonstrate that the INIs are more heterogeneous than previously thought. They may play an active role in the pathophysiology in OPMD by influencing the availability of some nuclear proteins.

Decreased palmitoylation of mutant huntingtin leads to abnormal trafficking and cellular toxicity. *A. Yanai¹, R. Kang², A. Mullerad², K. Huang², C.J. Opina¹, B.R. Leavitt¹, A.E-D. El-Husseini², M.R. Hayden².* 1) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver; 2) Department of Psychiatry, University of British Columbia, Vancouver.

Huntington disease (HD) is a hereditary neurodegenerative disorder characterized by severe motor, cognitive and emotional disturbances and a CAG expansion in the HD gene (*htt*). *Htt* is associated with vesicle membranes and its interactions with proteins involved in endocytic pathways, such as HIP1, suggest that *htt* is involved in intracellular trafficking. Post-translational modification by the fatty acid palmitate is crucial for correct membrane targeting for many proteins, including neurotransmitter receptors and those involved in signaling. The association of *htt* with cellular membranes highlighted the potential that *htt* is also modified with palmitate. This is further strengthened by the fact that *htt* interacts with HIP14, a putative mammalian palmitoyl acyl-transferase (PAT), in a polyQ dependent manner. Here we show that *htt* is indeed palmitoylated at cysteine 206. Furthermore, palmitoylation is modulated by CAG size as demonstrated by a marked decrease in palmitoylation ($p < 0.001$) of mutant *htt*. Decreased palmitoylation is associated with abnormal trafficking of mutant *htt*, leading to intracellular accumulation and aggregation and a marked increase (42%; $p < 0.01$) in intracellular toxicity and cell death. The significant modulation of palmitoylation by the mutation in HD and its subsequent effects on cellular toxicity highlight the potential role of altered palmitoylation in the pathogenesis of HD.

Identification and characterization of natural antisense transcripts (NATs) associated to genes involved in eye development. *G. Alfano¹, C. Vitiello¹, C. Caccioppoli¹, T. Caramico¹, M.J. Szego^{2, 3}, R.R. McInnes^{2, 3}, A. Auricchio¹, S. Banfi¹.* 1) Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy; 2) The Hospital for Sick Children, Toronto, Canada; 3) Department of Molecular and Medical Genetics; University of Toronto, Toronto, Canada.

Natural antisense transcripts (NATs) represent an intriguing class of genes whose role in controlling gene expression is becoming more and more relevant. We describe the identification of eight novel mouse NATs associated with transcription factors (Pax6, Pax2, Six3, Six6, Otx2, Crx, Rax and Vax2) that play an important role in eye development and function. These newly-identified NATs undergo extensive alternative splicing, overlap with the mature processed mRNAs or with the primary unprocessed transcript of their corresponding sense genes, and are predicted to represent either protein coding or noncoding RNAs. Expression studies, by RT-PCR and RNA in situ hybridization, demonstrate that most of these NATs, similar to their sense counterparts, display a specific or predominant expression in the retina, particularly at postnatal stages. Preliminary studies suggest that the overexpression of one of these NATs, CrxOS (Crx opposite strand), in mouse adult retina is able to significantly decrease the expression levels of the corresponding sense gene, Crx, further suggesting that these transcripts are functionally related to their sense counterparts. This subgroup of NATs may play an important role in the control of the molecular mechanisms underlying eye development and function both in health and disease.

USH1C interacting proteins in the retina. *B.R. Evans¹, J.C. Sowden², C.H. Sung³, M. Bitner-Glindzicz¹*. 1) Clinical and Molecular Genetics Unit, Institute of Child Health, London, United Kingdom; 2) Developmental Biology Unit, Institute of Child Health, London, United Kingdom; 3) Dyson Vision Research Institute, Weill Medical College of Cornell University, New York, USA.

Type 1 Usher Syndrome is the most severe form of a heterogeneous group of autosomal recessive deafness-blindness disorders; manifesting as congenital neurosensory hearing loss, progressive retinal degeneration and vestibular areflexia. 5 genes have been identified for the 7 known USH1 loci, and their protein products are thought to interact in both the auditory hair cells and in the retinal photoreceptor cells. USH1C, a PDZ domain containing protein has multiple isoforms that are known to display differing ultrastructural localisation patterns within the inner ear and retina. It is thought to be involved in the interlinking of cadherin 23 (USH1D) at the tips of the hair cell stereocilia, to the growing actin cytoskeleton and is itself correctly localised through interactions with myosin VIIA (USH1B). In the retina, these interactions are also presumed to occur at the ribbon synapses, the site of colocalisation of the Usher type 1 proteins, yet USH1C shows alternative sites of further expression, separate to myosin VIIA and cadherin 23. We undertook a yeast 2 hybrid study, to examine possible USH1C-protein interactions in the retina. We screened a bovine retinal library with the major isoform of USH1C, resulting in 175 colonies for further investigation. We identified other Usher type 1 proteins as expected, as well as scaffolding proteins and a protein that is enriched in the ribbon synapses. We further characterised the resulting interactions using constructs to the separate PDZ domains.

Secretion analysis of 36 myocilin variants, a protein implicated in primary open-angle glaucoma. *S. Gobeil, V. Raymond.* Molecular Endocrinology and Oncology Research Center, Laval University Hospital (CHUL) Research Center, Quebec City, Qc, Canada.

Primary open-angle glaucoma (POAG) is an ocular disease characterized by an optic neuropathy and a progressive loss of the visual fields. Only two of the seven GLC1 genes have been characterized: the trabecular meshwork-inducible glucocorticoid response (TIGR) gene, also known as myocilin (MYOC), at GLC1A, and optineurin (OPTN) at GLC1E. The MYOC gene encodes a secreted 504 aa polypeptide mainly localized in ocular tissues. More than 45 MYOC glaucoma-causing mutations have been reported and those, that have been investigated, prevented secretion of the polypeptides when transfected in cell lines in culture. To investigate if this was a general feature of the mutant polypeptides, we analyzed the secretion status of 36 variants reported in the literature. Myocilin variants were generated by site-directed mutagenesis of an expression vector encoding the human MYOC cDNA. COS-7 cells were transfected with the WT or mutated MYOC constructs. Myocilin proteins were detected in cells and extracellular media by immunoblotting. Cellular integrity was monitored by trypan blue staining. Out of the 36 variants, 15 were found to be secreted from COS-7 cells. Presence of these MYOC variants in the extracellular media was not caused by cell death. Of the 26 variations tested within the olfactomedin (Olf) domain (aa 246-501) of the protein, 19 remained sequestered intracellularly. All the sequestered proteins were disease-causing variants. Only two of the non-secreted variants were localized outside this domain. The first one, R46X, was a truncated protein. The second one, S502P, was only one aa outside the Olf domain. Our results demonstrate that variations localized near or in the Olf domain lead, in a large proportion, to the intracellular sequestration of myocilin showing that this region plays an important role in the folding and/or oligomerization of the protein. Testing for secretion of novel variants within or close to this highly mutated region will help to decipher if these variations may be classified as disease-causing mutants or polymorphisms.

X-linked Congenital Stationary Night Blindness (CSNB1): Nyctalopin is a cell surface glycoprotein attached by a GPI anchor in human but not in mouse. *E.J. O'Connor¹, T. Wang¹, J. Dalley², N. Bulleid², D. Trump¹*. 1) Academic Unit of Medical Genetics, Centre for Molecular Medicine, University of Manchester, Manchester, UK; 2) School of Biological Sciences, University of Manchester, Manchester, UK.

X-linked Congenital Stationary Night Blindness (CSNB) is a non-progressive eye disorder characterised by defective night vision. Complete CSNB (CSNB1) occurs due to mutations in the gene NYX, which encodes nyctalopin. The no b-wave mouse is a naturally occurring model with a deletion within the mouse *nyx* gene. Human nyctalopin, a novel member of the small leucine-rich repeat proteoglycan (SLRP) family, is predicted to attach to the cell membrane via a glycosylphosphatidylinositol (GPI) anchor. Human and mouse nyctalopin share 86% similarity and much of the variation is at the C-terminus (the GPI anchor signal sequence). We have investigated whether nyctalopin is present on the cell surface and whether the attachment is via a GPI anchor in human and mouse. We made constructs containing a flag tag inserted downstream of the signal peptide for both wild type genes (WT NYX, WT *nyx*) and NYX lacking the C-terminal sequence (NYX NA) and expressed these constructs in COS7 cells. We have demonstrated both human and mouse nyctalopin are present on the cell surface and NYX NA is secreted. Furthermore, treatment of cells with phospholipase D released only human nyctalopin into the cell medium confirming a functional GPI anchor in human only. We investigated this further using *in vitro* transcription/translation in semi permeabilised cells with hydrazine to compete with the lipid moiety during anchor addition. These results confirmed the presence of a GPI anchor in human nyctalopin and the absence of a GPI anchor in mouse. Sequence analysis suggests that chimp nyctalopin also uses a GPI anchor for membrane attachment, however rat nyctalopin is similar to mouse. The C-terminal sequence in mouse is predicted to be transmembrane and we are investigating this further. To our knowledge this is the first example of homologous proteins in different species having different methods of membrane attachment.

Functional analysis of the glaucoma-associated TIGR/myocilin protein: the coiled-coil motif at amino acid 78-105 acts as a nucleation site. V. Raymond, L. Letarte, S. Gobeil, M.-A. Rodrigue. Molecular Endocrinology and Oncology, Laval University Hospital (CHUL) Research Center, Quebec City, QC, Canada.

Mutations in *TIGR/myocilin* are associated with 3-4% of open-angle glaucoma, a disorder characterized by optic nerve degeneration and blindness. The protein forms dimers, migrating at 116-kDa, and higher molecular weight (MW) multimers above 180-kDa. Understanding the mechanisms generating these complexes should help to decipher the still unknown function of the polypeptide. We investigated the role of a putative coiled-coil motif at amino acids (AA) 78 to 105; the leucine-zipper at AA 114 to 183; and 5 cysteine residues, in complex formation. Expression vectors encoding normal or mutated myc-tagged myocilin cDNAs were tested by transfecting COS-7 and human trabecular meshwork cells in culture. Intra- and extra-cellular complexes were separated by non-reducing SDS-PAGE and analyzed by immunoblotting. Deletion of the coiled-coil motif (AA 78-105) severely impaired myocilin multimerization above 180-kDa without affecting its dimerization. In contrast, deletion of the leucine-zipper did not impair multimerization nor dimerization. Single substitution of critical AA in the first coiled-coil motif significantly abrogated the ability of the protein to form stable multimers. Triple substitutions between AA 84-99 abolished high MW complex formation without affecting dimerization. The single C to A substitution at position 185 and double C to A substitution at positions 47 and 61 abolished covalent multimerization above 180-kDa. Simultaneous substitutions of C 47, 61, and 185 resulted only in monomers. Mutation of the 245 and/or 433 C blocked myocilin secretion without altering its oligomerization. Our experiments thus demonstrate that the putative coiled-coil motif between AA 78 to 105 was essential for efficient myocilin multimerization whereas deletion of the leucine-zipper motif had no effect on complex formation. These data suggest that the coiled-coil motif at residues 78 to 105 may act as a nucleation site (a region involved in specific recognition of oligomerization partners), the oligomers being subsequently stabilized through disulfide bonds involving C 47, 61 and 185.

Studies of X-chromosome inactivation in cows and coast moles. *Z.C. Yen, S. Karalic, C.J. Brown.* Medical Genetics, University of British Columbia, Vancouver, B.C., Canada.

To date, X silencing has not been well studied in mammals other than humans and mice, yet these species show significant differences in the imprinting of inactivation, the number of genes that escape inactivation, and the functional Xist RNA that is critical for initiating X inactivation. To determine if these deviations are unique to humans we have investigated X inactivation in other Eutherian mammals, namely cows and coast moles, which will also serve to unravel functional regions of Xist via comparative sequence analysis. Thus far, the mechanism by which the Xist RNA coats and silences the X is unknown. Xist sequences of cow, vole, mouse, and human are available and we have recently sequenced >5.5 kb coast mole Xist. The addition of full-length coast mole Xist to a multiple species analysis may highlight conserved functional and structural domains of the Xist transcript. Initial results show that the coast mole Xist cDNA lacks sequence similarity to human exon 2 and mouse exon 5, yet contains additional similarity to a cow and human intron. Since insectivores (coast moles) are often considered basal Eutherians, the apparent lack of this additional mole exon in humans, mice and cows may argue for the loss of ancestral gene function during Eutherian evolution. Hence, the study of different species may identify the origin of this unique functional RNA. As only 5% of X-linked genes in mice escape inactivation, compared to 15% in humans, the inactivation status of various X-linked loci in other species will also allow us to evaluate whether incomplete silencing of the X is a unique human phenomenon. We therefore performed methylation analysis on cow and coast mole DNA for FMR1, ARA, ZFX and SMCX. In both species, ZFX and SMCX appear to escape inactivation, whereas ARA and FMR1 are subject to silencing, resembling the pattern seen in humans. On the contrary, all four loci in mice are found to be subject to inactivation. The status of other X loci will provide further insight into this human-mouse discrepancy. These comparative studies will ultimately paint a more complete picture of the evolution of dosage compensation in the Eutherian subclass.

A haplotype of angiotensinogen gene increases its promoter activity in liver cells and is associated with essential hypertension. *S. Jain, Y. Li, S. Patil, A. Kumar.* Pathology, New York Med Col, Valhalla, NY.

Hypertension is a serious risk factor for myocardial infarction, heart failure, vascular disease, stroke, and renal failure. The incidence of hypertension and complications due to hypertension are even greater in the African-American population. Previous studies have suggested that angiotensinogen (AGT) gene locus is linked with human essential hypertension. We have found an A/G polymorphism at -217 of the human AG gene promoter and have shown that frequency of allele A at -217 is significantly increased in the DNA of African-American hypertensive patients. We now show that -217A always occurs with -1074T in the promoter of human AGT gene. In order to understand the physiological role of these polymorphic sites, we have synthesized reporter constructs containing 1.2 Kb of the 5'-flanking region and 36 bp of the first exon of human AGT gene attached to the luciferase gene with -217A:-1074T and -217G:-1074G haplotypes. Transient transfection of these reporter constructs in human liver cells show that haplotype -217A:-1074T has almost two times increased promoter activity as compared to the haplotype -217G:-1074G. Our gel shift assays show that liver enriched transcription factor C/EBP beta and recombinant glucocorticoid receptor (GR) bind more strongly to an oligonucleotide containing -217A as compared to the same oligonucleotide containing -217G. In addition, liver enriched transcription factor HNF-3 beta binds more strongly to an oligonucleotide containing -1074T as compared to -1074G. Thus interaction of transcription factors C/EBP beta, GR and HNF-3 that bind to haplotype -217A:-1074T may be involved in increased expression of AGT gene containing this haplotype. In conclusion, we show that: (a) AGT promoter containing -217A and -1074T binds strongly to GR and liver enriched transcription factors C/EBP-beta and HNF-3 ; (b) reporter constructs containing haplotype -217A: -1074T have increased promoter activity as compared to the same reporter constructs containing haplotype -217G:-1074G. This increased promoter activity of haplotype -217A:-1074T may be responsible for increased expression of AGT gene and hypertension in human subjects containing this haplotype. Supported by grants from NHLBI and Phillip Morris foundation.

A promoter variation in the human perilipin gene decreases transcriptional activity by 5-fold. *N. Kavaslar, R. McPherson, R. Dent.* University of Ottawa Heart Ins, Ottawa, Ontario, Canada.

The adipocyte-specific protein perilipin is located at the surface of intracellular lipid droplets; in the basal state, it protects stored triacylglycerol from hydrolysis by cellular lipases. Perilipin is the most abundant protein kinase A substrate in adipocytes and plays an important role in PKA-mediated lipolysis. Perilipin has been shown to be an adipocyte-specific target gene of PPAR γ . The absence of perilipin in mouse results in leanness and resistance to diet-induced obesity. By SNaPshot and RFLP analyses, we screened more than 1400 human chromosomes in thin (BMI<25%ile for age and sex) and obese (BMI>30kg/m²) cohorts for variation in the promoter of the perilipin gene. We observed small differences between the genotypic frequencies of the two published perilipin promoter SNPs in these two populations. For the wild-type C allele of rs8179046, the thin cohort had a frequency of 0.73 vs. 0.78 in the obese (p=0.0496); for the wild-type C allele of rs8179045, the thin cohort had a frequency of 0.82 vs. 0.85 in the obese (p=0.0710). For the novel 8-bp deletion 958to-965del, the frequency of the deleted allele was 0.08 in the thin and 0.09 in the obese population. To investigate the effect of SNPs in the perilipin promoter region, we constructed luciferase reporter plasmids containing a 1.7-kb upstream region (positions 1728 to +56) of the human perilipin gene with the different alleles of the SNPs and with and without the deletion. These constructs were transiently transfected into the CHO-K1 cell line. Dual luciferase assays showed that only basal levels of luciferase activity were observed with all the constructs tested except for a construct that carries a point mutation A>G at 1215 bp upstream of the transcription start site. This variation was observed to decrease luciferase activity by 5-fold. MatInspector analysis demonstrated that this variation destroys a PPAR/RXR heterodimer binding site. Further studies will elucidate the functional significance of the putative perilipin promoter PPRE identified in this study.

A haplotype of angiotensin-II receptor type -1 increases its promoter activity and is associated with hypertension in Caucasian women. A. Kumar¹, A. Prater¹, M. Guruju¹, G. Venukonda¹, D. Velez², S. Williams². 1) Dept Pathology, New York Medical Col, Valhalla, NY; 2) Department of Genetics, Vanderbilt University, Nashville, TN.

Hypertension is a serious risk factor for myocardial infarction, heart failure, vascular disease, stroke, and renal failure. The renin-angiotensin system plays an important role in the regulation of blood pressure and angiotensin receptor blockers are potent antihypertensive agents. The promoter of the human angiotensin-II receptor type-1 (hAT1 receptor) gene contains at least five single nucleotide polymorphisms (SNPs) which are in linkage disequilibrium. These SNPs are T/A at -777, T/G at -680, A/C at -214, G/C at -213, and A/G at -119. We have shown that variant -680T always occurs with -777T, -214A, -213G, and -119A thus creating two haplotypes (TTAGA and AGCCG). We have studied the role of these haplotypes in hypertension in 218 hypertensive and 195 normotensive Caucasian subjects by examining the SNP at -680. The frequency of nucleoside T at -680 was 0.790 in hypertensive men and 0.793 in normotensive controls, which is not significant. However, the frequency of nucleoside T was 0.822 in hypertensive women and 0.736 in normotensive controls which is statistically significant ($p = 0.036$). In order to analyze the effect of these haplotypes on the promoter activity of hAT1 receptor we have synthesized reporter constructs containing 1.2 Kb of the 5-flanking region and 55 bp of the first exon. Transient transfection of reporter constructs in H295-R cells showed that haplotype TTAGA has approximately five-fold increased promoter activity as compared to the haplotype AGCGG. These experiments suggest that haplotype TTAGA may be increasing the expression of hAT1 receptor in Caucasian women that may lead to hypertension in this population. Supported by grants from NHLBI and Phillip Morris foundation.

A haplotype of angiotensinogen gene increases its promoter activity in adipocytes and is associated with essential hypertension. *Y. Li, S. Patil, S. Jain, A. Kumar.* Pathology, New York Medical College, Valhalla, NY.

Recent studies have suggested that angiotensinogen (AGT) gene locus is linked with human hypertension. AGT gene has an A/G polymorphism at -6, an A/C polymorphism at -20, and an A/G polymorphism at -217 in its promoter. These single nucleotide polymorphisms (SNPs) affect the promoter activity on transient transfection in human liver cells and are associated with human hypertension in different populations. Since AGT gene is also expressed in the adipose tissue and hypertension is more common in obese subjects, we have examined the role of these SNPs on its expression in preadipocytes (3T3L-1) and differentiated adipocytes. Reporter construct pHAGT1.3luc was constructed by attaching 1222 bp of the 5'-flanking region and 36 bp of the first exon of the hAGT gene to the luciferase gene in the basic vector pGL3luc (Promega). This reporter construct contains nucleoside A at -6, nucleoside C at -20, and nucleoside G at -217 positions. We performed site specific mutagenesis to convert nucleosides at each position and nucleotide sequence of the mutagenized construct was confirmed by sequence analysis. These reporter constructs (500 ng) were transiently transfected in preadipocytes, and three and six days differentiated adipocytes at 80% confluency in six well plates using Fugene reagent. Promoter activity was analyzed by luciferase assay after 48 h of transfection. Results of our experiments show that nucleoside A at -6 in the hAGT promoter had 1.9, 2.5, and 3 fold increased promoter activity in pre-adipocytes, three days and six days differentiated adipocytes respectively. Nucleoside C at -20 had 3 fold increased promoter activity in pre-adipocytes and three days differentiated adipocytes, and 3.5 fold increased promoter activity in six days differentiated adipocytes. On the other hand nucleoside A at -217 had 1.5 fold increased promoter activity in pre-adipocytes as well as differentiated adipocytes. In conclusion, we show that reporter constructs containing nucleoside A at -6, C at -20, or A at -217 in the hAGT gene have increased promoter activity in preadipocytes and differentiated adipocytes. Supported by grants from NHLBI and Phillip Morris foundation.

INFOGENE: AN IST PROJECT FOR THE CREATION OF AN INTERACTIVE PLATFORM FOR PERSONAL GENETIC PROFILE CONSTRUCTION AND DECISION SUPPORT. R. DUNLOP¹, C.

VERELLEN-DUMOULIN², X. FABRE³, E. VAN HIMBERGEN⁴, C. KONIALIS⁵, C. PANGALOS⁵. 1) INFERMED LTD, LONDON, United Kingdom; 2) CENTRE DE GENETIQUE HUMAINE, CLINIQUES UNIVERSITAIRES SAIN-LUC, BRUSSELS, BELGIUM; 3) VITAMIB SARL, MEYLAN, FRANCE; 4) POCKET AND SOUL BVBA, ANTWERP, BELGIUM; 5) DIAGNOSTIC GENETIC CENTER, ATHENS, GREECE.

Citizens with genetic concerns are often confronted with information that is difficult to understand. They may be unable to find appropriate answers to their questions. As a result those people who are not necessarily at risk place additional burdens on geneticists services. Other people who could be genuinely at risk from genetic disease can remain unaware of their possible risks and as a consequence they do not visit a specialist when they should. For both categories of people, the lack of information about genetics represents a gap between the modern scientific world of genetic knowledge and the general public. In order to fill this gap, INFOGENE, an IST project funded by the European Commission, is currently under development. The basic aim of the project is to provide general and, to a much greater extent, personalised user-specific genetic information. The INFOGENE system components are: 1) FrontDoor, a public web site providing the general and personalised information to the public, 2) InfoGenie, a personal software component to hold an individuals private information, 3) GeneAdvisor, a state-of-the-art medical decision support component that will produce personalised advice, 4) GeneKiosk, a knowledge database which will hold accredited information on genetic diseases, family factors, genetic testing, predictive genetics, and other genetic data. The genetic information included in the system, will be regularly updated and validated by, or under the supervision, of an editorial board of geneticists and healthcare professionals. At the end of the project, the system will contain the necessary technological components and sufficient medical content for convincing demonstrations.

Program Nr: 1397 from the 2004 ASHG Annual Meeting

Portable Mendelian Inheritance in Man Database: pdaMIM. *D.W. Stockton.* Dept Molec & Human Genetics, Baylor College Medicine, Houston, TX.

The Mendelian Inheritance in Man (MIM) is an indispensable collection of information on inherited disease that is publicly available through the Internet (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM>). Although access to this resource is becoming more convenient with increasing availability of computers in clinical settings and wireless networking, there are still many situations in which review of these data is desired but no Internet access is available. To increase the availability of this information a port of the database to a personal data assistant (PDA) was proposed. There are many technical challenges including the limited storage capacity and processor speed of PDAs. To minimize the limited storage capacity issues, several strategies were employed including fragmentation of the reference data and data compression techniques. To improve performance an indexing system was devised for performing searching of the records. An application for the Palm OS, called pdaMIM, was developed for viewing the database and a companion application to convert the format of the database to be compatible with the PDA. The application on the PDA is able to manage and integrate any data of similar structure as the MIM data through the MIM number reference. As an example an application to convert the Frequency of Inherited Disorders Database (<http://archive.uwcm.ac.uk/uwcm/mg/fidd/>) was developed to instantly associate the disease frequency data available with the other information available for a MIM entry. Continued performance and feature enhancements to the pdaMIM application are planned as well as extending the data available.

The Psychological Impact of a Variant of Uncertain Significance Test Result in BRCA1 and BRCA2 Clinical Testing. *B.W. Althaus, G. Ethington, J.L. Blum.* Baylor-Sammons Cancer Center, Baylor University Medical Center, Dallas, TX.

Purpose: Previous research in genetic diagnosis has shown that uncertainty of diagnosis can be uncomfortable and sometimes distressing for patients to experience. The purpose of this study was to determine the psychological impact of a variant of uncertain significance in clinical testing for hereditary breast and ovarian cancer syndrome. **Methods:** Study participants were recruited from a large hereditary cancer risk program in which cancer education, risk assessment, genetic counseling and a discussion of test results were provided. Hereditary cancer risk program participants (118) who received testing results in the following categories: positive for a deleterious mutation (36), negative for a deleterious mutation (46), and variant of uncertain significance (36) completed questionnaires to determine the impact of the test result. Data from the Quality of Life, Enjoyment and Satisfaction Questionnaire, the Hopkins Symptoms Checklist and the Mishel Uncertainty in Illness Scales were compared to measure the impact of an uncertain test result on the participant. **Summary of Results:** Participants diagnosed with a mutation of uncertain significance scored significantly different from the participants who received laboratory analysis of the presence or absence of a deleterious mutation. Quality of life and psychological distress were not significantly different between study participants who received diagnostic results that were positive, negative, or uncertain for a deleterious mutation. Uncertainty cannot be removed from the testing process, but psychological distress and a decrease in quality of life appear to be prevented by effective communication as shown by these results. Genetic counseling that thoroughly educates and prepares the participant for possible test results and their implications can lessen distress caused by positive or uncertain test results.

Program Nr: 1399 from the 2004 ASHG Annual Meeting

Patient Preferences Regarding Recontact by Cancer Genetics Clinicians. *C.A. Griffin, J.E. Axilbund, A.M. Codori, G. Deise, B. May, C. Pendergrass, M. Tillery, J.D. Trimbath, F.M. Giardiello.* Sidney Kimmel Cancer Center at Johns Hopkins University, Baltimore, MD.

Background: Advances in cancer genetics have lead to new opportunities for early disease detection, predictive genetic testing, & potential interventions. Limited information exists of patient preferences concerning methods of recontact to provide updated information. We hypothesized that colon cancer genetics patients wish to be recontacted about advances in medical genetics.

Methods: We mailed information to 495 individuals (including parents of 32 minors) seen at the Colon Cancer Risk Assessment Clinic at Johns Hopkins between 1996-2003. Included were: letter describing advances in gene testing technology & discovery of MSH6 & MYH genes; detailed fact sheets; & a 15-question survey of patient preferences for notification of & potential uses of new information.

Results: As of 6/1/04, 146 surveys (29.5%) were returned; 60 (11.9%) were undeliverable. 88.4% of those surveyed (S) & 90.4% of responders (R) were Caucasian, 48.8% (S) & 48.6% (R) were male, and mean ages were 51.6 (S) & 53.3 (R) yrs. Most answered that an ongoing relationship between genetics providers & patients should continue (77.3%); that it is the primary responsibility of genetics providers to initiate this contact (69.9%); & that contact should occur only when relevant to the patient (40.4%) or when new discoveries are made (34.9%). Most preferred personalized letters as a means of contact (61.0%). Reasons for/against recontact & circumstances in which individuals would pursue additional genetic testing were also tabulated.

Conclusion: People who have sought evaluation in a colon risk assessment clinic want updated information. This has implications for the consultative nonlongitudinal nature of such clinics & suggests patient preferences for personally-tailored information could be labor intensive. Comparison with responses of 357 participants in a colon cancer gene testing study, along with an estimate of cost of recontact, will be reported. (NCI5U24CA78148).

Perceived ovarian cancer risk: No impact of genetic counseling and testing. *K. Kelly¹, G. Ozakinci², H. Leventhal², M. Marvin³, D. Toppmeyer⁴, J. Baran⁴, M. Schwalb⁵.* 1) Univ of KY, Lexington, KY; 2) Rutgers Univ, New Brunswick, NJ; 3) Spectrum Health, MI; 4) CINJ, New Brunswick, NJ; 5) UMDNJ, Newark, NJ.

Understanding perceived risk of ovarian cancer (PROC) is important as PROC has been linked to ovarian cancer screening and bilateral prophylactic oophorectomy. Hence, individuals need accurate PROC to engage in optimal cancer management strategies. However, PROC has been largely neglected in the context of genetic testing for hereditary BRCA1/2 mutations. The current study is the first to: 1) explore new and theoretically-driven ways to conceptualize PROC; 2) examine change in PROC throughout the process of genetic counseling and testing; and 3) examine the differences between PROC and BRCAPRO model estimated ovarian cancer risk in those testing for BRCA1/2 mutations. Participants were 87 Ashkenazi Jewish women with and without a prior cancer at risk for hereditary BRCA1/2 mutations. PROC (percentage risk; projected age of ovarian cancer onset; survival time with ovarian cancer) was assessed at pre-counseling, post-counseling, and post-results. Repeated measures ANCOVAs were conducted to examine change over time and between-group differences (prior cancer and test result) controlling for age and BRCAPRO model estimated risk of having a mutation. Power analysis indicated our sample size was sufficient to detect small effects. No change in any measure of PROC from pre- to post-counseling or from post-counseling to post-result was detected. For those with no personal cancer history (n=43), PROC: percentage risk was compared to BRCAPRO model estimated ovarian cancer risk to determine the accuracy PROC. Accuracy of PROC did not improve from pre-counseling (mean overestimate: 22%) to post-counseling (mean overestimate: 17%) or from post-counseling to post-result (mean overestimate: 14%). In conclusion and in contrast with our studies of perceived risk of breast cancer, neither genetic counseling nor genetic testing influenced PROC. Innovative methods for communication of ovarian cancer risk are needed in order to increase the likelihood that women will engage in appropriate ovarian cancer risk management strategies.

Initial development of an Adult Medical Genetics Program. *A.C. Sturm¹, S.M. Fitzgerald¹, P.K. Binkley², E.A. Sparks², C.F. Wooley², M.T. Scheuner³, C. Eng¹.* 1) Div Hum Genet, Ohio State Univ, Columbus, OH; 2) Div Cardiovasc Med, Ohio State Univ, Columbus, OH; 3) Office of Genomics and Disease Prevention, CDC.

Over the last 6 months, the Ohio State University (OSU) Medical Center Division of Human Genetics formed The Adult Medical Genetics Program. This Program complements OSU's Clinical Cancer Genetics program by offering consultations for all other adult-onset medical genetics conditions, focusing primarily on cardiovascular, pulmonary, and benign hematological genetic conditions initially. Patients are referred for a comprehensive genetics consultation, where they meet with both a genetic counselor and physician as part of a virtual multidisciplinary clinic. In order to inform central Ohio physicians of this unique clinical offering and to facilitate appropriate referral of patients, the following steps were taken. Indications for referral fact sheets were developed for cardiac, pulmonary, and benign hematological genetic conditions and distributed to all faculty and staff within the Departments of Internal Medicine and Family Medicine at OSU and were mailed to 230 cardiologists and pulmonary specialists in Franklin and surrounding counties. The Director and senior adult genetic counselor visited the Divisions of Cardiovascular Medicine, Pulmonary Medicine, and Hem/Onc at OSU in order to educate these physicians about appropriate indications for referral. A Familial Cardiovascular Risk Assessment Tool was developed to screen patients at an OSU Congestive Heart Failure Clinic. This tool incorporates information about specific diagnosis and age at diagnosis on all 1st- and 2nd-degree relatives of the proband; a list of 22 medical conditions associated with cardiovascular disease facilitates ease of use. The completed tool is then used for triage of high risk patients to the Program for a complete genetics consultation. The tool is designed to ascertain families with a high risk of coronary artery disease, familial cardiomyopathies, arrhythmias, aneurysms, clotting disorders, and other genetic cardiovascular conditions. Thus far, a family with long QT syndrome and several families with either dilated cardiomyopathy or high risk coronary artery disease have been evaluated.

Raising awareness of behavior in genetic syndromes and fetal alcohol syndrome in foster care, changes parental framework for discipline. *R.B. Sampilo*¹, *A. Perszyk*². 1) Child Guidance Center, Jacksonville, FL; 2) Pediatric Multispecialty Ctr, Univ Florida, Jacksonville, FL.

Children in foster care may have speech problems, ADHD, history of maternal drug or alcohol abuse, or behavioral genetic syndromes. Information may not be maintained in a child's file. Awareness of the learning style and behavior concerns present in particular syndromes can change the disciplinary styles of house parents and influence long-term outcome, placement and successful rearing. Purpose: To teach awareness of different disorders, individual temperaments, and cognitive limitations to youth care workers, foster parents and case managers to influence individual behavior programs, improve placement and support long-term care plans. Method: Over a ten-year period, efforts to educate the foster parents, counselors, social workers and therapists with lectures and handouts, given to individuals, local or state agencies and programs that serve the foster care system. Additional, short-term programs to raise the knowledge base and better support those in the frontline of providing services for these children - often in areas with high turn-over. Questionnaires were given before and after lectures to assess short-term responses. Long-term follow-up was by phone call or direct face-to-face interview. Significant impact was found in the planned discipline program for the child. Secondary effects, such as school programs that were modified in like manner show carry-through of these disciplinary styles. Short-term indicators were measured in a limited study. Conclusion: Tangible responses could be measured from the social workers and youth care givers that work with disadvantaged youth. Straightforward talk with handouts, Internet website links, and useful tips for those dealing with children is a practical way to improve awareness and influence the treatment options. Continued support to help social services should be looked at regionally. Regional differences may vary but a positive response is expected based on the limited assessments reported.

Counseling the families of two patients with atypical phenotypes following the prenatal diagnosis of Turner syndrome. *C.T. Dvorak¹, C. Techakittiroj¹, H.C. Andersson^{1,2}, G. Pridjian^{1,2,3}, M.M. Li^{1,2}.* 1) Human Genetics Program, Tulane Sch Medicine, New Orleans, LA; 2) Dept of Pediatrics, Tulane Sch Medicine, New Orleans, LA; 3) Dept of OB-GYN, Tulane Sch Medicine, New Orleans, LA.

We counseled the families of two patients born with unexpected phenotypes following a prenatal diagnosis of 45, X (Turner syndrome) by amniocentesis. Patient A presented as a small for gestational age male with minor dysmorphic features (flat nasal bridge, midface hypoplasia, preauricular pits) and normal male genitalia. A peripheral blood chromosome analysis confirmed a karyotype of 45,X at the 650 band level. Subsequent FISH analyses revealed an unbalanced cryptic translocation between the short arm of the Y chromosome (containing the SRY gene) and the long arm of chromosome 15. Patient B was born with ambiguous genitalia (clitoral hypertrophy). A peripheral blood chromosome analysis revealed mosaicism of three cell lines: 45, X (8/25 cells), 46,XY (5/25 cells), and 46, X +mar (12/25 cells). A FISH analysis with X and Y chromosome specific probes demonstrated that the marker had originated from the Y chromosome. These cases illuminate the complexity of prenatal diagnosis and the need in routine prenatal care for referral to genetic specialists, who are able to provide informative, nuanced interpretations of test results. We discuss the clinical and psychosocial challenges faced when interacting with families confronted with unexpected clinical outcomes.

Self-Concept in Carriers of Balanced Chromosomal Rearrangements & the Perceived Impact of Genetic Make-Up on Self-Concept. *A. Thomas^{1,5}, D. Chitayat^{1,2,5}, E. Winsor^{3,5}, A. Kaiser⁴, C. Shuman^{1,5}.* 1) Clinical and Metabolic Genetics, The Hospital for Sick Children; 2) Prenatal Diagnosis and Medical Genetics, Mount Sinai Hospital; 3) Laboratory Medicine & Pathology, Mount Sinai Hospital; 4) Haematology & Oncology, The Hospital for Sick Children; 5) University of Toronto.

Self-concept is defined as how an individual perceives him or herself; some concern has existed in the genetic counselling profession that an individual's self-concept may be negatively impacted by one's genetic carrier status. The purpose of this study was to explore self-concept within a genetic context and had two main aims: 1) to measure the self-concept of carriers of balanced chromosomal rearrangements 2) to determine the perceived importance of genetic make-up on sense of self. The Tennessee Self-Concept Scale (TSCS) was used to measure self-concept. An additional questionnaire, entitled Self-Concept and Genetic Make-up (SCGM) was developed and used to examine the perceived impact of genetic make-up on self-concept. Twenty-six carriers of balanced chromosomal rearrangements and 41 control individuals completed both questionnaires. Results indicated no significant differences between the carriers and controls on the TSCS responses. This suggests that self-concept is not affected by the knowledge that one is a carrier of a balanced chromosomal rearrangement. The results of the SCGM questionnaire indicate that neither carriers nor controls consider their genetic make-up highly important to self-concept. However, carriers and controls varied significantly on their perceptions of the role of genetic make-up with regard to the physical aspect of self-concept; controls perceived the role of genetics as stronger ($p=0.002$). This decreased perception of genetic make-up on physical self-concept in carriers could be due to having been informed that being a carrier would not pose any health-related risks. The reliability of the SCGM scale was adequate but not ideal for clinical research. The data from this study indicate that self-concept is not affected by knowledge of carrier status, and that genetic make-up is not a primary consideration for individuals when they appraise themselves.

Program Nr: 1405 from the 2004 ASHG Annual Meeting

TELEGENETICA: AN ONLINE CONSULTATION SERVICE FOR HEALTH PROFESSIONALS. *M. Del Campo, B. Gener, J. Del Valle, V. Rodriguez, L.A. Prez Jurado.* Genetics Unit. Dept of Experimental Sciences, Universitat Pompeu Fabra, Barcelona, Spain.

Telegenetica (www.telegenetica.org) is an online consultation service in clinical genetics open to registered professionals who seek diagnostic support or specific information for a patient in Spanish. The website contains specific forms to guide non-genetics specialists in the clinical history and examination steps. The consultations are directly replied by board-certified genetics specialists. For those cases without a firm diagnosis, the patients are included in an online discussion board of collaborating specialists, integrated in a Network of Genetics Centers in Spain (www.recgen.net). The project has initiated a collaboration with Teledismorfologia, a similar project based in Chile who serves several Latinamerican countries. The program is also directly linked to Orphanet, the European online encyclopaedia and database of services in rare disorders (www.orpha.net). During the initial 18 months of Telegenetica, 179 health professionals have registered: mostly physicians, but also biologists, pharmacists, teachers, psychologists or nurses. Paediatricians, obstetricians, geneticists and family doctors submitted most consultations. A specific diagnosis has been established for over 50% of cases submitted. A satisfaction questionnaire for participating professionals and patients, and a pilot study for the blind evaluation of the patients referred online is being currently completed. The service is presented to the patient as a confidential and anonymous specialist consultation, but the referring doctor is responsible for providing genetic counselling or referring the patient to a Clinical Genetics service. According to all stakeholders in the project, Telegenetica is providing efficient diagnostic support and accurate genetic counselling to professionals and patients, as well as contributing to education in Genetics of other specialists. Telegenetica is funded by Novartis and Fondo de Investigaciones Sanitarias (FIS): proyecto PI021009 and Red de Centros de Genética Clínica y Molecular (C03/07).

Program Nr: 1406 from the 2004 ASHG Annual Meeting

Comparison of questionnaire and counseling family history information. *J.R. Sprague, W.C. McKinnon, M.E. Wood.* Hematology/Oncology, University of Vermont, Burlington, VT.

Purpose: An accurate cancer family history is an important tool in identifying syndromes and making decisions regarding genetic testing. We sought to assess the accuracy of our family history questionnaire by comparing data obtained in the questionnaire regarding cancer diagnoses to that obtained by the genetic counselor sitting with the patient. **Methods:** From 1995-now more than 700 families have been seen in the Familial Cancer Program Clinic associated with the Vermont Cancer Center. Charts from 100 families were chosen at random for this study. Questionnaire and genetic counselor data regarding individuals diagnosed with cancer and age at diagnosis were entered into a database. 1st and 2nd degree family member information was entered regardless of cancer history. 3rd degree family members were included only if they had cancer. Comparison was made between cancer cases identified by both methods. **Results:** The genetic counselor identified more total family members compared to the questionnaire (1855 vs. 1663) and fewer cancer cases (562 vs. 578). 54% of charts showed no difference between the total numbers of cancer cases reported by either method. 81% of charts had a difference of one or less, reported cancer case between the two methods. Exclusion of 3rd degree relatives increased this to 97%. 92% of charts had a difference of two or less reported cancer cases (98% if 3rd degree relatives excluded). The number of family members reported to have multiple cancers was nearly identical between the questionnaire and genetic counseling sessions (57 and 58 respectively). Closer examination of the data reveals that approximately 15% of the time, the affected individual was different in the questionnaire compared to that identified in the counseling session. **Conclusions:** This family history questionnaire appears to be a relatively accurate tool for obtaining a family history of cancer, future efforts will focus on the accuracy of cases reported (individual identified and pathology). Having a family history prior to genetic counseling sessions will lead to a more productive session and should be routinely done.

The Nowgen network: an on-line system to promote collaboration and information exchange within the human genetics community. *A.C. Rose^{1,2}, W.S. Johnson², G. Wainwright², J. McQuillian², H.R. Middleton-Price¹, D. Donnai¹, R. McDermott¹.* 1) Nowgen, St Mary's Hospital, Manchester, United Kingdom; 2) MerseyBIO, Crown Street, Liverpool, United Kingdom.

Nowgen aims to ensure that developments in human genetics research and thinking are successfully applied and widely understood. However, obstacles to this include difficulties in finding both up-to-date, relevant information and expert, collaborative partners. To address these issues, Nowgen and MerseyBIO have worked together to develop a technologically advanced website. Within the site, called the Nowgen Network, virtual 'communities' are being formed to support inter-institutional and interdisciplinary genetics initiatives, with members of the Nowgen team working closely with communities to support their use of the system. Initially, a number of pilot communities are being setup to focus on clinical, ethical, legal, scientific and educational issues associated with genetics. From a single point of access, users can utilise powerful tools, allowing them to identify partners, obtain expert advice and retrieve personalised, current information. Automatic information retrieval tools use advanced software that can search web pages and many different file types. Community interactions are supported by features including multi-user, real-time conferencing and chat facilities. Importantly, the website can accelerate information retrieval, support collaborations without geographical limitations and facilitate the dissemination of knowledge in support of the genetics community.

Orofacial clefts: Do mothers of children know why it happens? A case study. *M. Obara¹, T. Mosby^{1,2}, H.S. Oh¹, T. Pawar¹, A. Shaw¹, M.M. Tolarova¹.* 1) Craniofacial Genetics, Department of Orthodontics, University of the Pacific School of Dentistry, San Francisco, CA; 2) Pediatric St. Jude Children's Research Hospital 332 N. Lauderdale, Memphis, TN.

Cleft lip and palate are common, serious birth defects whose etiology is still not completely understood. A vast majority of studies are focused on analysis genetic factors, lifestyle, nutrition and other well defined factors. This pilot study explores as clues to the etiology of clefts the knowledge, beliefs, and reports of environmental exposures. All data for this study were collected through personal interviews with the mothers of cleft children during the Rotaplast missions to Guatemala City and Antigua Guatemala during the years 2001-2004. Our population consisted of 448 Guatemalan mothers of children with nonsyndromic cleft lip with or without cleft palate. Out of 449 mothers interviewed, 304 mothers (67.86%) answered the question: Why do you think your child was born with a cleft? The most common response to that question was that they didn't know the cause of the anomaly in their child (36.17%). A most common answer, after excluding those who didn't know, was the eclipse (23.03%). Other responses were: a lack of vitamins and other nutritional factors (12.5%), and heredity (11.19%). Interestingly, same percentage (34 %) of mothers of cleft lip and palate children and mothers of cleft lip children suspected the eclipse to cause a cleft. These findings raise many questions: Why is it such a popular answer? Is this a cultural belief or is there an association through some genetic or environmental factor that we do not know? For example, are mothers with a family history of clefts more likely to have received through many generations, a traditional explanation such as an eclipse? Is this answered confounded by the mothers education? These and other clues will be analyzed, controlling for known factors (low socioeconomic factors, poor nutrition, familial occurrence of a cleft) and will lay down a cultural background for the interpretation of other genetic-environmental causes of clefts. The fieldwork for this study was supported by Rotaplast International Inc.

Educating genetic counsellors in Australia: Developing an international perspective. *M. Aitken*^{1, 4}, *M.A. Young*², *L.J. Sheffield*^{3, 4}, *M. Sahhar*^{3,4}. 1) Genetics Education Unit, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 2) Peter MacCallum Cancer Centre, East Melbourne, Victoria, Australia; 3) Genetic Health Services Victoria, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 4) Department of Paediatrics, University of Melbourne, Parkville, Victoria, Australia.

The demand for genetic counselling services is increasing worldwide. The development of the education and training process in Australia has been different to those of other countries namely the United States of America (USA), the United Kingdom (UK) and Canada. In Australia the profession of genetic counselling has developed over the last 25 years. Based directly on the American model of working in a team with the clinical geneticist, the training has, due to local geographic, health care system and educational factors, evolved differently. Nevertheless, the core competencies of the profession are similar to those developed in other countries, notably the UK and the USA. A new Australian set of core competencies is proposed. The major difference with the Australian genetic counselling programs is that they are a 1-year graduate diploma course as opposed to a 2-year masters program. One of the reasons for this related to the pressing need for trained genetic counsellors who were then available to complete their clinical training while on the job. This is proposed as a model for genetic counsellor training in other countries, especially developing countries. To this end, there is the potential for an Australian role in training genetic counsellors in South East Asia. Nevertheless, changes to the Australian education system in the past five years and increasing numbers of genetic counselling graduates mean that there is a possibility for the Australian system to consider moving to a 2-year masters program. This would also enable dialogue to continue regarding genetic counselling certification and reciprocity between Australia and other countries.

FAMILY COMMUNICATION OF PROSTATE CANCER RISK: A PILOT STUDY. *M. Alvarado*¹, *K. Siegmund*², *J. Fauror*³. 1) Kaiser Permanente, Pasadena, CA; 2) USC/Norris Comp. Cancer Center, Los Angeles, CA; 3) Genzyme Genetics, Long Beach, CA.

Prostate cancer (PC) is the most common non-cutaneous malignancy in males. Approximately 5% to 10% of PC, and a higher proportion of early onset cases (Bratt, et al, 1999), may be due to dominantly inherited alterations in cancer susceptibility genes. At least half a dozen different loci have been identified in affected families (Nwosu, et al, 2001). Evidence suggests that men with a close relative affected by PC have an increased risk of the disease. Awareness of their increased PC risk and available screening options may lead to earlier diagnosis and increased survival for men with familial risk. We explored factors influencing communication about PC among affected men and their sons and brothers. Two hundred surveys were distributed to a convenient sample of PC clinic patients and support group participants at an NCI-designated cancer center. Forty-four men completed the anonymous 6-page survey that included questions on demographics, personal and family history of cancer, perception of PC heritability and perception of their relatives' PC risk. Participants had a mean age of 69.4 years and most were Caucasian. Two-thirds were recruited from support groups. Thirty-three of the 44 participants had living brothers or sons, and most reported speaking to their relatives "a few" or "many times" since their diagnosis (79% for sons, 69% for brothers). Most participants (73%) believed that PC can run in families and overestimated the proportion of PC that is inherited ("60%-69% of PC is inherited" was the most common answer). Nine (20%) men reported that one of their physicians discussed the PC risks of their relatives, and this proportion was higher for those with a family history of PC. Conclusions: The majority of men in this study communicated with their sons and brothers about PC, regardless of the family history of cancer. Few reported any barriers to communication. Since most participants came from PC support groups our sample may be biased. Educational tools about familial PC risk may help physicians who care for men with PC in counseling their patients regarding family history and PC.

Women's attitudes toward testing for fragile X carrier status: a qualitative analysis. *A.E. Anido¹, L.M. Carlson², L. Taft¹, S.L. Sherman¹.* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Rollins School of Public Health, Emory University, Atlanta, GA.

Fragile X syndrome (FXS) is primarily due to a repeat expansion mutation found in the FMR1 X-linked gene. We have conducted a qualitative analysis of responses from women concerning their attitudes toward testing for carrier status of the fragile X mutation among reproductive-age women. We obtained responses from focus groups including women with and without FXS in their families. We found the following themes: 1) the motivation for carrier testing and need for information differed by family history of FXS and parental status, 2) the timing of carrier testing with respect to a woman's life stage dictates whether carrier information will be viewed as beneficial or detrimental and 3) mothers of children with FXS have difficulty formulating their opinions on population screening because of their unique experiences surrounding their own carrier diagnosis and their relationship with their children with FXS. There was evidence that non-carrier women from the general population would be wholly unprepared for positive carrier results. These findings have significant implications for genetic counseling as well as for population screening. Preliminary data of in-depth interviews of carrier women from the general population will be presented.

Expectations and satisfaction with genetic counselling services. *F.P. Bernier¹, S.G. Crawford², B. Sibbald³, R. Kohut⁴, D. Dewey^{2,5}.* 1) Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Behavioural Research Unit, Alberta Children's Hospital, Calgary, AB, Canada; 3) Alberta Congenital Anomalies Surveillance System, Alberta Children's Hospital, Calgary, AB, Canada; 4) Calgary Health Region, Calgary, AB, Canada; 5) Pediatrics, University of Calgary, Calgary, AB, Canada.

Objective: To explore novel ways of evaluating and improving genetic counselling services by examining the relationship between patients expectations and their satisfaction with the genetic counselling. **Methods:** This study was a prospective cross-sectional survey in which the expectations and satisfaction of patients seen in an outpatient setting through a Medical Genetics clinic were assessed. Pre-counselling expectations were assessed using the questionnaire by Michie et al.(1997), while the post-counselling questionnaire asked what information was provided to patients at counselling, whether their expectations were met, and also included the Satisfaction Inventory developed by Shiloh et al. (1990). Fifty eight patients completed both questionnaires, and 320 completed the post-counselling questionnaire. **Results:** Overall satisfaction with the genetic counselling service was high (3.69/4.00). No significant correlations emerged between client satisfaction and the expectations ratio (# of services hoped for divided by # of services received), or expecting and being offered DNA testing. A higher total # of services, as well as receiving positive information, was significantly correlated with higher satisfaction scores, however, having previous experience with the condition was significantly correlated with lower instrumental, procedural and total satisfaction scores.

Conclusion: The nature of the information received at the counselling session was an important predictor of client satisfaction, as were patient expectations and previous experience with the condition. Without suitable measures or an understanding of the processes that influence patient satisfaction with the genetics counselling service, implementing improvements to the service remains challenging.

Birth Prevalence of Cleft Lip with or without Cleft Palate in Asian Populations: A Meta-Analysis. *M.E. Cooper¹, J.R. Sank², M.L. Marazita¹*. 1) Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Division of Genetics, Department of Pediatrics, University of Florida.

Cleft lip and cleft palate are among the most common congenital abnormalities. Reported birth prevalences range from 1/1,000 in Caucasians to as high as 2 per 1,000 in Asians. Accurate estimates of birth prevalence rates are necessary for genetic analyses and genetic counseling. The aim of this study is to clarify the birth prevalence of clefts via a meta-analysis of 45 studies involving non-overlapping Asian populations, representing 12,612,166 total pregnancies (TP=live births and pregnancy losses). The table below summarizes the 95% C.I. on the estimated birth prevalences per 1,000 pregnancies for nonsyndromic (NS) cleft lip with or without cleft palate (CL/P), NS plus syndromic (S), total pregnancies (TP), and live births (LB) only. For All Asians as well as Chinese, Japanese and Other subsets, the birth prevalences are significantly greater than the Caucasian rate of 1.0/1,000. Notably, no C.I. includes the often quoted figure of 2.0/1,000 for Asians which appears to be based on early Japanese studies that included large numbers of pregnancy losses and both S and NS cases. From the table, the S+NS TP CL/P Japanese rates are significantly higher than the Chinese or Other subgroups, but if only NS LB are considered, there are no significant differences among the Asian subgroups. These results demonstrate the extreme importance for current population-based studies of clefts to include careful delineation of syndromes, cleft type (CL, CL+P, CP), and birth status (live births versus pregnancy losses). Supported by NIH GRANT #DE09886.

	All Asians	Chinese	Japanese	Other Asians
S+NS TP CL/P	1.33(1.31, 1.35)	1.26(1.23, 1.28)	1.77(1.69, 1.85)	1.41(1.34, 1.48)
NS LB CL/P	1.19(1.13, 1.25)	1.20(1.11, 1.28)	1.18(1.09, 1.28)	1.22(1.04, 1.42)

Title: Perceived personal control as an outcome measure of genetic testing for hearing loss. *M. Fox¹, A. Martinez¹, B. Crandall¹, N. Shapiro¹, M. Telatar¹, Y. Sininger¹, W.W. Grody¹, L.A. Schimmenti², C.G.S. Palmer¹.* 1) Dept Pediatrics & Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Pediatrics & Genetics, Univ Minnesota, Minneapolis, MN.

Abstract: We have begun a longitudinal prospective study to determine the impact of genetic testing on the EHDI process. Genetic testing for GJB2/GJB6 mutations in infants with hearing loss is offered to parents and results are given through a genetic counseling session. Parents accepting enrollment are given questionnaires to determine parental anxiety and perceived personal control (PPC) to measure the impact of genetic testing at enrollment, 1 month after receiving genetic test results and 6 months later. PPC is divided into three dimensions: cognitive control (the ability to understand genetic test results), behavioral control (the ability to undertake interventions based on the results) and decisional control (the ability to make informed choices that influence a child's future). We present data from 29 parents in 22 families at enrollment and 17 parents in 13 families one month after result disclosure. At enrollment, parents had a mean anxiety score of 40.8 (SD=12.1; 20=low anxiety to 80=high anxiety) and a mean PPC score of 38.6 (SD=5.1). One month after receiving results, parents whose infants received a definitive diagnosis of GJB2/GJB6 related hearing loss were more likely to agree that they understood why their baby had a genetic test, what the test meant for the future and why initial hearing tests suggested that the infant had hearing loss. Parents whose infants received a definitive diagnosis had higher average PPC scores (41.4; SD=3.4; n=7) versus parents who received non-diagnostic test results (38.3; SD=7.6; n=8). Mean anxiety scores did not differ between the groups (38.0 versus 37.6 respectively). These preliminary data suggest that parents who receive a definitive diagnosis of GJB2/GJB6 related hearing loss for their infant may have better perceived personal control. Increasing perceived personal control may improve parents ability to initiate early interventions that can improve outcomes in their children.

Multi-Institutional Survey to Assess the Need for Genetic Counseling in Pediatric Cardiology Settings-Patient Perspective. *D. Gruber¹, R.S. Cooper², J.D. Menasha³, M. Rutkowski⁴, D.T. Hsu¹, J.G. Davis², J.G. Pappas⁴.* 1) Columbia Presbyterian Medical Center, New York, NY; 2) Weill Cornell Medical Center of New York Presbyterian Hospital, New York, NY; 3) Mount Sinai School of Medicine, New York, NY; 4) New York University School of Medicine, New York, NY.

Advancements in human genetics over the last decade have had a tremendous impact on many fields of medicine, including Cardiology, while presenting a substantial challenge for both health care providers and patients. Our earlier study revealed a deficiency in knowledge of genetics and genetic counseling among the Cardiologists we surveyed, and significant differences in their responses to patients psychological concerns. This project sought to evaluate the genetic counseling needs in pediatric cardiology patients and their families. A patient/parent questionnaire (25 questions) was administered to a cross-sectional survey of pediatric patients (N=117) recruited from various pediatric cardiology care settings. The questionnaire for patients affected with congenital heart disease (CHD) or cardiomyopathy was designed to provide the medical community with information on patients' basic perceptions of recurrence risks, the genetics of their condition, and to assess parents and/or patients level of satisfaction with the genetic counseling provided by cardiologists. Additionally, the questionnaire was designed to demonstrate the extent of the patients willingness to share information with other family members, who could also be affected by the condition. The study revealed a deficiency in patients understanding of the genetics of their condition. In addition, patients expressed an interest in having genetic testing and genetic counseling as well as a willingness to share the results of the testing with other family members. In conclusion, the demonstrated willingness of the patients to participate in genetic testing, genetic counseling and to share information with at risk family members emphasizes the need for accurate patient education regarding the genetics of their condition.

Racial Differences in Acceptance of Genetic Counseling Referrals. *S. Hensley-Alford¹, R. Pollack¹, M. Ford², H. Gordon², L. Lamerato¹, J.R. Roberson¹, D.L. VanDyke³.* 1) Josephine Ford Cancer Ctr, Henry Ford Hosp, Detroit, MI; 2) Baylor College, Houston, TX; 3) Mayo Clinic, Rochester, MN.

The purpose of this study is to describe the clinical experience of the Henry Ford Health System (Detroit, MI) genetic counseling clinic with regard to referral uptake following breast cancer diagnosis. Henry Ford Health System (HFHS) is the largest health system in southwestern Michigan and serves approximately 800,000 patients in the region, 35% of whom are African American. The system operates a multi-disciplinary breast cancer clinic (MDBCC) for women with newly diagnosed breast cancer. During the Clinic, family histories are gathered from women and subsequently reviewed by a genetic counselor. Those with a history suspicious for a breast cancer mutation are sent a referral 6 months post-diagnosis to attend genetic counseling. The genetic counselor tracks all referrals made through the MDBCC for acceptance of genetic counseling. From January 1, 1999 through June 1, 2004, referrals were sent to 233 (61%) Caucasian women, 141 (37%) African American women, and 11 (2%) women of other races. Of those sent a referral, 33 (14%) Caucasian women, 8 (6%) African American women, and 2 (18%) women of other races responded by accepting a genetics consultation. Using the chi-square test, we calculated the associated odds ratio for referral response and the corresponding 95% confidence interval. We found that Caucasians were 2.74 times more likely to respond to referral than African Americans, with a corresponding 95% confidence interval of 1.97-3.81. African American women diagnosed with breast cancer appear to be less likely to attend genetic counseling than Caucasian women diagnosed with breast cancer. Further research is needed to identify the barriers to genetic counseling for African American women.

Asian groups differ in response patterns about relevant health history and perceived causes of disease. J.L.

Holup¹, W.M. Vollmer², E.L. Harris², N. Press³, T.M. Vogt¹. 1) Center for Health Research, Kaiser Permanente Hawaii, Honolulu, HI; 2) Center for Health Research, Kaiser Permanente Northwest, Portland, OR; 3) Oregon Health & Science University, Portland, OR.

The group "Asian" is defined by the U.S. Office of Management and Budget as the original peoples of the Far East, Southeast Asia, or the Indian subcontinent including Cambodia, China, India, Japan, Korea, Malaysia, Pakistan, the Philippine Islands, Thailand, and Vietnam. However, "Asian" is a pan-ethnic identity that is not recognized in Asian countries. The term emerged in the U.S. and blurs national origin distinctions. We questioned whether the broad term "Asian" may be masking differences and hypothesized that groups collapsed within this category differ on health history responses and perceived causes of disease. We tested for differences among Filipino, Japanese, and Chinese adults screened for DNA and blood iron marker abnormalities at the Kaiser Permanente-Hawaii site of the Hemochromatosis and Iron Overload Screening Study (n=594).

Chi-square tests compared the groups on: 1) assigning importance to factors for why "people get sick" (i.e., heredity, the environment, fate or chance, psychological factors, and lifestyle), and 2) answering whether they or their blood relatives have hemochromatosis or iron overload or have been treated by having their blood drawn on a regular basis. In all instances Filipinos were more likely to say they were "not sure" vs. assigning a level of importance or giving a concrete answer, respectively (p.05). Logistic regression controlling for age and gender confirmed that Filipinos differ from Japanese in being "not sure" in all instances (p.05) and from Chinese in all instances (p .05) except "heredity".

In summary, groups that are subsumed in the category "Asian" differ in responses on health history and perceived causes of disease. This may reflect different levels of awareness, or a distinctive response style for Filipinos. These results suggest that genetic counselors working with Asian populations tailor their approach to the specific community being served.

Comparison of two Decision Aids for Hereditary Breast & Ovarian Cancer (HBOC): Knowledge and Decision Conflict in Women and their Family Physicians. *R. Hughes¹, K. McLachlan¹, K. Blaikie¹, J. Liu¹, M. Angen², G. Fick³, A. O'Connor⁴.* 1) Oncology, Univ Calgary, AB; 2) Psycho-social Oncology, Calgary, AB; 3) Community Health Sci., Univ. of Calgary, AB; 4) Epidemiology & Community Health, Univ. Ottawa, ON.

We compared two HBOC decision aids: Canadian Cancer Society (CCS) and Alberta Cancer Genetics Program (ACGP). **SUBJECTS:** New patients (females) referred for HBOC counselling. Referring GPs were eligible if they had no previous contact with the clinic. **METHODS:** Physician/ patient pairs received either the CCS or ACGP decision aids based on GPs gender and year of graduation from medical school. Pre-intervention questionnaires completed and returned prior to receiving the intervention and post-questionnaire. **RESULTS:** 50 GPs invited: 42% declined, 14% no response, 48% agreed. 24 patients invited: 31.3% declined, 14.6% no response, 54.2% agreed. Mean age of participating GPs 49 yr + 13 yr SD. Mean age of patients 42 yr + 14 yr SD; majority married with more than high school education. Patient scores on pre-intervention knowledge questions 35% + 19% SD (CCS) and 30% + 15% SD (ACGP) (t-test $p=0.61$). Post-intervention knowledge scores 50% + 23% SD (CCS) and 90% + 15% SD (ACGP) ($p=0.008$). Increase in knowledge score using paired t-tests ACGP group ($p=0.002$) CCS group ($p=0.29$). GP scores on pre-intervention knowledge questions were 30.6% + 16.7% SD (CCS) and 35.2% + 10.9% SD (ACGP) ($p=0.61$), and post-intervention were 55.6% + 11.1% SD (CCS) and 57.8% + 16.5% SD (ACGP) ($p=0.84$). Increase in knowledge scores not significant using paired t-tests (ACGP $p=0.19$; CCS $p=0.07$). Patient mean scores on Decision Conflict Scale (DCS) were low (<2.5) both before and after the interventions. Factors influencing cancer surveillance choices included test discomfort and opinions of family, friends, doctors and genetic staff. Factors influencing choice for genetic testing included health concerns, family relationships, insurance, test reliability, opinions of doctors and genetics staff. **CONCLUSION:** ACGP decision aid (but not CCS) associated with significant improvement in HBOC related knowledge for patients but not their GPs. Funded by: Calgary Health Region.

Psychosocial Adjustment to Visual Loss in Patients with Retinitis Pigmentosa. A. Levin^{1,2}, D. Jangra¹, R. Thackray^{1,3}, L. Austin¹, A. Ulster^{1,3}, J. Sutherland¹, E. Heon^{1,2}, A. Ganesh⁴. 1) Dept Ophthalmology, M158, Hosp Sick Children, Toronto, ON, Canada; 2) Dept Genetics, Hosp Sick Children, Toronto, ON, Canada; 3) Dept Social Work, Hosp Sick Children, Toronto, ON, Canada; 4) Dept Ophthalmology, Sultan Qaboos University Hospital, Oman.

Objective: To investigate level of psychosocial adjustment to visual loss in patients with retinitis pigmentosa (RP). **Design:** Cross-sectional study. **Methods:** Thirty-three legally blind RP patients participated in the study. Information regarding the patients adjustment to their visual loss was obtained by employing the Psychological Adjustment to Illness Scale (PAIS-SR). Seven psychosocial domains were tested: Health Care Orientation, Vocational Environment, Domestic Environment, Sexual Relationships, Extended Family Relationships, Social Environment, and Psychological Distress. These scores were compared with the psychosocial adjustment of diabetic patients to their illness (normative mean). **Results:** Significantly elevated scores (a high score reflecting poor adjustment) were seen in 4 out of 7 domains and the total PAIS-SR T-Score, compared to the normative mean. The highest relative score was seen in the health care orientation domain (6514, p0.001) followed by vocational function (6111, p0.001), social environment (589, p0.001) and extended family relationships (559, p0.05), respectively. The total PAIS score was significantly elevated (588; p0.001) compared to the normative mean. **Discussion:** Patients with RP have difficulties in adjusting to their visual loss particularly with respect to health care orientation, vocational environment, social environment, and extended family relationships. They face more difficulties than diabetic patients in adjusting to their illness. This study identifies problems specific to patients with RP suffering from visual loss.

Parental Attitudes Toward Genetic Testing In Their Infants With Hearing Loss. *A. Martínez¹, M. Fox¹, B. Crandall¹, N. Shapiro¹, M. Telatar¹, Y. Sininger¹, W.W. Grody¹, L.A. Schimmenti², C.G.S. Palmer¹.* 1) University of California Los Angeles, Los Angeles, CA; 2) University of Minnesota, Minneapolis, MN.

We present preliminary data on parental knowledge, understanding of outcomes of genetic testing, and attitudes toward genetic testing for hearing loss as part of a study assessing the timing and impact of providing Connexin26/30 testing and counseling in the Early Hearing Detection and Intervention (EHDI) process. Families with a child under 3y with potential or diagnosed hearing loss and no other conditions are enrolled into the prediagnosis (failed newborn hearing screening, prior to diagnosis) or the postdiagnosis (diagnosed hearing loss) group. Genetic testing is considered in the context of genetic counseling. Results are disclosed in a second genetic counseling session. Parental data are collected after enrollment, 1 month and 6 months post result disclosure. Data on 50 parents (33 families) in the postdiagnosis group are described. Following enrollment the majority of parents understood heterogeneity and inheritance concepts and felt there were benefits of genetic testing. Some parents were concerned about potential harms of testing. 9 babies had biallelic Connexin26 mutations: 1m after disclosure 90% of parents of these babies indicated their child definitely had Connexin26-related hearing loss, and 100% indicated that genetic testing helped them understand the cause of hearing loss, and that the recurrence chance is 25%. Hearing loss of 24 babies was not explained by genetic testing: 1m after disclosure, ~80% of those parents indicated that their child did not have Connexin26-related hearing loss, and 70% indicated that the cause of their baby's hearing loss was undetermined, and that the test did not help them understand the cause of hearing loss. There was considerable variability in their understanding of recurrence chance. Conclusions: Incorporating genetic testing into the EHDI process will be welcomed by some parents. However, implementation should be carefully considered as these results illustrate that testing raises some concerns and that negative results are difficult to understand. Strategies for improving communication of negative results are needed.

Parental Perspectives on the Causes of Autism Spectrum Disorder. *L. Mercer*^{1,3}, *S. Creighton*^{1,3}, *J.J.A. Holden*^{2,3}, *M.E.S. Lewis*^{1,3}. 1) University of British Columbia, Vancouver, BC, Canada; 2) Queen's University, Kingston, ON, Canada; 3) Autism Spectrum Disorder-Canadian American Research Consortium (ASD-CARC; www.autismresearch.ca).

Autistic Spectrum Disorders (ASDs) are complex neurobehavioral disorders with many biologic causes, including genetic, syndromic and environmental contributors. Such etiologic heterogeneity impacts considerably upon a parent's need to understand and have an explanation for their child's diagnosis. A cross-sectional semi-quantitative survey was designed to investigate parental views on the cause of ASD in their child. Such research has not been conducted in almost 10 years and, therefore, recent data is warranted for effective patient support and counseling in the clinical setting. The study surveyed parents with at least one child with ASD. Questions in the survey consisted of various format types such as fill in the blank, dichotomous, Likert response, cumulative/guttman and nominal. Parents were encouraged to include comments. Among the 41 parents who filled out the questionnaire, genetic influences (90.2%), peripartum factors (68.3%), diet (51.2%), prenatal factors (43.9%) and vaccines (43.2%) were considered most contributory to ASD causation. Underlying genetic susceptibilities and triggers by a myriad of environmental factors (e.g. chemicals, food additives, illness during infancy and psychological factors) were frequent assertions by parents. Parents attribute many factors to, and often have strong beliefs about, the cause of their child's ASD. Parents reported inaccurately high recurrence risks, misperceptions of the contribution of various factors, feelings of guilt and blame regarding their child's diagnosis, as well as a lack of advocacy for genetic counseling by non-geneticist professionals. Genetic counseling would certainly benefit ASD families through the provision of information regarding diagnosis, the role of genetics and recurrence risks. This study offers clinicians and researchers further insight into what parents believe contributed to their child's diagnosis of ASD. Supported by research grants from CIHR.

The Use of Preventive Measures Among Healthy Women who Carry a BRCA1 or BRCA2 Mutation. K.A.

Metcalfe^{1,2}, J. Seidel², D. Hanna², C. Snyder³, H. Lynch³, S.A. Narod². 1) Faculty of Nursing, University of Toronto, Toronto, Ontario, Canada; 2) The Centre for Research in Women's Health, Toronto, Ontario, Canada; 3) Creighton University, Omaha, Nebraska.

Introduction: Tamoxifen has been shown to significantly reduce the risk of developing breast cancer in both high-risk women and those with a BRCA1 or BRCA2 mutation. The purpose of this study was to examine uptake rates of tamoxifen in BRCA1 and BRCA2 mutation carriers, to assess concerns about taking the chemopreventive drug, and to assess knowledge about tamoxifen. **Methods:** Women with a known BRCA1 or BRCA2 mutation, with no prior diagnosis of breast or ovarian cancer, were mailed a study specific questionnaire. The questions included in the questionnaire were based on input from health care providers and women seen in the genetics clinics. The items assessed the women's knowledge of tamoxifen, their usage of tamoxifen, and their need for additional information on tamoxifen. **Results:** Eighty-one of 125 eligible women returned the questionnaire (64.8%). Ten women (12.3%) had used tamoxifen and eight women had used raloxifene (9.9%). Twenty-two women (27.2%) had undergone prophylactic mastectomy and 54 women (66.7%) had had an oophorectomy. Twelve women (14.8%) did not recall discussing tamoxifen. Thirty-five women (58.3%) said their doctors had not provided them with sufficient information about tamoxifen to consider its use. Fear of side-effects was the most common reason for not taking tamoxifen. **Discussion:** Although tamoxifen has been shown to be effective in preventing breast cancer in women with a BRCA1/2 mutation, the majority of women choose not to take the drug. Fear of side-effects and a lack of education regarding tamoxifen were reported as the reasons for not taking the drug. Women were much more likely to elect preventive surgery than to take a preventive drug. Health care providers need to be aware of the misconceptions associated with tamoxifen, and provide accurate information about the risks and benefits so that women can make informed decisions about chemoprevention.

Patient knowledge, risk perception, health behavior and interest in genetic counseling and testing for familial melanoma. *K.B. Niendorf¹, B. Somoano⁴, W. Pirl², A. Muzikansky³, A. Sober⁴, H. Tsao^{1,4}.* 1) Center for Cancer Risk Analysis, Massachusetts General Hospital, Boston, MA; 2) Department of Psychiatry, Massachusetts General Hospital, Boston, MA; 3) Biostatistics Center, Massachusetts General Hospital, Boston, MA; 4) Department of Dermatology, Massachusetts General Hospital, Boston, MA.

Mutations in the CDKN2A gene have been identified in 20-40% of melanoma-prone families. Although clinical testing for CDKN2A mutations is available on a commercial basis, published recommendations propose that this genetic testing largely remain as part of research protocols. Provision of these test results, even on a research basis, is aided by an understanding of the patients' baseline genetics knowledge, risk perception, health behavior and interest in genetic testing and counseling for familial melanoma. For this reason, we queried patients with either family histories of melanoma or personal histories of multiple melanomas prior to provision of genetic counseling and testing for CDKN2A mutations. To date, 205 potential participants have been identified and 67 have completed the questionnaire. Prior to receiving genetic counseling as part of the study, most participants reported hearing/reading only a little bit or nothing regarding melanoma susceptibility genes. Sixty-eight percent of participants qualitatively rated their risk as high or very high for having a mutation associated with increased melanoma risk. Nearly all of the participants had at least one clinical skin examination performed in the past year; however, 61% reported being a little or moderately tanned at the end of summer. The majority of participants wished to pursue familial melanoma genetic counseling (64%) and genetic testing (66%). Thus, many individuals with familial melanoma risk indicate a lack of knowledge of melanoma genetics yet feel that they are at high-risk of carrying a hereditary melanoma predisposition genetic mutation. These data suggest that at-risk patients have a need for familial melanoma genetics information while also offering a foundation for understanding the potential utility of genetic counseling and testing.

Evaluating a family cancer registry: Benefits, distress and risk. *S. Petzel¹, A. Leininger², D. Rothenberger², L. Carson¹.* 1) OB-GYN, University of Minnesota, Minneapolis, MN; 2) Minnesota Colorectal Cancer Initiative, Minneapolis, MN.

PURPOSE. Psychoeducational outcomes were evaluated for a Familial Colorectal Cancer (CRC) Registry. CRC patients/family provide family history and receive written CRC and genetic risk- and surveillance-information.

METHODS. A survey mailed to enrollees measured: 1) Registry usefulness, based on Social Learning Theory (Likert scale/1, low-to-5, hi); 2) Lifetime (subjective) CRC risk, estimated by category (Ave, Incr, Hi/word) and linear analogue scale (0-100%/numeric); 3) Emotional distress (Impact of Event Scale and a Likert scale/0, no-to-10, hi). Risk-seriousness and health-demographic information were collected.

RESULTS. Subjects: 41 males and 74 females, primarily increased CRC-risk, Caucasian, ages 25-83 and in 4 health groups: CRC, CRC precursors; non-CRC; no cancer. Most (93%) rated registry pros/cons. Overall usefulness was not correlated with perceived risk, risk-seriousness, distress or demographic-health variables; pros were not correlated with cons. Notable pros: promoting coping and understanding cancer risk; probable barriers: negative attitudes. Cons were associated negatively with education, marital status, income; positively with distress (p.05). Distress was low and not associated with risk-recall accuracy or health-demographic variables except women were more distressed (p.0001). Risk was over-reported; accuracy, low. Word estimation was more accurate than numeric (41% vs 14%; p.003). Risk seriousness (p.0001) and subjective risk (p.02/word, p.0004/%) were associated with distress: the more serious the perceived risk or the higher the risk estimate, the greater the distress.

CONCLUSIONS. Some goals are being met: providing useful information without promoting distress is successful; promoting accurate risk perception less so. Low distress suggests this is not an emotionally vulnerable population or those electing to receive risk information were relatively resilient. In diverse at-risk cancer populations effective genetic education and counseling may require individualized tailoring.

Program Nr: 1425 from the 2004 ASHG Annual Meeting

Genetic and reproductive counselling for multiple sclerosis:current model and pregnancy register. *A.D. Sadovnick.* Prof/Med Genet/Div Neurology, Univ British Columbia, Vancouver, BC, Canada.

While the etiology of multiple sclerosis (MS)remains unknown, there is increasing evidence for a genetic component to both susceptibility and clinical outcome. Confounding factors include overall (not interfamilial) environment, gender of transmitting parent, family structure, and age of onset. In addition, disease modifying therapies (DMTs)are increasingly being recommended to individuals in the very early stages of disease. As MS shows a clear female predilection and strikes during the prime reproductive years, genetic recurrence risk information and reproductive counselling are increasingly being requested. A protocol for such counselling will be presented and will incorporate the most recent information about factors influencing recurrence and the safety of DMTs at conception, during gestation, and when breastfeeding. In addition, the need and paradigm for a disease-specific pregnancy register will be presented.

Prenatal Testing for BRCA1 Mutation. N.Scanlan¹, J.H.Jung¹, P.J. Ainsworth¹, G.Sheridan¹ 1) Cancer Genetics, London Health Sciences Center, London, ON, Canada. *N. Scanlan, J.H. Jung, P.J. Ainsworth, G. Sheridan.* Cancer Genetics, London Health Sciences Center, London, ON, Canada.

Prenatal testing for a familial BRCA1 mutation to determine the risk of an inherited predisposition to breast and/or ovarian cancer in the fetus represents a controversial ethical issue, with a view to selective termination of pregnancy in case of a female carrier. A 34-year-old G1P0 woman was referred for prenatal molecular testing for BRCA1. Two years previously, the woman and her partner had been counselled regarding the identification of a deleterious familial BRCA1 mutation (2561_2562insGC) carried by her partner. At that time the couple questioned the availability of prenatal testing if a pregnancy was achieved. They indicated that they wished to proceed with prenatal testing because they would consider the termination of a female mutation carrier. The couple was seen for additional genetic counselling to discuss medical, genetic and ethical issues related to prenatal BRCA testing and to discuss their reasons for wanting testing in this instance. The couple was referred to an obstetrician, who was aware of the family history, for further discussion of issues related to prenatal screening. The couple achieved a pregnancy and at 11 weeks gestation were seen for counselling related to age risk, chorionic villi sampling, amniocentesis procedures, BRCA inheritance risks and molecular testing options. Both prospective parents requested identification of the sex of the fetus as well as the BRCA1 mutation status. An amniocentesis was performed at 16 weeks gestation and the results confirmed that the mother was bearing a male fetus that was identified as a BRCA1 carrier. This information was provided to the couple who opted to proceed with the pregnancy. The complex medical genetic and ethical issues raised in this case illustrate the importance of close inter-disciplinary collaboration required in prenatal testing for adult onset diseases.

GENETICS MADE EASY Non-profit divulgation web on human genetics. *M.T. Sole - Pujol^{1, 2}, J.M. Carrera², J.M. Cantu³, F. Sole⁴, J. Antich¹.* 1) Centro Genetica Medica, Barcelona (B), Spain (S); 2) Servicio de Medicina Fetal. Instituto Universitario Dexeus, (B), (S); 3) Division Genetica. Instituto Mexicano del Seguro Social. Guadalajara. Mexico; 4) Laboratorio de Citogenetica y Biologia Molecular. Hospital del Mar, (B), (S).

Genetics Made Easy <http://www.lagenetica.info>, is a non-profit informative web on human genetics that has been written with the aim of bringing the scientific community closer to the general population. The web is an excellent complement to genetic counseling and a very useful teaching tool to clinicians and other healthcare professionals, in order to complement medical personal consultations as you will see through the index web, regardless of their area of expertise, as genetically inherited disorders are known across all medical specialties. Supplemented by static pictures and flash animation, at this moment is currently available on the Net in both Spanish and English, and during this year in Chinese. The web contains the information that any couple may need to know before embarking in parenthood, or if they have already children with some type of malformation or hereditary disorder. Additionally, a need arises for the general population of any age to be well informed, starting ideally at school age. The index web is: * Introduction, * The origin of life, * Cell specialization, * Chromosomes, * How do we acquire our inheritance, * What is heredity, * Types of inheritance, * Why do disorders develop, * What happens when our recipes combine with our partners recipes?: here on page 3 through the tree you can explain the specific mendelian risk for a family, complemented by flash animation, and links to look for the specific disease. * And how can we use this vast knowledge and benefit from it: On page 2 you have a tree with all the assisted reproduction techniques that we use at this moment, and in page 3 and 4 some of the risks that they conduct. * Origin of hereditary disorders: Go inside the yellow bar chromosomal disorders. * Prenatal diagnosis techniques: Complemented by flash animation, * Cloning, * Questions, * Links of interest: To be sure people get information from serious places, * Further reading, * Foreword. FORUM.

Pediatricians' knowledge and views on genetic counseling for cancer predisposition. *L. Squirrell^{1, 3}, A. Kaiser^{1, 3}, H. Druker^{1, 3}, A. Novokmet^{1, 3}, S. Meyn^{2, 3}, R. Weksberg^{2, 3}, D. Malkin^{1, 3}.* 1) Haematology/Oncology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Clinical Metabolics and Genetics, The Hospital for Sick Children; 3) Department of Pediatrics, University of Toronto, ON, Canada.

Genetic factors may play a role in a significant proportion of childhood cancers, and genetic counseling for cancer predisposition can accelerate medical intervention and allow advance planning. The pediatrician must often identify a child at risk for cancer, and effectively counsel and refer for genetic testing. We aimed to assess the knowledge, views, current practice and referral behaviours that pediatricians hold of genetic testing for cancer predisposition, and to evaluate the effectiveness of a cancer genetics lecture given at a Genetics CME 3-day update as an intervention tool. A questionnaire was distributed to pediatricians before and after they attended the lecture, and to an expert control group of pediatric oncologists, geneticists and fellows. 34 pediatricians responded to the pre-lecture questionnaire, and 31 to the post-lecture questionnaire (response rates = 60.7%, 55.4%). At this point 19 experts have responded to the questionnaire (response rate = 21.8%). On a knowledge-based test of cancer genetics, pediatricians scored 65.9% [95% confidence interval (CI), 61.1-70.7] before attending the lecture, and 76.0% (95% CI, 70.5-81.5) afterwards. The expert control group scored 76.8% (95% CI, 67.1-86.5). 96.8% of pediatricians felt that it is very important or important to detect genetic disorders in their patients. 100% of respondents did not feel they had sufficient knowledge of genetics to provide accurate counseling on cancer predisposition, yet 51.6% of pediatricians had independently provided genetic counseling, and 90.3% of pediatricians had referred a patient for genetic counseling. The results suggest that pediatricians recognize the importance of genetic counseling for cancer predisposition but may not hold the knowledge to effectively identify, counsel and refer their patients. Educational training is important to ensure cancer genetics services are accessed appropriately.

Counseling in cancer genetics using teleconferencing technology a single center experience of 130 consultations.

M.D. Tischkowitz¹, J. Coelho¹, J. Wiggins¹, L. Pennell¹, A. Arnold¹, J. Nayler², J. Mackay^{1,3}. 1) Clinical Genetics Unit, Institute of Child Health, London, United Kingdom; 2) Medical Illustration Department, Institute of Child Health and Great Ormond Street Hospital, London, United Kingdom; 3) Galton Institute of Genetic Medicine, University College London, United Kingdom.

The demand for cancer genetics services has increased dramatically over the last decade. While tertiary referral centers have been set up in the UK, patients are often long distances from these. Moreover there are few specialists in cancer genetics and time spent traveling to peripheral clinics reduces their work efficiency. We sought to reduce patient traveling time and increase the specialist efficiency by developing remote consultation clinics using real-time videoconferencing technology. The first clinic was set up in August 2002 and rapid expansion has led to the creation of three further telemedicine cancer genetic clinics covering the region. We now have two years experience in using telemedicine for cancer genetics and to date 130 consultations have taken place, 66% breast or breast/ovarian cancer families, 31% colorectal cancer families. Ten consultations were for predictive tests including two in children at 50% risk of Familial Adenomatous Polyposis. A questionnaire-based comparative study with face-to-face consultations showed no significant differences in levels of comprehension, anxiety levels and overall satisfaction with the consultation. We conclude that telemedicine is an effective and efficient tool in cancer genetics which can be used to deliver care over long distances and has the potential to give remote communities direct access to specialist services. We are currently looking to develop international collaborations to establish clinics outside the UK.

The Utility of NF 1 Mutational Analysis in the Clinical Setting. *E.H. Zackai¹, D.M. McDonald-McGinn¹, K.L. Ciprero¹, L. Medne¹, M.K. Maisenbacher¹, B. Korf², L. Messiaen².* 1) Clinical Genetics Center, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Medical Genomics Laboratory, University of Alabama at Birmingham, AL.

We reviewed the utility of NF1 mutational analysis, having a 95% sensitivity in NF1 patients fulfilling the NIH diagnostic criteria during the first 10-month period following its clinical availability in the US. 107 patients clinically evaluated using the NIH consensus criteria were divided into 4 categories: A-clinically unaffected, but presenting with atypical cafe-au-lait (CAL) spots (50); B-segmental NF (4), isolated pseudoarthrosis (2) or isolated plexiform neurofibroma (1); C-clinically affected, fulfilling NIH criteria (17); and D- not meeting criteria requiring follow-up (33). 23/107 had mutational analysis completed. In Category A, 3 patients tested to allay parental anxiety were negative. In Category B, 3 patients (2 likely having segmental NF and 1 with plexiform neurofibroma) were negative. In Category C, 5 patients underwent mutational analysis and a mutation was identified in all of them. In Category D, 12 patients were tested. In 5 children under age 1 year with CALs who were highly suspect, but were too young to have developed additional clinical signs, an NF1 mutation was found. One 7 yo with 3 CALs and axillary freckling had a mutation. In a sporadic 15 yo with CALs and axillary freckling a novel conserved missense mutation was found. Four patients with only CALs were negative. A 33 yo woman with >6 CAL spots was negative for the mutation identified previously in her sister fulfilling the NIH criteria. We believe that mutational analysis is a useful tool when combined with the clinical exam. It can: allay parental anxiety in patients with normal exams and in cases presenting with isolated features such as CAL-spots only, a plexiform neurofibroma or pseudoarthrosis; confirm a clinical diagnosis; and assist in the evaluation of children who are followed over time whose exam is not clear. Furthermore, mutation analysis allows for early diagnosis, eliminating long periods of uncertainty. Lastly, it allows one to provide definitive genetic counseling in clinically diagnosed cases.

Lessons learned: relevance of data warehousing to clinical research. *M. Szybowska, S. Hewson, D. Wherrett, T. Pyle, R. Babul-Hirji.* The Hospital for Sick Children, Toronto, Ontario, Canada.

In a healthcare setting, a data warehouse (DW) is an organized electronic database housing data which may be accessible to clinicians, administrators, information services, and clinical researchers. The DW at our centre was established in 1995 permitting ongoing collection and segregation of data since Oct/96. Today, the DW stores full demographic data for all patients that visited the hospital. Of direct relevance to clinical research, the DW also stores details of patient visits and diagnoses, admission and discharge dates, lab results, procedures and information on attending physicians. The standardized data is updated daily, time-stamped providing the means for historical analyses, and managed so that confidentiality is maintained. Non-confidential reports are available to all hospital staff. Reports necessitating access to confidential information require additional authorization. For ease of manipulation, all reports can be downloaded directly into available software. As part of our approved clinical research, we approached medical records to identify our patient population. As the data maintained by the hospital medical records pertains only to in-patients, we turned to the DW for further assistance. The electronic nature of the DW search allowed us to quickly identify our patient population and review only specific charts to confirm the diagnosis. The DW was able to provide a greater number of patients that met our inclusion criteria, thereby increasing our sample size. This was accomplished by searching lab test data specific to the diagnosis that we were studying and proved to be very effective. Clinical research is key to enhancing health and patient care. The evolution of the DW into the storage headquarters for data is the powerful tool that tertiary institutions performing clinical research have been awaiting. The use of the DW in clinical research may well become the norm in the future. From our experience, the DW dramatically cut down the time necessary to perform a patient population search while providing thorough, inclusive, and up-to-date data. In the long run, data warehouses are of direct benefit to clinical research and healthcare.

Genetic education for individuals at risk for Alzheimer's disease: a pilot study. *L. Cortellini¹, T. Moscarillo¹, R. Go², H. Holt², J. Stoler³, D. Blacker¹*. 1) Psychiatry, Mass General Hosp, Charlestown, MA; 2) Epidemiology, U Alabama, Birmingham, AL; 3) Genetics and Teratology, Mass General Hosp, Boston, MA.

For those at risk for Alzheimer's disease (AD), increasingly complex genetic information is a major concern. To address this concern, we developed educational materials for at-risk individuals and piloted them in a sample of 276 unaffected relatives recruited from a genetic linkage study (mean age 61, sd 9, range 40-81; 26% male; 97% white, 3% black; mean education 15 yrs, sd 3.5). Subjects were assessed at baseline, immediately after a randomized educational intervention (AD genetic educational video + pamphlet vs. the pamphlet alone vs. a placebo pamphlet), and 3-6 months later. We examined self-assessment of AD genetic knowledge, and also constructed three knowledge scores regarding 1) overall genetics, 2) AD genetics, and 3) AD general information. We also constructed two genetic testing attitude scores indicating 1) interest and 2) worry. At baseline, a substantial number (~40%) in all three groups felt they knew nothing at all about AD genetics and few (~10%) felt they understood it fairly well. At follow-up, the placebo group changed little, but both intervention groups, particularly video, improved considerably. With regard to objective knowledge, baseline scores in all knowledge domains were similar across the three groups with a fair to good understanding of general genetics (mean score ~6/9), a poor understanding of AD genetics (~1.5/7), and a fair level of general AD knowledge (~4.5/9). At first follow up, there were modest increases in knowledge of general genetics and general AD in all three groups, but a marked increase (~58%) in AD genetic knowledge among those in the two intervention groups. With regard to attitudes, there was little change in worry in any group, but a marked decrease in interest in both intervention groups, particularly video. Future results will include statistical analysis of these preliminary findings and analysis of the 3-6 month follow-up data. Effective educational methods, like this one appears to be, will be critical to any future treatment strategies entailing genetic testing for patient selection or treatment optimization.

A Pilot Study to Evaluate an Internet-based System of Patient Education and Informed Consent for Genetic Studies. *F. Facio*¹, *P. Young*², *R. Baum*¹, *C. Palmer*¹, *N. Kauff*¹, *K. Hurley*¹, *H. Peter*¹, *A. Schluger*¹, *P. Agre*¹, *N. Ellis*¹, *M. Robson*¹, *M. Paisner*², *P. Manasco*², *D. Wang*², *K. Offit*¹. 1) Clinical Genetics Service, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) First Genetic Trust, Deerfield, IL.

As genomic medicine expands, novel strategies to supplement genetic counseling may be needed. We assessed the feasibility of using a secure Internet-based process of patient education and informed consent for genetic studies. Individuals of Ashkenazi Jewish descent previously counseled in our clinic for *BRCA1/2* learned about colon cancer and the *APC11307K* allele (associated with an increased risk of colon cancer) via an Internet Education Tutorial (IET), including an interactive knowledge questionnaire. After completing the IET, participants accepted or declined testing for *APC11307K* via an electronic informed consent (EIC), and were asked to complete an electronic satisfaction questionnaire (ESQ). Internet services were provided by First Genetic Trust (FGT). 34 individuals enrolled between 2/03-2/04. Participants demonstrated a high level of information retention with 33/34 answering at least 7/9 questions correctly in the knowledge questionnaire. 33/34 accepted testing for the *APC11307K* using the EIC. 14/33 eligible participants completed the ESQ. Of these, 50% preferred receiving genetic education via the Internet than in person. 86% felt the IET was easy to understand and contained all the information they needed to decide about *APC* testing. 86% liked very much/felt OK using the EIC. 57% felt extremely/very confident that their genetic testing information would be confidential when using the FGT system. Overall, 21% reported being extremely satisfied, 57% very satisfied and 21% somewhat/not at all satisfied with this Internet-based system. Psychometric measures are in progress. These findings demonstrate that it is feasible to provide patient education and informed consent for low penetrance genetic markers using an Internet-based system. Future studies are needed to establish the best combination of in-person counseling and computer-based education to meet the informational demands of the genomic era.

A Web-Based Educational Learning Module for Fabry Disease. *J. Feiger¹, C. Barash², M. Taylor¹*. 1) Adult Medical Genetics Program, University of Colorado, Denver, CO; 2) Genetics, Ethics and Policy Consulting.

Background: Fabry disease (FD) is a rare X-linked recessive inherited metabolic condition unfamiliar to many general physicians. As there is now enzyme replacement therapy for this serious condition, there is a need to improve physician familiarity with and understanding of FD. We developed and tested a web-based educational learning module designed to target primary care physicians; the site also contains information intended for patients, families, and consumers with a moderate level of medical literacy. **Methods:** Our goal was to develop an effective yet easy to use, educational introduction to FD. The website contained 5 major topics: overview, signs and symptoms, diagnosis, genetics, and management. Video interviews of FD patients were also included to illustrate barriers to early detection. Educational content was designed to increase indices of suspicion, stress variability of clinical presentation, introduce state of the art disease diagnosis treatment, and general management issues, and improve understanding of the genetic basis of FD. To determine learning effectiveness pre and post-tests were used to measure baseline and knowledge increases. Our study population consisted of 51 internal medicine residents (IMR) and medical students (MS) from the University of Colorado. The content, delivery and effectiveness measures satisfied CME requirements and future users can obtain free CME credit. **Results:** Users spent 30 minutes on average reviewing the content; a 21% improvement in knowledge occurred ($p > 0.001$) across all categories of questions (assessed by pre and post test score differences); males and females showed equal improvements in knowledge scores; IMRs showed greater score improvements than the MSs ($p = 0.002$). Participant feedback was positive and the web-based medium for education was well received by participants. **Conclusions:** Our web-based approach to educating IMRs and MSs about a rare genetic condition resulted in general improvements in short-term knowledge and understanding of FD. Data demonstrate that this tool is effective and satisfying, suggesting that this model could be adapted to other diseases.

Program Nr: 1435 from the 2004 ASHG Annual Meeting

Development of an educational platform in genomic medicine in Mexico. *S. March*¹, *I. Silva-Zolezzi*¹, *U. Lopez*¹, *A. Lopez*¹, *L. Abreu*², *G. Jimenez-Sanchez*^{1,2,3}. 1) National Institute of Genomic Medicine, Mexico; 2) National Autonomous University of Mexico (UNAM), School of Medicine, Mexico; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Mexico develops a national platform in genomic medicine based on the genomic structure of the Mexican population and their medical needs, headed by the National Institute of Genomic Medicine. It includes educational programs for professionals and the general public. The former includes a joint program with the National Autonomous University of Mexico that has led to the first three graduate courses in genomic medicine in Latin America: Introduction to genomic medicine, Genomic applications in pediatrics and Genomic applications in internal medicine (<http://www.facmed.unam.mx/programas/index.html>). These courses review medical implications of genomic medicine in different areas of medicine. Our students have different educational backgrounds, including computational sciences, engineering, nutrition, pediatrics, oncology, chemistry, public health, neurology and, cardiology. Through these courses, students develop research proposals applying genomic medicine to a national health problem. Our program includes over 20 faculty members. These efforts will lead to the first doctoral program in genomic medicine in Latin America in the spring of 2005. Materials from our graduate courses, over 15 publications, 100 video-lectures and other tools for academic use have been incorporated to our web portal (www.inmegen.org.mx). This electronic resource has turned into a major educational tool in genomic medicine for Latin America. In the last 10 months, there has been total of 683,000 consultations with an average of 107 sessions per day. In addition, 37,083 publications and videos have been downloaded from this portal. Over 80% of the users are from Latin America. To ensure participation in this educational platform of faculty and students from across the country, in June 2003 the Mexican Society of Genomic Medicine (SOMEGEN) was founded (www.somegen.org.mx). This educational effort is envisioned as a strategic instrument to support the national platform in genomic medicine developing in Mexico.

Program Nr: 1436 from the 2004 ASHG Annual Meeting

Communication workshops for geneticists: facilitating public engagement. *K. Mathieson, D. Donnai, H.R. Middleton-Price.* Nowgen, St Mary's Hospital, Manchester, United Kingdom.

The medical applications of human genetic research are often in the public eye. At Nowgen (the North West Genetics Knowledge Park) we are committed to engaging in dialogue with the public about these advances; the myths and the reality. In 2002 a survey of BSHG (British Society of Human Genetics) members indicated that a majority would like to spend more time communicating their work with the non-specialist public and many requested further training to help them. In order to encourage members of the BSHG and other geneticists to talk to community groups and schools about their work, Nowgen is running a programme of communication workshops. We ran our first workshop in February and geneticists from a variety of disciplines attended. The workshop included interactive sessions on: becoming more aware of the needs of audiences, making presentations more creative, avoiding using loaded language, finding alternatives to scientific jargon and on facilitating debate. It received positive evaluation and future workshops will be developed based on the findings of this first experience. For all the workshop participants who want to practise their new found skills, Nowgen liaises with a school or community group to arrange a visit.

Program Nr: 1437 from the 2004 ASHG Annual Meeting

Essentials of Clinical Cancer Genetics: Internet-Based Curriculum. A. Matthews, T. Nosek, K. Papp, N. Wolf, G. Wiesner. Dept of Genetics, Case Western Reserve Univ, Cleveland, OH.

Cancer genetics evaluation and testing has changed medical management for at-risk populations. However, the lack of genetics education and experience has left physicians ill equipped to provide up-to-date cancer genetic information to their patients. To improve the education of future physicians, we are developing a dynamic multimedia cancer genetics medical school curriculum, entitled *Essentials of Clinical Cancer Genetics*. This interactive curriculum will be embedded in the Internet-based Case School of Medicine eCurriculum and will provide up-to-date information regarding the principles of cancer genetics and their application to clinical practice, genetic counseling, and patient care. It will also address the ethical, legal, and social issues inherent in counseling for cancer genetics. The text portion of the *Essentials* will be richly supported by illustrations, animations and clinical case studies that will help to illustrate the core objectives as well as more subtle concepts. Video clips and case studies will illustrate complex genetic counseling issues such as concerns and fears about the meaning of a cancer diagnosis, dealing with loss, grief, and discrimination. Students will be tested for competence in cancer genetics factual knowledge, comprehension and problem solving. Students completing the *Essentials* (the Intervention group, N= 140) will be assessed at these three tiers of competency and their performance compared to a group of historical controls, i.e., students who received the current nominal level of cancer genetics instruction without exposure to the *Essentials* curriculum (N=140). Moreover, the interactive nature of the *Essentials* will allow for the use of more innovative testing methodologies. Once completed, the *Essentials* will also be made available to other medical schools or other learners in the future. This work has been supported by NCI R25 CA092357-01A2.

Program Nr: 1438 from the 2004 ASHG Annual Meeting

Making Written Information More Accessible. *S.G. Nicholls¹, H.R. Middleton-Price¹, D. Donnai¹, L.M. Davies^{1, 2}.*
1) The North West Genetics Knowledge Park (Nowgen), St Marys Hospital, Manchester; 2) Health Economics Research at Manchester (HER@M), University of Manchester, Manchester.

The NHS and UK legislation now recognise the importance of involving patients in their own treatment and in NHS policy. Nowgen is committed to an active programme of service user and public engagement. Good communication is critical to fulfilling this objective: a lack of accessible resources reduces our capacity for engaging service users and the public in an informed dialogue. Reviews of information produced by scientists and doctors for the public suggest much of what is written is at a level beyond those to whom the material is targeted limiting its effectiveness and value. The objective of this study is twofold: 1) Review of current resources to develop practical guidelines for producing leaflets that are readable, accessible and acceptable to users of the NHS and the public. 2) To use these guidelines to review a sample of existing leaflets from clinical genetics services in terms of readability and accessibility. These Nowgen guidelines include ways to improve the visual clarity of the document, accessibility of language and document layout and attractiveness. We also highlight alternative options to standard print as a potential way of improving engagement. Initial analysis of information leaflets indicate that they vary in presentation and accessibility. None have met all the guidelines.

Building genomics capacity in the public health workforce in Minnesota: Advice to the Minnesota Department of Health from key people. *K.P. Oehlke¹, M.A. Casey, PhD², R. Krueger, PhD³.* 1) State Genomics Coordinator, Minnesota Dept Health, Minneapolis, MN; 2) Independent Consultant, St. Paul, MN; 3) University of Minnesota, St. Paul, MN.

The Minnesota Department of Health (MDH) is working to build capacity to assure appropriate integration of genomics into public health activities in Minnesota. To better understand what needs to be done related to this, five telephone focus groups were held in May 2004 with 23 people including researchers, educators, public health practitioners, healthcare providers, and healthcare advocates from across Minnesota. The purpose was to solicit input that could be used to shape genomics capacity-building activities. Questions included: 1) What issues are important related to genomics? What are your concerns? 2) What role should MDH play related to genomics? 3) What gathering or meeting format do you find most useful? Issues related to genomics were ranked from one (not at all important) to five (extremely important). The three most important issues were 1) ethical, legal and social issues (ELSI) (4.8/5); 2) public policy issues related to genomics (4.3/5); and 3) genomics in health education, health promotion and disease prevention (4.0/5). Participants advised MDH to provide education and training to audiences within and outside MDH, to provide support to public health practitioners to help them incorporate genomics into their existing programs, to maintain genomics data securely and to have a sound rationale for genomics data collection. Education should focus on basic genomics information, genomics in public health, ELSI, and updates on advances. MDH should support efforts for anticipating ELSI and assuring that public policies balance individual, research and public health priorities. Any meeting on genomics aimed at the public health community should have a defined audience, a clear purpose, a carefully considered venue and something special to attract the desired audience.

Clinical presentation based teaching of the metabolic diseases will speed diagnosis and successful treatment of rare inborn errors of metabolism. *G. Porras, A. Perszyk.* Pediatric Multispecialty Ctr, Univ Florida, Jacksonville, FL.

Metabolic disorders that present acutely in children are rare. Far more common are ingestions, injuries and infections in this age group. Therefore, genetic disorders of metabolism need to be discussed in the differential diagnosis of acutely ill infants and toddlers, to improve early recognition, confirmatory testing, and successful treatment. Purpose: To teach a practical approach to when and where to do metabolic testing. Rapid assessment and initial timing of the acute work-up for a child or infant that presents with altered mental status, hypoglycemia, shock or cardio-respiratory collapse is important to teach in a pediatric residency training program, and to nursing staff at the childrens hospital. Method: Pediatric Emergency Department and Pediatric Intensive Care Unit are supported with 24-hour call coverage utilizing dedicated genetic staff skilled in the metabolic work-up, diagnosis, intervention and treatment. Coordination of core lecture series for the pediatric house staff, critical care fellows, and ICU nursing in-service program. Education of Neonatal ICU attending and nursing staff, as well as the obstetrical attendings and residents all have a role in recognizing a metabolic disorder. Provided are algorithms and initial lab work-up for metabolic disorders for use with a palm pilot device. Conclusion: Awareness of metabolic disorders is the first step in the diagnosis of these conditions. Rapid response to resident calls and attending inquiries has improved the yield of diagnosis, timely interventions, and immediate and long-term outcomes for children that present acutely ill. Residents need access to and support for thinking of genetic and metabolic diseases. Correct diagnosis can yield many benefits to the child, family, future children, and the institution that cares and manages these children. A sensible clinical approach has been the basis for more than 10 years of didactic education. This approach is a significant reason for the correct diagnosis and the long-term treatment and support for children with metabolic disorders.

Barriers to use of cancer family history data by primary care providers. *M. Wood*¹, *A. Stockdale*², *B. Flynn*¹. 1) Hematology/Oncology, University of Vermont, Burlington, VT; 2) Education Development Center, Boston, MA.

Purpose: The cancer family history is key to identifying syndromes and recommending cancer screening. We sought to understand the barriers to obtaining a complete and accurate cancer family history in the primary care setting. **Methods:** Interviews with primary care providers (PCPs) in rural Vermont, urban and suburban Boston were performed by a medical anthropologist (AS). The interviews were semi-structured focusing on medical background, cancer family history taking (attitudes, interpretation, and impact on patient care) and cancer genetics (referral for testing, experiences and educational needs), lasting 45-90 minutes. We report here on responses from the first group of interviews regarding collection and use of family history information. **Results:** To date 18 PCPs have been interviewed (6 rural, 10 suburban and 2 urban). 61% were women and medical school graduation year ranged from 1963-98. Themes from interviews include: PCPs generally regard cancer family history as important but there is no standardized approach regarding content or process. Many PCPs collect limited data using questionnaires and confirm/expand this information in person. Time is an issue in collecting and updating family history. Cancer family history is regarded as most important for decisions about cancer screening; focus is on cancers for which screening is effective (breast, colon, etc). PCPs lack confidence interpreting cancer family histories and few referrals for cancer genetic counseling are made. Providers in urban settings have difficulty getting reliable family history; health care focus is on immediate issues and less on prevention. **Conclusions:** Results from this ongoing study suggest that family history collection focus is largely on data relevant to actions the PCP can confidently recommend (usually cancer screening). Future efforts to educate PCPs will need to focus on collection of accurate and appropriate family history information and clear criteria for referral for genetic counseling. Design of interventions will need to account for PCP focus on the patients immediate needs and the limited time available for each patient visit.

Service user and providers views of appropriate models of clinical genetics service. *L.M. Davies¹, K. Payne², M. McAllister², S. Nicholls², R. MacLeod², H. Middleton-Price², D. Donnai².* 1) HER@M, The University of Manchester, Manchester, United Kingdom; 2) Nowgen, St Mary's Hospital, Manchester, United Kingdom.

A variety of service delivery models exist, with no norm or agreed standard. This study forms part of the Nowgen research programme and aims to elicit users and service providers views about the relevant attributes and process of a service and inform a systematic review of existing service models to develop examples of best practice. Focus groups of user representatives, users and service providers are being conducted to elicit views of what constitutes appropriate and acceptable services. The focus groups were run by a trained facilitator and audio and video-taped. The tapes were fully transcribed. Qualitative analysis with ATLAS.ti software and the constant comparative method was used. Initial results indicate that users described important service attributes as those focussing on individual problems and service providers had a more global view. Examples of attributes that users felt should be provided included: (i) Up to date objective information, provided in a variety of formats tailored to the individual (and family) consulting; (ii) Open access for support and to ask questions, and regular review of the individual and family; (iii) Emotional and practical support to make informed choices; (iv) Advocacy; (v) Hope for the future. Service providers discussed (i) Co-ordination of a variety of screening, health care and social support services to manage the genetic condition; (ii) Counselling and empathy; (iii) Facilitating access to and contact with other people with similar conditions. These results indicate user involvement in the design and evaluation of services is important if user expectations are to be met.

Accounts of `self and `other family relations in genetic counseling for predictive testing. *S.K. Sarangi¹, L. Howell¹, K. Bennert¹, A. Clarke².* 1) Health Communication Research Centre, Cardiff University, Cardiff, United Kingdom; 2) Dept Medical Genetics, Univ Wales Col Medicine, Cardiff, United Kingdom.

Given the familial basis of genetic disorders, clients accounts of decisions about knowing and making known ones genetic status at the stages of decision about testing (DAT) and decision about disclosure (DAD) are rooted in thoughts and potential consequences for other family members. In South Wales, UK, the genetic counseling protocol allows for each clinic session to be a multi-party activity involving not just the individual requesting testing but also other family members. It thus becomes imperative for counselors to find out from the co-present family members what the absent-but-significant others' perspectives might be on the counseling process and outcome. Based on The Wellcome Trust funded project (2000-2004), we analyse 50 audio-recorded and transcribed genetic counseling sessions for HD and HNPCC. Beginning with a demographic map of the participation structure, we identify variations in how self-/other-family relations are constituted in the clinical encounter. Our analytic focus is two-fold. Firstly, we look at how other family members' characters/positionings are talked about in terms of inclusion/exclusion, sharedness/unsharedness, lived histories/future consequences. Secondly, we explore the strategic use of discourse devices such as contrast and reported speech either to endorse or contest various states of affairs. Our data analysis extends the well-established theoretical distinction between 'self' and 'other' to enable a juxtaposition of 'self-family' vs. 'other-family' relational dynamics with regard to the role of partners, siblings, parents etc. At a more specific level we argue that, in the case of DAT, the family relations are articulated using routine accounts (e.g. reproduction, future planning) whereas with DAD, clients' accounting practices are more complex. This complexity can be explained in relation to (1) context-specific familial rights and duties and (2) whether a positive or negative test result is the subsequent outcome.

A randomised trial of the effectiveness of a distraction-based coping intervention for women undergoing cancer genetic risk assessment. *C. Phelps¹, P. Bennett³, K. Brain¹, J. Gray².* 1) Cancer Genetics Service for Wales, University of Wales College of Medicine, Cardiff, United Kingdom; 2) Cancer Genetics Service for Wales, Institute of Medical Genetics, Cardiff and Vale NHS Trust, Cardiff, United Kingdom; 3) Clinical Psychology Department, University of Wales, Swansea, United Kingdom.

Background Studies report that around a third of women experience significant psychological distress when undergoing the early stages of cancer genetic risk assessment, prior to learning their level of risk (e.g. Cull et al, 1999; Fry et al, 2003). Psychological theory and evidence (e.g. Salkovskis & Campbell, 1984; Harvey & Payne, 2002) suggests that cognitive and behavioural distraction techniques may help individuals to control any unwanted intrusive thoughts and reduce distress during this period of waiting and uncertainty.

Method A distraction-based coping leaflet was developed and evaluated through a randomised trial with women referred into the Cancer Genetics Service for Wales. Participants were pre-randomised into either an intervention (distraction leaflet) or control condition (standard information) and completed a postal questionnaire upon referral (T1) and four weeks later, prior to receipt of genetic risk information (T2). 162 participants completed their T1 questionnaires (trial n= 86; control n=76) and 99 participants (n=51 and 48 respectively) completed T2 questionnaires.

Results Analysis of co-variance was conducted using the Impact of Event Scale as the key outcome measure. Amongst women with high levels of distress upon referral, the intervention resulted in significantly lower distress and fewer intrusive thoughts at follow-up than women receiving standard care.

Conclusion The distraction leaflet is an effective intervention for women undergoing cancer genetic risk assessment. The leaflet works by reducing the level of intrusive thoughts about the cancer genetic risk assessment procedure. This intervention may also be appropriate for other aspects of genetic counselling and testing.

The Genetics File: getting the gene into general practice. A. Flouris^{1,2}, C. Gaff^{2,3}, M.A. Aitken^{1,3}, J. Wallace^{1,3}, S.A. Metcalfe^{1,2}. 1) Genetics Education Unit, Murdoch Childrens Res Inst, Melbourne, Victoria, Australia; 2) Dept Paediatrics, The University of Melbourne, Victoria, Australia; 3) Genetic Health Services Victoria, Melbourne, Australia.

A practical genetics educational intervention was developed for general practitioners (GPs)/family physicians in Australia, following a needs assessment responding to greater recognition of the role of genetics in primary care. The intervention includes a resource, available as a printed up-dateable folder, CD-ROM and online, and a highly interactive case-based workshop. Content and format of the resource, The Genetics File, was informed by GPs. It includes sections on: talking with families about genetics (including ethical and counselling issues), familial cancers, haemochromatosis, adult-onset neurological conditions, testing during pregnancy, Down syndrome, fragile X syndrome, cystic fibrosis, newborn screening, glossary, and referral guidelines for familial cancers and clinical genetic services. Content includes information about the condition, which investigations should be performed, family implications, role of GPs in ordering genetic tests and management, when and where to refer, including support groups, and information for families. Resource/workshop content was developed in close collaboration with GPs, specialists and consumers. The educational intervention, attracting maximum Continuing Professional Development points, was rolled-out in July 2003 over 10 months, with a media/mailout campaign targeted to all GP practices in Victoria, and 23 workshops conducted. Evaluation includes a validated questionnaire measuring categories of knowledge, attitudes, skills and behaviour, administered prior to workshop, then 1 and 6 months later. Referrals to clinical genetics services, genetic testing and support groups are also included in the evaluation. These measures combined assess the impact of the intervention on practice of genetic medicine by these health professionals. The mean rating of the intervention by GPs was 8.9 out of 10. Results to date indicate there is a significant improvement in all categories of responses ($p < 0.0001$), which translates to changes in referral practice behaviour.

Virtual labs are the way forward for computer aided Genetics teaching to medical undergraduates: Our experience with VIRTLAB. *P.M. Frossard¹, M.A. Bangash²*. 1) Biological & Biomedical Sciences, Aga Khan University, Karachi, Pakistan; 2) School of Philosophy, University of Leeds, UK.

Virtual (dry) labs are the future of beginner-level medical teaching in Genetics. The high cost and the larger amount of time required in running and maintaining wet labs for medical teaching purposes makes such labs unsustainable in the long run. This is especially the case for medical undergraduates, where only a minority go on to practically employ the experimental skills they learn in medical school. Here we report our experience with VIRTLAB, a virtual laboratory of molecular biology based on the Problem-Based-Learning Pathway (PBL) (Lazzetti et al. *Bioinformatics* 1998; 14 (9): 815-6) VIRTLAB can simulate most of the basic molecular biology techniques: plasmid preparation, restriction enzyme digestion, analytical and preparative agarose gels, DNA cloning and DNA sequencing. We used VIRTLAB to supplement our lectures on Genetics to 2nd year Medical Undergraduates at the Aga Khan University, where we have recently initiated a PBL based curriculum. We designed clinically-oriented case studies involving prenatal diagnosis of a genetic disorder; here the exercises required the students to design experiments and run diagnostic tests on VIRTLAB simulations. A questionnaire delivered after the lab asked students to rate their responses; most found the lab to be highly interactive (79%), simple (75%), fast (86%), providing good feedback (61%) and simulating an actual laboratory well (52%). The overall effectiveness was on a highly favourable scale (81%). VIRTLAB will be of little benefit to those planning long-term career in Genetics research or as physician-investigators. However, its use for medical undergraduate teaching cannot be overemphasized; for this particular cohort, our model of virtual teaching calls for a greater emphasis on dry laboratories and computer simulations together with a sound theoretical background. Our subsequent experience with VIRTLAB and other virtual tools will undoubtedly shed more light on this exciting development.

Program Nr: 1447 from the 2004 ASHG Annual Meeting

The North West Genetics Knowledge Park (Nowgen)-Engagement with Genetic Support Groups. *H.R. Middleton-Price¹, D. Donnai², J. Ayres¹.* 1) Nowgen, St Mary's Hospital, Manchester, United Kingdom; 2) Regional Genetics Service, St Mary's Hospital, Manchester, United Kingdom.

Central to Nowgen's core work plan is an active programme of engagement with genetic service users. The first Nowgen Support Group Evening was held in April 2004 and is one of a number of innovative approaches adopted to promote dialogue between Nowgen and support group representatives, as well as to facilitate networking opportunities between these groups. We have developed a database of genetic support group information, and used this to facilitate initial contact. The Nowgen Support Group Database will be placed on the Nowgen website, currently under construction. A total of 128 introduction letters were sent and the event was also promoted on several websites and in support group publications. In total 57 came to the event, with 47 of the attendees representing support groups. The event was held in the evening and the programme included some brief introductory talks followed by a buffet and networking session. Twenty one evaluation forms were completed. The overall feedback was extremely positive. A large majority of participants stated that they wanted to have regular similar meetings and be actively involved in the Nowgen Centre. Nearly all respondents want to contribute to the Nowgen Newsletter and have representation on the Nowgen Website. Many appreciated the opportunity to meet together and discuss common issues with representatives of different groups. Nowgen is using this feedback to inform and direct our next steps in our active user and public engagement programme.

Genetic risk calculations for cystic fibrosis in neonatal screening by immunoreactive trypsinogen and CFTR

tests. *B. Gold*¹, *R.B. Wilson*², *P. Flodman*³, *W.W. Grody*⁴, *S. Ogino*^{5,6,7}. 1) Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD; 2) Dept. of Pathology and Lab. Med., University of Pennsylvania, Philadelphia, PA; 3) Dept. of Pediatrics, University of California Irvine, CA; 4) Depts. of Pathology and Lab. Med., Pediatrics, and Human Genetics, UCLA School of Medicine, Los Angeles, CA; 5) Dept. of Pathology, Brigham and Women's Hospital, Boston, MA; 6) Dept. of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 7) Harvard Medical School, Boston, MA.

Risk assessment is an essential component of genetic counseling and testing, especially for cystic fibrosis (CF), the most common severe autosomal recessive disease. Despite controversy, neonatal or newborn screening for CF is widely practiced commonly by immunoreactive trypsinogen (IRT) test followed by CFTR test if IRT test is positive. However, systematic methods for accurate risk calculations are currently lacking. Risk assessment is particularly problematic when IRT test is positive and only one CFTR mutation is detected. We meta-analyzed published data to evaluate assay characteristics of immunoreactive trypsinogen test. The probability that a neonate has positive IRT test, if the neonate is affected, a carrier or a non-carrier, is estimated to be ~1, 0.04, or 0.011, respectively. We provide methods to calculate genetic risks for a variety of commonly encountered scenarios. Our scenarios include neonates with mixed ethnicity, neonates with a family history of CF, and neonates of parents with genetic test results. Our Bayesian methods permit CF disease probabilities to be calculated accurately, taking into account all relevant information.

Bayesian risk calculations for cystic fibrosis: avoiding pitfalls in complex scenarios. *S. Ogino*^{1, 2, 3}, *R.B. Wilson*⁴, *B. Gold*⁶, *P. Hawley*^{3, 5}, *W.W. Grody*⁷. 1) Dept Pathology, Brigham & Women's Hosp, Boston, MA; 2) Dana-Farber Cancer Institute, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) University of Pennsylvania, Philadelphia, PA; 5) The Children's Hospital, Boston, MA; 6) National Cancer Institute, Frederick, MD; 7) UCLA School of Medicine, Los Angeles, CA.

INTRODUCTION: Risk assessment is an essential component of genetic counseling and testing, and Bayesian analysis plays a central role in complex risk calculations. We have previously developed generalizable Bayesian methods to calculate the autosomal recessive disease risk of a fetus when one or no mutation is detected, and another independent risk factor is present. Our methods are particularly useful to calculate the CF disease risk for a fetus with echogenic bowel. In practice of genetics, however, there are many other scenarios that cannot be calculated by our previous methods. **METHODS AND RESULTS:** We herein provide methods of calculating genetic risks for a variety of clinical settings that are rather common. Our scenarios include: different mutation panels have been used for the parents and for a fetus; genetic testing results are available on the proband or other relatives, in addition to the consultand; fetal ultrasound is negative for echogenic bowel while a family history of CF is positive; and the consultand has mixed ethnic background. **CONCLUSION:** Our versatile Bayesian methods are applicable to many different common scenarios, and that allow the autosomal recessive disease and carrier probabilities to be calculated accurately, taking into account all relevant information. Our methods will provide accurate genetic risk estimates to patients and their family members for CF or other autosomal recessive disorders.

Program Nr: 1450 from the 2004 ASHG Annual Meeting

HISTORY OF HUMAN AND MEDICAL GENETICS. *P. Harper.* Inst Medical Genetics, Univ of Wales Col Medicine, Cardiff, United Kingdom.

The history of our rapidly changing field will be seen in later years as one of the most important parts of the history of science and medicine. Since much of it is within reach of living memory, we have a unique opportunity to document it fully, but this will be lost if we do not take it rapidly. An international initiative is presented here which aims to encourage and link both geneticists and historians active and interested in historical aspects and to complement those activities already underway. Work in progress includes:- Expert archiving of scientific records of retired or deceased workers; A Human Genetics Historical Library of important books; International workshops to bring together those interested; Audio-recordings of interviews with key workers; A regular electronic newsletter and website (genmedhist.net); A linked structure for historical interest groups in different countries. It is hoped that these and other activities will help to ensure that the primary historical material underlying human and medical genetics will be preserved and made available for all those wishing to undertake more detailed studies.

SKELNET - German skeletal dysplasia network as a national interactive telemedical diagnostic and research approach to rare diseases. *S. Despres¹, O. Hiort², K.H. Klingebiel², A. Rauch², A. Reis², A. Winterpacht², K. vonderMark², A. Vortkamp², D. Haas², A. Superti-Furga², M. Hrabe de Angelis², M. Briggs², R. Schumacher^{1,2}, J. Spranger^{1,2}, B.U. Zabel^{1,2}.* 1) Molecular Genetics , University Childrens hospital, Mainz, Rhld.Pf., Germany; 2) SKELNET group.

The skeletal dysplasias are a clinically and genetically extremely diverse group of genetic diseases primarily affecting the development of the skeleton. The rarity, extensive heterogeneity and complex pathophysiology have made the skeletal dysplasias a challenge to study. Recently a pan-European integrated diagnostic and research network for skeletal dysplasias (ESDN, www.esdn.org) was established. Key features of the pilot project are (1) the diagnostic aspect focused on providing and evaluating an integrated clinical/radiological and DNA diagnostic network and (2) a coordinated research aspect focused on identifying the genes, mutations and disease processes that underlay skeletal dysplasias. This type of network has not previously been attempted and therefore the success of the project will have major implications for the delivery of future diagnostic services for rare genetic diseases. In the meantime ESDN will be complemented by the German skeletal dysplasia network SKELNET which will further concentrate on telemedically based X-ray composition and interchange for the complete medical patient care process. The SKELNET-server is an internet based server providing DICOM-PACS and patient records even through firewall protected environments. Radiographs or other media are assigned to a patient record, whereas personal data are stored and transmitted with state-of-the-art data protection. Experts can collect cases of certain diseases, can assign their lab data to the cases and can initiate consultations with SKELNET members in a safe way. Outpatient offices can send their data (patient information, ultrasound images, X-rays, even videos) to request help or continued care. SKELNET technology combines networking, knowledge collection, PACS and patient record database technology (RDE), internet security technologies and patient data protection mechanisms to an optimal rare disease collection, analysis and care workhorse.

Detection of large pathogenic *SCA2* and *SCA7* expansions by repeat-primed PCR assay. C. Cagnoli¹, G. Gerbino Promis², C. Michielotto², G. Stevanin³, M. Viemont³, E. Dragone², C. Gellera⁴, N. Migone^{1, 2}, A. Brusco^{1, 2}. 1) Dept Genetics, Biol & Biochem, University of Torino, Italy; 2) S. Giovanni Battista Hosp., Medical Genetics Unit, Torino; 3) INSERM U289, IFR70 & Dept Genetics, Salpêtrière Hosp. APHP, Paris, France; 4) Dept. Biochemistry & Genetics, Neurological Institute. C.Besta, Milan, Italy.

The CAG repeat in the *SCA2* and *SCA7* genes can expand above 100 repeats causing infantile and juvenile-onset spinal cerebellar ataxia (SCA). Routine assays for *SCA2* and *SCA7* based on fluorescent or silver-stained PCR, can not reliably detect such large expansions. We developed a fluorescent STR-primed PCR based on a labelled forward locus-specific primer, and a reverse primer complementary to the CAG repeat. We tested: 35 *SCA2* normal subjects (22-34 CAG) and 12 affected (10 in the range 37-53 CAG, one 23/200, and one 22/350, kindly provided by Molecular Genet. Lab., Mayo Clinic, USA); 39 *SCA7* normal subjects (9-34 CAG) and 26 affected (36-106 CAG). In case of an expansion, the pattern was characterized by an array of gradually descending spikes, that contained a bell shaped array of peaks in the right end of the profile whenever the expanded allele was small. Routine-PCR in our laboratory could not identify *SCA2* large expansions (200 and 350 repeats), or *SCA7* alleles above 80-CAG, whereas STR-primed PCR detected both the two *SCA2* large expanded patients and all *SCA7* expansions (up to the largest available of 106 repeats). STR-PCR, however, does not allow to infer the precise number of repeats in the expansion; small expansions in the borderline range around 36-40 repeats, were not discriminated from normal alleles in the upper side limit (>30 CAG). We conclude that this technique might be a valuable tool to identify expansions above 40 CAGs in the *SCA2* and *SCA7* genes, without false-positive or false-negative results. We think the test, easy to set-up and very reproducible, could be of practical value in the prenatal diagnosis offered to affected or pre-symptomatic at risk parents, or in routine screening for infantile or congenital hypotonia associated with non-specific neurological symptoms, a possible early-onset *SCA2* or *SCA7* disease.

Evaluation of paternal family history of breast cancer in primary care. *J. Culver^{1,2}, S. Hall², N. Press³, L. Pinsky¹, S. Reynolds¹, W. Burke^{1,2}.* 1) University of Washington, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Oregon Health and Science University, Portland, OR.

Overlooking paternal family history in breast cancer risk assessment may lead to underestimation of risk and inadequate preventive care. This study aimed to determine whether primary care physicians identify a paternal family history of breast and ovarian cancer and how such history influences patient care. We evaluated providers using concealed standardized patients (SP's) trained to present concerns and family history in a consistent way. The study included 86 internal medicine or family practice physicians in the Seattle area who consented to an unannounced, audio-taped SP visit. Physicians were randomized to receive one of three SP cases. We present results from 33 physicians who saw Rachel, a 36-year-old with a paternal family history of cancer. Rachel presents to establish care and renew a prescription for her stress-induced migraines, which were recently aggravated by the diagnosis of breast cancer in her 48-year-old sister. Unless asked, she does not reveal her paternal family history, including an aunt with breast cancer at age 42, an aunt with ovarian cancer in her 40s, and a grandmother with a female cancer. Analysis of visits revealed that 15/33 physicians identified her aunt with breast cancer, but only 2/33 identified all affected relatives. While 32/33 indicated Rachel has an increased breast cancer risk, only 2/33 communicated a significantly increased risk. Additionally, 8/33 discounted her genetic risk either because affected relatives are on her father's side or because her mother is unaffected. The majority (23/33) suggested she initiate mammography screening in the near future. When asked about genetic testing, only 1/33 indicated she is a candidate for testing and 3/33 discussed a genetic counseling referral. Thus, most physicians did not take sufficient family history to identify a high risk, some did not recommend early mammography, and few identified Rachel as a candidate for a genetics referral. These results indicate that paternal family history may be underappreciated in primary care, identifying an area of opportunity for physician education.

Challenges in assessing the clinical validity of BRCA1 testing. *J. Tranchemontagne¹, L. Boothroyd¹, J. Joyce², I. Blancquaert¹.* 1) Agence d'évaluation des technologies et des modes d'intervention en santé Montréal, PQ, Canada; 2) Canadian Coordinating Office for Health Technology Assessment Ottawa, Ontario, Canada.

In preparation for a health technology assessment report on molecular testing for hereditary breast and ovarian cancer (HBOC), the literature was reviewed to assess clinical validity. The evaluation of molecular genetic tests poses the challenge of choosing a gold standard. While the definition of HBOC relies on family history, there is currently no consensus on the minimal risk factors defining a HBOC family. This paper describes the challenges encountered while assessing the clinical validity of BRCA1 testing for HBOC and how it relates to penetrance and genetic heterogeneity. Method: Published and grey literature was identified in January 2003 for 1999 on (updating in July 2004) by searching PubMed, Cochrane Library, MEDLINE, CANCERLIT, EMBASE, and Biosis Previews, the Internet, trial registries, guidelines databases, and the websites of health technology assessment agencies. Results: Difficulties encountered included defining the HBOC phenotype, gaps in knowledge regarding mutation distribution, variations in the selection of individuals and techniques used for testing, as well as the nature of the available evidence and the means of reporting. Clinical sensitivity data was extrapolated from studies designed for other purposes, taking into consideration the potential misclassification of results for families with negative results following all mutation screening strategies. Estimates of the clinical sensitivity of exon and intron/exon junction screening techniques in BRCA1 were derived by examining the proportion of HBOC families carrying point mutations / small rearrangements versus those with large genomic rearrangements / non-coding region mutations. Clinical sensitivity values were expressed as a range of values. Conclusion: It is worthwhile pursuing research on clinical validity, in order to increase the precision of clinical sensitivity estimates, for instance. Future studies should, however, use sound methodology and clear selection criteria for the population of interest.

Colorado's First Adult Medical Genetics Clinic. *M. Taylor, L. Ku, J. Feiger.* Adult Medical Genetics Program, University of Colorado Health Sciences Center, Denver, CO.

Background: Adult clinical genetics is considered an expanding field, but currently there are few clinics dedicated to adult genetic conditions. We developed a general adult medical genetics (AMGP) clinic targeting all adult genetic conditions with the exception of hereditary cancers. The AMGP clinic is unique in Colorado and is supported entirely by our Department of Medicine. Here, we report on the structure and productivity of our AMGP clinic during its first 2 years of operation. **Results:** The clinic is staffed by one genetic counselor and one medical geneticist/internist. The main indications of referral consist of general genetics/dysmorphology (45%), connective tissue disorders (20%), neurogenetic conditions (19%), and neurocutaneous conditions (11%). 51% of patients have a personal history of a genetic condition, 22% a personal and family history, 24% a family history alone, and 3% were seen for population screening. New patient visits steadily increased in the first year, from only 4 visits/month in the first three months of operation to 15 new visits/month in the 9-12th months of operation. The majority of the new patient visits were new to our hospital system, indicating a heavy source of outside referrals; increasing internal referrals remains a challenge. Hospital policy does not permit institutional billing for genetic tests; therefore, genetic tests must be billed to the patient or to insurance directly. 45% of genetic tests were ordered from the in-house DNA Diagnostic Laboratory and 55% from outside laboratories. 8% of the patients elected to self-pay for the genetics visit; usually for privacy issues (rather than lack of insurance coverage). 59% of patients were insured by managed care. 21% of patients were insured by Medicare or Medicaid. **Conclusions:** In the two years since inception, our clinic has grown in terms of our referral and patient base as well as with the diversity of genetic diseases seen. Significant challenges remain in terms of obtaining financial support from our hospital, in facilitating genetic testing for our patients, and increasing visibility of the clinic services to the general community.

Advocacy Organization Owned Genetic Alliance BioBank is a Catalyst for Research. *E.W. Johnson^{1, 2}, G. Mason^{2, 3}, P.F. Terry², J. Scott², S.F. Terry².* 1) PreventionGenetics, Marshfield, WI; 2) Genetic Alliance BioBank, Washington, DC; 3) Inflammatory Breast Cancer Research Foundation, Bainbridge Island, WA.

Advocate owned research foundations represent the thousands of people affected by genetic conditions. These groups seek the tools that will enable them to characterize the range of the phenotype of the condition, rather than extremes, leading to earlier and better clinical methods of detection and diagnosis, with the ultimate goal of finding an effective treatment. Genetic disease research is often hampered by the lack of an easily accessible, linked, well-defined patient cohort. For rare conditions, existing resources are often fragmented, "competitively isolated" and under-funded. The Genetic Alliance BioBank (GAB) was established to help remove some of these barriers to effective research. The GAB enables advocacy organizations to partner in a comprehensive BioBank to facilitate disease specific research while sharing resources and expenses to accomplish what each group could not feasibly do alone. GAB provides high quality, centralized, standardized collection and archiving. Each advocacy organization has exclusive control over their samples and data. All member organizations use GAB IRB approved, standardized forms. Individual donors for the BioBank are recruited by the advocacy organizations in an atmosphere of support and trust following a culturally sensitive, comprehensive, informed decision-making process. Sample and information access for the research and clinical communities are facilitated significantly by the advocacy organizations. For the advocacy organizations involved, proven results include a role in gene discovery, mutation database development, and numerous research projects while maintaining rigorous participant protection. The involvement of the various disease specific advocacy organizations allows cross-disease research and unique collaboration. Ethical recontact and longitudinal studies are both part of this model. This new paradigm brings individuals and their organizations into a true partnership with researchers, ensuring the benefits outweigh risks and helps accelerate the translation of research.

Challenges with the uptake of nanotechnology into medical genetics. *G. Khushf¹, R. Best²*. 1) Center for Bioethics, University of South Carolina, Columbia, SC; 2) University of South Carolina, School of Medicine, Dept. Ob/Gyn, Columbia, SC.

Considerable attention has been given to the development of nanotechnology and the many practical applications it might bring including a wide range of tools for medicine. Federal research funding has increased dramatically for nanotechnology in recent years, and NIH has announced the development of programs in nanomedicine with major Nanomedicine Center funding beginning in 2005. Within the community of nanoscience researchers there is a belief that much of the fundamental work has transitioned to the application end, and indeed, much of the research is at the place where it could be applied. However, there is a significant disconnect between the basic science community and those providing clinical care. The disconnect is well exhibited in the area we explore in this presentation; namely the use of quantum dots and their potential use in clinical molecular cytogenetics. We address some of the conceptual, cultural, and institutional conditions that are critical for the transitioning of an emergent technology into the clinical setting. After exploring the challenges that have been associated with applying quantum dots into molecular cytogenetic testing, we provide recommendations for the development of trading zones between scientists and those in clinical practice so that there might be a more rapid transition from cutting edge research into clinical practice.

Use of a novel computer program to assess family history. *K.D. McKelvey Jr¹, J.P. Evans², J. Emery³.* 1) Dept of Family and Preventive Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Dept of Genetics, University of North Carolina, Chapel Hill, N.C; 3) Discipline of General Practice, University of Western Australia.

The purpose of this study was to determine the feasibility of using GRAIDS (Genetic Risk Assessment on the Internet and Decision Support) software as a screening tool for assessing hereditary cancer risk by family history in an office setting. Advances in cancer genetics have the potential for significant impact in primary care, but the application of these advances in the context of a busy medical practice is an enormous challenge. Genetic testing for cancer susceptibility involves time-intensive counseling prior to testing, carries with it unique psychosocial issues, and population-based genetic screening is not feasible or appropriate. Therefore a screening method is necessary to identify patients at elevated hereditary risk who may benefit from individualized surveillance strategies and further genetic consultation. Family history is often the most significant risk factor for cancer and is a useful screening tool but is underutilized in preventive healthcare. GRAIDS software (a proprietary software package from AP Benson) was used to help obtain family history and assess risk in a primary care practice. Patients in the waiting area at an outpatient primary care facility were offered the opportunity to participate in this study by means of a notice posted at the check in desk. Over a 20 work day period, 71 patients out of an estimated 800 chose to use the program and provide their family history pertinent to cancer to a medical professional (KM) trained in the use of GRAIDS software. Of the participating subjects, 7 (10 percent) met predetermined eligibility for further genetic referral. The average length of each session was 18 minutes. The data indicate that it is feasible to obtain and enter a targeted three generation family history into a computer program and discuss inherited cancer risk during the course of a routine office visit. This study provides a necessary step toward establishing the feasibility of automating family history risk assessment.

Program Nr: 1459 from the 2004 ASHG Annual Meeting

Craniofacial Brazil project: access for genetic evaluation and genetic counseling in the Reference Net for Craniofacial Treatment. *V.L. Gil da Silva Lopes¹, I.L. Monlleo²*. 1) Genética Médica, UNICAMP, Campinas, São Paulo, Brazil; 2) Pediatria, FM/UNICISAL, Alagoas, Maceió, Brazil.

This present study is part of the Craniofacial Brazil Project, which is the first initiative for national characterization of the health care in craniofacial area in Brazil. The majority of the affected individuals has been treated in one of the 29 public specialized centers, in a Reference Net for Craniofacial Treatment, which was created in 1998. In order to characterize the access for genetic evaluation and genetic counseling for individuals in this centers, it was used a patterned questionnaire, by mail. Among the 13 centers with clinical geneticist, 61,8% had one professional and were situated in Universities, most of them in the state of So Paulo. In spite of few clinical geneticists in the composition of the teams, 22 centers referred that patients and parents asked for etiology and prevention. These informations were given in 80% of the centers and in 55% of them by non-specialized physicians. The clinical geneticist is involved in recognize, notified and registry congenital defects, as well as in the determination of natural history, anticipatory management of complications and genetic counseling for the family and the proband, in the future. The absence of this professional certainly makes uncompleted the follow up of craniofacial patients and families. This results suggested that the access for clinical geneticist is not enough and it would be necessary the revision of parameters for inclusion of this specialist in craniofacial centers teams. Also these data suggested the need to establish the better health policy for CFA individuals in our country. E-mail: cranface@fcm.un.

Student Screening for Genetic Blood Diseases in Bahrain (1999-2004). *S. Al Arrayed.* Genetic Dept, Salmaniya Medical Ctr, Manama, Bahrain.

The inherited disorders of hemoglobin is common in Bahrain. The student screening project had been initiated in 1999 and continues for the subsequent six years 2000-2001-2002-2003-2004. We are presenting this project and comparing the results of these six years. The aim is to raise awareness among the students about hereditary anemias, and determine prevalence among them. **Material and Method:** The plan was to screen all the students in the 11th grade (2nd Secondary). The project includes education sessions, blood collection, laboratory testing, data processing, distribution of cards, data analysis, and reporting. Permission for screening was taken from parents, and the response rate was 80-85% every year. The students were fully informed about the diseases through educational sessions. The total number of students screened was 5685, 5677, 6978, 5883, 5410, 6228 students respectively. The total number of students screened until now is approximately 36,000 students. Technicians visited the school to withdraw the blood samples and these were tested on the same day. High pressure liquid chromatography (HPLC machine) was used to perform the hemoglobin electrophoresis. The blood samples were also tested for, G6PD deficiency testing. A coded form was designed with the demographic information of each student and included the results of the tests. At the end of the campaign each student received a card with the lab results. **Results:** Comparing the prevalence results during the years 1999-2000-2001-2002, 2003-2004 The study showed that the Prevalence rate of Sickle cell disease among these students was 1.2%, 1.3%, 1.09%, 1.09%, 1.3%, 1.25% respectively. Sickle cell trait was found in 13.8%, 13.8%, 14.2%; 14%; 13%, 14%, respectively. While Beta thal trait was found in 2.9%, 3.6%, 2.6%, 3.7%, 2.9% respectively, and G6PD in 23.3%, 23.4%, 21.9%, 20%, 20.7%, 23%; respectively. The study included reports on the prevalence of these diseases by region, and by school. It also showed the level of hemoglobin S, F, A₂, and H in each group. **Conclusion:** Preventive measures such as health education, carrier screening and premarital counseling remain the best ways of dealing with these diseases. As prevention can result in significant financial saving, social and health benefits.

Program Nr: 1461 from the 2004 ASHG Annual Meeting

A model for outreach and education for Ashkenazi Jewish Genetic diseases in a large Jewish community. A. Schneider, L. Gross, D. Dorsainville, R. Keep. Dept Genetics, Albert Einstein Medical Ctr, Philadelphia, PA.

The Ashkenazi Jewish (AJ) community in Philadelphia is spread out over a large geographic area. Outreach and education are made more difficult in that many members of this community are not affiliated with religious centers and do not strongly identify themselves as Jewish. It is estimated that 1 in 4 individuals of AJ ancestry is a carrier of 1 of the 8 diseases more common in this community (Tay-Sachs, Canavan, Gaucher, Niemann-Pick, Bloom, Fanconi, Familial Dysautonomia and Cystic Fibrosis); thus we would expect to find about 50,000 carriers among the approximately 200,000 Jewish individuals in Philadelphia and its adjacent counties. The Ashkenazi Jewish Genetic Disease Screening Program at Albert Einstein Medical Center in Philadelphia was established in 1999. The Program provides outreach, education, genetic counseling and carrier screening to individuals of Ashkenazi Jewish descent. Despite extensive efforts to educate the public and physicians, the overall interest from the Jewish Community has been disappointing. To date we have screened about 500 individuals. Of these individuals, 85 are carriers of one disease, 9 are carriers of 2 diseases and 1 has Gaucher disease and is a carrier of another disease. Overall approximately 1 in 5 is a carrier of one of these diseases. We concluded that hiring an outreach coordinator to help focus our efforts on our most responsive groups—engaged couples, married couples with no children, and college students—would help to increase uptake of testing. We will discuss how the addition of an outreach coordinator has enhanced our ability to reach the community in general and college students and newlyweds in particular.

Awareness of family history of cardiovascular disease: Implications for public health. *M.T. Scheuner^{1, 2}, W.C. Whitworth², P.W. Yoon², M.J. Khoury².* 1) Dept. of Health Services, UCLA School of Public Health, Los Angeles, CA; 2) Office of Genomics and Disease Prevention, CDC, Atlanta, GA.

Family history tools can improve risk assessment for cardiovascular disease (CVD). For these tools to be effective the public must be aware of the disease status of their close relatives. We examined awareness of family history of coronary heart disease (CHD) and stroke among 4035 respondents to the HealthStyles 2003 national survey. We asked about each respondent's mother, father, siblings, mother's relatives and father's relatives. Response options for CHD and stroke were: yes diagnosed at or before age 60; yes diagnosed after age 60; no; and don't know. Awareness of disease status was gauged by the frequency of don't know responses. Respondents were 60% female, 72% white, and mean age was 48.4 yrs (SD 14.4 yrs, range 19 to 93 yrs). There were 257 (6%) with personal history of CHD and 171 (4%) with stroke. The proportion that did not know about CHD and stroke for mothers was 7.6% and 6.2%, respectively, compared to 11.4% and 10.5% for fathers. The proportion that did not know about CHD and stroke for mother's relatives was 31.7% and 32.0%, respectively, compared to 38.4% and 36.9% for father's relatives. Logistic regression analysis assessed the influence of personal factors on awareness of disease status in relatives. Age, personal history of CHD, education and income were highly significant factors associated with awareness of CHD in relatives ($p < 0.0001$); sex and race were not. Results were similar for stroke; however, personal history of stroke showed a weaker association ($p=0.02$) and sex was weakly associated ($p=0.02$). In conclusion, most individuals can report a status of CHD and stroke in their relatives, particularly their first-degree relatives. There is more awareness about maternal relatives. Age, education, income and personal history of disease are significant factors that influence awareness of CVD status in relatives. Understanding these differences through further study could lead to targeted educational programs that increase awareness about the importance of family history, which may ultimately improve familial risk assessment and prevention efforts.

Program Nr: 1463 from the 2004 ASHG Annual Meeting

Genomic tools for the diagnosis and evaluation of mental retardation: emerging legal and ethical issues. *M. Lacroix, B.M. Knoppers.* CRDP, Faculte de droit, Universite de Montreal, Montreal, Quebec, Canada.

The inclusion of vulnerable populations such as children and persons with disabilities in research studies has received special protection since the adoption of the Nuremberg Code. More recently, the need to include children in research has gained recognition, as has the need to guard against group harms in human genetic research involving ethnic groups or sub-populations. This presentation will use the *Genomic Tools for Diagnosis and Evaluation of Mental Retardation* project as a case study to illustrate the ELSI issues that may arise in research related to DNA sampling and vulnerable populations. This multi-centre research project aims to evaluate high-resolution BAC microarray comparative genomic hybridization as an alternative method of identification of chromosomal abnormalities in people with mental retardation. It will obtain patient data and specimens through the Canadian Molecular Cytogenetics Research Consortium, a group of clinical geneticists and cytogeneticists throughout Canada, and will compare samples from affected individuals and their family members with those from healthy adults. The project raises a number of ethical, legal and social issues which will also be examined by the research team, such as: the implications of singling out children with mental retardation for study, the implications for, and the rights of, other family members, the implications for health care services or counselling, and the involvement of ethnically diverse healthy adults in genetic variation studies unrelated to the presence or absence of disease.

Program Nr: 1464 from the 2004 ASHG Annual Meeting

The Iranian Human Mutation Database. *M. Motazacker*¹, *E. Taherzadeh*¹, *Z. Hussein*², *M. Kamyab*², *H. Najmabadi*¹. 1) Genetics Research Ctr, USWR Univ, Tehran, Iran; 2) Tebyan IT institute, Tehran, Iran.

Regional genetic databases provide scientists all over the world with a valuable resource of specific information about the genetic structure of a particular region in order to promote diagnosis, treatment and basic research on genetic disorders. Iranian population consist of different races, tribes and religions has a highly heterogeneous gene pool and mutation spectrum which in many cases can also be extrapolated to the mutation spectrum in the neighbouring countries in the middle east. The Iranian Human Mutation Database (IHMD) established in February 2004, is the collection of the information about published or submitted mutations and related polymorphisms from Iranian population and is created to facilitate accessing to such a great resource of genetic data. IHMD is accessible through World Wide Web using url: <http://www.uswr.ac.ir>. Up to know more than 392 mutations related to 95 genetic diseases with distinct gene have been submitted with the information about mutation(s) or polymorphism of each gene. References and authors are also listed by the mutation.

Program Nr: 1465 from the 2004 ASHG Annual Meeting

Iranian Human Mutation Gene Bank. *M. Neishabury, Y. Shafaghati, M. Motazacker, K. Kahrizi, M. Jalalvand, S. Bany Hashemi, B. Moghimi, A. Noorian, S. Mosayyebi, K. Javan, H. Najmabadi.* Genetics Res Ctr, Univ Of SWRS, Tehran, Iran.

With the increasing number of disease causing genes identified and the existence of genetic variation between different populations in the world, establishment of population-specific DNA banks could provide valuable sources of information and sample for medical genetic research in the field of diagnosis, prevention and hopefully cure of hereditary diseases world-wide. Iran, a country with nearly 70 million population, represents a highly heterogeneous gene pool and mutation spectrum due to the unique nature of its geographical, cultural and ethnical diversity. The data base of Iranian Human Mutation Gene Bank is a comprehensive source of information on DNA samples collected in this bank during the last 6 years. The samples belong to the patients with genetic disorders with mendelian mood of inheritance studied in Iran. Some of the samples are assigned to common or novel mutations and some others belong to patients with clinical profiles associated with particular genetic diseases but unidentified mutation. The new version of the software presents different categories of genetic disorders including Hemoglobinopathes, Neuromuscular disorders, Mental Retardations and Hearing loss. With the exception of personal data, which is strictly kept confidential, clinical profile for each individual, and genetic information including pedigree (if available) for each family is presented in this data base. In order to facilitate collaboration with other scientists in the world with the same interests, we also display the information regarding our experimental projects at this center on some of these genetic disorders. This DNA bank offers a free of charge sample resource from a large heterogeneous population to all the scientists in the world, who are working on the various aspects of genetic disorders from prenatal diagnosis to gene structure and function. No commercial benefit is involved in establishment of this DNA bank.

Program Nr: 1466 from the 2004 ASHG Annual Meeting

The Parkinson disease mutation database (MutPD). *N. Pankratz, T. Foroud.* Medical & Molec Genetics, Indiana Univ Sch Medicine, Indianapolis, IN.

In the past six years, scientists have identified seven genes that have been shown to cause Parkinson disease (PD). As more and more individuals with PD are tested for mutations in these genes, it is imperative that their significance is properly understood. This is particularly relevant for the *parkin* gene, in which almost 100 unique mutations have been identified. Already population studies have found several of these mutations in roughly equal frequency among patients and controls. Since genetic counseling should be required with all genetic testing, the presence of non-pathogenic polymorphisms creates a formidable challenge in interpreting the significance of any genetic variation. The Parkinson disease mutation database (MutPD) aims to collect all known mutations and non-pathogenic coding variations in the genes related to PD. With this data in a centralized location, scientists and genetic counselors alike can use the data to better interpret the significance of a mutation. This database will also lay down the framework for an understanding of genotype-phenotype correlations. The MutPD website was launched in July 2004 and is being updated continuously.

Program Nr: 1467 from the 2004 ASHG Annual Meeting

Relational Database System for Management of Molecular Diagnostic Laboratory Services. *Z. Rennert, C. Sadowl, D. Nielsen, D.G.B. Leonard, V. Van Deerlin, H. Rennert.* Path. and Lab. Medicine, University of Pennsylvania, Philadelphia, PA.

We have designed and developed a modular relational database system for managing molecular diagnostic data from all stages of molecular testing using Microsoft ACCESS. The system resides on a shared drive, is pass-word protected and can be accessed via the laboratory net work. The system allows rapid storage and tracking of data including demographic, clinical, specimen description and test results information in a longitudinal fashion. For simplification and standardization, most of the data is accessed using pull-down menus. All information pertaining to specimen, tests ordered and test results is coded via set up screens and the values are selected via look-up tables. All data in all tables that pertain to any particular patient are linked together by a unique identifier. Extensive search screens are provided for locating patients, specimens, tests ordered and results previously logged into the system. Test results are entered into test-specific screens tailored specifically for the information required for each test. Statistical reports are provided via Excel spreadsheets and Excel Pivot tables can be generated for easy data manipulation. The database is easy to use and useful, greatly improving data management, quality assurance and patient care in our laboratory. In addition, the modular design allows modification and expansion of the database to accommodate special studies.

Identification of Knowledge and Misinformation Associated with Uptake of *BRCA1/2* Testing Among Community Women with Early Onset Breast Cancer. *J. Stopfer*¹, *N. Peters*², *R. Polis*², *A. Rose*², *S.M. Domchek*^{1,2}, *K. Armstrong*^{1,2,3,4}. 1) Abramson Cancer Ctr; 2) Department of Medicine; 3) Center for Clinical Epidemiology and Biostatistics; 4) Leonard Davis Institute; University of Pennsylvania.

Women identified with mutations in *BRCA1/2* can benefit from interventions shown to lower risk and enhance early detection. There has been a lower than expected level of uptake among individuals with a significant chance of having a *BRCA1/2* mutation. Limited information is currently available about how knowledge deficits and misinformation are associated with testing uptake. Here we have investigated the association between attitudes, knowledge and use of *BRCA1/2* testing among women with early onset breast cancer.

A mailed survey was sent to members of two Mid-Atlantic support groups. Knowledge, attitudes, use of *BRCA1/2* testing and sociodemographic characteristics were measured. Of 2400 mailed questionnaires, 493(21%) were returned. 406 respondents had a diagnosis of breast cancer, of whom 248 were diagnosed prior to age 50 and included in the analysis. 83.1% (206/248) of these women had heard of *BRCA1/2* testing yet only 12.5%(31/248) had undergone testing. Women who had undergone testing had significantly higher knowledge than women who had not undergone testing ($p=0.02$) with the largest differences seen for knowledge about the risk of ovarian cancer, paternal transmission of mutations and the prevalence of *BRCA1/2* mutations. Women undergoing testing were younger ($p=0.03$), more likely to have a college education ($p=0.03$), more likely to have a family member who had undergone *BRCA1/2* testing ($p=0.005$), and had more positive and fewer negative attitudes about *BRCA1/2* testing ($p=0.004$ and $p=0.004$).

In this sample of women, lack of information regarding how genetic testing might alter health care decisions (particularly with regard to ovarian cancer risk) and fear about the genetic testing procedure, its costs and the possibility of false positive results were associated with low uptake of genetic testing. Further education regarding these specific points may enhance the use of this genetic testing.

Cancer Genetic Testing and Genetic Discrimination: A Pre-Cancer Risk Counseling Survey of Patient Knowledge and Opinions. *K. Banks¹, J.N. Weitzel², A. Metzenberg¹, V. Vandergon¹, K.R. Blazer².* 1) California State University at Northridge, Northridge, CA; 2) City of Hope, Duarte, CA.

Approximately 5-10% of all cancer is associated with a single-gene inherited trait. For many familial cancer syndromes, genetic testing is available and can potentially quantify an individual's risk for developing specific types of cancer and indicate the need for increased surveillance or preventive measures. Several retrospective studies have reported that patient concern about genetic discrimination is a deterrent to genetic testing for cancer predisposition. In this study, we set out to characterize pre-counseling knowledge and opinions about genetic discrimination amongst cancer genetic counseling patients via a self-administered, confidential survey. The survey gathered demographic information, measured beliefs and behaviors on a Likert-type rating scale and knowledge about protective legislation in a true-false-dont know format. Of 62 consecutive new patients at the City of Hope Cancer Screening & Prevention Program, 46 completed and returned the survey prior to the beginning of the cancer risk counseling session. The majority reported that they were not worried or neutral about genetic discrimination with 20% reporting fear of genetic discrimination. Participants who had never had cancer were significantly more worried about genetic discrimination than participants who had been affected with cancer (p -value = 0.018). The most common answer to the knowledge questions was Dont Know (53%), followed by correct answers (36%), and incorrect information was the least common answer at 11%. Additionally, in our cohort, 41% reported never having heard of the possibility of genetic discrimination before taking the survey. The responses to our study and previous reports indicate that patient, population, and professional education is needed regarding genetic discrimination and that the majority of patients presenting for cancer risk counseling are not worried about genetic discrimination. To determine if fear of genetic discrimination prevents at-risk individuals from pursuing genetic cancer risk assessment and genetic testing, studies of that population are needed.

A study of parental disclosure of genetic test results to young adults, adolescents and children. *A.R. Bradbury^{1,2}, C.K. Daugherty^{1,2}, S. Auh¹, F.J. Hlubocky¹, S. Cummings¹, M. White¹, O.I. Olopade¹.* 1) Hematology/Oncology, University of Chicago Hospitals, Chicago, IL; 2) MacLean Center for Medical Ethics, University of Chicago Hospitals, Chicago, IL.

Genetic testing of minors for adult-onset diseases has generally been discouraged. However, controversy regarding testing continues to exist. One study reported 53% of parents with a BRCA1/2 mutation discussed test results with their minor children. Thus, despite a restriction on genetic testing in individuals under the age of 18, many teenagers and children are being informed of their genetic risk. The purpose of this study is to evaluate the rate of parental disclosure of BRCA1/2 results to adult and minor children, under the age of 25 years old, within our Cancer Risk Clinic. To date, 23 BRCA1/2 carriers having completed an open-ended telephone survey, with 83% of participants women; 91% Caucasian. Median age of probands: 43 years old. Subjects had a total of 49 children; 63% female. The median age of the children at time of testing was 11 years old (25% were 18-25; 34% were 10-17; 41% less than 10 years old). Eight (35%) parents reported disclosure to at least one child; 15 (65%) had not disclosed. In those with children less than 18, 2/18(11%) discussed test results with their children. Of those who did not disclose, when asked when they would share test results with their children, 35% reported plans to disclose before or at the age of 18. Overall, 42% of parents either have disclosed, or plan to disclose, genetic test results to their children prior to the age of 18. When asked if genetic testing of minors should be permitted, 70% responded no, 22% were in favor and 9% were undecided. A significant number of individuals screened within a cancer risk clinic for BRCA mutations either have communicated, or plan to communicate, their genetic test results to their children prior to the recommended age of genetic testing. Despite this, most at risk individuals do not agree with direct testing of children. Further research is needed to describe the communication process among parents and children at risk of BRCA mutations and the impact of these communications on children and family dynamics.

Impacts of whole genome analysis on health management. *K.T. Buck, T. Kreiner.* Corporate Affairs, Affymetrix, Santa Clara, CA.

Genetic testing and the debates surrounding its use have, thus far, been focused primarily on the use of tests for rare and highly-penetrant single-gene disorders. However, as we understand the relative contributions of human variation to different diseases and traits, and interventions are increasingly targeted towards individuals, it becomes possible to imagine screening entire populations for genetic information. Concurrently, the development of whole-genome, high-throughput, and affordable genetic analysis tools make the future possibility of widespread pre-symptomatic population screening both possible and potentially cost-effective.

When considering population screening, it is useful to examine the 50 existing state-run newborn screening programs which, between them, screen the 4 million infants born every year in the US. Newborn screening programs provide a potential infrastructure for future population screening as well as a template for alternative programs that might seek to screen individuals at various points in their life. Those involved with these screening programs have already discussed a number of the issues surrounding genetic testing such as privacy and confidentiality, informed consent, storage and access to biospecimens, diversity in testing requirements, and appropriate clinical follow-up. As the breadth of genetic tests continues to expand, the critical importance of health professional expertise in both the science and the social issues surrounding the use of genetics in medicine also becomes increasingly clear. This is a huge challenge calling for systemic changes in our educational infrastructures as well as increased discussion and debate among scientists, physicians, the media and the public.

In order to capitalize on the promise of genetics and move medicine from crisis-driven intervention to predictive medicine, it will be critical that we take what lessons we can from existing genetic testing and public health screening programs. This presentation will examine these opportunities from the perspective of a technology innovator that has enabled whole genome analysis.

Genetic information: special or not? Responses from focus groups with Health Plan members. *B. Diergaarde¹, E. Ludman², J. Culver¹, D. Bowen¹.* 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Group Health Cooperative, Seattle, WA.

The use of genetic information will become more and more common in medicine. Some experts have argued that genetic information is qualitatively different from other medical information and, therefore, raises unique social issues. This view, called genetic exceptionalism, has importantly influenced policy efforts in the last few years, e.g., special laws to protect against abuse of genetic information. Other experts have argued that genetic information is like other medical information and that treating it differently may actually result in unintended disparities. Little is known about how the lay public views genetic information. To identify opinions about ELSI issues regarding genetic and other medical information among the general population, we conducted 10 focus groups. Participants were women and men between ages 18 and 74, living within 30 miles of Seattle and members of the Group Health Cooperative. A structured discussion guide was used to ensure coverage of all predetermined topics. Sessions lasted ~2 hours; were audio taped and transcribed. Participants recognized that currently their medical information is used and stored at many different locations. They did not view genetic information as being different from other medical information; reported that all sensitive medical information should be treated better; and were particularly concerned about the potential of discrimination and stigmatization for all types of medical information. Personal choice (i.e., right to choose whether to know and to choose and control who else knows what) was reported to be of key importance with the exception of when it could harm others. To conclude, people don't think genetic information is unique and have some understanding of the issues related to sharing medical information. Consensus exists around several key issues.

Assessing genetic services along the Texas-Mexico Border: Surveys of genetics providers. *V.B. Enciso¹, J. Martinez², M.A. Aguilar¹, J. Benkendorf³, J. Cooksey³, S.K. Shapira¹, A. Furino².* 1) Pediatric Genetics, Univ Texas Health Sci Ctr, San Antonio, TX; 2) Center for Health Workforce Studies, Univ Texas Health Sci Ctr, San Antonio, TX; 3) Univ of Maryland School of Medicine, Baltimore, MD.

PURPOSE: This assessment of clinical genetic services in the Texas-Mexico border area is linked to the national study of genetic services and the health workforce (UMB). It focuses on determining how genetics services are provided in Texas, especially to the rural border communities, where distance, culture and language barriers present unique challenges. **METHODS:** Prospective surveys from 2000 and 2001 by the former Texas Genetics Network (TEXGENE) were used to evaluate patterns and characteristics of referrals from border areas to genetic centers, and distances traveled for services. To document changes since TEXGENE data were collected, informal surveys of current genetic centers in Texas were done to update present practices, outreach clinics, and ability to provide services to the border communities. **RESULTS:** Analysis of over 12,000 patient visits from 2000/2001 indicates how genetic services were provided to the border area. Patients who receive services in urban centers may travel 150-350 miles to a genetics center. Outreach clinics located in the border cities of Brownsville, Harlingen, McAllen, Laredo and El Paso decrease patients' travel time and expense to access services. In 2004, surveys of genetics providers indicate that the clinic in Laredo has closed, new outreach clinics started in El Paso, McAllen and Harlingen, and an MD geneticist established a practice in McAllen. Private practice and laboratory-run genetic services increased statewide, but they have largely not benefited the border communities directly. **CONCLUSIONS:** Over the past 5 years there has been expansion of genetic services in urban areas around Texas, but there is little evidence of growth in provision of genetic services to border residents. Genetic providers report that major difficulties are the cost of setting up outreach clinics directly in border cities, and inadequate reimbursement for time spent providing clinical services.

REGULATORY APPROACHES TO REPRODUCTIVE GENETIC TESTING. *R.M. Isasi, B.M. Knoppers.* Centre de recherche en droit public Universite de Montreal, Montral, Quebec, Canada.

This presentation analyzes the ethical and legal aspects of reproductive genetic testing in 11 countries, (Australia, Austria, Canada, France, Germany, India, Israel, Japan, Netherlands, Switzerland and United Kingdom). The legal status of reproductive genetic testing in these countries is difficult to generalize due to the different regulatory systems adopted. These approaches reflect the legal traditions and cultural and socio-religious beliefs which inform and shape public policy on assisted reproductive technologies and genetic testing. Generally, countries favour either a public ordering legislative, top-down model or a private ordering that is a non-legislative and bottom-up model. Even limiting our analysis then to a number of countries that span the range from restrictive to pragmatic approaches, there is remarkable symmetry in both the (I) substantive requirements (i.e. gravity, health indications generally) and (II) procedural safeguards (i.e. informed consent, counselling, confidentiality, civil status, oversight and accreditation). Indeed, irrespective of whether a country adopts a prohibitive or a permissive approach through legislation or self-regulation or a mix of both, the ultimate decision is and should continue to be - a medical one. Nowhere, is this more evident than in the substantive requirements. We will demonstrate how these approaches constitute a useful template for policymaking in this controversial area.

Defining DNA Diagnostic Screening Tests Appropriate for Standard-of-Care. *R.V. Lebo¹, H.E. Wyandt², A. Milunsky².* 1) Dept Pathology, Akron Children's Hospital, OH; 2) Center for Human Genetics, Boston Univ Sch Med, MA.

State-of-the-art clinical testing beyond cystic fibrosis screening for pregnant Caucasian women can be optimized by developing a prioritized list of the most common genetic diseases with their most common mutations that would identify the largest proportion of affected patients among those tested. When developing a microbead, mass spec, or microchip based test with many sites tested per sample, an investigator would simply select the optimal number of sites to be tested, and then proceed down the age-specific list to select the optimal number of highest priority mutations that deliver the most comprehensive test with the highest rate of abnormal pickup that optimally utilizes the available testing format. List items would be prioritized according to (1) frequency of affected patients, (2) frequencies of the most common mutations to be tested, (3) disease severity that helps define the most appropriate age-specific screening category, (4) the targeted test population and whether each tested disease is worldwide or reported in specific ethnic groups, and (5) locations characterizing gene and chromosome aneuploidy. Three disease lists developed according to these principles will be presented for screening fetuses, pregnant couples, and older adults. This approach would provide a more widespread, reasoned testing strategy than individual laboratory offerings sometimes focused on test patents, cost and percentage profit. Updated public lists developed according these principles would provide professionals, laboratories, oversight committees, insurance companies, and government officials an objective means to optimize health care test costs and address ethical issues. Fetal screening could include the common diseases with high de novo mutation rates like Rett syndrome as well as testing aneuploidy for 35 disease genes selected to reveal 98% of chromosome abnormalities in viable newborns. Ethical testing issues would be reviewed according to age-of-onset, disease severity, and counseling issues for each tested age category.

Institutional challenges for expanding genetic health care services: A case study of cancer genetics in Ontario.

F.A. Miller, C.M. Ahern, J.D. Ogilvie. Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, Ontario, Canada.

Developments in genetic science are expanding the role of genetics in health care. Recently, cancer care has been undergoing this expansion with the availability of predictive testing services for familial cancers. This trend will likely continue as new research elucidates relationships between genes and a range of common multi-factorial conditions such as Alzheimer's and cardiovascular disease. We report on a study exploring the institutional challenges of moving new genetic technologies into clinical service, using the implementation of BRCA1/2 and HNPCC testing in Ontario as a case study. We conducted (approx.) 50 qualitative interviews with medical and laboratory geneticists, oncologists, genetic counsellors, nurses, and government policy-makers. The participants responded to open-ended questions about the development of the service, the roles of different professionals and decision-making processes. Documentary sources, such as government publications and committee minutes, were also analyzed. Qualitative analysis software (NVivo) assisted the identification of emerging themes and concepts for analysis. Several institutional challenges face the expansion of genomic medicine. In particular, there are clear tensions between professional groups who have distinct, and sometimes contradictory, views of their 'genetic territory', who owns and controls cancer genetics, and who should make decisions about what constitutes appropriate service provision. Geneticists interpret cancer genetics as a genetic service, whereas oncologists understand a genetic test as only one aspect of comprehensive cancer care. These differing views reflect different models of holistic care and different ethical and procedural norms that are not simply reducible to battles over 'turf'. Such tensions create substantial challenges for the translation of research into new genetic services by delaying service provision, producing fragmented care and increasing the costs of implementation. These institutional factors create ethical, economic and practice problems for both policymakers and clinicians.

Risks and benefits in gene transfer research (GTR) involving participants diagnosed with glioblastoma multiforme (GM): an interpersonal approach. *G. Nycum*. Faculty of Law, McGill University, Montreal, CAN.

The Declaration of Helsinki states: In medical research on human subjects, considerations related to the well-being of the human subject should take precedence over the interests of science and society. It also states: Medical research involving human subjects should only be conducted if the importance of the objective outweighs the inherent risks and burdens to the subject and that in the evaluation of research protocols [s]pecial attention is required [...] for those who will not benefit personally from the research.

These statements sanction research with an important objective even where the objective is not a benefit to participants. An example of this type of research is GTR involving participants diagnosed with GM. Since direct medical benefits to these participants are unknown, the risk/benefit analysis involves direct non-medical benefits and indirect benefits to society and future patients.

In the US, a web of institutional bodies review GTR protocols. In the case of non-medical and indirect benefits, the risk/benefit analysis should be difficult at the institutional level because every participant will have a personal and unquantifiable encounter with non-medical and indirect benefits.

Institutional bodies must ensure that researchers and institutions are knowledgeable about the potential for coercion and therapeutic misconception on the part of terminally ill participants who will not benefit personally from research; as well as the importance of participant autonomy, especially for those at the end of life. Because direct benefits may be unquantifiable, in the review of GTR, institutional bodies should put forward the importance of interpersonal communication between researchers and participants. Part of the institutional review process should be the design of education and tools for researchers for communicating with potential participants. This would ensure that the substantive value of the protection of human subjects is not diluted by institutionalized procedures such as the acquirement of informed consent.

Genetic origins of homosexuality: Public beliefs and social implications. *E.M. Petty¹, C.A. Pfeffer², M.B. Feldbaum², T.E. Jayaratne², J.P. Sheldon³.* 1) Med Sch, Univ Mich, Ann Arbor, MI; 2) IRWG, Univ Mich, Ann Arbor, MI; 3) Behav Sci, Univ Mich-Dearborn, Dearborn, MI.

Diverse theories on the origins of homosexuality exist. Some suggest a genetic basis. Given the complexities and controversies surrounding sexual orientation, we sought to explore public beliefs about genetic contributions to homosexuality. We conducted open-ended IRB-approved phone interviews with 86 Black and White adults from across America to learn their beliefs on the origins of homosexuality, what shaped their beliefs, and their views on implications. Responses were analyzed for thematic content. Half felt genes played no causative role, noting factors from choice and upbringing to Satan. Eight felt homosexuality was totally genetic, 25 felt it was partly genetic, and 5 felt genes played a role only in some gays. A third cited factors in 2 or more areas: genetic/biological, environmental, choice, and other. Twenty-six confused sexual orientation with sex: Youve got so many X and Y chromosomes...you get more of one chromosome when its a homosexuality person. Others confused it with gender roles. Beliefs were shaped by: gay friends/acquaintances, media, gay family members, religious teachings, non-gay family/friends, science, and personal experiences. Family trees influenced half (e.g. it can't be genetic if only one family member is gay). On how finding genetic factors may help people, positive responses included: increase heterosexuals tolerance, help gays self-acceptance, and show homosexuality isnt a choice. Responses on developing cures, gene tests, and prenatal tests implied that eradicating homosexuality would help. On how genetics could be harmful responses included: increase hate/discrimination, change/eliminate genes, and increase family blame. Some noted harm could result by legitimatizing homosexuality. We found that limited genetic understanding led to simple reasoning concerning heritability of a complex trait and that genetics was used to support diverse opinions, including negative eugenic agendas. Thus, caution is needed as we seek genetic mechanisms underlying complex human traits; especially those that may impact oppressed minority populations.

Predictive genetic tests for neuropsychiatric diseases. *M.DC. Rietschel^{1,2}, F. Illes^{1,2}*. 1) Genet Epidemiol Psychiat, ZI, Mannheim, Germany; 2) Dep. Psychiat, Univ. Bonn, Germany.

Introduction

Neuropsychiatric diseases are caused by an interaction between various susceptibility genes and environmental factors. These genes are currently being identified and predictive genetic testing may soon become feasible. The contribution of each gene is small, and predictive testing based on single genes will not allow prediction of onset and progression in individual cases. The aim of our study is firstly to assess public attitudes to genetic testing and secondly, to measure the level of understanding and ability to interpret risk amongst the general population.

Methods

We chose Alzheimerss disease (AD) as an example of neuropsychiatric disease. It is well known, everyone has a substantial risk of becoming affected, and a risk gene (APOE4) has already been identified. A representative sample of the German general population (n = 2000), 83 relatives of AD patients and 43 physicians were interviewed regarding their attitudes towards genetic tests for AD, and their perception and interpretation of risk. The study is ongoing and to assess the influence of genetic counseling, 200 people are questioned before and 4 weeks after they have been provided with detailed relevant information.sp; Results

Our results show that the majority (85%) of the representative sample is in favour of predictive genetic testing for AD. 43% of the general population, 50% of the relatives and 30% of the physicians expressed an interest in being tested for APOE4. 25% of the general population, 10% of relatives, and 2% of physicians were in favour of prenatal testing. The majority had difficulty interpreting risk information. Only 34% understood the meaning of risk estimates given as percentages. Preliminary results suggest that genetic counselling significantly improves this understanding.

Women's perspectives on genetics: understanding, expectations and values. *B. Wilson¹, B. Potter¹, Y. Chorny¹, I. Boland¹, I. Graham², M. Walker², D. Coyle².* 1) University of Ottawa, Ottawa, Ontario, Canada; 2) Ottawa Health Research Institute, Ottawa, Ontario, Canada.

Purpose: This project is designed to examine the relationship between what people actually understand about genetics, their personal values on the acceptable use of genetic technologies, and their expectations of what it is appropriate for a publicly funded health service to provide. These issues are being explored in a sample of individuals likely to have considered some of them in a personal way, i.e. women who have been offered routine screening tests in past pregnancies. **Methods:** This is the first part of a multi-method study. Women who delivered a healthy child at the Ottawa Hospital between 1994 and 2004 are recruited using a purposive sampling strategy. Data collection is by semi-structured interviews. Thematic analysis is conducted as the data are collected, allowing for an evolving range of issues to be explored. A modified grounded theory approach is used for the analysis of transcripts. Approximately 72 women will be interviewed by fall 2004. **Results:** Key themes emerging so far are: (1) influences on the perceived personal value of testing (e.g. personal notions of risk, understanding of the difference between predictive and diagnostic tests, the value of information as an end in itself, the perceived value of medical technologies); (2) personal decision-making processes (e.g. the role of social networks and shared experiences, active and passive decision-making styles); (3) the importance of freedom of individual choice (e.g. others should be allowed to make their own choices irrespective of the views of the interviewee, the perceived importance of self-awareness); and (4) issues related to the health care system (e.g. fair access to services, willingness to pay, potential targeting of genetics services, the concept of necessity, differences between prevention and treatment goals). **Anticipated value:** This study will provide insight for policy decision makers and providers who wish meaningful feedback from citizens and service users. It will also provide evidence on the utility of methods for public engagement in health care decision making.

Molecular analysis of 32 common CFTR mutations in Chilean patients with cystic fibrosis. *G.M. Repetto¹, A. Puga¹, M.L. Boza², M.A. Perez³, R. Kogan³, O. Fielbaum⁴, C. Pierry⁵, M. Linares⁶, M. Mendez⁷, H. Poggi⁸, R.A. Pardo⁸, E. Romeo⁸, A.C. Foradori⁸, P. Astudillo⁹.* 1) Dept Genetics, Univ del Desarrollo-Clinica Alemana; 2) Hospital San Borja Arriaran; 3) H. Exequiel Gonzalez Cortes; 4) H. Luis Calvo Mackenna; 5) H. San Juan de Dios; 6) H. Padre Hurtado; 7) H. Sotero del Rio; 8) P. Universidad Catolica de Chile; 9) Ministerio de Salud, Santiago, Chile.

A National Cystic Fibrosis (CF) Program was initiated in Chile in 2000 to improve access to diagnosis and therapy for known patients in the country. Two hundred and seventy patients have been registered, accounting for more than 90% of known patients. With a mean survival age of 12 years, this would imply a disease incidence of about 1 in 15,000, but the actual figure is unknown. We report initial data on molecular analysis on patients in the program and an evaluation of the frequency of F508 carriers in healthy population to estimate the disease frequency. DNA samples from 60 unrelated patients were analyzed for the presence of 32 "common" mutations by PCR-OLA using the commercial assay Cystic Fibrosis v3.0 (Celera Diagnostics USA). The detection rate was 38.5% and 6 mutations were found: F508 in 27% of alleles, R334W in 5%, G542X in 3.3%, 3849+10kb CT in 1.6%, W1282X and 1078delT in 0.8% each. The relatively high frequency of R334W and G542X is consistent with the Spanish contribution to Chilean population admixture. The presence of F508 was evaluated by allele specific PCR in 300 healthy individuals representative of the mixed population of Santiago. The mutation was found in 2 alleles. Given these data, the carrier rate for any mutation was estimated to be around 1 in 40 and the disease frequency, 1 in 6400. The results are similar to other Latin American countries and emphasize the need to improve clinical and molecular diagnosis of CF in the region.

Cost Comparison of Genetic and Clinical Screening in Families with Hereditary Hemorrhagic Telangiectasia.

*J.H. Cohen*¹, *M.E. Faughnan*¹, *M. Letarte*², *K. Vandezande*³, *S.J. Kennedy*⁴, *M. Krahn*⁵. 1) Respiratory Medicine, St.Michael's Hospital, Toronto, Ontario, Canada; 2) Cancer Research Program, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) HHT Solutions, University Health Network, Toronto, Ontario, Canada; 4) Dept. of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Department of Medicine, University Health Network, Toronto, Ontario, Canada.

Background: Endoglin (ENG) and ALK-1 mutations cause Hereditary Hemorrhagic Telangiectasia (HHT), an autosomal dominant disorder leading to vascular dysplasia in the form of mucocutaneous telangiectasia and visceral arteriovenous malformations (AVMs). **Aims:** To compare costs of two alternative strategies for management: screening HHT families by a molecular diagnostic test followed by clinical screening only for individuals who carry the family's mutation versus conventional clinical screening. **Methods:** Direct health care costs associated with clinical and genetic screening for a hypothetical HHT family were evaluated using a decision analytic model. The family consists of one index case (an individual with a clinical diagnosis of HHT) and 13 of their relatives. The clinical screening protocol was determined from the medical literature and expert opinion from the Canadian HHT Center in Toronto. Unit costs for clinical screening were in Canadian dollars and were obtained from the 2002 Ontario Health Insurance Schedule of Benefits. Genetic screening costs were estimated for Quantitative Multiplex PCR and sequencing of Endoglin (ENG) and ALK-1 genes, as performed at HHT Solutions, Toronto. **Results:** Based on a weighted average of all family members screened, it was determined that the genetic/targeted clinical screening strategy costs \$3544 per individual versus \$4933 for the clinical screening strategy. Thus performing genetic screening strategy would save \$1389 per family member that totals \$18,057 saved per family. Sensitivity analyses revealed that the genetic screening strategy was cost saving over all plausible ranges of input variables for all hypothetical families tested.

Workplace screening for hemochromatosis does not cause psychological morbidity in participants and reveals an increased rate of fatigue in C282Y homozygotes. *M. Delatycki^{1,2}, A.E. Nisselle¹, V. Collins¹, S. Metcalfe^{1,2}, M.A. Aitken^{1,2}, D. duSart¹, J. Halliday^{1,2}, I. Macciocca¹, A. Gason^{1,2}, R. Williamson^{1,2}, K.J. Allen^{1,2}.* 1) Murdoch Childrens Research Institute, Victoria, Australia; 2) Department of Paediatrics, University of Melbourne, Victoria, Australia.

Introduction- There is debate as to whether community genetic screening for hemochromatosis should be implemented, due to issues including disease penetrance, health economic outcomes and concerns about community acceptance. Hemochromatosis is a common, preventable iron overload disease, due in over 90% of cases to C282Y homozygosity in the *HFE* gene.

Methods- C282Y screening was undertaken in the workplace. Questionnaires were administered following group education and to a subcohort following result disclosure. Anxiety was measured by the STAI.

Results- 11 042 people had screening. Analysis is from the first 10 472 participants. Of those eligible, 9.3% (range 3-86%) attended information and screening sessions, of whom 93.3% chose to be tested. 48 C282Y (1:218) homozygotes and 1195 heterozygotes (1:8.8) were identified. 22/34 (65%) C282Y homozygotes had abnormal iron indices. One C282Y homozygote fulfilled the criteria for liver biopsy (ferritin 4036g/L) and had precirrhotic fibrosis. C282Y homozygotes had a significantly higher rate of fatigue (CC- 57.6%; CY- 59.2%; YY- 81.8%. $\chi^2 = 8.94$, $p=0.01$). There was no significant difference seen between the groups for abdominal pain, arthritis or liver disease. Pre and post test anxiety was not significantly different in C282Y homozygotes compared to heterozygotes or wildtype homozygotes. There was a non-significant decrease in anxiety with the diagnosis of C282Y homozygosity or heterozygosity (CC pre 34.3, post 35.3; CY pre 35.4, post 30.0; YY pre 35.2, post 32.1).

Conclusion- Widespread screening for hemochromatosis is readily accepted in a workplace setting and C282Y homozygosity does not result in increased anxiety. There is an increased rate of fatigue among C282Y homozygotes.

A randomized trial on acceptability of DNA versus blood marker testing to detect hemochromatosis in primary care settings: The HEIRS study. *R.T. Anderson¹, N. Press², D. Tucker³, L. Wenzel⁴, B. Snively¹, M. Hall¹, S. Ellis¹, A. Walker⁴, E. Thomson⁵, O. Lewis-Jack⁶, R.T. Acton³.* 1) Wake Forest University, Winston-Salem, NC; 2) Kaiser Permanente Center for Health Research, Portland, OR; 3) University of Alabama at Birmingham (UAB), AL; 4) University of California, Irvine (UCI), CA; 5) National Human Genome Research Institute, Bethesda, MD; 6) Howard University, Washington, DC.

Genetic screening may enable timely and effective detection and treatment of hemochromatosis (HH) in primary care settings. However, little information is available about the acceptability of DNA testing vs. conventional blood marker tests of iron stores. Within the HEIRS Study, a multi-site primary-care-based screening study for HH, a separate study was conducted to assess patients willingness to be tested for HH by type of test among black and white patients. Participants were randomized to receive brief information on HH DNA or blood marker testing; study outcomes included willingness to be tested and attitudes toward HH testing. Results: A total of 2,186 participants were recruited from waiting rooms of primary care practices prior to contact by HEIRS staff, of these 2,165 met the final study criteria. Adjusting for age, Field Center, gender, educational attainment and global health rating, there were no differences in acceptability by DNA (55.8%) versus blood marker (58.6%), $p=.078$. Among Field Centers, blacks in Alabama were least likely to accept either form of test (44.7% and 49.6%) than whites, as were participants who were: aged 45-64 years, female, or who rated their health less than very good. Accepting HH testing was associated with the desire to know more about health (81%), and to help family members (71%). Reasons for refusing testing included a need for more information about HH from doctor (44%), privacy concerns (32%) and dislike of blood tests (29%). Conclusion: DNA testing for HH was not less acceptable than blood tests of iron stores in this diverse patient sample. Patient education on nature of test, importance of HH, and privacy protection appear to be essential for achieving high rates of participation of either test.

Detection of muscular dystrophy genotypes via universal condition direct sequencing (UCDS). *R.R. Bennett¹, H.E. Schneider¹, R.C. Nutter², P.S. Lai³, C.E. Barrett¹, V. Lip¹, B.L. Wu¹, B.T. Darras¹, L.M. Kunkel¹.* 1) Genetics, Children's Hosp, Boston, MA; 2) Applied Biosystems, Foster City, CA; 3) Department of Pediatrics, National University of Singapore, Singapore.

Currently, mutations in many of the genes causing the various forms of muscular dystrophy remain undetected in patients because of the unavailability of a reliable and cost effective assay to detect them. One promising strategy requires the amplification of all salient portions of a gene or many genes at one single set of PCR conditions. This is achieved by designing amplicons of uniform large (~1000bp) size. Internal primers are then used for sequencing (Flanigan et al. 2003). A second strategy being employed by Applied Biosystems, Foster City Ca. in its VariantSEQr resequencing system is to use automated primer design tools to seek primers for all salient portions of many genes. Using Amplitaq GoldPCR system, these amplicons will all amplify at a single set of PCR conditions. In addition, by using M13F and M13R tails on the primers, a universal sequencing plate can be utilized in this process. We have developed a high throughput 384 well plate robotic process with dried primers using the Applied Biosystems VariantSEQr resequencing system for genes associated with any form of muscular dystrophy. The new sequencing strategy provides more than an order of magnitude reduction in cost, time to detect mutation and complexity of analysis. Detection of mutations is facilitated rapidly using SeqScape v2.1 software (Applied Biosystems, Foster City Ca.). This software incorporates a consensus sequence based on the NCBI database, complete gene annotation of all NCBI and Celera transcripts for the gene of interest and a tab process for tabing through all variations between patients and consensus. It also features rapid identification of known polymorphisms versus unknown variants as well as insertions and deletions. As of June 2004, we have tested this process called UCDS (Universal Condition Direct Sequencing) for the DMD, CAV3, TRIM32, CAPN3, FKRP and FCMD genes using control DNA and two DMD patients. More genes and more patients will be studied over the summer.

Immunodetection of myotubularin for expression studies and for diagnosis of myotubular myopathy. A. Buj-Bello, J. Laporte, G. Duval, J.L. Mandel. Molecular Pathology, IGBMC, CNRS/INSERM/ULP/College de France, ILLKIRCH, France.

X-linked myotubular myopathy (XLMTM) is a severe congenital myopathy characterized by generalized hypotonia and respiratory insufficiency at birth. The gene responsible for the disease, MTM1, encodes a phosphoinositide phosphatase named myotubularin with an essential function in skeletal muscle that is conserved in mice, as *Mtm1* deficient (KO) mice develop a progressive centronuclear myopathy during postnatal life leading to death. MTM1 belongs to a large disease-associated gene family with 14 members in humans, which includes MTMR2 and MTMR13, mutated in Charcot-Marie-Tooth demyelinating neuropathies type 4B1 and 4B2, respectively. Direct sequencing of the 15 MTM1 exons and flanking intronic sequences generally establishes the molecular diagnosis. More than 300 mutations have been identified in approximately 85% of patients with an XLMTM-like phenotype. Mutations in some patients may be located in the promoter or in other intronic regions of the gene, which are not routinely analyzed. We have established a novel protocol by immunodetection of myotubularin that can be used as an alternative approach for diagnosis of XLMTM. For this, we have generated a novel polyclonal antibody against myotubularin that can detect the endogenous protein by direct western blotting. We prepared protein homogenates from lymphoblast, fibroblast and myoblast cell lines and found abnormal levels of myotubularin in most analyzed XLMTM cell lines, with either a decrease or absence of the protein. More importantly, we are also able to detect myotubularin in lymphocytes isolated from peripheral blood of normal individuals, which should avoid transforming cells to apply this procedure. This technique may thus be useful for molecular diagnosis, especially in cases in which MTM1 mutations have not been found and to analyse the effect of variants of uncertain pathogenicity on expression of the protein. In addition, we have analyzed myotubularin expression during mouse development by immunoblotting and observed a postnatal accumulation of myotubularin in skeletal muscle, that correlates well with the postnatal onset of muscle pathology in *Mtm1* KO mice.

Cost-effectiveness of a schools-based Tay-Sachs disease (TSD) and cystic fibrosis (CF) genetic carrier screening

program. *L. Burnett*¹, *E. Warren*², *R. Anderson*², *A. Proos*¹, *K. Barlow-Stewart*³, *J. Hall*². 1) Pacific Laboratory Medicine Services (PaLMS) and Kolling Institute of Medical Research, Royal North Shore Hospital, St Leonards, NSW, Australia; 2) Centre for Health Economics Research and Evaluation (CHERE), University of Technology Sydney, Sydney, NSW, Australia; 3) Centre for Genetic Education, NSW Genetics Service, Royal North Shore Hospital, St Leonards, NSW, Australia.

Aims: To explore cost-effectiveness (CE) of a school-based two-disease genetic carrier screening program, compared with no school-based screening and various other scenarios.

Method: A decision analytic model was developed to estimate the incremental CE of a school-based TSD and CF genetic carrier screening program, relative to no screening program. The cost of the program was built up using a micro-costing approach, and effectiveness measured as the number of genetic carriers detected. Data relating to ethnicity, test-accepting behaviour and result notification schemes were sourced from a reference program in Sydney, Australia. The impact on CE of underlying assumptions in both screening and no screening alternatives has been explored in sensitivity analyses.

Results: The estimated annual cost of the reference school screening program for TSD and CF is A\$137 per student screened. Relative to no screening program, the incremental CE of the reference program is ~A\$6,000 per additional carrier detected, implying a cost per TSD or CF child avoided of ~A\$530,000. More efficient strategies for detecting genetic carriers have been identified, including restricting access to testing only to those at increased *a priori* ethnic risk; this reduces the cost per additional carrier detected to ~A\$5,000. Sensitivity analysis shows that the CE ratio is most sensitive to changes in genetic test accuracy, cost of laboratory assays, and the relative weighting CF and TSD genetic carriers. The model allows estimation of the cost of any future equally efficient non-schools-based public awareness campaign for genetic carrier screening.

Controversies in determining appropriate uses of genetic information in the diagnosis, treatment and prevention of Autosomal Dominant Polycystic Kidney Disease. *S. Cox, S. Yew, B. Askwith.* Centre for Applied Ethics, University of British Columbia, Vancouver, BC, Canada.

Aims: This qualitative study investigates patient, family and health care provider perspectives on the uses of genetic information in the diagnosis, treatment and prevention of autosomal dominant polycystic kidney disease (ADPKD). The aim is to inform appropriate clinical practice, patient education, health services and policy. **Background:** ADPKD is a common hereditary disorder that causes fluid-filled cysts on the kidneys and progressive loss of renal function. Diagnosis is typically made using ultrasound although the absence of renal cysts is not definitive for persons < 30 years. Genetic testing of the PKD1 and PKD2 genes by linkage or mutation analysis is available but uptake for presymptomatic and prenatal testing in Canada is low. **Methods:** In-depth interviews with 30 PKD patients and family members, and 15 health care providers were conducted in Canada in 2003-2004. Thematic analysis of the data focuses on awareness of the availability of genetic testing, perceived clinical utility, and associated benefits and harms. **Findings:** Awareness and perceived utility of genetic testing varies widely amongst persons at risk for or diagnosed with PKD, family members and health care providers. Three case studies featured in this presentation exemplify social, ethical and clinical challenges in using genetic testing for: 1) presymptomatic diagnosis, 2) identification of potential living related kidney donors, and 3) targeted surveillance for ADPKD patients at high risk of associated complications such as cerebral aneurysm. **Conclusion:** Clarification of social and ethical as well as clinical controversies surrounding the utility of genetic testing for ADPKD will lead to the development of criteria that assist health care providers, policymakers, nonprofit associations, patients and families in defining appropriate uses of genetic information. In the next phase of research, the controversies identified here will be used to stimulate dialogue in focus group discussions with a range of ADPKD stakeholders.

Frequent finding of duplications in the DMD gene in patients with Duchenne / Becker muscular dystrophy identified by MLPA. *R. Fahsold, K. Hager, C. Ehlers, H. Monir.* Institute Med. Genetik, Dresden, Germany.

The dystrophinopathies - the severe type Duchenne (DMD) and the milder type Becker (BMD) are the most common inherited disorders of muscle with a prevalence of 1:3500 live male births. Both BMD and DMD are X-linked diseases resulting from a defect in the huge gene DMD (~2,4 Mb of genomic sequence), that encodes the protein dystrophin. In most studies, deletions of one or more exons are found in approximately 65 % of patients; duplications account for 6 % of mutations, and point mutations account for the remainder. The detection of copy-number changes in the DMD gene, especially the verification of duplications in effected males, was only possible with complex, specific and labor intensive quantitative techniques (e.g. Southern blotting and real-time PCR). But now there is a simple and effective method to establish the copy number of specific sequences: Multiplex Ligation-dependent Probe Amplification (MLPA). With MLPA, it is possible to quantify all of the 79 DMD-Exons simultaneous in only two multiplex PCR reactions. Our experiences and results with the use of MLPA shows, that the rate of duplications in effected males seems to be higher than expected in previous studies. We will present our cases, for example a novel duplication in the 3-region of the DMD gene.

Non-Profit Reference Laboratories to Implement Genetic Tests for Complex Orphan Diseases. *B. Gallie*^{1,2,3,4}, *K. Vandezande*^{2,3}, *M. Letarte*^{3,4}. 1) Ontario Cancer Institute, Toronto ON; 2) Retinoblastoma Solutions, Toronto, ON; 3) HHT Solutions, Toronto, ON; 4) The Hospital for Sick Children, Toronto, ON, Canada.

We document ongoing projects to establish self-sustaining reference labs for two orphan genetic disorders: retinoblastoma (RB) and hereditary hemorrhagic telangiectasia (HHT). Both diseases result from mutations in large genes and each affected family has its own unique mutation. We formed non-profit corporations to achieve the highest quality testing at affordable cost, developed molecular assays for each class of potential mutation, and optimized for maximum test sensitivity and minimum turnaround time. For both RB and HHT, we are achieving the highest test sensitivity yet documented. Despite the inherent complexity of mutation detection for these diseases, clinical impact studies suggest that optimized molecular tests can achieve lower healthcare cost and higher quality of life. Standard care without molecular knowledge requires frequent, expensive and invasive clinical screening. Health outcomes improve when molecular tests identify carriers of a familial mutation for early intervention. Health costs are reduced when individuals at risk are shown not to carry a mutation and no longer need clinical surveillance. For these two complex disorders, optimized molecular diagnosis improves the quality of life and decreased health costs, indicating that the application of genome knowledge to healthcare does not necessarily increase costs. Public clinical diagnostic labs are ill-funded for technical and economic optimization of tests, while private industry sees investment risks in molecular tests for rare and difficult disease genes. We propose that self-sustaining labs with disease-specific focus should receive national and international support and become "global" reference labs for a specific number of orphan diseases. We find that non-profit charitable form offers distinct advantages for reference labs over alternative organizational structures.

Program Nr: 1491 from the 2004 ASHG Annual Meeting

Quantitative PCR for the rapid detection of deletions in Hunter syndrome. *J.R. Jones, H. Risheg, T.C. Wood, M.J. Friez.* Greenwood Genetic Center, Greenwood, SC.

Hunter syndrome or mucopolysaccharidosis type II (MPS II) is an X-linked recessive lysosomal storage disease resulting from a deficiency of the enzyme iduronate-2-sulfatase (IDS). Features include mental retardation, short stature, coarse facies, skeletal deformities, stiff joints, and cardiovascular disorders. Molecular analysis has identified many different types of alterations in the IDS gene, including small deletions, missense, nonsense, and splice site mutations. In addition, a variety of techniques have identified large deletions in a small fraction of cases. Unfortunately, when large deletions are identified in affected males, it is difficult to determine whether female relatives are carriers of the deletion. In order to assess carrier status in at-risk females, we have developed a rapid method for determining IDS gene dosage using real time PCR. During the validation of this technique, we compared the absolute quantitation method using 3 reference genes to the comparative threshold cycle method (Ct) using only RNaseP as the internal reference. Testing was performed using DNA samples from females with affected male relatives who were suspected of having a deletion based on the failure of PCR to amplify the coding region of IDS. Thus far, 4/4 males have been confirmed to have a deletion involving the IDS gene, and 2/5 females have been found to carry a deletion. Interestingly, one of the 2 carriers is an affected female with highly skewed X inactivation. The Ct method gave consistent results while the absolute quantitation method showed some variation and discrepancies in results possibly due to deviations within the standard curves. Our results indicate that the Ct method of real time PCR is a rapid, reliable approach for the identification of IDS gene deletions in affected individuals and carrier females.

Cystic Fibrosis Carrier Testing: The Collection and Utility of Ethnicity/Race Information on the Laboratory

Requisition Form. *I.M. Lubin^{1,5}, M. Caggana^{2,5}, D.J. Wolff^{3,5}, C. Constantin¹, L. Kalman¹, J.A. Nowak^{4,5}.* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) New York Dept. Health, Wadsworth Center, Albany, NY; 3) Dept. Path./Lab. Med., Medical University of South Carolina, Charleston, SC; 4) Dept. Path., Advocate Lutheran General Hospital, Park Ridge, IL; 5) Association for Molecular Pathology, Clinical Practice Committee, Bethesda, MD.

DNA-based cystic fibrosis (CF) carrier testing is useful for counseling prospective parents about their risk of having an affected child and other family members at risk. Knowledge of the patient's ethnicity/race is used to calculate residual risk when no mutations are found. This report describes the variation in clinical laboratory requisition forms (n=32, commercial and academic) in requesting ethnicity/race data and implications for calculating residual risk. All requisitions requested ethnicity/race information. The majority of requisitions was designed for ordering multiple tests and the ethnicity/race information requested may be pertinent to tests other than CF. Eight (25%) requisitions requested such information but did not provide specific choices. The remaining laboratories offered 2 to 11 choices including the option to specify a category not listed. ACMG and ACOG CF guidelines provide carrier risk data for five ethnic/racial groups. Of the laboratories offering specific descriptors (n=24), 14 (58%) provide additional choices and 4 (17%) provide fewer. Six requisitions (25%) offered five choices, not necessarily matching those in the guidelines. Carrier frequency data for certain CF mutations are available in the literature and some laboratories use additional data ascertained locally. Risk estimates can therefore be variable based upon what ethnicity/race information is used. There is a need for practice guidelines in the selection, collection, and use of ethnicity/race information to assure appropriate determination of residual risk. Admixture is a related topic requiring consideration. These issues will gain added significance as we expand beyond CF to other carrier and predictive tests that will influence health care decisions.

Attitudes regarding testing adolescents for carrier status. *T. Mulhaupt*^{1,2}, *A. Lovell*^{1,2}, *L. Mills*², *R. Hopkin*^{1,2}. 1) Allied Health Sciences, University of Cincinnati; 2) Cincinnati Children's Hospital Medical Center.

Based on the premise that there are no immediate medical or psychosocial benefits, a position statement published by ASHG/ACMG recommends deferral of testing adolescents for carrier status until adulthood in most cases. To characterize the application of the position statement, we determined factors that genetic service providers considered influential in a decision to test adolescents for carrier status and if their knowledge of the position statement was helpful in considering this issue. We invited genetic counselors, medical geneticists and genetic nurses to participate in an online survey. We measured the factors that influenced the decision by asking subjects to rank the top five of sixteen reasons for testing in their most recent case. The factor that was selected most frequently was judged the most influential. We assessed the use of the position statement by asking subjects to rate the helpfulness of their position statement knowledge. 152/181 subjects (84.0%) tested an adolescent within the last year; 112 provided their reasons for testing. The decision to test was most influenced by adolescent desire (15.3%), adolescents competence/understanding (13.8%) and adolescent sexual activity/pregnancy status (12.0%). Overall, more subjects reported their knowledge of the position statement as unhelpful (22.9%) than those who reported their knowledge as helpful (13.7%). Ensuring that adolescents participate in the decision was a priority for those clinicians who offered testing. Although adolescent desire and competence/understanding are discussed in the position statement as reasons testing may be considered, it does not address the issue of carrier status testing in sexually active or pregnant adolescents or many other reported factors. Also, many subjects were unsatisfied with their knowledge or unfamiliar with the position statement recommendations. These findings suggest: 1) carrier testing is commonly offered to adolescents in the clinical setting, 2) the current position statement fails to address important issues relating to testing adolescents for carrier status, and 3) the position statement is not familiar to many genetic service providers.

A fourteen year technical, ethical and social struggle towards creating a model to prevent -thalassemia in Iran. *H. Najmabadi^{1,2}, A. Ghamari^{1,2}, F. Sahebjam¹, R. Kariminejad¹, T. Khatibi¹, A. Samavat³, E. Mehdipour¹, B. Modell⁴, M.H. Kariminejad¹. 1) Genetic Research Ctr, Kariminejad Najmabadi Genetics, Tehran, Iran; 2) The social welfare and rehabilitation sciences university, Genetic Research Center, Tehran, Iran; 3) Center for Disease Control, Deputy for Non-communicable Disease, Tehran, Iran; 4) RF & UCMS Dept of Primary Care & Population Sciences, and UCL Centre for Health Informatics and Multiprofessional Education (CHIME), Holborn Union Building, Whittington Campus, London, UK.*

For fourteen years Iranian scientists have worked to develop a national thalassemia prevention program. Historically abortion was considered unacceptable in Iran; however, intensive consultations led to the clerical approval of therapeutic abortion of cases with major type of -thalassemia in 1997, and a nation-wide prevention program with screening, counseling and prenatal diagnosis networks has been developed. This paper reports the experience from one of the two national prenatal diagnosis reference laboratories. From 1990 to 2003 we performed a total of 906 prenatal diagnoses from 718 families at risk for thalassemia. Direct and indirect mutation detection methods were applied for all cases. In total, 22 mutations were tested routinely and an additional 30 rare mutations were identified. 208 fetuses were found to be normal, 215 fetuses were major, and 435 fetuses were trait. In 40 cases we only defined one allele. We were unable to provide 8 cases with any diagnosis, corresponding to 0.9%. Our data supports the functionality of Iranian -thalassemia prevention program. The success of this system in Iran as a multiethnic and Islamic-based country would mean that it might be applied as an adaptive system for neighboring and other Islamic countries.

Communicating BRCA1 and BRCA2 test results: Data from a telephone interview with 332 women tested within the German Consortium on Hereditary Breast and Ovarian Cancer. *I. Nippert¹, C. Vogel¹, L. Wingen², D. Gadzicki², B. Schlegelberger².* 1) Women's Health Research, UKM, Muenster, Germany; 2) Institute of Cell and Molecular Pathology, MHH, Hannover, Germany.

Introduction: In order to promote safe and effective testing for BRCA1/2 mutations in clinical practice the German Consortium on Hereditary Breast and Ovarian Cancer (HBOC) has been established. To improve practice, evaluations based upon the views of patients who have undergone testing concerning the impact of the genetic diagnosis and the quality of the services they receive and require are undertaken. **Methods:** 332 women from HBOC families who had obtained their test results at least 6 months earlier were interviewed by telephone. The interview includes open and standardised questions. **Results:** Almost all women (98%) had consulted at least one family member before undergoing testing. 10% reported conflicts with at least one family member about whether or not the test should be taken. The communication process about the test was characterized by selective and preferential information of female family members both before testing and after obtaining the test result. Women with breast cancer showed a greater tendency to inform their children than women without breast cancer. 10% were asked by at least one family member not to tell results. Mutation carriers reported more conflicts with other family members in communicating test results than non-carriers (22% vs. 3%, $p < 0.05$). **Discussion:** Genetic counselling needs to raise awareness that both sexes may inherit the mutation and may benefit from information. Strategies need to be developed and evaluated regarding how to facilitate the dissemination of information within families without potentially overstraining the messenger patient at least when a mutation has been found..

Carrier frequency of familial hyperinsulinism mutations in Ashkenazi Jews. C. Oddoux, L. U, C.M. Clayton, H. Ostrer. Div Human Genetics, New York Univ Sch Medicine, New York, NY.

Familial hyperinsulinism (HI) is characterized by severe, recurrent hypoglycemia associated with an inappropriate elevation of serum insulin. It presents in neonates and infants and carries a substantial risk of death or severe brain damage and mental retardation.

The disorder is heterogeneous and variable and has been found to be caused by both recessive and dominant mutations in several genes including most commonly the SUR1 (ABCC8) and the KIR6.2 genes. Together, these encode the pancreatic beta cell K-ATP channel. Both are found on chromosome 11p15.1. In addition, 30% of HI cases represent a focal form where paternally inherited mutations in either SUR1 or KIR6.2, paired with *somatic* deletion of this imprinted region from the maternal chromosome results in an imbalance in growth factors leading to hypertrophy of pancreatic beta cells that are hemizygous for the paternal mutation and consequently over express insulin.

Estimates of the frequency of HI range from 1:50,000 births in Europe to as much as 1:2,500 births in isolated populations in which there are founder mutations. Among Ashkenazi Jews, two founder mutations in the SUR1 gene have been identified which account for 88% of detected mutations and most likely represent >95% of heritable mutations in light of the contribution of somatic deletion. Using a novel fluorescence assay we analyzed 900 Ashkenazi Jewish individuals to determine the carrier frequency of these two mutations: 3992-9 g->a and F1388. Six carriers of 3992-9 g->a and one carrier of F1388 were detected resulting in an overall carrier frequency of 0.8%. This frequency is comparable to that of Bloom syndrome and Fanconi anemia, which are commonly screened for in this population. Carrier screening for HI in this population provides a valuable means of early diagnosis to guide clinical management of patients which cannot easily be provided by a newborn screening program because of the early onset, high morbidity, and significant contribution of paired heritable and somatic changes in this disease.

A novel approach to ensuring the quality of DNA sequencing output - an international external quality assessment scheme. *S. Patton*¹, *A. Wallace*². 1) European Molecular Genetics Quality Network (EMQN), c/o National Genetics Reference Laboratory, St Mary's Hosp, Manchester, United Kingdom; 2) National Genetics Reference Laboratory, St Mary's Hosp, Manchester, United Kingdom.

Genetic testing is now a routine part of laboratory medicine. Many different technical approaches are used but DNA sequencing is widely regarded as the gold standard for mutation detection. But how accurate is DNA sequencing, and can we be sure we are getting the correct result 100% of the time? External Quality Assessment (EQA), or Proficiency testing, is one approach to independently quantifying the accuracy of the sequencing output from testing laboratories and sequencing facilities. We will present the results of novel EQA scheme for DNA sequencing run by the European Molecular Genetics Quality Network (EMQN) in 2003. The scheme consisted of two parts; a participant questionnaire and a practical assessment designed to assess the SENSITIVITY and ACCURACY of DNA sequencing and review the QUALITY of data provided. Test samples contained a range of different genotypes covering all the main types of sequence change. Results were evaluated for genotype and output quality. Sixty-one laboratories from twenty-one countries participated. Thirty-six (59%) of laboratories scored maximum for genotyping. Nine laboratories (15%) failed to detect sequence variants. The quality of the raw data produced was good. This scheme now gives laboratories an opportunity to compare their performance and use EQA to help and improve the quality of their DNA sequencing.

Molecular analysis of the MECP2 gene in Rett syndrome, Angelman-like and nonsyndromic mental retardation phenotypes. *R. Polli, L. Anesi, A. Casarin, A.M. Laverda, P. Drigo, A. Murgia.* Dept Pediatrics, Univ Padua, Padua, Italy.

Mutations of the Methyl-CpG-binding protein (MECP2) gene, known to be the main cause of Rett syndrome have also been described in individuals with partially overlapping phenotypes. We report the results of a molecular analysis of the MECP2 gene in subjects with neurodevelopmental conditions suggestive of Rett syndrome, in patients with Angelman-like phenotype without alterations of the PWS/AS critical region on 15q11-13, and in subjects with unexplained non syndromic mental retardation. The molecular strategy originally adopted for the study included PCR/SSCP/Sequencing for identification of point mutations or small-size deletions/insertions. This type of analysis allowed the identification of 14 different MECP2 alterations 8 of which disease-causing and 6 polymorphic variants. We found disease-causing mutations in 9/18 female subjects referred for suspected Rett syndrome and in 1/57 individuals with a suspected Angelman syndrome. No MECP2 pathologic variants were identified in 33 subjects with isolated mental retardation. No new disease-causing mutations have been identified, and only two of these are among the most common MECP2 variants. Two of the polymorphisms detected, both in the 3'UTR region, are new variants. Recently a new protocol of Real-Time quantitative PCR, has been implemented and applied to 11 MECP2 negative samples. The new method has allowed to detect, in one female subject with Angelman-like phenotype, the presence of a large deletion that we have been able to document only as a gene dosage reduction on genomic DNA. The fact that only 50% of our clinically Rett syndrome cases resulted to carry MECP2 pathogenic mutations could at least partially be due to the clinical criteria adopted for the selection of the patients. On the other hand, it is likely that MECP2 large genomic deletions/rearrangements are more frequent than previously thought and play a much more relevant role in the aetiopathogenesis of Rett syndrome and other neurodevelopmental diseases. The introduction of new and more precise techniques for the detection of these alterations will probably significantly improve the rate of mutation detection in the MECP2 gene.

Analysis of common alpha-thalassemia point mutations and deletions by reverse-hybridization. *H. Puehringer*¹, *E. Baysal*², *H. Najmabadi*³, *W. Krugluger*⁴, *C. Oberkanins*¹. 1) ViennaLab Labordiagnostika GmbH, Vienna, Austria; 2) Genetics Department, Al Wasl Hospital, Dubai, UAE; 3) Genetics Research Center, The Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 4) Department of Clinical Chemistry, Municipal Hospital Rudolfstiftung, Vienna, Austria.

Alpha-thalassemia (alpha-thal) is the most common inherited hemoglobin disorder worldwide. It is observed in high frequencies throughout Southeast Asia, India, the Middle East, parts of Africa and the Mediterranean area. Alpha-thal is characterized by the reduced synthesis or absence of alpha-globin chains due to mutations affecting one or both genes located in tandem on chromosome 16. Unlike the prevalence of point mutations in beta-thal, the majority of alpha-thal alleles are derived from single gene deletions (-alpha3.7, -alpha4.2) or from double gene deletions (--alpha20.5, --MED, --SEA, --THAI, --FIL). The clinical phenotype varies from asymptomatic to lethal (Hb Barts hydrops fetalis syndrome) according to the number of affected alpha-globin genes and the resulting imbalance of hemoglobin subunits. We have developed a reverse-hybridization assay (Alpha-Globin StripAssay) for the rapid and simultaneous detection of common alpha-globin point mutations, single gene and double gene deletions. The test is based on multiplex DNA amplification (including gap-PCR) and hybridization to teststrips presenting a parallel array of allele-specific oligonucleotide probes for each variant. The entire procedure from blood sampling to the identification of mutations requires less than 6 hours, and hybridization/detection may be carried out manually or essentially automated using existing instrumentation (e.g. TECAN profiBlot). The test is simple and convenient, and requires very small amounts of samples, which is of particular importance for prenatal diagnosis. Although the spectrum of alpha-thal mutations is known to be highly population-specific, the broad range of variants covered by the Alpha-Globin StripAssay should make it a globally useful diagnostic tool. (oberkanins@viennalab.co.at).

Willingness to pay for hereditary breast cancer testing: variation by exposure to Direct-to-Consumer advertising.

D.P. Ritzwoller¹, R. Meenan², J. Mouchawar¹, J. Ellis¹, S.H. Alford³, M.L. Finucane², A.K. Rahm¹. 1) Clinical Research Unit, Kaiser Permanente, Denver, CO; 2) Center for Health Research, Kaiser Permanente, OR and HI; 3) Henry Ford Health System, Detroit, MI.

Background: In September 2002, Myriad Genetics, Inc. initiated a direct-to-consumer advertising (DTC-ad) campaign associated with its BRCA 1/2 genetic test in Denver and Atlanta. Genetic testing is a covered benefit in many managed care organizations, but uncertainty exists about the value to members. **Purpose:** To employ willingness-to-pay (WTP) methodology to assess the value of genetic testing services for breast cancer among female MCO members, and compare such values by exposure to the DTC-ad. **Methods:** Written surveys were mailed to a random sample of women aged 25-54 at Kaiser Permanente Colorado (KPCO) in Denver, where the DTC-ad took place, and at Henry Ford Health System in Detroit, where there was no DTC-ad. The survey included WTP questions that varied both with respect to underlying 15-year breast cancer risk as well as bidding algorithms. Recipients were asked for their WTP directly for a genetic test for breast cancer risk, as well as for increasing their monthly insurance premium. **Results:** Overall response rate was 47% with 63% of respondents reporting exposure to information regarding BRCA 1/2 testing; 45% reporting exposure to DTC-ad, with 72% being KPCO members. No significant level of correlation was found across SES variables. Controlling for SES and risk scenario, respondents exposed were 66% more likely than those not exposed to be willing to pay a positive amount out of pocket for testing, with 60% willing to pay \$200, and 24% willing to pay \$500. Of those willing to pay an increased monthly insurance premium, 27% would pay \$15 more per month, 21% would pay \$5 more. No significant start point bias was found. **Conclusion:** Exposure to information regarding genetic testing along with a woman's perceived underlying cancer risk may positively influence her WTP for genetic testing services. Given that testing may only provide value for small percentage of the general population, these results could support variation in co-pay and co-insurance by risk status.

Semi-automated, high throughput fluorescent comparative polymerase chain reaction (FC-PCR) determination of -globin gene dosage: implication for population screening of alpha thalassemia deletions. *S. Wang¹, F. Quan¹, R. Tseng², W. Sun¹, C.M. Strom¹.* 1) Dept. of Molecular Genetics, Quest Diagnostics Nichols Inst, San Juan Capistrano, CA; 2) Dept. of Hematology & Oncology, Quest Diagnostics Nichols Inst, San Juan Capistrano, CA.

Alpha thalassemia is caused by deficient synthesis of -globin, encoded by nearly identical genes, 1 and 2. Over 95% of -thalassemia alleles are caused by deletions involving either or both of the genes. More than 30 different -thalassemia deletions have been reported. The severity of -thalassemia is inversely correlated to quantity of normal -globin genes. Co-inheritance of an -thalassemia allele can ameliorate the phenotypes of -thalassemia, whereas amplification of -globin gene may exacerbate the severity of -thalassemia. To determine the gene dosage, the one-tube FC-PCR amplifies 6 gene fragments by 4 fluorescent primer pairs: **1)** Upstream fragments of both 1 and 2 genes (differ in size by 7-bp) are amplified by same primer pair; **2)** Downstream fragments of both 1 and 2 genes (differing in size by 8-bp) are amplified by second primer pair; **3)** FACC and HEXA genes are analyzed as controls. PCR products are analyzed on an automated DNA analyzer and fragment size and signal intensity analyzed by GeneMapper software. -Globin gene dosage is determined by the collective analysis of fluorescent signal ratio of all amplicons. The assay accuracy was validated by blinded analyses of 44 DNA samples with various copy numbers (0-5) of genes with 100% accuracy. To evaluate utility for population screening of -thalassemia deletion, DNA samples from 88 unrelated individuals, presumably representing diverse ethnic background of US population, were studied. A total of 9 alleles carrying deletion of one -globin gene were detected, representing the carrier frequency of more than 10%. The high throughput and cost effectiveness of this FC-PCR method make population screening for -thalassemia deletions a possibility. In addition to the postnatal diagnosis of thalassemia and evaluation of phenotypic variation of -thalassemia, this method is extremely valuable in prenatal diagnosis of Hb Bart's and Hb H diseases.

Molecular genetic testing for PTPN11 gene mutations in Noonan syndrome. *J. Wiszniewska, A. James, J. Lescher, K. Hoon, P. Fang, M. Hegde, B.B. Roa.* Baylor Medical Genetics Laboratories, Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, Texas, USA.

Noonan syndrome (NS) is an autosomal dominant disorder with an estimated prevalence of 1 in 1,000 to 2,500. Clinical characteristics include facial dysmorphism, growth retardation, skeletal malformations and congenital heart disease as the most common features. NS is genetically heterogenous, wherein mutations in the PTPN11 gene encoding the non-receptor protein tyrosine phosphatase SHP-2 account for approximately 50% of both familial and sporadic cases. Our laboratory implemented clinical molecular testing by sequence analysis of the entire PTPN11 coding region. Analysis of 15 coding exons and the flanking exon/intron boundaries of the PTPN11 gene were performed through PCR amplification and bi-directional DNA sequencing. We studied a cohort of 94 patients referred to our laboratory for Noonan syndrome molecular testing. This group included 5 patients who were indicated to have a definite diagnosis of Noonan syndrome, 65 patients referred with a possible diagnosis, and 24 patients for whom minimal information was provided by the various referral sources. Mutations in the PTPN11 gene were found in a total of 25 out of 94 patients; these were comprised of 1, 19 and 5 mutation positive patients belonging to the first, second and third groups, respectively. Nineteen different mutation alleles were identified. These included two missense variants, 1472CT (P491L) and 1529AC (Q510P), which are allelic substitutions for two previously reported PTPN11 mutations. In addition, we found a novel variant, 155CT (T52I), whose clinical significance is currently undefined. Parental analysis was recommended in these cases. The majority (84%) of mutations were found in exons 3, 8 and 13. Our diagnostic testing experience demonstrates the value of PTPN11 mutation analysis in patients for whom a diagnosis of Noonan syndrome is being considered. These results are consistent with the phenotypic variation that has been reported among patients with PTPN11 mutations.

A novel mutation screening protocol in patients with Wiskott-Aldrich Syndrome (WAS) and related disorders. *K. Zhang¹, D.J. Marmar², A.H. Filipovich², R.J. Wenstrup¹*. 1) Division of Human Genetics, Children's Hospital, Cincinnati, OH; 2) Division of Hematology/Oncology, Children's Hospital, Cincinnati, OH.

Wiskott-Aldrich syndrome is an X-linked recessive disorder characterized by thrombocytopenia, eczema and immunodeficiency. Without bone marrow transplantation and other supportive treatments, median survival is approximately fifteen years of age. WAS is caused by mutations in the gene encoding an intracellular protein, WASP, that is involved in signal transduction and regulation of actin cytoskeleton organization of hematopoietic cells. The gene responsible for WAS has 12 exons, encodes a 502 amino acid proline-rich protein. To date, about 170 mutations have been reported in the WAS gene, resulting in classical WAS and several other leukopoietic disorders including X-linked thrombocytopenia (XLT) and X-linked congenital neutropenia (XLN). These mutations are broadly distributed through all the exons. Linkage analysis, single-strand confirmation polymorphism (SSCP) mutation screening, and X-chromosome inactivation studies have been used to identify the mutations in WAS. However, given the size and molecular composition of the WAS gene, these protocols are either labor intensive or lack the sensitivity which is required in a clinical setting. We developed a PCR and direct-sequencing based protocol for WAS mutation screening. A single PCR program was designed and optimized to amplify the entire coding region and all twelve exon/intron boundaries at once. The PCR products were then used to perform sequencing analysis. This protocol requires only 4 hours of technician time and approximately one day of machine time. Six patients and/or obligate carriers were tested by this method. Two novel mutations have been identified. The results are supported by intracellular WAS protein analysis in leukocytes using a monoclonal antibody by flow cytometry. This new protocol has been shown to be reliable, sensitive, specific and cost effective. It provides the opportunity for physicians to make timely diagnosis of WAS.

Maternal Serum Screening in Northern Alberta: The Need for a Provincial Program. *K.J. McElligott¹, S.M. Christian¹, S.A. Kieffer², J. Reeve³, F. Bamforth³, J.S. Bamforth³.* 1) Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) University of British Columbia, Vancouver, British Columbia, Canada; 3) University of Alberta, Edmonton, Alberta, Canada.

Background: Utilization of maternal serum screening in Alberta is significantly lower than in other provinces in Canada with structured screening programs. **Method:** In an effort to understand this low utilization rate, knowledge, attitudes and practice patterns of physicians in Northern Alberta were assessed through a survey. **Results:** This survey found that only 22 % of physicians were appropriately offering the screen to all their pregnant patients. Physician age, number of prenatal patients followed, and whether the physician felt that the test was standard of care and medically-legally necessary to offer, significantly influenced practice patterns. Finally, physician views on termination also significantly influenced practice patterns. **Interpretation:** The under utilization of a test that is offered as standard of care across Canada places Alberta patients at a disadvantage. One avenue, which has been adopted in other provinces, is the development of a provincial screening program. By way of a comprehensive program, educational issues, and appropriate counselling and follow up which are current barriers to the provision of care, can be addressed.

Efficient mutation detection in Hereditary Hemorrhagic Telangiectasia using Temperature Gradient Capillary Electrophoresis, Conformation Sensitive Gel Electrophoresis, and High-Resolution Melting Analysis. *P. Bayrak Toydemir^{1,2}, L-S. Chou¹, J.G. Vandersteen², F. Gedge¹, C.T. Wittwer^{1,2}, E. Lyon^{1,2}, R. Mao¹.* 1) Associated Regional & University Pathologists, Inc.(ARUP), Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Hereditary Hemorrhagic Telangiectasia (HHT) is an autosomal dominant vascular dysplasia with an estimated frequency of 1-2 in 10,000. Affected individuals have epistaxis, mucocutaneous telangiectases and visceral arteriovenous malformations. Two molecular sub-types are now recognized: HHT1 is caused by mutations in the endoglin gene (*ENG*) and HHT2 is caused by mutations in the activin receptor-like kinase 1 gene (*ALK1*). Although mutations in these genes account for more than 90% of HHT cases, developing simple and reliable diagnostic approaches has been difficult because of the lack of common alleles. Thus, sensitive mutation scanning approaches followed by targeted sequencing might be useful in clinical settings.

Many scanning techniques have been developed to detect mutations, which differ in sensitivity, specificity, throughput, and cost. In this study, we evaluated three mutation screening techniques, all based on heteroduplex formation: Temperature Gradient Capillary Electrophoresis (TGCE), Conformation Sensitive Gel Electrophoresis (CSGE), and High-Resolution Melting Analysis (HRMA).

We studied 15 HHT cases with a confirmed clinical diagnosis and known mutations. Mutation scanning by TGCE, CSGE and HRMA was performed for the entire coding region and intron/exon boundaries of both *ALK1* and *ENG* genes. The sensitivity of CSGE, TGCE, and HRMA techniques for identifying HHT mutations were 63.64%, 93.33%, and 100%, respectively. We have found that both TGCE and HRMA are favorable mutation scanning techniques to identify the mutations responsible for HHT.

How effective are clinical genetic services? *M. McAllister¹, K. Payne¹, L. Davies², S. Nicholls¹, R. MacLeod¹, H. Middleton-Price¹, D. Donnai¹.* 1) Nowgen, St Mary's Hospital, Manchester, United Kingdom; 2) HER@M, The University of Manchester, Manchester, United Kingdom.

There is a lack of appropriate instruments to measure the benefit of clinical genetic services (CGS). The nature of a good outcome is not clearly understood and outcome measurement is problematic since patients are generally healthy. This study forms part of the Nowgen research programme and aims to identify users and service providers views about the positive and negative effects of genetic conditions on individuals and families and compare these to existing measures used to evaluate genetic services. Focus groups were used to identify key aspects of health and social well-being that are affected by genetic conditions, and CGS (outcomes). The focus groups were run by a trained facilitator and audio and video recorded. The findings were transcribed and analysed using the constant comparative method. A systematic literature review is being used to evaluate the relevance and usefulness of instruments to evaluate CGS. Initial results from the focus groups indicate positive and negative effects that genetic diseases have on individuals and families: emotional, that may be influenced by culture, socio-economic status and gender (eg. guilt, worry, family disruption; practical (eg. financial burden and reduced life choices) and physical (eg. mobility problems and lifelong care). An initial review of outcome measures used to evaluate CGS indicates that (i) no single measure encompasses all the attributes that were identified by the focus groups as important to service users and (ii) that there are insufficient valid and reliable instruments to measure all the attributes. Further work is required to develop an array of instruments to measure all relevant attributes and weight them according to their importance.

Valuing preferences for a clinical genetic service. *K. Payne¹, M. McAllister¹, H. Middleton-Price¹, D. Donnai¹, L. Davies².* 1) Nowgen, St Mary's Hospital, Hathersage Road, Manchester, UK; 2) HER@M, The University of Manchester, Manchester, UK.

Discrete choice experiments (DCEs) are a type of survey instrument that have been used successfully to value peoples preferences for health care services but, to date, not used widely in the valuation of genetic services. The method is rooted in economic theory (random utility theory), which closely reflects how we make decisions about which products to choose and use every day. The theory assumes that the total value (utility) someone attaches to a product (service) is described by the sum of individual attributes (or characteristics). These attributes can relate to the clinical outcome of the service (eg. accuracy of risk information) or the process of providing the service (eg. who provides the service). The ability to incorporate outcome and process attributes is one of the advantages of this method. The attributes are then described by levels, which indicate the different values the attribute can take. DCEs estimate the individual effect these attributes have on a population of peoples preferences for a service. The theoretical basis of DCE assumes that consumers make trade-offs between the attributes. A vital step in the design of any outcome measure is detailed exploration of what factors (or attributes) are/should be considered when describing the processes of service delivery and the outcomes. The aim of this paper is to illustrate how DCEs may be used as a robust valuation tool to provide a measure of service users and providers preferences and values for process and outcome attributes associated with the delivery of clinical genetic services. The paper will also describe how the results of focus groups and systematic reviews completed as part of the Nowgen research programme can be used to inform the design of a DCE.

Resequencing on a Chip: Is it ready for prime time? A. Ganguly¹, C. MacMullen², C. Stanley². 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Division of Endocrinology, The Childrens Hospital of Philadelphia.

Resequencing of multiple large genes in parallel can be achieved by using high density oligo-nucleotide microarrays. We summarize our experience of resequencing using Custom-Seq chips synthesized by Affymetrix, CA in the context of Congenital Hyperinsulinism (HI). HI, the most common cause of persistent hypoglycemia in infants, is caused by mutations in 4 genes: the KATP potassium channel comprised of the sulfonylurea receptor (SUR1) and inwardly rectifying ion pore (Kir6.2), glutamate dehydrogenase (GDH), and glucokinase (GK). Children unresponsive to medical therapy undergo pancreatectomy. The extent of pancreatectomy correlates to the mutation status of the SUR1 and Kir6.2 genes. We designed the HI-CHIP for detecting variations in the 65 coding exons including flanking intronic regions of the 4 HI genes. We evaluated the resequencing method using genomic DNA from 13 individuals: 1 negative control, 2 positive controls, and 10 unknowns, and compared the results to conventional automated fluorescent sequencing. Initial base call rates averaged 92% (9393bp/10210bp) with a range of 61 to 96%. This translates to an average of 12 n calls per tiled exon. Under relaxed settings for the analysis software, the average base call rate improved to 96% (9851bp/10210bp) with a range of 84- 98%. This resulted in an average of 6 n calls per exon. About 60% of the amplicons had to be directly sequenced after scanning due to presence of undefined n calls within possible exonic and/or splice sites. The sequence context of these n's is predominantly a stretch of Cs (>3 in a row). Visual inspection of the probe hybridization data indicate the possibility of better base calls if the algorithm could be trained to look at the data from one strand only. The method has yet to be optimized to perform as well as direct sequencing for any custom set of genes. In conclusion, resequencing on HI-CHIP has the potential to generate HI genotypes efficiently. In future, HI-CHIP can be a clinically useful pre-operative diagnostic tool to determine the extent of pancreatectomy in medically unresponsive HI cases.

Sensitive RNA/DNA mutation detection for dystrophinopathies through uniform direct sequencing. *A.L.J. Kneppers, D.J. Verbove, A.S. Hoogenboom, E. Bakker, H.B. Ginjaar.* Center for Human and Clinical Genetics, Leiden University Medical Center, P.O.Box 9503, 2300 RA Leiden, the Netherlands.

In about one third of dystrophinopathy patients small mutations in the large dystrophin gene are identified as the disease causing defect. Different mutation detection techniques on both RNA and DNA level are used to scan for such mutations. Besides a large number of nonsense mutations the mutation spectrum for small mutations also shows mutations affecting splicing. Along with splice site acceptor and donor mutations deep intronic mutations leading to a splicing artefact are also found in patients. Dystrophin RNA studies are needed to detect this type of mutations and therefore should be included in a mutation scanning protocol for dystrophinopathies. For the exact identification of all small mutations and subsequent family studies the gold standard remains the direct sequencing of the fragment containing the mutation. A standardized procedure using M13 tailed exon specific primers allows direct sequencing using the M13 sequence primers for all PCR fragments in a uniform manner. We have developed, optimised and validated a uniform direct sequencing protocol for dystrophin gene analysis of both the coding sequence on mRNA level as well as all 79 exons including splice sites on the genomic level. Starting with RNA isolates of lymphocytes or muscle biopsies 20 overlapping PCR fragments are generated in 2 subsequent PCR reactions after cDNA synthesis. For the genomic analysis 78 exon specific fragments are generated. The procedure can be automated for PCR and sequence reaction set-up. All PCR fragments are sequenced for both forward and reverse strand and analysed in a semi-automated fashion after data collection. So far mutation scanning in 97 patients revealed a mutation in 94 % of all cases. Classification of the mutations showed 38 % nonsense, 27 % frame shift and 27 % splice site mutations of which 3 % appeared to be deep intronic mutations. This uniform sequencing approach complements the initial deletion/duplication scanning in dystrophinopathy patients, enables a standardized procedure for mutation scanning and has been successfully applied to other genes.

Program Nr: 1510 from the 2004 ASHG Annual Meeting

CFTR gene mutations in Iranian cystic fibrosis patients: Detection of

F508, G542X, W1282X, N1303K, A120T, R117H and R347H mutations. *F. Mirzajani¹, R. Mirfakfraie¹, M. Jalalirad¹, N. Yazdanpanahi², M. Mojarad², Gh. Babamohammadi¹, E. Talachian³, M. Rafiei⁴, P. Derackshandehpeikar², M. Goharbari¹, M. Houshmand¹.* 1) Medical Genetics Dep., National Institute of Genetic Engineering & Biotechnology, Tehran, Iran; 2) Tehran Medical University, Tehran, Iran; 3) Aliasghar Hospital, Tehran, Iran; 4) Children Medical Center, Tabriz, Iran.

50 unrelated CF families were screened for the most common mutations including F508, G542X, W1282X, N1303K and G551D in the CFTR gene using ARMS-PCR method. Exons 4, 7, 10 and 11 were screened for any other possible mutations using SSCP-Sequencing method. F508 mutation covered only 18% of the mutated alleles, which is one of the lowest frequencies detected worlds wide so far. G542X, W1282X and N1303K mutations accounted for 8%, 8% and 2% of the mutated alleles respectively. SSCP-Sequencing method also revealed the occurrence of R117H, R347H and A120T mutations in the studied population..

Shwachman-Diamond Syndrome: one year Experience in a Molecular Diagnostic Laboratory. *L. Steele¹, J. Rommens², N. Bulgin¹, Y. Yang¹, L. Han¹, M. Eliou¹, T. Wright¹, P.N. Ray^{1,2}, T. Stockley¹.* 1) Dept Paed Lab Med; 2) The Research Institute, The Hosp for Sick Children, Toronto, ON, Canada.

Shwachman-Diamond Syndrome (SDS) is an autosomal recessive disorder with an incidence of 1 in 50,000 births. The primary features of SDS include bone marrow problems, a defect in the pancreas, skeletal abnormalities, and short stature. The SBDS gene at 7q11 has recently been found to be the causative gene for SDS. A pseudogene, SBDS-P, exists within a distally duplicated region and shares 97% nucleotide sequence identity with the SBDS gene. A majority of SDS patients have mutations resulting from recombination and gene conversion between the SBDS and SBDS-P genes. The two common conversion mutations are reported to account for 75% of all SDS disease alleles. Here we report our experience with molecular genetic testing for SDS in a clinical diagnostic laboratory at the Hospital for Sick Children. The strategy consists of two stages: A direct mutation detection assay is used to test proband samples for the two common mutations in exon 2 of the SBDS gene, 183_184TA->CT and 258+2t->c. A proband is expected to have one of these common mutations 90% of the time. If one mutation is found, samples would undergo direct sequencing of all exons and intron/exon boundaries for a rare mutation in the SBDS gene. Approximately 31% (11/35) of probands referred were confirmed by molecular testing to have the diagnosis of SDS; 82% (9/11) of these had two common mutations whereas 18% (2/11) had a common and a rare mutation. None of the probands without a common mutation who also had full SBDS gene sequencing (31%) were found to have a rare mutation (11/35). Parental samples, if available, were useful in distinguishing whether the two common mutations were in cis or in trans. Prenatal diagnosis has been performed on 5 cases to date and predicted a favorable outcome in all cases. An accurate diagnosis can now be made in families affected with Shwachman-Diamond Syndrome and prenatal diagnosis is available as an option for these couples who are confirmed carriers.

Program Nr: 1512 from the 2004 ASHG Annual Meeting

Extensive Mutational Analysis in Duchenne/Becker Muscular Dystrophy. *T.L. Stockley, S. Akber, L.K. Steele, P.N. Ray.* Molecular Genetics Laboratory, Hospital for Sick Children, Toronto, ON, Canada.

Duchenne and Becker muscular dystrophies (D/BMD) are neuromuscular disorders caused by mutations in the dystrophin gene. It is reported that 65% of mutations are partial gene deletions, 5% are partial gene duplications and 30% are point mutations. Our laboratory has developed extensive molecular diagnostic assays for detection of mutations in the dystrophin gene. These assays include (1) quantitative PCR multiplex assays for all 79 exons of the dystrophin gene and the brain promoter to detect partial gene deletions and duplications and (2) complete sequencing of all exons of dystrophin and intron/exon boundaries from genomic DNA to detect point mutations. These assays are predicted to detect the majority of mutations in dystrophin causing D/BMD. We have applied these assays to detection of mutations in an unselected sample of 187 males referred for D/BMD testing to our clinical molecular laboratory from 1990 to 1994 inclusive. All samples were tested initially using the complete multiplex analysis for deletions/duplications in all exons. 110 males were found with partial gene deletions and 15 males were found with partial gene duplications. A significant number of single exon deletions (20/110) and duplications (7/15) were identified. Of deletions and duplications identified, 9% of deletions and 25% of duplications would be missed by current protocols using multiplex analysis of 18 dystrophin exons. The 62 males without deletions or duplications were further assessed for sequencing. 10 samples were unlikely D/BMD on review of clinical information. The remaining 52 samples underwent sequencing of the dystrophin coding region, and 14 samples have been identified with point mutations to date. The remainder of samples without identified mutations are being further analyzed. This study has implications for refining the frequency of mutations causing D/BMD.

Australian views on commercial and government interests in genetic test results and implications for public policy. *K. Barlow-Stewart¹, S. Treloar², S. Taylor², M. Saleh¹, I. Muchamore¹, M. Stranger³, M. Otlowski³.* 1) Ctr Genetics Education, Royal North Shore Hosp, Sydney, Australia; 2) Scl Soc Wk, Univ Queensland, Brisbane, Australia; 3) Scl Law, Univ Tasmania, Hobart, Australia.

Aim: To study Australian views on current and future use of genetic information in life insurance, employment and immigration and support for genetic testing overall. **Method:** A new biennial mailed, self-completed Australian Survey of Social Attitudes was sent to 5,000 randomly selected people on the 2002 Australian electoral role in 2003 by the Australian National University. 20 questions on human genetics were included with a 41.7% response rate. **Results:** 45% of respondents linked inherited health problems with human genetic information, providing a measure of genetic health awareness. 49% correctly think genetic test results are currently used in life insurance underwriting. 58% think it is not currently used in employment which appears to be the case in Australia. 77% disagree with insurance companies being able to genetically test policy applicants in the future and 75% disagree with its use in the workplace, even in the context of safety for both current and future employees. While over 30% agree with genetic testing potential immigrants for future health problems, their support is closely linked to other attitudes about migrants. One in three who disagree with genetic testing on themselves in insurance or employment support its use on others who wish to migrate to Australia. Nevertheless twice as many respondents strongly disagree with genetic testing of immigrants for future health problems than strongly agree. 66% support genetic testing overall, as opposed to 17% with concerns about its misuse and 17% found this choice too hard to make. The main influencing factors on awareness and opinions were respondent's demographic, social and political values rather than their level of genetic health awareness. **Conclusion:** Education is crucial if utilisation of genetic testing is to be on an informed basis. Australians express strong opposition to the use of genetic information by commercial and government interests. Public policy must therefore ensure its use is monitored and regulated.

Reproductive genetic testing: Options for policymaking. *S. Baruch, K. Hudson, G. Javitt.* Genetics and Public Policy Ctr, Johns Hopkins University, Washington, DC.

An array of medical procedures and genetic tests can inform individuals about possible outcomes of current or future pregnancies. These tests and procedures, including carrier testing, preimplantation genetic diagnosis, and prenatal testing, can determine whether a genetic alteration is present that is likely to cause a specific disease or condition. As our knowledge of the human genome increases, the number of conditions for which testing is possible will increase accordingly, as will legal and ethical questions.

Current government oversight of reproductive genetic testing is limited and confusing. This presentation will describe the current state of regulation. Various federal and state entities have asserted authority over some aspects of reproductive genetic testing, but gaps remain. Federal and state policymakers are considering whether additional oversight is needed to guide the use and development of reproductive genetic technologies.

The Genetics and Public Policy Center has developed a range of innovative policy options, informed by extensive social science research and outreach to stakeholders. Policy preferences are shaped by a variety of factors, including an individual's expectations of existing and future applications of tests, core beliefs about the moral and ethical impact of testing, assumptions about the expected costs and benefits and how they will be distributed, and fundamental views about the proper balance between government involvement and individual liberty.

The options presented will reflect the range of perspectives revealed in our research and will include the strongest arguments for and against each option. Options include approaches for federal and state oversight, as well as self-regulation by professional organizations. Options respond to a range of concerns about the safety and accuracy of tests, whether they are being offered and performed at the right time, what diseases or traits patients are testing for, and what impact reproductive genetic testing may have on individuals, families, and society.

Setting research priorities to support policy making in genetics. *I. Blancquaert¹, G. Cleret de Langavant¹, W. Foulkes², D. Gaudet³, B. Godard³, N. Laflamme⁴, A. Marcoux⁵, F. Rousseau⁶, R. Battista³, APOGEE-Net Network.* 1) Genetics Unit, Agence d'évaluation des technologies et des modes d'intervention en santé (AETMIS), Montreal, Quebec, Canada; 2) McGill University, Montreal, Quebec, Canada; 3) Université de Montréal, Montreal, Quebec, Canada; 4) Institut National de Santé Publique (INSPQ), Montreal, Quebec, Canada; 5) Conseil de la Santé et du Bien-être (CSBE), Québec, Quebec, Canada; 6) Université Laval, Québec, Quebec, Canada.

More trans-disciplinary policy-oriented research is needed to ensure that the wealth of knowledge that is produced in genetics be both useful and usable by policy makers in their efforts to implement a judicious technology transfer in genetics. In addition, an active strategy of knowledge translation is essential to achieve such a goal. APOGEE-Net is a knowledge network that brings together producers, disseminators and users of knowledge to support policy making in the area of genetics. More specifically, university based researchers in a variety of disciplines, researchers from organizations whose mandate is to counsel decision makers and to promote knowledge translation, clinicians, public representatives and policy makers from five Canadian provinces participate. Knowledge transfer, trans-disciplinary research and capacity building (research and receptor) are key objectives of the network. The original knowledge transfer strategy rests on iterative interactions between decision makers and researchers at different stages of the research cycle : in setting research priorities and in the interpretation of research results. These exchanges provide an opportunity to progress towards a shared understanding of the challenges and issues related to the application of new genetic technologies. This communication describes the first priority setting exercise, based on a combination of a Delphi survey and a Nominal group technique, both adapted to the specifics of the APOGEE-Net network. Priorities in all three research axes were identified: genetics and health services, genetics and public health and genetics and citizen dialogue.

Program Nr: 1516 from the 2004 ASHG Annual Meeting

Developing a Sustainable Process to Provide Quality Control (QC) Materials for Genetic Testing. *B. Chen¹, D.J. Boone¹, L. Silverman², I. Lubin¹, J. Amos³, J. Beck⁴, M. Chan⁵, D. Farkas⁶, R. Lebo⁷, C. O'Connell⁸, C.S. Richards⁹, B. Roa⁶, The QC Materials for Genetic Testing Group.* 1) Ctrs for Disease Control & Prevention; 2) Univ of Virginia; 3) Specialty Laboratories; 4) Coriell Inst for Medical Research; 5) Food and Drug Administration; 6) Baylor College of Medicine; 7) Childrens Hospital Medical Ctr of Akron; 8) National Inst of Standards & Technology; 9) Oregon Health & Science Univ.

The quality of genetic testing services can be compromised by the lack of available QC materials. Therefore, in September 2003 and March 2004, the Centers for Disease Control and Prevention organized two QC Materials for Genetic Testing conferences, to develop recommendations for practical, sustainable mechanisms for making QC materials available to the genetic testing community at a reasonable cost. More than 50 leaders in genomics and genetic testing participated in the conferences and formed subcommittees to address the following needs: 1) determining genetic tests in the greatest need of appropriate QC materials, 2) developing networks of material contributors, 3) using existing cell banks as material sources, 4) facilitating research collaboration, 5) developing validation processes, 6) determining needs for professional guidance, 7) clarifying regulatory oversight, and 8) improving funding support. The progress, ongoing activities, and further recommendations from the group will be presented. Among the recommendations for future projects was identifying a National QC Materials Coordinator to provide continuing support and coordination for development and provision of QC materials. Proposed activities include: 1) facilitating development, collection, submission, validation, and distribution of QC materials; 2) monitoring community needs; and 3) improving information exchange among users, repositories and manufacturers of control and reference materials. A third QC Materials for Genetic Testing conference will be held in November 2004 to further develop project plans and obtain additional input. Information regarding the QC material activities is available at <http://www.phppo.cdc.gov/mlp/qcgeneticconference/proceedings.asp>. **QC Materials for Genetic Testing.**

Carrier Screening for Recessive Diseases: Reasons for Caution about Cystic Fibrosis Carrier Screening. *A.M. Laberge, K. Porter, W. Burke.* Institute for Public Health Genetics and Department of Medical History and Ethics, University of Washington, Seattle, WA.

Using key informant interviews and literature review, we evaluated the policy history of carrier screening for Tay-Sachs disease (TSD) and other genetic disorders prevalent in the Jewish community, beta-thalassemia (BT), and cystic fibrosis (CF). TSD and BT screening are considered highly successful. Their features include: 1. Severe disease; 2. Limited phenotypic variability; 3. Lack of treatment; 4. High test sensitivity; 5. Availability of prenatal diagnosis. Both TSD and BT screening programs are also characterized by community involvement, support of parents groups, and evidence of a strong consensus in favor of avoiding affected births. Initial programs for TSD in the US and for BT in Cyprus and Sardinia were rapidly replicated and have significantly reduced disease incidence within screened communities. By contrast, because of wide phenotypic variability and availability of treatment, a lack of consensus is currently seen about the inclusion of Gaucher disease in expanded Jewish panel carrier tests, in spite of community support for carrier screening in general. In this context, NIH (1997) and ACOG/ACMG (2001) recommendations for population-based CF carrier screening raise concerns. CF does not share the features of TSD and BT: it has wide phenotypic variability, available treatments have significantly improved life expectancy and quality of life, and testing is complex. Test sensitivity varies greatly by ethnicity, results can be difficult to interpret, and phenotype is hard to predict from genotype. Furthermore, the Cystic Fibrosis Foundation does not identify CF carrier screening as a part of its mission, and current Canadian practice guidelines specifically state that the offer of CF carrier screening does not constitute a standard of prenatal practice. Like Gaucher disease, the need to avoid CF is debated because of wide phenotypic variability and increased life expectancy. Together, all these factors point to a lack of consensus about CF carrier screening and the need for caution in promoting it.

Identification and characterization of patients at-risk for hereditary breast cancer in a community-based study in Southern Brazil. *P. Ashton-Prolla*^{1,2,3,4}, *M. Caleffi*⁴, *E.I. Palmero*³, *L. Kalakun*¹, *R. Giugliani*^{1,2,3}, *L. Schuler-Faccini*^{1,2,3}. 1) Service of Medical Genetics - HCPA; 2) Department of Genetics - UFRGS; 3) Postgraduate course in Genetics and Molecular Biology - UFRGS; 4) Hospital Moinhos de Vento, Porto Alegre.

Hereditary breast cancer (HBC) accounts for a minority of breast cancer cases (BC) in most populations, but the identification of at-risk patients is important because they have a higher lifetime risk of BC and other tumors; other at-risk relatives may be identified, and, effective prevention strategies are available. In Brazil, BC is the 1st cause of cancer-related deaths in women of all ages. In Rio Grande do Sul, the southernmost State, BC is the first cause of all deaths in young women (30-49 ys). The states capital, Porto Alegre, has the highest BC incidence and mortality rates in the country. This study will examine the contribution of genetic risk factors to such distinct BC statistics in the area. This question will be addressed through identification and characterization of HBC at-risk patients and families in a sample of 10.000 women residing in a section of Porto Alegre. Women over the age of 15 will be actively recruited by municipal health agents and submitted to an HBC risk-questionnaire that consists of 6 questions to assess presence of a 1st degree relative with BC and/or OC; male relative with BC; relative with BC under 50; 2 or more relatives with BC and/or OC; relative with bilateral BC; relative with both breast and ovarian cancer. If any of these is identified the patient will be invited for genetic counseling and if applicable, genetic testing. Additional questionnaires (cancer knowledge, risk perception, family dynamics) will be applied to all eligible patients. Expected outcomes are determination of specific patient profiles (i.e. regarding HBC knowledge, risk perception, attitudes) and contribution of mutations in each of the specific BC predisposition genes studied (BRCA1, BRCA2, p53, CHEK2). Two months after beginning of the study, approximately 500 women were recruited and about 20 percent reported at least one positive risk factor in the screening questionnaire.

Program Nr: 1519 from the 2004 ASHG Annual Meeting

Nowgen-the North West Genetics Knowledge Park. *D. Donnai*¹, *H.R. Middleton-Price*². 1) Regional Genetics Service, St Mary's Hospital, Manchester, United Kingdom; 2) Nowgen, St Mary's Hospital, Manchester, United Kingdom.

Nowgen (The North West Genetics Knowledge Park) is one of a network of six Genetics Knowledge Parks in the UK initiated and funded by the Departments of Health and Trade & Industry. Nowgen is a partnership between four universities and a teaching hospital in the North West of England. Nowgen's research and work programmes cover three themes: improving the provision of genetic services; improving public engagement and professional education; developing ethical and legal frameworks. In addition, Nowgen: Provides information resources to professionals and the public. Has created a forum for education and dialogue around human genetics. Supports industry by providing training and knowledge transfer in issues relating to human genetic information. Has involved genetics service users and the public in all aspects of its activities. Has developed a sophisticated web based knowledge management system to link and empower communities concerned with human genetics. Has built a new Centre in Manchester, UK the Nowgen Centre (opening late 2004). To date Nowgen's activities include: Contributing to the Manchester Masters programme training genetics professionals. Workshops on: Communication Skills; Disability and Reproductive Choice; Preferences Values and Risk in Genetics Based Health Care. A public debate: GeneHype. The UK network of Genetics Knowledge Parks have complementary strengths and are collaborating on many aspects of their research programmes, on education and training, and on delivering workshops and conferences.

Program Nr: 1520 from the 2004 ASHG Annual Meeting

The Sino-American Genomics Foundation (SAG). *R. Fineman*¹, *A. Chen*². 1) Sino-American Genomics Foundation, Seattle, WA; 2) CDC, Atlanta, GA.

SAG's mission is to improve maternal and child health in developing countries through the practical application of public health genetics and genomics. This expertise, though readily available in the US and other technically advanced countries, is not widely available in the People's Republic of China (PRC), India, and most developing regions of the world. SAG's mission is being carried out in China using simple, practical, cost effective and time-tested public health policies and practices (for example, utilization of the public health core functions) capable of being reproduced in other developing countries in the future. Our initial, infrastructure-building efforts encompass a process (primarily in six locales in China totaling 230 million people) that includes, for example, improvements in China's newborn screening and birth defects surveillance and monitoring systems; a web site in Mandarin and English to facilitate ongoing communications, education, public relations and monitoring of progress; a sister hospital exchange program; and genetics and genomics education programs (including, for example, one for folic acid diet supplementation) aimed at health care professionals, decision-makers, families of affected children, and the lay public with special emphasis on individuals 15-45 years of age. To the best of our knowledge, SAG is the only public health genetics and genomics 501(c)(3)-approved, private, non-profit, foundation of its kind in the US. China is where SAG's efforts will begin, not end. Working together, SAG and its partners in China and the US aim to increase access to genetic and genomic health care services worldwide.

Many prominent individuals in public health and other fields, in both the US and China, have become actively involved in SAG's activities, and they have endorsed SAG's vision of preventing severe mental retardation and birth defects in tens of thousands of babies born in China every year.

Analysis of Inquiries to a Federal Education Resource on Genetic and Rare Diseases. *J. Lewis¹, K. Hagerty¹, L. Lanier², H. Hyatt-Knorr³.* 1) Aspen Systems Corp, Rockville, MD; 2) NHGRI, Bethesda, MD; 3) ORD, Bethesda, MD.

For more than 2 years, the Genetic and Rare Diseases (GARD) Information Center has provided a bridge between information-seekers and reliable resources on genetic and rare diseases. Inquiries to GARD have been collected and analyzed during 32 months of operation. Personal identifiable information obtained in developing responses to inquiries is not retained in any form. The data analyzed are in the aggregate. The National Human Genome Research Institute (NHGRI) and the Office of Rare Diseases (ORD), NIH, launched GARD to provide free and immediate access to reliable information about genetic and rare diseases in English and Spanish. GARD Information Specialists respond to inquiries received through toll-free telephone, TTY, email, fax, and letter. Data analysis of inquiries includes: audience segments and characteristics; inquiry topics, by audience, channel, region and language (English or Spanish); resources requested and provided; trends in volume, by channel and time of year; the impact of outreach efforts on volume. Data have been collected for the 8,000+ inquiries handled by GARD to date. Of the people who provided information about themselves (86%), inquiries came from patients (28%), their families (42%), health professionals (10%), and the general public (20%). Approximately 92% of GARD users request information about a specific disease. With 3000+ disease inquiries received, trimethylaminuria and cystic fibrosis are the top two. Ten percent of inquirers requested information about genetic services, testing, and research. Being aware of the types of information people search for and obtain when they contact GARD will help genetics professionals stay abreast of trends in their clients information-seeking behaviors, help them understand their clients underlying questions and informational needs, and enable them to more effectively structure patient sessions and communicate with allied health professionals. Other stakeholders in genetics (researchers, allied health professionals, and others) might also find it helpful to know how they can use GARD to assist them in connecting people to information and resources about genetic and rare diseases.

Genetic and environmental risk factors in mental retardation: Knowledge, perceptions and attitudes of health professionals. *A.P. Marques-de-Faria¹, A.M.S.M. Moraes^{1,2}, L.A. Magna¹.* 1) Dept. of Medical Genetics, State University of Campinas School of Medicine, Campinas, SP, Brazil; 2) Dept. of Medicine, University of Maringá, PR, Brazil.

As a consequence of advances in medical genetics, demand for clinical genetic services has increased, reinforcing the need for programs towards the management and prevention of genetic diseases and birth defects. Considering mental retardation (MR) as a major problem in clinical genetics, a survey has been developed in Maringá, PR, a 283,792 inhabitants Brazilian town, with good health indicators for public and private care. A total of 156 health care professionals, encompassing 90 physicians (pediatricians, internists, obstetrician-gynecologists, family practitioners) and 66 nurses, were surveyed to assess their knowledge, perceptions and attitudes about genetic and environmental risk factors for MR. In addition, an interview was carried out among 100 women in the puerperal period, all of them recorded as having a healthy newborn. A profile has been delineated and some aspects deserve mention as most of health professionals demonstrating lack of knowledge in relation to issues as epidemiology and MR preventive measures or the national newborn screening program. They also answered not have self-assurance for taking family history and advising about prenatal diagnosis procedures. Although they declared that usually verify MR risk factors occurrence, the majority of women interviewed denied this procedure. Ignorance about genetics, difficulties to carry out complementary studies and refer patients to genetic services, besides the long time required to record medical history, were considered disadvantageous factors in the evaluation of patients with genetic diseases. The improvement of health care providers by the integration of genetics content into the knowledge base of professionals and students of the health professions, as well as the education of general population, are among the respondents suggestions, which also pointed out the presence of a clinical geneticist at the public health service as essential for implementing preventive strategies and for the success of community programs in MR.

Genetic risk assessment of oocyte donors. *M. Topping*¹, *A. Matthews*¹, *S. Kingsberg*^{1,2}, *T. Hassold*¹, *P. Hunt*¹. 1) Case Western Reserve University, Cleveland OH; 2) University Hospitals of Cleveland, Cleveland OH.

The role of genetics in gamete donor evaluation varies among assisted reproductive technology (ART) clinics. To investigate the implementation of the American Society for Reproductive Medicine genetic screening guidelines and examine the potential impact of genetics professionals (geneticists/genetic counselors), in vitro fertilization programs in the Society for Assisted Reproductive Technology (SART) registry were surveyed. The survey included questions on the frequency of screening for recessive disorders in high-risk populations in the absence of family history, how ART clinics handle potential donors with positive family histories (cystic fibrosis, Huntington, cleft lip, mental retardation, breast cancer), and the extent to which genetics professionals are involved in risk assessment. Thirty percent (116/380) of the SART registry participated. Results reported are from 77 ART clinics responsible for genetic risk assessment of potential oocyte donors. While the majority of programs follow standard of care guidelines, many do not. Only 25% of programs karyotype potential donors. Donors are least likely to be tested for Canavan disease (54.2%), -thalassemia (54.4%) and -thalassemia (56.9%) in their respective high-risk ethnic populations. More clinics always screen for cystic fibrosis among Caucasians (77.5%) and Ashkenazi Jews (78.1%), and Tay-Sachs disease (83.3%). In the presence of a positive family history, programs were more likely to exclude donors regardless of the genetic risk involved in order to potentiate the most desirable pregnancy outcome and to maximize the potential of recipients selecting such donors in light of program costs and efficiency. When genetics professionals are involved, the frequency of screening and counseling for genetic risk increases, suggesting that the use of geneticists improves the extent of risk assessment. Therefore, increased focus on genetics in gamete donor selection is warranted, including the utilization of genetics professionals for more consistent and accurate risk evaluation, psychosocial counseling and future guideline development.

National Information Center about Teratogens (SIAT): analysis of its impact over the pregnant women health during its 14 years of service. *L.H. L. Rossi¹, R. Pers¹, M. Sanseverino¹, G. Maegawa², C. Ribas¹, M. Jann¹, S. Costa¹, M. Golbert¹, L. Schuler-Faccini¹.* 1) Medical Genetics Service, Medical Genetics Service, HCPA, Porto Alegre, RS, Brazil; 2) Div. Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, CA.

The National Information Center about Teratogens (SIAT) was established in 1990 in Porto Alegre, RS as the first Latin American service in this field. The objective is to provide accurate information about teratogenic risks related to chemical, physical or biological agents to which most pregnant women can be exposed. The service is devoted to health care providers and also to the general community. All the information required are filed in a data bank in order to be used for future studies in human teratogenesis and investigate the potential teratogen effect of several agents. Besides its health care assistance role, the SIAT has been participating in several studies about the potential environmental agents. The main objective of the present study is to analyze the type of consults and the assistance provided by the SIAT. Until June 2004, SIAT received 5,318 consults and 4,467 were analyzed. Physicians represented 42% of the total consultations. The general community presented 40%. There was an increase in the amount of inquiries from health care professionals since past years. With regards to the education level, 55.0% of non-health care individuals had concluded high-school or college. In terms of the main motif of the consultations, 71.0% were related to a specific pharmacologic substance, 12% related to other chemical substances and 4.7% related to radiation exposure and 4.0% maternal infections. The SIAT has an important assistance role for the health care professionals and for the general community while being a crucial source for better understanding the teratogenesis among humans.

Carrier Detection in Haemophilia using DNA Polymorphisms. *M. Singh¹, P. Singh¹, S.S. Mastana², K.P.S. Khushwaha³, H. Kaur⁴.* 1) Department of Human Biology, Punjabi University, Patiala, 147002, India; 2) Human Genetics Lab., Department of Human Sciences, Loughborough University, Loughborough, LE11 3TU, UK; 3) Forensic Science Lab., Madhuban, Karnal, Haryana, India; 4) St Boniface Hospital, Manitoba, Canada.

Background: The haemophilia is an X-linked recessive bleeding disorder associated with a chronic burden of morbidity and early mortality. It affects 1 in every 10,000 male births. Detection of carrier women and genetic counseling are important parts of haemophilia care and effective strategies for the genetic control of the disease. The aim of the present study was to assess the carrier status of the females in 52 families of the haemophiliac patients. **Methods :** Two polymorphisms of the factor VIII gene were analyzed using polymerase chain reaction, one on intron 18 recognized by BclI and another extragenic variable number tandem repeat (VNTR) locus recognized by St14. **Results :** There were 96 females and pedigree analysis revealed that 58 were probable carriers (whose carrier status was not known) and 38 obligatory (confirmed) carriers. Sixty one percent females were heterozygous for the intragenic polymorphism (BclI) whereas 86% females were informative for extragenic marker (St 14). Seven females were non informative with any of the marker used. Using both markers together, carrier status could be diagnosed in 92% of the females. **Conclusion:** Employing the above polymorphic markers of FVIII gene, diagnosis could be made in the majority of the families.

New genetic variability of flavin containing monooxygenase 3 and its functional characterization. *C. Charon*^{1,2}, *G. Steventon*¹, *C. Dolphin*¹. 1) King's College London, Pharmacy Department, UK; 2) CNG, Cell/DNA Department, Evry, France.

Flavin monooxygenase 3 (136132) is the principal human adult isoform of FMO expressed in the liver. A loss of function of the FMO3 gene on exon 4 was primarily found to be responsible for trimethylaminuria. FMO3 oxidizes sulfides into sulfoxides, phosphorous and nitrogen atoms in xenobiotics, environmental toxins and certain drugs such as cinetidine, ranitidine and antipsychotic medications. The most common polymorphisms and mutations coding for amino acids exchanged have already been reported (M66I, P153L, E158K, V257M, E305X, R492W, E308G). The discovery of SNP paves the way to the studies of inter-individual responses towards drug metabolism. DHPLC screening followed by sequencing revealed heterozygotes on positions c.341 (a>g), c.394 (g>c), c.441 (c>t), c.1055 (t>c), in a diverse ethnicity panel. Alleles frequencies were determined by PCR restriction digests in different cohorts. The amino acid change L352S was found in the African population. The non-synonymous variant N114S was found in both Chinese (6.6%) and Japanese (7%) populations whilst the polymorphism D132H was detected in Afro American (5%) and American Indians (10%). The synonymous biallelic marker S147 was present across all populations. Some individuals heterozygotes D132H were also heterozygotes at position 158. Among the polymorphisms cloned to determine the phase with the nearby common SNP the alleles were D132K158 and H132E158. FMO3 variants were produced after site directed mutagenesis in the heterologous baculovirus expression system (Bac-to-Bac, MOI of 5). Metimazole oxidation was affected by the microsomes isolated from cells infected with AcFMO3S114E158 and AcFMO3H132E158. Catalytic activity of human recombinant S114-FMO3 was greater than the human recombinant H132-FMO3, but at least 40% lower than the wt FMO3. The results indicate that polymorphisms found in non-caucasians could impair the oxidation of substrates. The substitution of aspartic acid into a basic amino acid histidine, H132, had a more drastic effect upon the protein activity than an asparagine-to-serine change at position 114. Both amino acids are essentials for FMO3 full enzyme activity.

Nonlinear Structural Equations for Reconstructing Genetic Networks. *L. Lin¹, X. Fang¹, M. Xiong²*. 1) Statistics, Beijing University, Beijing, China; 2) Human Genetics, University of Texas - Houston.

When the response of transcription of the gene to the activation of other genes and external stimuli is a nonlinear function of the expression levels of the activator genes, the genetic networks cannot be properly represented by a system of linear equations in both parameters and variables. In practice, gene regulations often show nonlinear relationship. Therefore, the general mathematical models for reconstructing genetic networks should incorporate nonlinear gene-gene interactions into the models. A general nonlinear Bayesian network model has not been fully developed and will not be easily developed even in the near future because its formulation is not very suited for developing nonlinear models. In this report, we propose to use nonlinear structural equations for modeling genetic networks. The full information maximum likelihood methods coupled by two extensions: (1) allowing random exogenous variables and (2) incorporating structure searching algorithms such as genetic algorithms and Tabu search into modeling development will be used to identify the structure of the genetic networks and estimate the parameters in the model. The proposed nonlinear structural equation model for genetic networks was applied to colon cancer data. The results shows that the nonlinear structural equations fit the data better than linear structural equations.

Discovery of novel disease genes by neural network approach to very large datasets. *M.A. Bakay¹, Z. Wang¹, O. McIntyre¹, J. Xyan², Y. Wang³, E.P. Hoffman¹.* 1) Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Computational Bioinformatics & Bioimaging Lab Dept of Electrical Engineering & Computer Science The Catholic University of America, Washington, DC; 3) Computational Bioinformatics & Bioimaging Laboratory Virginia Polytechnic Institute and State University, Alexandria, VA.

We hypothesized that diagnostic mRNA signatures could be developed by studying large numbers of mutation-known human muscle biopsies by mRNA expression profiling, using neural network classifiers, and then testing the performance of the system using bio-informatics methods.

We generated a 124 muscle biopsy data set (13 diagnostic groups) adhering to strict QC/SOP, then used a novel multilevel perceptron (MLP) approach for defining highly sensitive and specific diagnostic genes for each disease type. Each MLP at one node of the class grouping tree is responsible for classifying specific classes or groups, and the gene subset fed to each MLP is selected by focusing on the specific classes or groups involved in that classification task. We found high consistency between the diseases groupings and the biological background, suggesting pathway-specific information at the group-specific nodes.

We then tested a muscle biopsy of an undiagnosed muscular dystrophy patient and our Adaptive Hierarchical Subspace Explorer (AHSE) predicted that the unknown patient was affected with Calpain 3 (LGMD2A) disease. The Calpain 3 gene was sequenced and no mutation found. We then hypothesized that pathway-specific genes at the Calpain 3 node may be responsible for the patients disorder. We identified a single transcript whose behavior in the unknown is opposite to that in Calpain samples, suggesting nonsense mediated decay of this transcript. We sequenced this gene and found a 12 bp deletion that was not present in 186 control chromosomes. Sequencing of additional LGMD patients identified additional mutations.

Our data suggests that the Calpain 3 pathway-defined transcript is a new muscular dystrophy gene resulting in a form of limb-girdle muscular dystrophy.

High resolution microarray CGH of prostate cancer and application of custom informatics suite for analysis and annotation of genomic profiling. *B. Beheshti*¹, *S.K. Watson*², *W.L. Lam*², *J.A. Squire*¹. 1) University of Toronto, University Health Network, Toronto, Ontario, Canada; 2) BC Cancer Research Centre, Vancouver, British Columbia, Canada.

BACKGROUND: Molecular cytogenetic studies of early prostate cancers (CaP) and cell lines have shown frequent alterations on chromosomes 7, 8, 10, 13, 16, suggesting involvement of genomic intervals on these chromosomes in tumor development. Low resolution (> 10 MB) metaphase comparative genomic hybridization (CGH) fails to detect focal imbalances within cytobands that may harbor gene(s) of interest. High resolution microarray CGH offers fine structure mapping of genomic imbalance in these regions. **METHODS:** Genomic profiling of previously characterized CaP cell lines (LNCaP, DU145, PC3, 1532T, 1542T) was performed using Spectral Genomics BAC microarrays in order to delineate DNA dosage changes. Custom software (freely available at <http://www.utoronto.ca/cancyto/>) was produced in this laboratory to facilitate analysis of microarray CGH results, including data normalization, noise filtering, results plotting, LOWESS curve smoothing, & automated region imbalance determination. **RESULTS:** Genomic profiling refined and/or complemented existing characterization of CaP cell lines. For example, metaphase CGH of PC3 (Nupponen et al., 1998) identified two regions of gain at 1q21-q25 & 1q32-q44. No changes were detected at chromosome 3. Conversely, these same regions were refined by microarray CGH to be 1q23.3-q24.2 & 1q32.1-1q42.13, & novel gains were identified at 1pter-1p36.23 and 1q42.3-qter. The analysis also identified gains of 3p26.1-q21.2 (with interstitial deletion at 3p14.2-p14.1) and deletion of 3q22.1-q25.2. Other alterations will be presented. **DISCUSSION:** Our microarray CGH investigations, facilitated by custom analytical software, were able to refine an increased complexity of patterns of alterations in these cell lines than previously possible. These results are consistent with previous characterizations of prostate cancer, which have shown an ongoing genomic instability process perpetuating genomic imbalance and ploidy changes and contributing to the complexity of the karyotype observed by CGH.

Haplotype structure of human adrenergic receptor genes. *I. Belfer*^{1,2}, *B. Buzas*^{1,2}, *H. Hipp*^{1,2}, *G. Phillips*^{1,2}, *J. Taubman*², *I. Lorincz*^{1,2}, *C. Evans*^{1,2}, *R.H. Lipsky*², *M-A. Enoch*², *M.B. Max*¹, *D. Goldman*². 1) Pain and Neurosensory Mechanisms Branch, NIDCR, NIH, Department of Health and Human Services, Bethesda, MD; 2) Laboratory of Neurogenetics, NIAAA, NIH, Department of Health and Human Services, Rockville, MD.

Adrenergic receptors (AR) mediate the physiological effect of epinephrine and norepinephrine and are targets of a large class of therapeutic drugs. Interindividual differences in physiological states regulated by the adrenergic system may be in part due to genetic variations in the AR genes. We determined the haplotype architecture of nine human AR genes (*ADRA1A*, *ADRA1B*, *ADRA1D*, *ADRA2A*, *ADRA2B*, *ADRA2C*, *ADRB1*, *ADRB2* and *ADRB3*) in the Caucasian (CA) and African American (AA) populations. *ADRA1A* comprised of four haplotype blocks in CAs, while in the AAs Block 1 split. *ADRA1B* had four blocks in CAs, and in the AAs Block 4 split into two blocks. *ADRA1D* had 2 blocks in the CAs and Block 1 split into three blocks in the AAs. The *ADRA2A* and *ADRA2B* regions each had a single conserved haplotype block 11 kb and 16 kb in size, respectively, and spanning the entire gene, in both AAs and CAs. The *ADRA2C* gene had two haplotype blocks, 3 kb and 14 kb in size in CAs. In AAs Block 2 was split into two blocks 4 kb and 10 kb in size. For *ADRB1*, *ADRB2* and *ADRB3*, a single haplotype block was observed in both populations. In general we observed shorter haplotype blocks and more haplotype diversity in the AAs than in the CAs. The frequency of common haplotypes in each block differed significantly in the two populations. 3-5 common haplotypes were generally sufficient to give 80% population coverage, and a similar number of markers (2-5) per block was sufficient to capture maximum diversity in either population. For alpha 2 and beta AR genes, each marker panel included known functional markers. For each gene, haplotype captured the information content of each functional locus, even if that locus was not genotyped, and presumably haplotype would capture the signal from unknown functional loci whose alleles are of moderate abundance. Thus, these haplotype maps and marker panels are useful tools for genetic linkage studies.

UMD : a generic software to build Locus Specific DataBases. *C. Beroud¹, D. Hamroun¹, G. Collod-Beroud¹, S. Tuffery-Giraud¹, C. Boileau^{2, 3}, T. Soussi⁴, M. Claustres¹.* 1) Dept of Molecular Genetics, CHU de Montpellier, Montpellier, France; 2) INSERM U383, Paris, France; 3) Dept of Molecular Genetics, Boulogne, France; 4) Laboratoire de Genotoxicologie des tumeurs, Paris, France.

The creation of the Universal Mutation Database (UMD) tool was initiated 10 years ago and the first generic software was released in 2000. During this period the human genome project has released an almost complete sequence of the human. Thanks to the flexible database structure, the 2004 release of UMD includes all intronic and regulatory sequences of a specific gene. Other major developments have been performed to integrate clinical data, pictures, monoclonal antibodies and polymorphic markers. Since the beginning we focus on the creation of specific analysis tools. We have come a long way since the first application to the TP53 gene and the development of molecular epidemiology. Today UMD retains all specifically designed tools to analyze mutations at the molecular level and a new set of routines to search for genotype-phenotype correlations. With the creation of 25 LSDBs, almost 30.000 mutations are included in UMD-LSDBs. This led us to create specific tools for infrequent mutations such as gross deletions or duplications and deep intronic mutations. A set of dedicated routines is now available for intronic mutations (CV calculation of potential splice sites, search for ESE motifs). Other major developments have been performed to use graphical displays for various analyses such as geographic distribution of mutations. Concomitantly, we have created specific routines to help researchers to design new therapeutic strategies such as exon skipping, aminoglycosides read-through of stop codons or monoclonal antibodies selection and epitopes scanning for gene therapy. These tools pave the way for clinical trials and associations between genotypes and drugs response. The UMD generic software is today a reference tool to build LSDBs and is adapted to genes involved in genetic diseases or cancers. Since the beginning we have wrought to make a freely accessible tool of it. It can be downloaded at <http://www.umd.be>. We also offer to the various curators our hosting capacities for their UMD-LSDBs.

Ab-initio gene prediction in the minimum lost region at 17q21-23 and its partial characterization/annotation in sporadic breast cancer. *M. Bhuvanagiri*¹, *N. BAIRWA*², *R.N.K. BAMEZAI*¹. 1) NCAHG,SLS, Jawaharlal Nehru University+, New Delhi, India; 2) Department of Pathology,Carver College of Medicine, UIHC, University of Iowa, Iowa City, IA-52242.

The present study combined Insilco methodology with molecular biology approaches to map as yet un-annotated potential regions of putative tumor suppressor gene(s) in patients with sporadic breast cancer. Investigation of LOH in chromosomal region 17p13-3 covered by D17s5, D17s379 and 17q21.23 covered by D17s855, D17s934 and D17s787 showed maximum LOH in the regions surrounded by D17s934 and D17s787 markers in most of the tumor. Ab-initio gene prediction analysis of the genomic region surrounding D17S934 was carried out to search for putative TSG or novel gene(s). Insilco transcript map of the region was generated on Build 34 Sequence map information provided by NCBI. It was observed that approx 50kb region which included D17S934 marker showed sparse UNIGENE information. EST, Morbid and Breakpoint maps were studied using MAPVIEWER option provided by NCBI to know the EST's, disease association and breakpoints associated within the predicted region. Three genes were annotated in D17S787 and a gene with three exons was predicted in D17S934 region using GENSCAN. Further this region was analysed for in vitro presence of transcripts. Primers were designed using OLIGO software version 2.0, BLAST analysis was carried out to check the specificity of designed primers. The amplified genomic product was confirmed by sequencing using ABI PRISM 3100AVANT, Genetic Analyser. The experimental validation of one of the predicted exon revealed the presence of novel EST (Ac no-AY343912) in the D17S934 loci region. RT-PCR amplified product of these predicted exons was sequenced and when compared with genomic sequences using CLUSTALX software It turned out to be identical. The predicted coding regions were also analyzed for the presence of instability or somatic variation in tumor samples. This study exploits the sequence and map information generated by Human Genome Project, for finding novel expressed sequences that might be related to the sporadic form of breast cancer.

Program Nr: 1533 from the 2004 ASHG Annual Meeting

Speaking the Same Language. *E.A. Bruford^{1,2}, M.W. Wright^{1,2}, R.C. Lovering^{1,2}, M.J. Lush^{1,2}, H.M. Wain^{1,2}, V.K. Khodiyar^{1,2}, C.C. Talbot Jr.^{1,3}, S. Povey^{1,2}.* 1) HUGO Gene Nomenclature Committee (HGNC); 2) The Galton Laboratory, Department of Biology, University College London, Wolfson House, 4 Stephenson Way, London, NW1 2HE, UK; 3) The Johns Hopkins School of Medicine, Institute of Genetic Medicine, The Johns Hopkins University, Baltimore, MD, 21205, USA.

The aim of the HUGO Gene Nomenclature Committee (HGNC) is to designate unique and meaningful names and symbols to every human gene. Approved gene symbols are based on names describing structure, function or homology where possible. When placing genes in families we strongly encourage the development of hierarchical stem (or root) symbols, with a numbering system to distinguish individual members. This is an efficient and useful way to name large numbers of related genes. Some genes are not related by extensive homology or proven function, but rather by the presence of intrinsic domains and motifs. Members of such "gene groupings" might have an inferred function based upon these shared domains, and hence can be named on this basis. Examples of such families and groupings will be discussed. An exciting development in genome informatics is gene ontology (GO), which like the HGNC seeks to reduce confusion through the use of systematic controlled vocabularies. The HGNC is uniquely placed to provide GO terms for human genes as a result of the scientific evaluations, investigations and consultations undertaken during the nomenclature assignment process. Consequently, the HGNC are now working with the GO consortium to update their database. Assigning the same gene symbol to orthologous genes reduces interspecies confusion, and hence dedicated HUMOT (Human and Mouse Orthologous Annotation) curators have now been appointed at both the HGNC and the Mouse Genomic Nomenclature Committee (MGNC). These curators will liaise on human/mouse orthology problems to enhance communication and further strengthen collaboration between the two committees. Illustrations of the effects of these developments with GO and the MGNC on human gene nomenclature will be provided. Please come and visit us at our booth in the Exhibit Area, or go to <http://www.gene.ucl.ac.uk/nomenclature/> for further information. Supported by NIH contract N01-LM-9-3533.

Comparative genomic approach to disease gene discovery: Application to Bardet-Biedl Syndrome (BBS3). *A.P. Chiang¹, D.Y. Nishimura¹, K. Elbedour³, R. Carmi³, T.E. Scheetz¹, T.A. Braun¹, E.M. Stone^{1,2}, T.L. Casavant¹, V.C. Sheffield^{1,2}.* 1) University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA; 3) Genetic Institute, Soroka Medical Center, Ben Gurion University of the Negev, Beer-Sheva, Israel.

We report a computational comparative genomics strategy that identifies biological features shared by some organisms, but absent in other species, and utilizes this information for the identification and ranking of disease candidate genes. We successfully apply this approach to identify a Bardet Biedl Syndrome (BBS3) gene. BBS is a genetically heterogeneous disorder characterized by obesity, retinal degeneration, polydactyly, male hypogonadism, renal abnormalities and cognitive impairment. One of the eight known BBS loci (BBS3) was previously mapped to chromosome 3 by using linkage analysis of a single large inbred Israeli Bedouin kindred. We refined the BBS3 locus to a region of ~5 cM. A paucity of other BBS3 families limited further refinement of the disease interval. We hypothesized that the genomes of model organisms that contain the orthologs to known BBS genes would also likely contain BBS3 orthologs. We implemented a computational approach that prioritized genes in the ~5 cM BBS3 genetic interval based upon conservation in the genomes of species that have orthologs of the previously known BBS genes. Subsequent sequencing of prioritized candidate genes led to the identification of a homozygous stop mutation in an ADP-ribosylation factor-like (ARL) gene in all affected members of the original BBS3 pedigree. We hypothesize that a generalization of this comparative genomic approach may be employed in the study of other genetic disorders.

Program Nr: 1535 from the 2004 ASHG Annual Meeting

CodeLink Whole Genome High Performance Bioarrays:For Comprehensive Gene Expression Profiling. *B. Chui, G.L. Kiser, T. Giesler, R. Svirskas, P. Gwynne, M.E. Morrison, J. McGowen, R. Lockner, R. Bonner, M. Gaskin, R. Shippy, T. Sendera, H. Samartzidou, T. Kaysser-Kranich.* CodeLink, GE Healthcare, Chandler, AZ.

CodeLink Whole Genome Bioarray product offerings, including the CodeLink Human and Rat Whole Genome Bioarrays, are the result of three main technological improvements: a new slide surface, production robotics for dispensing, and software for spot quantification and data analysis. These improvements enabled increased density and performance leading to bioarrays with the most comprehensive genome coverage for human and rat gene expression profiling. These bioarrays show typical CodeLink high reproducibility and offer sensitivity down to 1:1,024,00 (estimated mass ratio), with a linear dynamic range of ~3 logs. In addition to the high density bioarrays, the system includes optimized reagents and protocols for target preparation, hybridization, secondary-labelling, and detection, as well as software for data extraction and analysis. Content is based on the UniGene, RefSeq and Ensembl public databases. An improved control probe set includes 384 negative control and 360 positive control bacterial sequence probes. The Rat Whole Genome Bioarray System provides expression profiling of ~35,000 rat gene targets in a single bioarray. Here we describe the performance of this Whole Genome Bioarray System.

Divergent evolution of GAA triplet repeats in primate genomes. *R.M. Clark, S.S. Bhaskar, M. Miyahara, S.I. Bidichandani.* Biochemistry & Molecular Biology, University of Oklahoma Health Sci Ctr, Oklahoma City, OK.

Abnormal expansion of triplet repeats causes several neurodegenerative diseases. While CAG/CTG and CGG/CCG expansions cause several disease phenotypes, expansion of GAA/TTC repeats is presently only known to cause Friedreich ataxia. We have previously shown that of all ten triplet repeats, GAA repeats have expanded the most in the human genome. There are 29 instances of (GAA)₃₀₊ sequences in the draft human genome, i.e. corresponding to premutation alleles that display germline instability at the Friedreich ataxia locus. Given our previous observation that GAA triplet repeats overlap with Alu elements, we were curious whether these potentially premutagenic GAA triplet repeats also exist in non-human primates. Analysis of all ten triplet repeats in the entire chimpanzee genome also revealed that GAA triplet repeats have undergone the most expansion, with 56 instances of (GAA)₂₅₊ sequences. However, the loci containing long GAA repeats in the human genome did not correspond to those in the chimpanzee genome, and vice versa. Indeed, in 70% of cases the homologous chimpanzee loci of the human (GAA)₃₀₊ sequences contained <8 repeats. Likewise, 45% of human loci corresponding to the chimpanzee loci with (GAA)₂₅₊ had <8 repeats. In two cases we even found TAA repeats at the corresponding human loci in place of (GAA)₂₅₊ in the chimpanzee genome. To evaluate the validity of the potentially unstable GAA sequences we analyzed 50-100 normal human chromosomes at nine of the human (GAA)₃₀₊ loci (at which the chimpanzee genome has <8 triplets). At seven of these nine loci, chromosomes were identified that carried >100 GAA triplet repeats, corresponding to disease-causing expansions at the Friedreich ataxia locus. Our data indicate that while GAA triplet repeats have undergone significant expansion in primate genomes, individual loci show substantial inter-species divergence. These differences constitute a potential source of difference at the genomic level between humans and chimpanzees, species that otherwise share >95% sequence homology.

GeneRetriever extracts the data needed to design a custom microarray containing probes of all genes and transcripts in between two genetic markers. *M. Clement-Ziza¹, Y. Brody², A. Munnich¹, S. Lyonnet¹, C. Besmond¹.* 1) INSERM U393, Hopital Necker-Enfants Malades, Paris, France; 2) Department of Biology and Computer Science, Bar Ilan University, Ramat Gan, Israel.

Identifying the genes that are responsible for human genetic disorders with complex inheritance patterns (e.g. multigenic diseases) proves to be somehow difficult. Indeed, as the mode of inheritance is unknown, classical parametric linkage studies are not relevant. Nonparametric linkage analysis can help approximate the candidate loci. However, this type of analysis often leads to the identification of large intervals (10-20 cM) which may contain hundreds of genes thus rendering the candidate gene approach rather tedious. Microarray expression studies of the genes located within such genetic intervals and performed on relevant tissues may significantly reduce the number of candidate genes. The design of a custom microarray containing probes of all the genes located in the intervals of interest is required to carry out such experiments. Designing such microarrays involves gathering much additional information concerning these genes. Collecting these data manually is time-consuming and very error-prone.

GeneRetriever is a Perl-based data mining tool developed to automate, accelerate, and secure the process of retrieving, from NCBI databases, user chosen information needed to design a custom expression microarray containing all genes and transcripts located in between two genetic markers. These data include gene description (full gene name), DNA strand, type of gene (either known or predicted), cytogenetic localization, summary of functional annotations, Entrez Gene identifier, as well as the number of transcripts for each gene. Versioned GeneBank accession numbers, structural information (i.e. number of exons) and nucleotide sequences of transcripts can also be collected. GeneRetriever provides both graphical and command-line interfaces. It is fast and requires only an Internet connection. GeneRetriever was used to help design a custom microarray with all genes from three genetic intervals involved in Hirschsprung disease.

Program Nr: 1538 from the 2004 ASHG Annual Meeting

Annotation tools for human and mouse Affymetrix gene expression microarrays. *R.J. Clifford, K.H. Buetow.*
National Cancer Inst, Bethesda, MD.

The Affymetrix GeneChip microarray is a popular platform for gene expression studies. GeneChips were designed against clusters from past UniGene clusters builds: the HG-U133 series, for example, is based on clusters from UniGene build Hs133. Since the design of these arrays, UniGene clusters have been refined in response to improved knowledge of gene structure. Clusters containing sequences from homologous genes have been split. Distinct UniGenes representing alternative products of a single gene arising from differential splicing or polyadenylation site selection have been merged. Unnamed genes have been given HUGO approved gene symbols and novel loci have been discovered. For these reasons it is critical to maintain current annotations for GeneChip probe sets. To address this need, Affymetrix provides quarterly annotation updates on its website. We provide an alternative set of annotations for the human HG-U95 and HG-U133 and murine MG-U74 and MOE430 chip sets. At each UniGene update, we use BLAST to map each microarray probe sequence against the complete set of mRNA and ESTs sequences included in the current UniGene build. Our WWW-based tool (<http://lpgws.nci.nih.gov/cgi-bin/AffyViewer.cgi>) displays human and mouse GeneChip probes in the context of mRNA sequences. Antisense probes and probes that do not specifically recognize their target loci are flagged. The BLAST evidence used to map probes onto transcripts and genes is also available. Plain text annotation files and mask files can be downloaded via FTP. This work utilizes the high-performance computational capabilities of the Biowulf PC/Linux cluster at the National Institutes of Health, Bethesda, MD (<http://biowulf.nih.gov>).

Identification of Xenobiotic-responsive Target genes by Tandem Machine Learning. *D. Dinakarbandian¹, V. Raheja¹, S. Mehta¹, P.K. Rogan^{1, 2}.* 1) Schools of Computing and Engineering and; 2) Medicine, Children's Mercy Hospital, University of Missouri-Kansas City, MO.

Motivation: One of the challenges in Bioinformatics is to understand the regulatory signals embedded within the human genome that are responsible for the initiation and regulation of DNA transcription.

Approach: In this collaborative project, we have developed a tandem machine learning approach to the identification of target genes for the xenobiotic-sensitive transcription factor PXR/RXR within the human genome. An information theory-based weight matrix was first derived and refined from validated PXR/RXR binding sites. Then, gene candidates identified by microarray and published studies that were known to be regulated by this transcription factor were scanned to identify putative binding sites. An information density-based clustering algorithm was then used to identify clusters of information rich sites. Finally, transformed data representing metrics of location, strength and clustering of binding sites were used for classification of promoter regions using an ensemble approach involving neural networks, decision trees and Naive Bayesian classification.

Results: The method was evaluated on a set of 24 known target genes and 288 genes known not to be regulated by PXR/RXR. We report an average accuracy (proportion of correctly classified promoter regions) of 71%, sensitivity of 73%, and specificity of 70% based on n-way cross-validation and exhaustive leave-out-one strategy. The performance on an unknown test set of 10 genes showed that 8 (80%) were correctly classified.

Conclusion: We find that the clustering of sites with high individual information contents is an important determinant of target specificity. While the goal is to identify all genes that are regulated by PXR/RXR, the method is general enough to be applicable to the identification of target genes for other transcription factors..

GeneSniffer - a gene prioritisation tool. *K.S. Elliott^{1,2}, J. Blangero^{2,3}, J. Jowett^{1,2}*. 1) International Diabetes Institute, Australia; 2) Chemgenix Pharmaceuticals, Australia; 3) Southwest Foundation for Biomedical Research, USA.

Localization of genes influencing susceptibility to complex diseases generally results in the need to evaluate numerous potential candidates in a large genomic interval. The choice of positional candidate genes is usually based on subjective criteria and the invocation of luck. In this presentation, we describe a semi-quantitative objective method for the efficient prioritisation of positional candidate genes in regions of linkage. The strategy involves computer-intensive database mining for bioinformation on the genes under a linkage peak as a prelude to the expensive molecular lab work subsequently required. This process can be tedious and very time consuming since there can be hundreds of genes to choose from for further analysis. GeneSniffer is a computer program developed in house to assist with this task. For each gene within a given linkage interval, GeneSniffer downloads appropriate webpages from the Locuslink, OMIM and PubMed databases and interrogates the text using a list of disease specific keywords (assigned a score between 1-10 depending on significance). Homologs of each gene are identified by BLAST and scored for content of their Locuslink, OMIM and PubMed entries. These scores are weighted according to the degree of homology and a cumulative hit-score is calculated for each gene. Jackson pages for available mouse orthologs are also scored. The resultant output is presented in linked webpages (in html format) to provide the investigator with information as to the source of the hits and links to relevant external webpages for further information. The method leads to an objective ranking of genes based on multiple criteria that can be further processed statistically and graphically if desired. Like all bioinformatic methods based on potentially error-prone public databases, the output of the program still needs to be closely examined, but significant time is saved compared to manually sifting through the large quantity of data. Additionally, the process takes advantage of the dynamic nature of public databases since scripts can be rerun at any time to incorporate database updates.

Subspace Identification for Genetic Networks. *X. Fang*¹, *L. Jin*³, *M. Xiong*². 1) Dept Statistics, Beijing Univ, Beijing; 2) Human Genetics, University of Texas - Houston; 3) University of Cincinnati.

Genetic networks are complex systems that require accomplishing complex tasks with high accuracy. A very powerful approach to modeling complex systems is the state-space approach. The state-space approach is a good choice for modeling regulation due to the following reasons. First, the concept of state variables is very suitable for description of the regulatory process. Second, the state-space approach is in the core of modern control theory. Third, development of RNA interference for repression of gene expression and synthetic biology in designing artificial regulatory circuits. Their successful applications to the development of smart drugs require state-space representation of dynamics of genetic networks and applications of modern control theory to design and analysis of genetic networks. State-space approach provides a general framework and a powerful tool for application of control theory to analysis of genetic networks. A key issue for modeling genetic networks is how to model regulation of a gene. We first use state space equations with two state variables for modeling a transcriptional process of the gene. We then use block diagram as a graphical representation of the genetic networks. We define mathematical operations on the block diagram to organize genes into a genetic network. The parameters in the genetic networks are estimated by subspace method, a new generation of system identification algorithms. The proposed model and estimation procedures were applied to DNA Repair network in *E. Coli*. The accuracy of the estimation by the state-space model is even higher than that of kinetic models.

The Mutation Database Initiative 10 years on: where are we today? *O. Horaitis*¹, *R.G.H. Cotton*^{1, 2}. 1) Genomic Disorders Research Ctr, Melbourne, Australia; 2) The Univ. of Melbourne, Dept of Medicine, Australia.

Ten years ago at ASHG Montreal, a small meeting was organized to discuss the problem of incomplete mutation collection with a group of the worlds senior geneticists. Issues such as non-uniform nomenclature of mutations throughout publications and databases, databases being mutation focussed rather than proband/phenotype focussed and central database curators not being experts in specific genes were discussed. From this meeting stemmed a group known as the Mutation Database Initiative that quickly grew to around 600 members interested in capturing human genome variation. In October 2001 at the annual meeting at ASHG it was decided that the group should become a formal Society and it is now known as the Human Genome Variation Society (HGVS; www.hgvs.org), of which there are almost 100 members to date and growing. The main objectives of the HGVS remain to ensure documentation, collection and free distribution of all variation information. We have made progress in areas of standardization of mutation nomenclature- our nomenclature is now accepted as the standard in naming variations, the creation of Locus Specific DataBases for a large number of genes- 85 new gene-specific databases have been created due to our encouragement, the creation of databases specific to ethnic or national groups- there are now databases specific for Arab, Cypriot, Finnish, Greek, Iranian and Turkish genetic disease with others under construction. Recommendations for quality control of data and standardizing database content in mutation databases have been made and many databases comply. The design of an Allele Variant Entry Form to be used for submission of data to LSDBs is now being used by 24% of LSDBs that allow submission of mutations directly to their database for their collection of mutation data. A comprehensive alphabetically organised by gene catalogue of LSDBs was created and is maintained in online format. Some mutations discovered in the research or diagnostic laboratory will never be reported. The challenge is to catch these mutations and disseminate them through the WWW for access by all; this is the raison d'etre of the MDI now HGVS. See www.hgvs.org.

Comparison of evaluation methods for the quality control of diagnostic oligonucleotide chip. *C.M. Kim^{1, 2}, H.K. Park², H.J. Jang³*. 1) Department of Biochemistry, College of Medicine, Pusan Natl Univ, Busan, Korea; 2) Busan Genome Center, College of Medicine, Pusan Natl Univ, Busan, Korea; 3) Department of Microbiology, College of Natural Science, Pusan Natl Univ, Busan, Korea.

The monitoring of spot-uniformity and probe-attachment and quantification of mixed type of target product are critical to manufacturing the diagnostic oligonucleotide chip. In this study, we described a new quality control (QC) probes as a means of monitoring uniformity of attached probes and quantifying mixed types of target products. We compared the results of the evaluation methods containing QC and target probes and methods containing only target probe of oligonucleotide chip. We designed two types of QC probes. The T20-F probe was comprised 20-mer poly T and was labeled by the TAMRA dye at the 3end. The T20-F probe was mixed with target specific probes for oligonucleotide chip fabrication. The END-F probe was labeled by the TAMRA dye at the 3end of target specific probe. The END-F probe was performed at once QC probe and target specific probe. The fluorescent images by a QC and target probes were obtained at 532 nm and 635 nm. The oligonucleotide chip containing T20-F or END-F probe could be assessed spot quality of all process. But the oligonucleotide chip containing only target probe could not be assessed spot quality. To quantify mixed type of target product, we used signal intensity of QC probe to normalize variations in spot quality and hybridization. The two biotin labeled-PCR products were mixed at 0:10, 1:9, 5:5, 9:1, and 10:0 wt-to-mutant ratios for each concentration. The oligonucleotide chip contained QC probe was hybridized with biotin-labeled target product. We could distinguish ratio of major and minor from mixed type. Two QC probes could detect from 0:10 to 10:0 of that compared to signal intensity of QC probe and target probe (in case of T20-F probe, 1:5.5 at 0:10, 1:2.2 at 1:9, 1:1.1 at 5:5, 1:0.2 at 9:1, and 1:0.1 at 10:0). However, the oligonucleotide chip containing only the target probe could not distinguish ratio. This methods containing quality control probe can assess spot quality of all process and quantify ratio of major and minor from mixed type.

Identification of 93 hair keratin-associated protein (KAP) genes in human genome. *J. Kudoh¹, K. Shibuya¹, I. Obayashi¹, S. Yahagi^{1, 2}, T. Sasaki¹, A. Shimizu¹, N. Shimizu¹.* 1) Dept Molecular Biology, Keio Univ Sch Medicine, Tokyo, Japan; 2) COSMOS Technical Center Co., Ltd., Tokyo, Japan.

Major components of human hair are keratin intermediate filaments (KIFs) and keratin associated proteins (KAPs). KAPs are low-molecular weight proteins and have been classified into four types according to their amino acid compositions; ultra-high sulfur (UHS) KAP (>30% for cysteine content), high sulfur (HS) KAP (16-30% for cysteine content), high glycine-tyrosine (HGT) KAP (35-60% for glycine and tyrosine content), and the unconventional type which belongs to neither UHS/HS nor HGT type. KAP genes (gene symbol KRTAP) consist of single exon and can hardly be identified by exon prediction software. We analyzed human whole genome sequence and found that 93 KAP genes are located as 5 separate clusters (11p15.5, 11q13.5, 17q12-q21, 21q22.11, and 21q22.3) in the human genome. The cluster on 11p15.5 spans over 110 kb and consists of 6 authentic genes for UHS KAP. The cluster on 11q13.5 spans over 56 kb and consists of 5 authentic genes and 2 pseudogenes for UHS KAP. Precise analysis of the cluster on 17q12-q21 revealed that the cluster consists of 34 authentic genes for HS or UHS KAPs. The cluster on 21q22.11 spans over 800 kb and consists of 32 authentic genes and 18 pseudogenes for HGT KAPs or the unconventional type KAPs. Eight out of 32 authentic genes are newly identified genes including 4 novel types of KAP genes for the unconventional type KAPs. The cluster on 21q22.3 spans over 165 kb and consists of 16 authentic genes and 5 pseudogenes for HS KAP. Interestingly, all these authentic genes are located within introns of another gene TSPEAR (gene symbol C21orf29) spanning over 214 kb. Surprisingly, transcriptional direction of 8 out of 16 authentic genes is the same as that of TSPEAR gene. This finding suggests a novel transcription mechanism in which TSPEAR gene transcription passes over the multiple transcriptional termination sites of the KAP genes. Furthermore, we have identified similar KAP gene clusters in two primates, chimpanzee and baboon, and the detailed comparison revealed the process of KAP gene cluster formation during evolution.

Intra-species genome comparison reveals 802 polymorphic Alus and dynamic Alu distributions in human

genome. *P. Liang*¹, *J. Wang*¹, *L. Song*¹, *M.K. Gonder*², *S.A. Tishkoff*², *S. Azrak*¹. 1) Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY; 2) Biology, University of Maryland, College Park, MD.

Alu elements, as the most active and successful SINE-type retrotransposons constituting 10% of the human genome, are now known to play important roles in human genome. By employing an in silico approach to compare the public and Celera versions of human genome sequences, we identified a total of 802 polymorphic Alu elements with over 750 being novel. PCR screening of a randomly selected 16 Alus using a panel of diversified human DNA samples revealed a very high specificity of the method. Our unbiased analysis of all Alu subfamilies reveals that Alu insertion activity differs dramatically across Alu subfamilies with Ya5, Yb8, Yb9, and Ya4b being the most active and a few S subfamilies also showing a low level of activity. These polymorphic Alus, representing the most recent Alu insertions in human genomes, are characterized by the presence of target site duplications and longer polyA-tails with the pre-integration sites mostly following the NT-AARA motif. Like all Alus in general, these recent Alus are distributed heterogeneously in the genome. Very interestingly, the density of old Alus in chromosomes is positively correlated to the gene density accumulating against the availability of Alu sites. In contrast, the density of new Alus is reversibly correlated with Alu and gene density, but positively correlated with Alu site availability. As an exception, Y chromosome has the lowest density of both old and new Alus, although it has an average level of Alu site availability and gene density, suggesting the existence of a mechanism suppressing Alu insertions in Y chromosome. While old Alus show accumulation towards the gene-rich regions, particularly the promoter regions, the new Alus are biased towards intergenic regions, suggesting that a post-insertion selection mechanism is responsible for the biased accumulation of old Alus in gene regions. Our report presents the first attempt to identify all polymorphic Alus between two individuals, and the unprecedented large list of polymorphic Alu markers offers new opportunities for comprehensive population genetics studies.

MutScreener: a web-based tool of primer design for mutation screening by PCR-direct sequencing. *C. Liu^{1,2}, F. Yao², R. Zhang², Z. Zhu², J. Xia², E.S. Gershon¹*. 1) Dept Psychiatry, Knapp Res Ctr, Univ Chicago, Chicago, IL; 2) National Lab of Medical Genetics of China, Central South University, Changsha, P.R. China.

Polymerase Chain Reaction (PCR) amplification with direct DNA sequencing is the major technology for mutation screening of candidate genes. Optimal PCR primer design is one of the most important procedures to obtain high quality results. In order to perform automated annotation of human candidate genes and PCR primer design for mutation screening, we developed a web application named MutScreener. BLAT, Primer3 and DNannotator are used as major data processing components. MutScreener uses sequence data from NCBI and UCSC genome databases or from users own lab. It has three different tracks to handle three different types of input data: 1) cDNA sequence or Genbank ID and human chromosome number; 2) gene annotation produced by DNannotator and users own genomic DNA sequence; 3) gene annotation from Genome Browser. It can analyze genes intron/exon structure (if the first track is used) and pick up multiple PCR and DNA sequencing primers for multiple exons of multiple genes. The second track gives the user opportunity to re-sequence target regions other than promoters and exons, as the annotation features table can be edited. Splicing sites and low quality sequencing region produced in sequencing machine are considered to ensure complete coverage of high quality sequencing data over target sequences. Results are in tabular text format for easy management. MutScreener can be accessed at <http://sky.bsd.uchicago.edu/MutScreener.html>.

Prediction of TaqMan SNP assay genotyping performance of Whole Genome Amplified DNA using wgaDNA yield and STR genotyping performance. *Y. Qi¹, A. Bergen^{1,2}, K. Haque¹, M. Beerman¹, R. Welch¹, S. Chanock^{1,2}.* 1) Core Genotyping Facility, National Cancer Institute, 8717 Grovemont Circle, Bethesda, MD 20877; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, 6120 Executive Boulevard, MSC 7242, Bethesda, Maryland 20892-7335.

The aim of this study was to identify predictors of SNP genotyping performance. Data were collected from an evaluation of Whole Genome Amplification (WGA) using genomic DNA (gDNA) derived from lymphoblastoid cell lines and using a range of gDNA inputs (1-100ng). gDNA from 22 lymphoblastoid cell lines was amplified using a commercially available Multiple Displacement Amplification WGA protocol. Whole Genome Amplified DNA (wgaDNA) was quantified by UV spectroscopy, the PicoGreen assay (Molecular Probes), and a quantitative TaqMan assay specific to human DNA. wgaDNA genotyping performance was evaluated using genotypes determined from both gDNA and wgaDNA using the N=15 STRs in the AmpFISTR Identifiler assay and N=49 TaqMan SNP genotyping assays. We observed a significant positive correlation ($p < 0.01$) between STR and SNP genotyping performance. Linear regression analyses were performed to determine the wgaDNA yield and AmpFISTR Identifiler STR genotyping performance factors that are significantly associated with wgaDNA TaqMan SNP genotyping assay performance. Two models were constructed with dependent variables SNP completed genotypes and SNP concordant genotypes, respectively. Independent variables included: STR completed genotypes, STR concordant genotypes, STR Genotype Quality score, STR Peak height (Allele 2), wgaDNA yield (as measured by quantitative PCR), and gDNA input into WGA reaction. In the model, SNP completed/concordant genotypes are the total number of completed/concordant genotypes over 49 SNP assays and STR completed/concordant genotypes are the total number of completed/concordant genotypes over 15 STR assays. The final best predictive model included STR completed genotypes and STR concordant genotypes, with a R-Square of 0.9987 and p values 0.0001. Completed genotypes from 15 STR markers can be used to predict completed genotypes from 49 SNP assays with a linear regression model.

Large-scale Production of BAC Clone Representations for Microarray Comparative Genome Hybridization. D. Smailus¹, M. Krzywinski¹, J. Stott¹, C. Mathewson¹, D. Lee¹, P.J. de Jong², D. Albertson³, J. Friedman⁴, M. Marra¹, J. Schein¹, R. Holt¹. 1) BC Cancer Agency , Genome Sciences Centre, Vancouver, BC Canada; 2) BACPAC Resources, Children's Hospital Oakland Research Institute, Oakland, CA USA; 3) UCSF Cancer Center, San Francisco, CA USA; 4) Dept. of Medical Genetics, University of BC, Vancouver, BC CANADA.

Microarray comparative genome hybridization (maCGH) detects chromosomal aberrations that result in DNA copy number changes. Bacterial artificial chromosome (BAC) clones are commonly used as hybridization targets for maCGH. The large insert size of BACs allows integration of hybridization signal over a large region and provides sufficient sensitivity to routinely detect single copy number changes. Previously, we selected a tiling set of 32,855 human BACs from various libraries that gives 75 kb average sampling resolution and 99% coverage of the sequenced portion of the genome (Krzywinski et al., *Nucleic Acids Res.*, in press). These clones have been arrayed into chromosome specific sets and validated by restriction fingerprinting. Because preparation of BAC DNA is labour intensive and gives low yields of high molecular weight (and therefore difficult to handle) DNA, we have implemented an automated, high-throughput ligation-mediated PCR pipeline to generate BAC clone representations suitable for spotting. Briefly, clone DNA is prepared by alkaline lysis, digested with MseI, and oligonucleotide adapters are ligated to the ends of fragments. The fragments are amplified by two rounds of PCR using adapter-specific primers. Final PCR products (~10ug per clone) are precipitated, then re-suspended overnight in 15 ul of 20% DMSO solution. A Beckman Coulter BiomekFX dual head 96-tip P20/200 liquid handler with ART barrier tips is used for all liquid handling steps. Using this method we are currently generating approximately 6000 BAC clone representations per week, for use in fabrication of a whole genome tiling microarray.

The SPEED Toolkit: A resource for evolutionary analysis in Human genetic studies. *A. Solidar*¹, *J.E. Paschall*¹, *C.M. Malcom*², *G.J. Wyckoff*¹. 1) Div. Mol. Biol. and Biochem, U. Missouri-Kansas City, Kansas City, MO; 2) 2Dept. of Anthropology, The University of Chicago, Chicago, IL.

We detail a website devoted to integrating evolutionary information into human genetic studies. This suite of tools is geared toward choosing genes of clinical interest, targets for genomic or proteomic analysis, and possible human disease genes. The database allows for evolutionary analysis of genes that have been under-studied because their adaptive significance has been underestimated. This is particularly important in light of recent data that suggest that evolutionary rate and constraint may be correlated with the likelihood that a gene is involved with human disease. The website, located at <http://bioinfobase.umkc.edu/>, is open to the public, and all information within is annotated so that even scientists with little formal evolutionary training can grasp the meaning and utility of the information presented. The website itself is carefully designed to allow queries from a wide variety of starting perspectives. For example, the toolkit includes a search for disease association, a user-defined protein motif search, and a browsing tool for relative evolutionary rate. As an example of the toolkits utility, we show how a researcher using a peptide sequence, gathered for example from an MS/MS experiment, can query the database to obtain a set of genes, with evolutionary information, within a few minutes. These techniques save enormous amounts of analysis time and can be integrated into a pipeline for current laboratory analysis procedures. The rational, multi-entry design of the website means that obtaining interesting and useful results is quick and can be performed by investigators at multiple levels: from simple, exploratory assays to thorough, detailed analyses for publication.

Accurate detection and classification of heterozygous indels by direct sequencing. *J. Sorenson, A. Pradhan, S. Vijaychander, B. Sangari, T. Nguyen, B. Jones, D. Guo, Q. Doan.* Applied Biosystems, Foster City, CA 94404.

A heterozygous insertion/deletion (indel) mutation is defined by the presence of two alleles differing by an insertion or deletion---a length polymorphism. It has been estimated that 20% of the polymorphisms in the human genome are length polymorphisms. However the direct sequencing of heterozygous individuals is complicated by a phase shift in the electropherogram trace at the site of the indel mutation. Quality-based sequencing pipelines discard this data as noise or spend significant time and effort trying to call the polymorphism correctly. Starting with SeqScape Software v2.0, we introduced an algorithm to predict when samples were exhibiting the presence of a heterozygous indel mutation (HIM). This algorithm has been refined in subsequent releases of the software to include basecalling the inserted/deleted sequence, mapping the polymorphism to the reference sequence, displaying the mutation in the HUGO-approved format, and assigning a quality value to the mutation. Recently we have been able to improve the algorithm further by accumulating numerous in-house and customer examples of this trace feature and developing a pipeline for annotation and automated testing. Results from this testing show a significant improvement in the ability of the software to correctly call heterozygous indel mutations versus earlier analysis pipelines. This ability to accurately detect and characterize heterozygous indels offers a valuable solution to a previously difficult problem in the analysis of resequencing data.

Program Nr: 1551 from the 2004 ASHG Annual Meeting

Visualization of valid polymorphisms within the human genome. *B.J. Staats¹, L. Qi¹, M. Beerman¹, H. Sicotte¹, B.R. Packer¹, S.J. Chanock², M. Yeager¹.* 1) Intramural Research Support Program, SAIC-Frederick, NCI-FCRDC, Frederick, MD, USA; 2) Section on Genomic Variation, Pediatric Oncology Branch, National Cancer Institute, National Institutes of Health, Gaithersburg, MD, USA.

The Annotator web application serves as a tool for viewing publicly available variations together with those validated by the Core Genotyping Facility (CGF) at the National Cancer Institute. Users are able to see human variation in genomic and proteomic contexts along with population-specific information, enabling them to make informative decisions based on the polymorphisms that are present in a given population. Currently, users can search by gene or variation to retrieve a gene-centric view of the gene and/ or variation. Intergenic regions are also viewable. CGF administrators can add new annotations from the CGFs SNP discovery/validation pipeline directly through the Annotator user interface in an intuitive and productive manner. The Annotator is linked to other CGF databases such as the laboratory information management system, to automate annotations relevant for assay design and validation. Among the many links the Annotator has to other resources, there are links to and from the SNP500 cancer web site which presents data generated by the CGF. Ongoing development for the Annotator includes visual analysis results from genotype data and additional information from public resources.

Program Nr: 1552 from the 2004 ASHG Annual Meeting

SNPHunter: A Bioinformatic Software for Single Nucleotide Polymorphism Data Acquisition and Management.

*L. Wang*¹, *S. Liu*^{2,3}, *X. Xu*¹, *T. Niu*^{1,3}. 1) Program for Population Genetics, Harvard School of Public Health, Boston, MA 02115, USA; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA 02115, USA; 3) Division of Preventive Medicine, Department of Medicine, Brigham and Womens Hospital, Harvard Medical School, Boston, MA 02215, USA.

SNPs serve as important markers for identifying genetic variants for human diseases. Current public database (dbSNP) contains information for ~9 millions SNPs in the human genome, half of which with varying degree of confirmation. Retrieval of SNP data from dbSNP has emerged as a major bottleneck in genetic research. We developed a software tool, SNPHunter, which retrieves SNP data (e.g. physical map position, function class, flanking sequences, heterozygosity, and confirmation status) from NCBI dbSNP website according to user specified criteria, and allows downloading of such data for local storage and management. SNPHunter consists of three functional modules: (1) Direct dbSNP Query ("SNPSearch"); (2) SNP Data Extraction and Management ("SNP Management"); and (3) LocusLink SNP Query ("LocusLink SNP"). In these modules, SNPHunter retrieves SNPs according to gene list and automatically filter SNPs by interacting with user, which greatly facilitate candidate SNP selection in genetic studies. Furthermore, SNPHunter can extract SNP flanking sequence with annotation of all SNPs within the sequence. As an illustration, we applied SNPHunter for selecting SNPs for 10 major candidate genes for type 2 diabetes. SNPHunter does not require any local database support, and always retrieve the latest SNP and sequence data from NCBI. Its user-friendly design offers researcher an easy and intuitive interface and it is freely available at:<http://www.hsph.harvard.edu/ppg/software.htm>.

Global landscape of unusual genetic architectures for *Homo sapiens*. E. Wang^{1,3}, G. Kodama², P. Baldi^{1,2,3}, R. Moyzis^{1,3}. 1) Biological Chemistry, Univ of California, Irvine, Irvine, CA; 2) School of Information and Computer Science, University of California, Irvine. Irvine, CA 92697; 3) Institute of Genomics and Bioinformatics, University of California, Irvine, Irvine, CA 92697.

From our previous reports of the unusual genetic architecture of the human Dopamine Receptor D4 (*DRD4*) gene locus, we noted that a Bayesian statistical model could be used to describe the signature left by directional selection. With the availability of the International Human Haplotype Map (HapMap) data, we use this approach to uncover the global landscape of unusual genetic architectures associated with recent selection. We ask how often would we find regions similar to known selected genes such as the human Glucose-6-phosphate Dehydrogenase (*G6PD*) V202M locus? Our model describes a scenario where complete Linkage Disequilibrium (LD) for one allele does not decay to noise until 500,000 base pairs away. Here, we show that such inferred selective events are not random and quite common in human DNA. Following literature-based confirmation, we outline the major statistically over-represented Gene Ontology (GO) categories, representing several predominant biological themes. These over-represented categories include various systems likely associated with pathogen response, genes associated with DNA metabolism/cell cycle/gametogenesis, and pathways associated with neuronal function.

The importance of sequence context in SNP genotyping assay design and performance. *R. Welch^{1,2}, M. Yeager^{1,2}, B.R. Packer^{1,2}, A. Crenshaw^{1,2}, M. Kiley^{1,2}, A. Eckert^{1,2}, L. Burdett^{1,2}, A.W. Bergen¹, S.J. Chanock^{1,3}.* 1) Core Genotyping Facility, DCEG/NCI/NIH, Gaithersburg MD; 2) Intramural Research Support Program, SAIC-Frederick, NCI-FCRDC, Frederick MD; 3) Section on Genomic Variation, Pediatric Oncology Branch, NCI/NIH, Gaithersburg MD.

Millions of SNPs have been deposited in public databases, however, annotations of SNP records in public databases do not always include representation of adjacent flanking SNPs, even if they are known. Such omissions could have a significant impact on the design and performance of SNP genotyping assays, particularly since most current genotyping platforms analyze small fragments of sequence (~100bp). In addition, because genetic diversity is observed among ethnic groups, it is important that the verification and characterization of SNPs and their surrounding sequence include a diversity of ethnic groups. To address these issues, our candidate gene genotyping pipeline includes bi-directional re-sequencing verification of targeted SNPs and characterization of immediately adjacent SNPs in an ethnically-diverse panel of unrelated individuals (N=102) for use in genotyping assay design. An analysis of 1433 target SNPs of interest showed that while 443 (31%) targeted SNPs did not have adjacent SNPs present within an average of 98bp (range 1 to 378), 990 (69%) others had at least one SNP nearby. Furthermore, a substantial number (N=365, 25.5%) of targeted SNPs had at least one of these potentially interfering SNPs present within the expected area of genotyping assay design (within 50bp), even when excluding those SNPs observed in only 1 of 204 chromosomes (mean distance = 23bp, mean MAF = 10.6%). The use of sequence information from public databases for SNP genotyping assay design poses potential problems in assay optimization as well as assay performance (obtaining true genotypes) because adjacent SNPs may interfere with assay performance, leading to genotyping miscalls (i.e. loss of heterozygotes) or assay failure. Such performance issues may contribute to the abundance of false positive results, namely reported studies that do not replicate, since many studies do not use common assays for each interrogated SNP.

High Resolution Human Leukocyte Antigen (HLA) Typing by Mass Spectrometry. *M. Beaulieu, C. Honisch, Y. Chen, D. van den Boom.* Sequenom Inc., San Diego, CA.

The extended collection of genes on the short arm of human chromosome 6 at 6p21.3 is called the Major Histocompatibility Complex (MHC). The locus was named for its role in tissue rejection following transplantation and many of the genes are involved in the biology of the immune system. Because MHC class I antigens are expressed ubiquitously by human leucocytes, they were called Human Leukocyte Antigens (HLA). Structural differences in the HLA molecules expressed by transplant donors and recipients are the major cause of rejection. Underlying these differences is a high degree of genetic polymorphism. During the past 40 years, serological techniques were employed to match potential donors with recipients. The drawbacks of serology include the lack of precision and the need for viable cells. Recently introduced, molecular typing methods require only small amounts of genomic DNA and can offer greater precision. Most molecular methods are derived from locus-specific PCR. Most alleles can be discriminated based on the sequence of exon 2 (HLA class II genes) and exons 2 and 3 (HLA class I genes). Current signal detection platforms are based on gel/capillary electrophoresis and microarrays. These platforms either lack the resolution necessary to distinguish the known alleles, or offer only low throughput capacity. Here we describe a novel molecular HLA typing method based on base-specific cleavage and MALDI-TOF mass spectrometry using the MassARRAY platform. PCR primer pairs for an 863 bp region encompassing exon 2 through exon 3 of the HLA-A locus, and a 234 bp amplicon from the exon 2 of HLA-DQA1 locus, were designed. Twelve (A) and 71 (DQA1) previously typed reference DNA samples were used for initial system validation. The PCR products were submitted to the MassCLEAVE process consisting of an in vitro transcription and base-specific cleavage. The cleavage fragments were analyzed by MALDI-TOF MS. The mass signal patterns of the spectra obtained were cross-compared with sets of theoretical peak patterns of the currently known alleles. Results demonstrate the possibility of using MALDI-TOF mass spectrometry for high-throughput and high-resolution HLA typing.

Expression profiling of candidate genes for brain development and function in neocortex of normal and trisomy 21 fetuses. *T. Haaf¹, G.E. Weiss¹, C. Neuser¹, T. Tralau², U. Zechner¹, D. Galetzka¹.* 1) Inst Human Genetics, Mainz Univ Sch Medicine, Mainz, Germany; 2) Dept Pediatric Pathology, Mainz Univ Sch Medicine, Mainz, Germany.

Human brain development depends on correct spatiotemporal expression of numerous genes. Disturbances of this highly coordinated process are an important cause of mental retardation and other brain disorders. The same set of genes may also contribute to cognitive variation in humans. Identification of genes involved in development of the human neocortex and characterization of their spatiotemporally regulated expression patterns may provide a better understanding of cognitive processes. Microarrays allow monitoring the expression of numerous candidate genes for cognition during fetal brain development in parallel. To this end we have developed a cDNA chip with approximately 600 genes that are known to play a role for brain development and function in humans, mice and/or *Drosophila*, along with 100 control house-keeping genes. This customized gene chip was used to quantify the mRNA expression levels in fetal brain samples from frontal cortex (prospective area A10) between weeks 15 and 25 of gestation. Essentially all control house-keeping genes on the chip displayed detectable expression levels in fetal neocortex. Of the 600 candidate genes tested, approximately 350 showed medium to strong expression and approximately 50 weak expression during fetal brain development. The expression level of a subset of genes changed significantly over developmental time. Approximately 50 genes showed at least twofold expression differences between normal and trisomy 21 brain samples of the same gestational weeks and/or changes in their temporal expression patterns. Some of these genes were reported previously to be expressed differentially in trisomy 21 brains. However, most identified genes, including genes of the MAPK signaling and the Alzheimer disease pathways, have not been associated with trisomy 21 in the literature. Microarray expression data were confirmed by reverse Northern blot experiments. Immunolocalization of the corresponding proteins to specific cell types in fetal brain sections is underway.

Microarray analysis in human and non-human primate brains suggests spatial clustering of the most divergent genes. *M.C. Oldham*^{1,6}, *S. Tsung*², *M. Cáceres*^{3,5}, *J.W. Thomas*³, *S. Horvath*^{2,4}, *T.M. Preuss*⁵, *D.H. Geschwind*⁶. 1) Neuroscience IDP, UCLA, Los Angeles, CA; 2) Dept of Biostatistics, UCLA; 3) Dept of Human Genetics, Emory Univ School of Medicine, Atlanta, GA; 4) Dept of Human Genetics, UCLA; 5) Div of Neuroscience, Yerkes Primate Research Center, Emory Univ; 6) Dept of Neurology, UCLA.

Several groups have employed Affymetrix microarrays to assess the extent to which gene-expression differences in the brain distinguish human from non-human primates. Here we merge two such datasets consisting of 37 human and non-human primate microarrays to increase statistical power (Enard, 2002; Cáceres, 2003). MegaBlast was used to identify all probes with sequence differences between human and chimp, which were removed from the dataset. Global normalization was achieved via MAS 4.0 and expression values calculated using the average difference model. Local normalization was performed for each probe set to eliminate the strong laboratory effect. We identified 336 known, unique genes that were differentially expressed between human and chimp. For each gene, mean absolute divergence (MAD) values were calculated using average expression values from the four species. 150 genes exhibited pronounced expression changes specific to humans. 82% had higher expression levels in human versus chimp, consistent with the human up-regulation noted by Cáceres *et al.* However, the percentage of genes in this list with at least one duplicated coding exon in the human genome (16%) was not significantly different from the percentage found in a list of 13,351 human RefSeq genes (13%), suggesting that duplications alone are not responsible for the observed up-regulation in human (Bailey, 2002). When these 150 genes were mapped to their genomic locations (UCSC), 40% were found within 3 MB of another divergent gene, and almost 20% were found within 1 MB, including 5 pairs of adjacent genes. These findings raise the possibility that changes in shared regulatory regions or chromatin structure affecting the expression of multiple genes simultaneously may have served as catalysts during recent human evolution. Supported by the James S. McDonnell Foundation.

Genetic and Functional Analysis of a Novel Missense Mutation in the Rho-kinase Gene that Potentially Causes Coronary Vasospasm in the Japanese. *H. Kamiunten, G. Koike, J. Mashiba, H. Shimokawa, A. Takeshita, K. Sunagawa.* Cardiovascular Medicine, Kyushu Univ, Fukuoka, Japan.

Background-Coronary vasospasm is one of the major causes of ischemic heart disease (IHD) and its prevalence is known to be higher in the Japanese than that in the Caucasian. Recently, we have shown that Rho-kinase plays a crucial role in coronary vasospasm in humans. However, the genetic impact of Rho-kinase gene (ROCK2) variation on coronary vasospasm remains unknown. Methods and Results-We have recently identified a novel single nucleotide variation, G930T (K310N), in the catalytic domain of Rho-kinase. Japanese patients with vasospastic IHD (n=242) and Caucasian ones from the ENCORE I trial (n=318) were genotyped for this variation, and also for additional 4 polymorphisms of interest, including ACE I/D, angiotensinogen C704T, angiotensin II type 1 receptor A1166C, and eNOS C-786T in each population. The Japanese patients were classified into 3 groups based on their coronary responses to intracoronary acetylcholine administration; large epicardial coronary artery spasm group (LAS), microvascular spasm group (MVS), and normal group (N). The frequency of the T930 allele is higher in the LAS+MVS group (4/129 for the LAS group and 2/59 for the MVS group) than that in the N group (0/54) and the general population (1/98, $p=0.026$) in the Japanese. Interestingly, no Caucasian patients had T930 allele. In addition, CC genotype of the angiotensinogen gene is significantly associated with microvascular spasm. To elucidate whether this ROCK2 variation alters Rho-kinase function, human coronary artery smooth muscle cells were infected with adenoviruses expressing the wild type (G930) or the mutant (T930) Rho-kinase. Western blot analysis revealed a significant increase in phosphorylation level of ERM in cells infected with the mutant Rho-kinase compared to that in cells infected with the wild type after bradykinin stimulation. Conclusions-The G930T variation of ROCK2 has a significant association with coronary vasospasm in the Japanese. The functional analysis demonstrated that this ROCK2 variation could induce hyperresponse to vasoconstrictive stimuli leading to coronary vasospasm.

Identification of candidate genes for congenital heart defects in the NF1 microdeletion interval by expression analysis. *P. Riva, M. Venturin, A. Bentivegna, S. Moncini, R. Moroni, L. Larizza.* Dept Biol & Genetics, Univ Milan, Milan, Italy.

We have previously shown that congenital heart disease is significantly more frequent in NF1 patients with microdeletion syndrome than in those with classical NF1. The outcome of congenital heart disease in this subset of patients is probably caused by the haploinsufficiency of one or more genes in the deletion interval. Following the *in silico* analysis of the deleted region, we found two genes known to be expressed in adult heart, the Joined to JAZF1 (JJAZ1) and the Centaurin-alpha 2 (CENTA2) gene, and seven other genes with poorly defined patterns of expression and function. With the aim of defining their expression profiles in human fetal tissues (15th-21st weeks of gestation), we performed expression analysis by RT-PCR and Northern blotting. We found that HCA66, JJAZ1 and CENTA2 mRNAs were mainly expressed in fetal heart. As at 15th week of gestation heart morphogenesis has mainly been carried out, and due to the unavailability of human fetal RNA from earlier stages of development than those considered, we performed RT-PCR on mouse 7 dpc and 8.5 dpc total embryos, and 10.5 dpc, 12.5 dpc and 14.5 dpc embryonic heart and brain, to identify those that are expressed before during heart development. We found that the orthologous genes Hca66, Jjaz1 and Centa2 mRNAs are also expressed in early stage of development, before (7 and 8.5 dpc) and during (10.5 dpc, 12.5 dpc and 14.5 dpc) the formation of the four heart chambers. By means of bioinformatic tools, we could predict the presence of the binding sites of Nkx2-5, a transcriptional factor expressed early during heart development, in all three mouse orthologous genes, thus reinforcing the hypothesis that they might be involved in heart development and be plausible candidates for congenital heart disease.

Genome Stability Determinants: Diversity of Genes and Mechanisms. *C. Warren*¹, *K. Yuen*², *T. Kwok*², *O. Chen*¹, *P. Hieter*², *F. Spencer*¹. 1) Inst Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) CMMT, University of British Columbia, Vancouver, British Columbia.

Proteins and pathways that maintain genome structure have been identified in many genetic screens, and exhibit a high degree of conservation across species. However, traditional mutagenesis and screening methods seldom reach saturation even in model organisms, and more players remain to be identified. The budding yeast deletion collection supports large-scale phenotyping encompassing null alleles for virtually all known nonessential genes. We have examined these mutants using three distinct marker instability assays. Together, these screens detected elevated rates of increased chromosome nondisjunction, loss, mitotic recombination, nonreciprocal rearrangement, and gene conversion. 310 budding yeast genes (6.5% of nonessentials) that contribute to genome stability were identified. Among the 310, annotations on 40% of genes are consistent with known functions contributing to genome stability, 20% are unannotated, and 40% are annotated for functions not previously directly tied to genome stability, such as macromolecular modification and metabolic pathways. 134 of 310 genes exhibit homology to proteins predicted from human, mouse, fly, worm, and/or pombe genomes with BLASTP values $<1 \times 10^{-10}$. The assays exhibited differentiation among the genes identified, with only 10% of genes shared among all three. Studies to determine the mechanisms which distinguish the assay results are underway. This large-scale view of genome stability determinants in a model organism provides a resource for testable hypotheses addressing conservation of protein functions and physiological pathways across eukaryotes..

Association of the mitochondrial T9957C MELAS mutation with Non-Arteritic Anterior Ischemic Optic Neuropathy. *K. Abu-Amero*¹, *T. Bosley*², *S. Bohlega*³. 1) Department of Genetics, King Faisal Specialist Hospital, Riyadh, Saudi Arabia; 2) Neuro-ophthalmology Division, King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia; 3) Department of Neurosciences, King Faisal Specialist Hospital, Riyadh, Saudi Arabia.

Background: Recently, multiple mtDNA mutations were reported in a group of patients with non-arteritic anterior ischemic optic neuropathy (NAION), raising the possibility that mtDNA changes may be a risk factor for NAION. One patient had a T to C transition at nucleotide 9957, which was previously reported in association with mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). **Purpose:** To assess the significance of changes in mitochondrial DNA and mitochondrial respiratory function in a man with clinical NAION OU. **Methods:** The patient was examined clinically and with magnetic resonance imaging and spectroscopy. The entire coding region of the mitochondrial genome was sequenced, and mitochondrial function was assessed by flow cytometry after staining with fluorescent dihydroethidium. **Results:** This 76 year-old man did not have MELAS, but he did have seizures beginning at age 69 and bilateral optic nerve injury beginning at age 70. Serum and brain lactate were normal, but mitochondrial functional testing revealed a severe defect in mitochondrial complex III activity. This information was combined with data from a child with MELAS and the same mtDNA mutation. **Conclusions:** The nt-9957 mitochondrial DNA mutation may precipitate both optic nerve and brain injury in some circumstances. Documentation of a mitochondrial metabolic defect strengthens the hypothesis that mitochondrial DNA changes may be a risk factor for NAION.

Correlation of over-expressed IFN-inducible genes with sicca manifestations and autoantibodies in Sjogrens syndrome. *E.S. Emamian¹, J. Leon¹, S.Q. Rao², C.M. Meyer¹, A.N. Leiran¹, E.C. Gillespie¹, T.W. Behrens¹, B. Segal¹, N.L. Rhodus¹, K.L. Moser¹.* 1) University of Minnesota, Minneapolis, MN; 2) Lerner Research Institute, Cleveland, OH.

Sjogrens syndrome (SS) is an autoimmune disorder characterized by lymphocytic infiltration into lacrimal and salivary glands leading to dry eyes and mouth. The etiology of the disease is not well defined. We have used microarray technology to compare global gene expression profiles in peripheral blood samples of SS patients and controls. Initial studies using peripheral blood mononuclear cells indicated that differential gene expression patterns were detectable in SS patients (n=21) compared with healthy controls (n=23). Using three criteria for gene list filtering, 425 differentially expressed genes were identified. A prominent pattern of overexpressed genes known to be induced by interferons (IFNs) was identified. We independently confirmed this gene expression pattern in a second dataset consisting of 16 patients and 22 controls using whole blood samples. Comparison of differentially expressed genes in both datasets revealed a list of 38 overlapping genes, most of which are known to be inducible by IFNs. To assess potential correlations of gene expression levels and clinical manifestations, we evaluated an expanded dataset consisting of 34 patients and 22 matched controls. Clinical variables included erythrocyte sedimentation rates (ESRs), whole unstimulated salivary flow (WUSF), tear flow by Shirmers test (ST), and titers of anti-Ro/SSA and anti-La/SSB by ELISA. Within the SS patient group, each of the five clinical variables were correlated ($p < 0.05$) to genes present in the over expressed IFN-inducible cluster. Anti-Ro titers, anti-La titers, and ESRs were positively correlated to the expression values of the clustered interferon stimulated genes. WUSF and ST values were negatively correlated to these genes, indicating that patients with lower amounts of saliva and tears had higher expression of IFN stimulated genes. These results demonstrate a convincing role for interferon-related pathways in SS and show that expression of these genes is correlated with clinical manifestations.

Cockayne Syndrome: mutation identification using whole genome primer sets. *D. Ginzinger¹, R. Skurat², S. Nidtha³, J.E. Cleaver^{2,4}.* 1) Genome Analysis Core facility, Comprehensive Cancer Ctr, Univ California, San Francisco, San Francisco, CA; 2) Auerback Melanoma Laboratory, Comprehensive Cancer Ctr, Univ California, San Francisco, San Francisco, CA; 3) Applied Biosystems, Foster City, CA; 4) Dermatology & Pharmaceutical Chemistry and Comprehensive Cancer Ctr, Univ California, San Francisco, San Francisco, CA.

Cockayne syndrome (CS) is a progressive neurodegenerative disorder associated with a DNA repair defect. Two genes CSA and CSB, are specifically involved in the CS disorder, and three other genes, XPB, XPD and XPG give rise to various symptoms of xeroderma pigmentosum (XP) or CS according to the particular mutations carried by the patients. The genes involved in CS symptomology are all linked to excision repair of ultraviolet damage (UV) in transcriptionally active genes (transcription coupled repair, TCR). The diagnosis of multigenic diseases like XP and CS are a particular challenge because of the need to repeatedly sequence several genes for detection of potentially novel mutations. The rarity of these diseases, 1-5 per million of the US population means that the potential load for patient diagnosis would be no more than 5 to 10 new cases per month from the whole of the US. Thus, it is difficult to establish a financially sound diagnostic service, especially given the historical need to optimize PCR and sequencing procedures for the coding regions. Re-sequencing is also needed to validate cell lines received from cell banks, because of the possibility of earlier mistakes in assignments. We have employed the new Applied Biosystems VariantSEQr™ resequencing system that uses pre-validated gene-specific primer sets, protocols and analysis software, SeqScape, which incorporates a quality value for each base-call for the detection of individual mutations. Using this system we have quickly and successfully analyzed mutations in 6 cases of CS from a cell bank, validating or correcting previously reported mutations and identifying new ones. This is a preliminary validation study for a 2-gene disease, prior to the greater challenge of re-sequencing XP that has 8 genes. Work supported in part by the Luke OBrien Foundation (to J.E.C).

Study of *RAII* variations in Smith-Magenis syndrome patients without 17p11.2 deletions. *S. Girirajan*¹, *R.E. Slager*³, *C.N. Barth*⁴, *T.L. Newton*⁴, *S.H. Elsea*^{1, 2, 4}. 1) Dept of Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Dept of Pediatrics, Virginia Commonwealth University, Richmond, VA; 3) Genetics Graduate Program, Michigan State University, East Lansing, MI; 4) Dept of Zoology, Michigan State University, East Lansing, MI.

Smith-Magenis syndrome (SMS) is usually associated with a deletion involving chromosome 17p11.2; however, a previous study from our laboratory showed that SMS in patients with no FISH-detectable 17p11.2 deletion may be caused by dominant frameshift mutations in *RAII* (Nat Gen 33(4):466-8, 2003). These data indicate that haploinsufficiency of *RAII* is likely responsible for the majority of the SMS phenotype, including craniofacial and neurological anomalies. SMS is characterized by distinctive facial features, delayed milestones, cognitive impairment, and mild to severe mental retardation. Behavioral abnormalities include significant sleep disturbances and maladaptive and self-injurious behaviors. We studied 67 putative SMS patients referred to us for evaluation who were first assessed for deletion by preliminary FISH studies using 17p11.2-specific probes. Deletions involving 17p11.2 were not found in 38 of these patients, who were then considered for the *RAII* study. Patient samples were analyzed for variations in the *RAII* coding region and all possible splice variants by a PCR-based sequencing strategy. Interestingly, we identified small deletions, missense mutations, and known SNPs in several of these patients. The number of polyglutamine repeats in all the samples was variable between 9 and 13; no expansions were seen. Some reported SNPs were identified in all patients evaluated. This study has also yielded us with new unclassified synonymous nucleotide changes that are appropriate for the SNP database. With more sequencing based studies, we plan to build a database of all the variants in the *RAII* gene and their relationship to the features of Smith-Magenis syndrome.

Refinement of an 8q Duplication by FISH and CGH in a Patient with Langer-Giedion Syndrome. *M.L. Adam¹, O. Abdul-Rahman¹, J. Milunsky²*. 1) Division of Medical Genetics, Department of Pediatrics, Stanford University, Stanford, CA 94305; 2) Center for Human Genetics, Department of Pediatrics, Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Langer-Giedion syndrome is a disorder characterized by distinctive craniofacial and skeletal abnormalities. Multiple cartilaginous exostoses are seen in virtually all patients by the age of four. Variable mental retardation with significantly delayed onset of speech is seen in most patients. 75% of patients with Langer-Giedion syndrome are found to have a cytogenetically detectable deletion of 8q24.1. This deletion results in loss of functional copies of TRPS1 and EXT1. We present a patient with features of Langer-Giedion syndrome who was found to have a duplication of 8q22.1q23.3, which encompasses the TRPS1 and EXT1 loci. The subject is a 13 year-old Hispanic female born to a 27 year-old primigravida mother at term gestation. Family history was unremarkable. At 4 years, she was noted to have global developmental delay, microcephaly, and dysmorphic features, including a high forehead, bulbous nasal tip, long philtrum, thin lips, and prominent ears. A skeletal survey demonstrated coned epiphyses, madelung deformities of the forearms, and multiple bony exostoses. An initial karyotype was performed and demonstrated a direct duplication of 8q described as 46,XX dir dup (8) (q22.3-q24.13). By age 13, exostoses had developed in the distal radii, scapulae, distal femurs, and right distal tibia with no significant pain. She has severe mental retardation with only 3 words, but has maintained some receptive language skills and remains ambulatory. In an attempt to further characterize her duplication, fluorescence in situ hybridization for TRPS1 and EXT1 was performed and confirmed duplication of both loci. Comparative genomic hybridization was performed and further refined the duplicated region (q21.3q23). It is still unclear how a duplication in this region can lead to clinical features of Langer-Giedion syndrome.

Discordant amplification of genes comprising low copy repeats on 22q11.2 in hominoid species. *M. Babcock*¹, *M. Brenton*², *S. Yatsenko*³, *P. Stankiewicz*³, *J.R. Lupski*³, *J.M. Sikela*², *B.E. Morrow*¹. 1) Molecular Genetics, Albert Einstein College of Med, Bronx, NY; 2) Human Medical Genetics, University Colorado Health Sci Ctr, Denver, CO; 3) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Low copy repeats (LCRs; segmental duplications) constitute roughly 5% of the human genome and are known to mediate chromosome rearrangements associated with mental retardation and congenital anomaly disorders. The 22q11.2 region is particularly susceptible to chromosome rearrangements via LCR22s, leading to deletions, duplications and translocations. LCR22s are composed of blocks or modules containing genes (*USP18*, *BCR*, *GGT*, *GGTLA*) as well as partially duplicated and unprocessed pseudogene copies creating a complex mosaic. Each full-length gene lies in a different LCR22, suggesting varied evolutionary processes. By examining the breakpoint regions in humans, we found evidence for Alu-mediated recombination mechanisms. To trace the evolutionary steps responsible for shaping the LCR22 gene structure in hominoid species, microarray comparative genome hybridization (aCGH) with cDNA arrays, was performed on genomic DNA from human, bonobo, chimpanzee, gorilla and orangutan. If all the hominoid species have a similar number of copies of LCR22 genes, they would be considered stable during evolution. However, we found differences in LCR22 gene copy number, indicating that LCR22s have been quite unstable. Intensity changes were not in proportion to the estimated divergence times of each hominoid species, suggesting that significant amplifications occurred during speciation. Gorilla genomic DNA showed the greatest expansion of LCR22 copy number. Some of the LCR22 genes had similar patterns, indicating that their dosage was altered as a cluster. This was consistent with fluorescence in situ hybridization mapping using BAC clones spanning LCR22s. Quantitative PCR studies using conserved, exon specific probes, are underway. This data suggests that LCR22s have been prone to rearrangements during hominoid speciation. It is possible that similar mechanisms might occur in humans as well, resulting in genomic disorders.

Organization of the regions flanking the centromere of human chromosome 21. *M.R. Bozovsky¹, S.A. Shukair¹, M.R. Cummings², J.L. Doering¹*. 1) Department of Biology, Loyola University Chicago, Chicago, IL; 2) Department of Biological Sciences, University of Illinois at Chicago, Chicago, IL.

It is clear that heterochromatic regions play an important role in genome architecture and maintenance. These regions, which dominate human centromeres, have been largely excluded from the completed genome sequence. Although the sequence requirements for a functional centromere have not been defined, alphoid repetitive DNA clearly plays a role. The D21Z1 alphoid array is a 1.0Mb long, homogeneous array in the centromere of HC21. Using sequence information from the human genome as well as YAC clones which map to 21p, we have begun to determine the sequence organization in the regions flanking the D21Z1 array. The p-arm edge contains a 0.3Mb long satellite-I array that is highly polymorphic in the population. D21Z1 and satellite-I sequences are both found on a 76kb fragment, indicating that these two repetitive arrays are quite close together. Using BAC clone 21B49A22, the last clone in the q-arm sequence which spans both non-repetitive and satellite DNA, our preliminary mapping work has placed the q-arm sequence termination to within 180kb of the D21Z1 array. This region contains a small array of monomeric alphoid DNA that is highly heterogeneous, showing as little as 74% sequence similarity between monomers, and is devoid of both CENP-B boxes and higher-order repeat structure. The monomeric array forms a distinct evolutionary clade from the main D21Z1 array, branching at the root of the tree. This suggests these two arrays have established and evolved independently of each other. Not only does this finding support recently proposed models of centromere evolution, but it also indicates that the monomeric alphoid array may contain HC21 specific sequences. We have subcloned a region of the 21q monomeric alphoid array that is highly polymorphic and which BLAST analysis indicates may be chromosome specific. An HC21 specific centromeric marker would be useful in diagnosing aneuploidy and permit more accurate scoring of a nondisjunction event.

Detection of Microdeletions and Duplications in Human Genetic Disorders Using the Spectral Genomics

Constitutional Chip. *X.Y. Lu¹, R. Locker¹, J.W. Kim¹, W.S. Hutto¹, C. Chinault², A. Patel², A. Beaudet², S.W. Cheung², R.C. Johnson¹.* 1) Spectral Genomics Inc., Houston, TX; 2) Molecular and Human Genetics Department, Baylor College of Medicine, One Baylor Plaza, Houston, TX.

Chromosomal aberrations, such as deletions, duplications and unbalanced translocations, are among the main pathogenic mechanisms that underlie many human genetic disorders. However, conventional chromosome banding is not sensitive (<5Mb) enough to identify subtle chromosome aberrations. Therefore, a rapid and accurate identification of such genetic imbalances could improve diagnosis, which might lead to better treatment. Array-based comparative genomic hybridization (array-CGH) has emerged as a powerful, high-resolution tool, capable of detecting genomic imbalances in one experiment by co-hybridizing differentially labeled test and reference DNA to an array of mapped human genomic DNA fragments (~100-200 kb). We, in collaboration with the Department of Molecular and Human Genetics at Baylor College of Medicine, recently developed a Constitutional Chip which consists of 464 BAC/PAC clones mapped to the telomeric and sub-telomeric region for each chromosome and 41 known constitutional syndromes. We used this Constitutional Chip to study 15 well-characterized, commercially available cell lines derived from patients with known constitutional syndromes. All Constitutional Chip results corroborated previously reported results by FISH and/or conventional G-banding. This study clearly demonstrates the power of the Constitutional Chip in detecting microdeletions and/or duplications without the need for multiple hybridizations using locus-specific probes by FISH. This newly developed Constitutional Chip is a sensitive and rapid diagnostic tool to detect many congenital and constitutional genetic diseases associated with developmental delay and dysmorphism.

Optimization of custom high-density oligonucleotide microarrays for array Comparative Genomic Hybridization (arrayCGH). *R. Selzer¹, T. Richmond¹, N. Pofahl¹, M. McCormick¹, C. Brennen², B. Wittner², B. Khulan³, J. Greally³, L. Chin², R. Green¹.* 1) R&D, NimbleGen Systems Inc., Madison, WI; 2) Dermatology, Harvard Medical School, Medical Oncology, Dana-Farber Cancer Institute; 3) Albert Einstein College of Medicine, Bronx, NY, Department of Molecular Genetics and Medicine (Hematology).

Changes in DNA copy number are one of the hallmarks of the genetic instability common to most cancers and many other diseases. DNA copy number changes include loss of heterozygosity, homozygous deletions, and amplification events. Array-based Comparative Genomic Hybridization (arrayCGH) provides a high-resolution, quantitative method for the assessment of genomic copy number changes. Using NimbleGens maskless array technology, custom 50mer arrays of more than 390,000 oligonucleotides were used to tile at high resolution through a 10 Mb region of mouse chromosome 7, resulting in an average probe density of one 50mer probe every 48 bp, in duplicate. From the resulting tiling data, optimal probes were selected that were able to detect and distinguish both a homozygous (2-copy) and heterozygous (1-copy) deletion within this region. In addition to custom tiling designs, we have optimized a gene-centric whole-human genome CGH array. This design, which includes 26 probes/gene for the 30,391 known and Retseq genes (NCBI build 34, hsg16), was hybridized to DNA samples with known DNA copy number changes. From this array 5 probes per gene were selected that were optimally responsive to changes in target concentration. The result is an optimized oligonucleotide CGH array that is able to detect gene copy number changes from total genomic DNA. On the basis of these results, we anticipate that arrayCGH will become a routine method of high resolution and genome-wide screening for a wide range of chromosomal abnormalities.

Genome-wide Mapping of DNaseI Hypersensitive Sites by Massively Parallel Signature SequencingTM (MPSSTM). *G. Crawford¹, I. Holt¹, J. Whittle¹, S. Luo², D. Zhou², T. Wolfsberg¹, T. Vasicek², F.S. Collins¹.* 1) NHGRI, NIH, Bethesda, MD; 2) Lynx Therapeutics, Inc., Hayward, CA.

The human genome is currently estimated to contain 22,000-25,000 protein-coding genes, but little is known about how most of these are regulated. For over 25 years, mapping DNase I hypersensitive (HS) sites has been used to accurately identify active regulatory elements, but the labor-intensive nature of this technique has limited its application to only a small number of human genes. We have developed a novel protocol to identify gene regulatory sequences on a genome-wide scale by generating a library of DNase HS sites. Approximately 100,000 clones from a library generated from quiescent primary human CD4⁺ T cells were sequenced using MPSSTM, an innovative technology capable of generating 1 million sequence tags per run. Of the clones that uniquely mapped to the genome, we identified 1300 regions that had multiple MPSS clones that mapped within a 500 base pair window. Using a real-time PCR strategy, we determined that 90% of these clusters represent valid DNase HS sites. Over 60% of these clusters do not map within 2kb upstream or 1st introns of known genes, indicating this procedure identifies areas outside of obvious regions known to contain regulatory elements. In fact, some of these sites are greater than 250 Kb from a known gene. By statistical analysis of the frequency of repeat hits to individual DNase HS sites, we estimate there are 100,000 HS sites within CD4⁺ T cells. Almost all of the identified sites in CD4⁺ T cells are also hypersensitive in primary B and CD8⁺ T cells. However, 10% of the DNase HS sites are not hypersensitive in primary hepatocytes and HeLa cells, indicating that this protocol can identify gene regulatory elements that control cell type specificity. A number of these T cell specific DNase HS sites are near genes known to be important in T cell function, including CXCR4, GATA3, and protein kinase C, theta. This strategy, which can be applied to any cell line or tissue, will allow us to better understand how chromatin structure dictates cell function and fate.

Program Nr: 1571 from the 2004 ASHG Annual Meeting

Mapping chromatin structure with ChIP chip experiments. *R. Green*¹, *M. Oberley*², *M. Singer*¹, *P. Farnham*². 1) R&D, NimbleGen Systems Inc., Madison, WI; 2) McArdle Laboratory for Cancer Research, University of Wisconsin Medical School, Madison, WI.

Chromatin Immunoprecipitation (ChIP) chip experiments are a powerful method for determining protein DNA binding interactions. ChIP chip experiments can also be used to define chromatin structure. By using antibodies to modified histones and hybridizing the resulting ChIP samples to custom tiling arrays, we are able to map the chromatin structure of the human genome at unprecedented resolution. We present data showing the location of AcK9 of histone 3, 2MeK9 of histone 3, 3MeK9 of histone 3 as well as RNA Pol II binding across 30 Mb of human genomic DNA. The data show a very high correlation between AcK9 of histone 3 with RNA Pol II binding and a very low correlation between 2MeK9 and 3MeK9 of histone 3 with RNA Pol II binding. The binding of RNA Pol II and the AcK9 of histone 3 also correlate very well with known and predicted promoters. We also present data showing ChIP chip with AcK9 of histone 3 and binding of RNA Pol II can be used to identify new transcripts in the human genome.

Biological Network Analyses: A Current View from Budding Yeast. *F. Spencer*^{1,3}, *B. Peyser*¹, *P. Ye*², *X. Pan*³, *J. Boeke*³, *J. Bader*². 1) McKusick-Nathans Inst of Genetic Medicine, Johns Hopkins Univ Sch of Med, Baltimore, MD; 2) Biomedical Engineering, Johns Hopkins University, Baltimore, MD; 3) Molecular Biology & Genetics, Johns Hopkins Univ Sch of Med, Baltimore, MD.

Biological networks are robust. The mechanisms of robustness can be probed by synthetic lethality, in which it is observed that a cell survives individual loss of function for nonessential genes but cannot survive loss of specific gene pairs. A synthetic lethal interaction provides strong evidence that two genes act in parallel redundant pathways compensating each others' function.

Large-scale synthetic lethality screens are currently being generated for *Saccharomyces cerevisiae*. System robustness observed in synthetic lethality may be defined in two ways: by the synthetic lethal gene pairs themselves, or in gene pairs with similar synthetic lethal interaction sets (congruent pairs). We propose the use of a genetic congruence network to efficiently represent the complexity of genetic interactions. This network supports presentation of genetic interactions at different congruence score cutoff values to accommodate investigation at various levels of network significance.

As susceptibility to common human diseases may encompass gene mutations in multiple pathways, defining the principles of network robustness from analysis of synthetic lethality can provide a framework for understanding disease processes in humans.

The DNA sequence and analysis of human chromosome 11. *T.D. Taylor¹, A. Toyoda¹, Y. Kuroki¹, T. Itoh², Y. Totoki¹, H. Noguchi¹, T. Yada³, A. Fujiyama^{1,4}, M. Hattori^{1,5}, Y. Sakaki¹, Human Chromosome 11 Sequencing Consortium.* 1) Human Genome Research Group, RIKEN Genomic Sciences Center, Yokohama, Japan; 2) Mitsubishi Research Institute, Inc., Tokyo, Japan; 3) Human Genome Center, University of Tokyo, Tokyo, Japan; 4) National Institute of Informatics, Tokyo, Japan; 5) Kitasato University, Sagamihara, Japan.

As a member of the International Human Genome Sequencing Project, our group led the effort for completion of the sequence of human chromosome 11. As major sequence contributor and coordinator, our center took responsibility for analyzing and annotating the entire chromosome (134 Mb).

The current tiling path of chromosome 11 consists of 8 contigs (ranging from 503 kb to 49.6 Mb) containing 1121 accessions. We reached the centromere on both sides and the telomere on 11q. Only six internal clone gaps remain, totaling about 270 kb; continued efforts to close the remaining gaps include long-PCR based on human and chimpanzee whole-genome shotgun data.

Chromosome 11 is relatively gene-dense and harbors genes for several well-known disorders such as: type 1 diabetes, ataxia telangiectasia, and Long QT syndrome. In addition, three medically important regions (IGF2/H19, beta-globin cluster, APO cluster) have been targeted for study as part of the ENCODE project.

The chromosome is being manually annotated according to Hawk standards. The sequence is analyzed by comparing it to all sequence data from other available species, as well as the rest of the human genome. Full-length cDNA and EST sequences are aligned to the sequence in order to try and identify all transcript variants, for both known and novel genes. Several *ab initio* and homology-based gene/exon prediction programs were used in addition to other programs that identify CpG islands, promoter sites, etc. Functional motifs and domains are also identified on the sequence. Comparison with other available genome assemblies will be made to identify additional genes and conserved regions that may be involved in gene regulation. The recent assembly and analysis of the sequence will be presented.

The human X chromosome contains a preponderance of large highly homologous inverted repeats which contain testes genes. *P. Warburton¹, J. Giordano¹, F. Cheung¹, Y. Gelfand², G. Benson²*. 1) Mount Sinai, New York, NY; 2) Boston University, Boston, MA.

The human genome contains a complex pattern of highly homologous genomic duplications. Inverted repeats (IRs) consist of two inverted complementary arms of homologous DNA around a central spacer region. IRs in theory form cruciform structures important in chromosome structure and function. Inverted Repeats Finder (IRF) is novel highly efficient software that can find and index all IRs in the human genome in a few hours on a PC. Repetitive DNA was Repeat Masked during IR detection, but was included in IR extension and alignment. IRF detected 22,624 IRs in the human genome with arm lengths 25bp to 500kb and 75% homology, and spacers 100kb. The 166 IRs detected by IRF with arm lengths 8kb were filtered to exclude IRs in unfinished/ unassembled regions of the genome, or clustered with other closely related IRs, resulting in a robust set of 96 large IRs with an average size of 40kb. 25% of these (24/96) were found to be on the X chromosome, although it represents only ~5% of the genome. Furthermore, 83.3% (20/24) of X chromosome IRs were 99% homologous, compared to only 27.6% (16/58) of autosomal IRs, which suggested that the X chromosome IRs represent either more recent duplications or were undergoing arm to arm homogenization. PCR amplification of both left and right arm/spacer boundaries confirmed at least eight of these IRs in human genomic DNA. Six of these IRs were also present in great apes, suggesting that they are considerably older than their homology suggests. 11 of the 24 X chromosome IRs contained gene families predominantly expressed in testis, including eight cancer-testes antigen genes. These results are remarkably reminiscent of recent findings on the human Y chromosome, which contains 10 large and highly homologous IRs which contain Y-specific testes genes and maintain sequence integrity by gene conversion. The prevalence of large highly homologous IRs that contain testes genes on both the X and Y chromosomes suggest possible roles in controlling gene expression of sex linked genes in the male germ line or during meiotic sex chromosome inactivation.

Standards for Telomerase (TRAP), hTERT, and TaqMan Telomerase Activity Assays. *J.P Jakupciak¹, P.E. Barker¹, W. Wang², S. Srivastava², D.H. Atha¹.* 1) National Institute of Standards and Technology, Gaithersburg, MD; 2) National Cancer Institute, Early Detection Research Network, Rockville, MD.

Cells lose telomeric repeats as they divide in the absence of telomerase. Eventually, telomeres become dysfunctional and cause chromosomal instability that drives the multiple genetic changes required for the formation of a carcinoma. Telomerase activity is a critical factor that increases the replicative potential of tumors. Telomerase activity is the most common biomarker of cancer, characterized in ~90% of all types of cancer. Despite the demonstrated utility of telomerase activity measurements in tumors and in non-invasively collected samples, there is not a clinical diagnostic. Until recently telomerase activity measurement protocols have been low-throughput and not robust enough to accommodate the required statistical analysis to validate telomerase activity as a practical cancer (prediction/early detection) biomarker. Moreover, there is currently no agreed upon standard method for measuring or quantifying telomerase activity. Standards will help to address the extent of telomerase activity specific to the stages of cancer progression and normal tissue. They are necessary as internal/external quality controls to monitor sample integrity or concentration of inhibitors. They will facilitate reliable telomerase activity quantification and help answer if this information is clinically relevant. The EDRN and NIST are developing telomerase standards that function across cancer diagnostic technologies to allow for a normalized and accurate assessment of tumor burden and decisions of response to therapy. To address standardization, we have isolated telomerase and total RNA from the cancer cell line, A549 under different cell cycle states and with different isolation methods. Telomerase was obtained using CHAPS buffer or sonication. We characterized three detection technologies: RAPidTRAP, hTERT RT-PCR, and TaqMan. For example using RAPidTRAP, we compared the variation between single and multiple capillary systems (ABI 310 and 3100). Although these have comparable sensitivity and reproducibility, we found the 3100 to be better suited for sensitivity and high-throughput.

Identification of potential homologues of the human repeat D4Z4, deletions of which are causally associated with facioscapulohumeral muscular dystrophy. *J. Clapp*¹, *J. Fantes*², *J.E. Hewitt*¹. 1) Institute of Genetics, Queens Medical Centre, University of Nottingham, Nottingham, NG7 2UH, UK; 2) MRC Human Genetics Unit, Western General Hospital, Edinburgh, EH4 2XU, UK.

Facioscapulohumeral muscular dystrophy (FSHD) is a dominant human neuromuscular disorder that affects 1 in 20,000 individuals. Typically, FSHD presents in the second decade of life with wasting of facial, upper arm and shoulder muscles. The phenotype can also include retinal vasculopathy, subclinical hearing loss, epilepsy and mental retardation. FSHD is caused by the deletion of an integral number of D4Z4 repeats from a tandem array at 4q35. In the general population there are between 12 and 100 copies of D4Z4 at 4q35; an individual with FSHD has 11 copies. The mechanism whereby this mutation causes FSHD is still debated, but current models favour epigenetic effects such as de-repression of 4q35 genes and altered methylation. D4Z4 contains an open reading frame (ORF) potentially encoding a homeodomain protein. However, DNA hybridization techniques have so far only identified homologues in higher primates, consistent with a non-coding function of D4Z4. Here we show that bioinformatics analysis of draft genome sequences has enabled us to identify potential homologues of D4Z4 in mouse, rat and macaque. The sequence and organisation of mouse D4Z4 (mD4Z4) has been confirmed by a combination of PCR and physical mapping. The mD4Z4 unit is 4.9kb, compared to 3.3kb in human. mD4Z4 contains an ORF of 2025bp, potentially encoding two homeodomains with 55% aa similarity to those encoded by human D4Z4. There is no significant sequence conservation outside the coding region. The mD4Z4 repeat units are arranged in large tandem arrays, with FISH analysis suggesting a single chromosome locus. The rat homologue of D4Z4 potentially encodes a homeodomain protein with 66% aa similarity to the mouse protein. Macaque D4Z4 is longer than human due to an insertion, however the potential ORF is intact. The conservation of the ORF between these species and the identification of several mouse ESTs suggest a coding function for D4Z4. Furthermore, our findings provide potential for the development of a mouse model of FSHD.

Integrated Genetic and Physical Mapping Resources for the Vervet Monkey (*Chlorocebus aethiops*). *N.B.*

Freimer^{1,2}, R. Minhas³, S.K. Service¹, H. Sandhu¹, O. Lee¹, E. Sobel², F. Ervin⁴, R. Palmour⁴, L. Fairbanks⁵, M. Nefedov⁶, K. Osoegawa⁶, P.J. de Jong⁶, T.J. Hudson³, K. Dewar³, R.A. Ophoff^{1,2}. 1) UCLA Center for Neurobehavioral Genetics; 2) Dept. of Human Genetics, Los Angeles, CA; 3) Dept. of Human Genetics, McGill University and McGill University and Genome Quebec Innovation Centre; 4) Dept. of Psychiatry, McGill University, Montreal, Canada; 5) Center for Primate Neuroethology & Vervet Research Colony, Neuropsychiatric Institute, UCLA, Los Angeles, CA; 6) Children's Hospital Oakland Research Institute, Oakland, California.

Studies of non-human primates are invaluable for furthering the understanding of a wide range of human traits, especially complex behaviors. The utility of such studies derives from the fact that humans are much more similar to other primates than they are to commonly-used mammalian model organisms such as the mouse. The vervet, or African green monkey, is widely used in biomedical research. We are developing resources to make the vervet monkey a useful model for genetic and genomic research. All resources developed are made available to the scientific community. Tools developed so far include: (1) a large-insert genomic vervet BAC library CHORI-252 (<http://bacpac.chori.org/monkey252.htm>) ; (2) the construction of a vervet genetic map consisting of 378 microsatellite markers; and (3) a first generation, integrated map of microsatellite markers and SNPs of vervet chromosomes 13 and 17, the orthologues of human chromosome 6; Further refinement of the genetic map and expansion to a genome-wide SNP map comprising >5,000 are in progress. We are also developing a web site (<http://www.vervetgenome.org>) summarizing the advances of the project and providing access to the raw data produced by the collaborating groups. Future plans for new resources include large-scale BAC-end sequencing and the creation of physical maps, and the development of brain-specific expression arrays. In addition to development of genetic and genomic tools of immediate use to the scientific community, this project also serves as a model for development of resources for species that are unlikely to be sequenced in the near future.

Wide genome comparisons reveal the origins of the human X chromosome. *H. Hameister¹, M. Kohn¹, H. Kehrer-Sawatzki¹, W. Vogel¹, J.A.M. Graves².* 1) Dept. of Human Genetics, University Ulm, Ulm, Germany; 2) Comparative Genomics Research Group, Research School of Biological Sciences, Australian National University, Canberra ACT 2601, Australia.

Comparative gene mapping between mammalian species has proven the X chromosome to be one of the most conserved gene arrangements, although comparisons with distantly related mammal groups pointed to separate origins of the short and long arms. The recently made available draft sequence of the chicken genome in combination with the genome sequences from pufferfish and zebrafish allows surprising new insight into genome conservation, which can be traced back to the roots of the common vertebrate ancestor 400 to 450 MYA. Most of Xp (Xp11.2-pter including PAR1) is found conserved on chicken chromosome 1q13-q31 in exact colinear order. Proximal Xp and nearly the complete Xq arm including PAR2 are found conserved in a second segment of common synteny on chicken chromosome 4p, but is found in scrambled gene order. This is due to the former microchromosome history in birds of that segment. There are two further small, but gene rich insertions in Xp11.2 and Xq28, which in the fish species can be traced to a common chromosome. The reconstruction, made possible by this combined analysis, favors a model of the ancestral chromosome, which in the mammalian lineage gave rise to the X chromosome, that combines already the later Xp and Xq arm on one chromosome and therefore resembles in a surprising manner the mammalian X chromosome. This ancestral chromosome may have undergone fission in a tetrapod ancestor with fusion of Xp11.2-pter to another chromosome (most probably the later chromosome HSA 21) and refused in the eutherians to the current X chromosome. To our surprise we learn that the X chromosome has been strikingly conserved for 450 million years with relocation to the X of only a limited number of new genes. Therefore, old genes got recruited to further and new functions during evolution. We are studying this scenario by a comparative analysis of human X chromosomal mental retardation, MRX, genes in mammals and birds.

Multispecies comparative sequence analysis of the glucocerebrosidase gene locus. *M.E. LaMarca¹, D.S. Lieber¹, M.E. Portnoy^{2,3}, K.S. Hruska¹, E.D. Green^{2,3}, E. Sidransky¹, NISC Comparative Sequencing Program.* 1) Dept Molecular Neurogenetics, NIMH/NHGRI, NIH; 2) Genome Technology Branch, NHGRI, NIH; 3) NIH Intramural Sequencing Center, NHGRI, NIH, Bethesda, MD.

The human glucocerebrosidase gene (GBA) is located in a gene-rich region of chromosome 1q22, in which 15 genes and at least 2 pseudogenes have been mapped within a 200 kb region. Defects in GBA are the cause of Gaucher disease (GD), the most prevalent lysosomal storage disease. While over 200 mutations in GBA have been identified, genotype-phenotype correlations are limited. Identification of regulatory elements in non-coding regions or in nearby genes and pseudogenes, in conjunction with analysis of the human glucocerebrosidase protein sequence and structure, will contribute to better understanding of the genetic bases of the wide phenotypic variation in this disorder. A target region of approximately 200 kb containing the GBA gene was physically mapped in 8 diverse mammalian species (galago, cow, dog, hedgehog, armadillo, bat, rat and wallaby) and 1 non-mammalian vertebrate (the pufferfish *Fugu rupribes*). Orthologous BACs were isolated and sequenced. For three additional species (chimpanzee, mouse, chicken), orthologous sequence was obtained from the most recent whole genome assemblies. The sequences were aligned to the human genome sequence from July 2003 (UCSC Genome Browser) using MultiPipMaker. Examination of the 58.5 kb region comprising the genes *c11orf2*, GBA, *metaxin 1* (MTX1) and *thrombospondin 3* (THBS3) demonstrated strong conservation of the exonic regions of all four genes in the mammals, but significant alignments in chicken and pufferfish were only seen in THBS3. Screening for Multispecies Conserved Sequences (MCSs) in this region among the mammalian species yielded 77 MCSs at the 95% identity level, 57 in coding regions and 20 in non-coding regions, with an average length of 38 bp. Analysis of the MCS segments and comparative analysis of the translated protein sequences from multiple species will define which Gaucher mutations are in highly conserved regions and whether observed intronic and intragenic variations among patients may also contribute to phenotypic expression.

Clone-based products, high-throughput services and data for functional genomics via GenomeCube. *F. Behrens¹, K. Jürchott¹, P. Neubert¹, B. Drescher¹, E. Rees², B. Korn², J. Maurer¹.* 1) RZPD German Resource Center for Genome Research GmbH, Berlin, Germany; 2) RZPD Heidelberg.

RZPD is a non-profit provider of clones, clone related products and high-throughput services for genome research. In numerous collaborations, RZPD has established a publicly available clone and data collection of more than 35 million clones from 32 different species, and systematically categorizes, verifies and annotates its resources. Increasing demands for optimal clones for various research purposes led to RZPD's **GenomeCube**, a comprehensive and intuitive-to-use database interface. Being gene-based, it provides direct access to biological material and data derived thereof: **siRNA resources.** Several thousand highly gene-specific, long human dsDNAs containing T7 promoters are provided for the generation of highly efficient siRNAs. By the end of 2004, all human genes and about 15,000 genes of mouse and rat will be represented. **Full ORF clones.** Provided in Gateway and Creator shuttle vectors, several thousand human and mouse genes are available as *closed format* clones with natural stop codon, and *open format* clones without stop codon, allowing the generation of C-terminal fusion constructs. **Full-length cDNA clones.** With 2/3 of all human and 1/3 of all mouse genes, RZPD offers an extensive full-length cDNA clone collection including Mammalian Gene Collection (MGC) and The German cDNA Consortium clones. **Verified short cDNA clones.** Ideally suited for microarray production, they are available as genome-wide, non-redundant, sequenced clone collections for human, mouse, and Xenopus. **Genomic clones.** A genome-wide BAC/PAC-clone collection of human origin (24,500 clones, sequence verification in progress) as indispensable resource for matrixCGH and large-scale promoter analysis. **Protein arrays.** High Density Protein Arrays on PVDF membranes, each carrying 27,648 proteins in duplicate, are highly valuable for antibody screening or identification of DNA/RNA binding proteins. In 2003, RZPD became the first genomic resource center worldwide to be granted **ISO 9001:2000** certification stating that RZPD is concerned with product quality, accuracy, and dependability to the benefit of the user.

Program Nr: 1581 from the 2004 ASHG Annual Meeting

Information Visualization of Haplotype and LD Data. *B. Fry*¹, *P. Sabeti*², *D. Altshuler*^{2,3,4}, *J. Maeda*⁵. 1) Aesthetics & Computation Group, MIT Media Laboratory, Cambridge, MA; 2) Program in Medical and Population Genetics, Broad Institute, MIT, Cambridge, MA; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Departments of Medicine and Molecular Biology, Massachusetts General Hospital, Boston, MA; 5) Physical Language Workshop, MIT Media Laboratory, Cambridge, MA.

Biology has rapidly become a data-rich science, where the amount of data collected can outpace the speed with which it can be analyzed and subsequently understood. The quantity of this data makes it extremely difficult to gain a "big picture" understanding of its meaning. The amount of data necessitates new software-based tools, and its complexity requires extra consideration be taken in its visual representation in order to highlight features in order of their importance, reveal patterns in the data, and simultaneously show features of the data that exist across multiple dimensions. We have developed a series of tools that examine the Haplotype and Linkage Disequilibrium (LD) data that extend upon current methods for analysis by providing a means for understanding continuously changing, large-scale data sets. Users can quickly move between multiple representations of the same data set, revealing several perspectives on the data in question, while maintaining context between them. These software tools enable researchers to gain an intuitive, "visual" understanding of their data and expose the patterns and relationships found within. <http://acg.media.mit.edu/people/fry/haplotypes/>.

Meta-Analysis of Gross Insertions Causing Human Genetic Disease: Novel Mutational Mechanisms and the Role of Replication Slippage. *J. Chen*¹, *N. Chuzhanova*^{2,3}, *P. Stenson*³, *C. Férec*¹, *D. Cooper*³. 1) INSERM (Institut National de la Santé et de la Recherche Médicale) U613, Génétique Moléculaire et Génétique Epidémiologique, Université de Bretagne Occidentale, Etablissement Français du Sang-Bretagne, Centre Hospitalier Universitaire, Brest, France; 2) Biostatistics and Bioinformatics Unit, Cardiff University, Heath Park, Cardiff CF14 4XN, UK; 3) Institute of Medical Genetics, Cardiff University, Heath Park, Cardiff CF14 4XN, UK.

Although gross insertions (>20 bp) comprise fewer than 1% of gene mutations causing human genetic disease, they nevertheless represent an important category of pathological lesion. In an attempt to study these insertions in a systematic way, 173 gross insertions (132 sequence-known) were identified using the Human Gene Mutation Database (<http://www.hgmd.org>). Some 64% of gross insertions were found to represent sequence duplications of different types (tandem, partial tandem or complex) whilst ~10% were attributable to non-polyglutamine repeat expansions. The duplications ranged in size between 21bp and ~10 kb, were often associated with flanking direct repeats of 2-49 bp, and displayed an inverse relationship between the frequency of insertion and the length of the duplison. Evidence is presented to support the contention that both insertional duplications and triplet repeat expansions are caused by a common mechanism, replication slippage, rather than by unequal crossing over. Some 16% of gross insertions, all 276 bp in length, were found to be due to LINE-1 (L1) retrotransposition involving different types of element (L1 trans-driven Alu, L1 direct, and L1 trans-driven SVA). A second example of pathological mitochondrial-nuclear sequence transfer was identified but appears to arise via a novel mechanism. Finally, evidence for another novel mechanism of human genetic disease is also presented. Thus, whilst gross genomic insertions causing human genetic disease may vary considerably in size, their careful meta-analytical study has revealed extensive diversity in terms of the inserted DNA sequence and has provided new insight into the nature of the underlying mutational mechanisms.

Program Nr: 1583 from the 2004 ASHG Annual Meeting

NCBI and Resources for Genomic Analysis. *D. Maglott, NCBI Annotation Team.* National Center for Biotechnology Information (NCBI), National Library Medicine, NIH, Bethesda, MD.

The National Center for Biotechnology Information (NCBI) of the National Library of Medicine (NLM) at the U.S. National Institutes of Health (NIH) integrates information from numerous sources to support research and understanding of current knowledge of multiple genomes. Information can be accessed by text (symbols, words, phrases, database identifiers), sequence (BLAST), and genomic position in multiple coordinate systems and genomic assemblies (Map Viewer). Tools are also provided to make it easier to take advantage of pre-computed relationships among different types of data (i.e. proteins related by sequence or by conserved domains, homologous genes, PCR primers that appear to be gene-related based on e-PCR or linkage to phenotypes of interest, etc.).

There are several recent developments that will be demonstrated. Text-based queries can now be submitted across multiple databases (Entrez's Global or cross-database search), with related records also being indicated from the Entrez Links menu. Advanced query/Limits pages have been added to key databases such as Map Viewer and Gene to facilitate constructing detailed queries. The number of connections between phenotype and sequence have increased as a result of increased computational and curatorial efforts.

Genomic annotation has been improved by working with external groups to identify members of gene families and/or to compare genomic alignments and gene predictions. We also continue to benefit from the many interested users who identify areas where we can improve our reference sequences (RefSeqs).

Examples of discoveries that can be made using the data and tools will be provided, with emphasis on new features and future directions.

Development of molecular and clinical database resources for human genetics research at The Centre for Applied Genomics. *T.A. Paton¹, J. Herbrick¹, J. Danska^{1,2}, P. Ray^{1,3}, J. Rommens^{1,3}, D. Bulman⁴, L. Osborne^{3,5}, L.-C. Tsui¹, A. Paterson¹, G. Duggan¹, E. Kanematsu¹, J. Zhang¹, J. Cheung¹, R. Khaja¹, T. Tang¹, S.W. Scherer^{1,3}.* 1) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Program in Developmental Biology, The Hospital for Sick Children, Toronto, ON; 3) Department of Molecular and Medical Genetics, University of Toronto, Toronto, ON; 4) Ottawa Hospital Research Institute, Ottawa, ON; 5) Toronto General Research Institute, Toronto General Hospital, Toronto, ON.

The Centre for Applied Genomics (TCAG; www.tcag.ca) is a Canadian infrastructure established to facilitate research and development in genetics and genomic biology. With the objective of providing core resources and technologies to support large-scale and service-related research projects, five infrastructures operate - (1) Genome Resources, Gene Isolation & Cytogenomics Facility, (2) Genetic Analysis Facility, (3) Microarray Facility, (4) DNA Sequencing and Synthesis Core, and (5) the Bioinformatics and Statistical Analysis Facility. To serve the community TCAG has developed, TCAG curates and hosts several relevant databases to facilitate clinical and basic research in human genetics. The Chromosome 7 Annotation Project database is the most comprehensive resource of genomic, structural, functional and clinical information available for this segment of the genome. Another resource is the Human Genome Segmental Duplication Database - containing information about segmental duplications across the human genome that can be involved in chromosome rearrangements leading to human disease. Descriptions of mutations, polymorphisms and chromosomal rearrangements relating to specific diseases can be found in the Cystic Fibrosis Mutation, Lafora Progressive Myoclonus Epilepsy Mutation and Polymorphism, and Autism Chromosome Rearrangement databases. Most recently, TCAG has developed a database to capture genomic polymorphism data generated from array comparative genomic hybridization (CGH) experimentation. Background on the database structure, curation and other activities will be presented.

Low-copy-repeats database and its application in molecular medicine. *H. Sun*^{1, 2, 6}, *Y.F. Chen*², *P.L. Kuo*³, *S.J. Tsai*^{2, 5, 6}, *C.S.J. Fann*⁴, *K.F. Chen*⁵, *C.C. Lin*⁵, *H.H. Chan*¹. 1) Inst Molecular Medicine, National Cheng Kung Univ, Tainan, Taiwan; 2) Institute of Basic Medical Sciences, National Cheng Kung University Medical College, Tainan, Taiwan; 3) Department of Obstetrics and Gynecology, National Cheng Kung University Hospital, Tainan, Taiwan; 4) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 5) Department of Physiology, National Cheng Kung University Medical College, Tainan, Taiwan; 6) Bioinformatics Center, Center for Biotechnology and Biosciences, National Cheng Kung University, Tainan, Taiwan.

The completion of human genome project has revealed that about 5% of the human genome is comprised of region-specific low-copy-repeats (LCRs). Genomic duplications that lead to chromosomal variations, phenotypic differences and evolutionary changes were well documented. Currently more and more studies have shown non-allelic homologous recombination between LCRs that flanking unique genomic segments may account for significant amounts of human genetic diseases through deleterious loss or gain of genomic segments, which were referred to as genomic disorders. To dissect the structure and content of these LCRs, and study their impact upon human health and genetic diseases, we developed software to search, identify, and analyze region-specific LCRs using sequence information in the human genome database. To further test the application of this information on molecular medicine, specific LCRs on human chromosome 22q11.2, which were commonly deleted in DiGeorge and velocardiofacial (VCFS) syndromes, have been used to design quantitative PCR assay for rapid validation of chromosome 22p11 deletion. Results from this study demonstrated that the LCR database is a good resource to develop rapid approach for molecular diagnosis. In addition, our data suggested that many novel genomic disorders might remain to be identified.

Association of KCNJ11 gene E23K polymorphism with type 2 diabetes in Saudi population. *O. Alsmadi¹, K. Al-Rubeaan², S. Wakil¹, F. Imtiaz¹, P. Carroll¹, M. Rajab¹, S. Al-Katari², B. Meyer¹.* 1) Aragene, Research and Development, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; 2) Diabetes Center, King Abdulaziz University Hospital, Riyadh, Saudi Arabia.

Polymorphism in KCNJ11, E23K, alters the ATP-potassium channel function by inducing spontaneous over-activity of pancreatic beta cells, thus increasing the threshold ATP concentration for insulin release. Previous studies have shown that the E23K polymorphism is associated with type 2 diabetes in Caucasian populations. Significant variability has been observed with allelic associations in polygenic diseases such as type 2 diabetes. To date there is little or no data on the impact of the E23K polymorphism upon type 2 diabetes in Arab populations. This is particularly so in the Saudi population in which there is a high incidence of type 2 diabetes. We developed a molecular beacon based real time PCR assay for genotyping of the E23K polymorphism. The assay was validated by direct sequencing of a subset of samples. Genotyping was performed in 1162 Saudi patients diagnosed with type 2 diabetes based upon WHO criteria. Genotypes observed were E/E (732;63%), E/K (431;35.5%), and K/K (18;1.5%). Hardy-Weinberg (HW) analysis was performed using this data. Given the incidence of the E and K alleles, the number of heterozygotes (E/K) in the 1162 samples was expected to be 223, whilst that observed was 413. Chi-square analysis indicated the difference between the observed and expected to be highly significant ($p < 0.00001$), indicating deviation from HW equilibrium. The first assumption of HW equilibrium (random mating) is not satisfied by the population studied. However analysis of the same sample set for other polymorphisms showed complete equilibrium. This data supports association of the KCNJ11 gene E23K polymorphism in susceptibility to or pathogenesis of type 2 diabetes in the Saudi population.

Oligonucleotide ligation assay-based SNP genotyping technology allows accurate, cost and time efficient multiplex genotyping of hundreds of SNPs in thousands of samples. *T.M. Frayling, S. McGinn, I.G. Gut.* Centre National de Genotypage, Evry, France.

Comprehensively assessing the role of genes in a complex trait typically requires the genotyping of 100s of single nucleotide polymorphisms (SNPs) in 1000s of samples. Current genotyping technologies do not accommodate this scale of project without large time and cost considerations. We aimed to assess a new technology, the SNPlex System (Applied Biosystems), that genotypes 48 SNPs in a single multiplex reaction for 5000 samples. Reactions are based on oligonucleotide ligation assays followed by PCR with universal biotinylated primers, and separation of hybridised Zipchute markers on capillary sequencers. Four 384 well plates can be processed in 3 person-days at a cost of \$0.05-0.10 using <1ng DNA per genotype. We selected 130 SNPS from the Celera database that randomly covered three type II diabetes candidate genes. In silico searches for incompatible sequences using the SNPlex assay design web-site excluded 36 SNPs, and produced two panels of SNPs. We used 32 CEPH DNA samples from four families (each including 6 meioses) each present in 10 or 12 wells to assess accuracy and reproducibility of the SNPlex assay. Genotypes were tested for compatibility with family relationships using PEDCHECK. Results from a panel of 46 SNPs showed that 42 produced accurate and reproducible results (91%) and that 12 were monomorphic in 32 Caucasian chromosomes, of which 8 (67%) were unvalidated dbSNPs and one unique to the Celera database. For the remaining 30 SNPs 99.8% of 10,860 genotypes were scored. No errors of reproducibility were detected (100%). Three errors of Mendelian inheritance were detected for one marker but later attributed to weak signal strength. Concurrent genotyping of 10 SNPs using Taqman (Applied Biosystems) on a 7900 platform in 30 samples resulted in one discrepancy. In conclusion, the SNPlex System provides an accurate and efficient method of genotyping 100s of SNPs in several 1000 samples. Our study also reflects the likelihood of a SNP being polymorphic when using SNP databases without prior sequence validation and thus evaluates current SNP databases.

Ultra High Sensitivity Ribo-SPIA Amplification Technology for Expression Profiling of Small RNA Samples Using Affymetrix GeneChip Arrays. *G. Deng¹, S. Wang¹, S. Koritala¹, A. Dafforn¹, W. Xiao^{2,3}, R.W. Davis^{2,3}, N. Kurn¹.* 1) NuGEN Technologies, Inc, San Carlos, CA 94070; 2) Department of Biochemistry, Stanford University School of Medicine, Stanford, CA 94305-5307; 3) Stanford Genome Technology Center, 855 California Avenue, Palo Alto, CA 94304.

Microarray technologies have become powerful tools for global gene expression profiling in drug discovery and clinical research. Limiting factors in such analyses include the RNA quantity required and complexity of protocols for target preparation. The T7-based methods usually require tens of micrograms of total RNA, or multiple rounds of amplification, which are tedious and time consuming, and thus hinder the application of this technology to large scale analysis of precious biologically significant samples. Furthermore, the adaptation of these technologies to clinical small RNA samples will require rapid target preparation methods. The NuGEN's RNA amplification and labeling system called Ribo-SPIA is incorporated in the NuGEN's commercially available Ovation Systems. Ovation Systems are currently suitable for rapid target preparation from 5-100ng total RNA samples. Further enhancement of the Ovation procedure for smaller samples, in the range of 1ng or lower total RNA input will be presented. This new procedure represents a major breakthrough in target preparation for global expression profiling and analysis, potentially down to the single cell level. The major attributes of this procedure are: 1. Higher sensitivity for small RNA samples: This new method generates enough cDNA target by one round of amplification from as little as 1 to 0.1ng total RNA input for hybridization on Affymetrix GeneChip. It has been successfully applied to expression analysis in a variety of clinical samples with limited RNA input from sorted and non-sorted human white blood cells. 2. Simplicity of protocol: The entire target preparation procedure is accomplished in a single day, and is amenable to automation. 3. High sensitivity and reproducibility of array results: GeneChip array results showed excellent reproducibility and high concordance with the standard T7-based target preparation for gene call, and differential gene call.

Program Nr: 1589 from the 2004 ASHG Annual Meeting

The International HapMap Project: Community Engagement. *B. Knoppers.* Dept CRDP, Univ de Montreal, Montreal, PQ, Canada.

The goal of the International HapMap Project is to develop a resource that will describe the common patterns of human genetic variation. 270 DNA samples from four populations are being used, at least initially, to develop the resource: the Yoruba in Ibadan, Nigeria; Japanese in Tokyo; Han Chinese in Beijing; and CEPH (existing samples from Utah residents with Northern and Western European ancestry). No names or medical information were collected, so there is little risk to the privacy of individual donors. However, the HapMap will show which population each sample came from, making it possible to compare patterns of variation among both individuals and populations. This feature raises ethical concerns, including concerns about the potential for group stigmatization or discrimination; concerns about the ability of the HapMap to facilitate population history research (which could lead to findings in conflict with religious convictions or established legal or political claims); and concerns that sampling based on ancestral geography could result in largely socially constructed categories, such as race, being incorrectly viewed as highly precise biological constructs. The Project undertook a community engagement or public consultation process in each community where people were approached for samples. The purpose was to give these people an opportunity to share their views on the ethical, social, and cultural issues the HapMap raises for themselves and their communities, provide input into the way their samples would be collected and described, and offer other relevant input. A Community Advisory Group (CAG) has been organized for each community, so the communities can stay abreast of how the HapMap and samples are being used. While the effectiveness of the community engagement processes and the Community Advisory Groups can only be assessed over time, the experience so far suggests that asking people respectfully about participating in Projects of this type, providing complete, balanced, and accurate information, giving them a chance to express their views, and (where possible) incorporating their input, need not unduly impede research. Instead, it can create a climate in which research proceeds in an atmosphere of openness and trust.

Comparative analysis of the Marsupial *ATRX* and *ATRY* genes. *K. Huynh¹, D.J. Park¹, M. Familiar¹, J.A.M. Graves^{1,2}, M.B. Renfree¹, A.J. Pask¹.* 1) Zoology, The University of Melbourne, Victoria, Australia; 2) Research School of Biological Science, Australian National University, ACT, Australia.

Mutations in the human *ATRX* gene are responsible for the X-linked Alpha-Thalassemia and mental Retardation syndrome. Male patients display varying degrees of gonadal dysgenesis, suggesting that in addition to its role in globin regulation, *ATRX* has a fundamental role in the testis development pathway. In the tammar wallaby (*Macropus eugenii*), there are two *ATRX* orthologues, one on the X chromosome (*ATRX*) and one on the Y (*ATRY*). The full sequence of *ATRX* and *ATRY* is being determined in the tammar wallaby by a combination of RT-PCR, 3' and 5'RACE walking and BAC library screening.

Our investigation into the conservation of a male specific Y-linked *ATRX* homologue in mammals and other vertebrate species by Noahs Ark blot analysis suggest that *ATRY* may have been lost only recently, with the presence of a Y-linked *ATRX* orthologue found in the monodelphis and the seal. This finding further supports the hypothesis that *ATRY* was an important gene in the mammalian sex differentiation pathway that has been supplanted by expression of *ATRX* in the testes leading to redundancy of *ATRY* function [1].

Wallaby orthologue expression analysis has shown that *ATRY* is expressed only in the testis, while *ATRX* retains a broad expression as in humans. Anti-mouse *ATRX* antibodies that cross react with both *ATRX* and *ATRY* in the tammar show *ATRX*/Y protein present in the testis and ovary from day 23 of fetal development (shortly after the appearance of the gonad and well before gonadal sex determination) to the adult [1]. During testis differentiation, *ATRY*/*ATRX* immunostaining was localised in the Sertoli cells, the Leydig cells and the germ cells suggesting that *ATRX*/*ATRY* may play a role in testicular organization.

Mapping of a New Adult-Onset Primary Open Angle Glaucoma (POAG) Locus (GLC1G) to Chromosome 5q and Mutation Screening of Candidate Genes. *S. Monemi*¹, *G. Spaeth*², *A. Child*³, *A. DaSilva*¹, *S. Popinchalk*¹, *J. Coppin*¹, *J. Argon-Martin*¹, *R.P. Crick*⁴, *M. Sarfarazi*¹. 1) Molecular Ophthalmic Genetics Laboratory, University of Connecticut Health Center, Farmington, CT; 2) Wills Eye Hospital, Philadelphia, PA; 3) St. Georges Hospital Medical School, London, UK; 4) International Glaucoma Association, London, UK.

Glaucoma is the second cause of blindness with approximately 70 million affected subjects worldwide. In 2003, we presented preliminary evidence for an Adult-Onset POAG locus (GLC1G) on chromosome 5q (ARVO Abst. #1128; ASHG Abst. #2139). The aim of this study was to reduce the GLC1G region and to search for the defective gene in a group of our POAG linked families by candidate gene screening. Our original linkage to the GLC1G locus was identified in 3 POAG families with a total of 29 scoreable meioses, including 16 affected and 2-glaucoma suspects. Recently, a group of 638 individuals (including >400 affected subjects) in 139 POAG families were screened for the entire genome. As this screening also covered the GLC1G locus on 5q, a number of new families showed potential linkage to this region. Additional saturation mapping in these families enabled us to narrow down the GLC1G region to an interval of <5 cM. Since our initial mapping of the GLC1G locus, we have selected 12 potential candidate genes based on their ocular/neuronal expression or their potential protein domains/biological functions and screened them for mutation by direct sequencing of PCR products and/or by SSCP analysis. Several sequence alterations were identified in these 12 genes. However, only one of these variations significantly alters the composition of its encoded amino acid. This alteration perfectly segregates in one of our originally linked families and it is absent in over 470 normal control chromosomes screened by restriction enzyme digestion. Sequencing of this gene in other smaller but potentially linked families is currently in progress. In conclusion, a new Adult-Onset POAG locus maps to 5q and one of the observed sequence variations is segregating in at least one of the GLC1G-linked families. Supported by EY-09947 and M01RR-06192.

Discovering biological relationships in genome-wide expression studies. *W.T. Barry*¹, *A.B. Nobel*², *F.A. Wright*¹. 1) Dept of Biostatistics; 2) Dept of Statistics, Univ of North Carolina, Chapel Hill, NC.

In high-throughput genomic and proteomic experiments, investigators monitor co-expression across a set of conditions in order to gain understanding of the biological phenomena involved. Standard analysis methods test for differential expression of individual genes, yielding a ranked list of significant genes. However, investigators are frequently more interested in finding associations to cellular processes. In order to test hypotheses about the sets of genes associated with cellular processes, investigators have been limited to *post hoc* analyses of gene lists that are potentially biased and subjective by nature. We provide a general framework for conducting valid tests of such gene categories *ab initio* through a 2-stage, structured, permutation-based method, that can be applied to various experimental designs. To illustrate the utility and flexibility of our method, we applied it to a study of human lung carcinomas by Bhattacharjee *et al.* (2001) using gene categories generated from Gene Ontology (GO). Our analysis focused on a subset of the data consisting of microarrays from 16 normal samples and 125 adenocarcinomas. Differential expression of a gene was measured via appropriate "local" statistics for: (1) normal versus adenocarcinoma (t-test), and (2) survival among the adenocarcinomas (Cox proportional hazards model). The Wilcoxon rank sum of local statistics was used as a "global" statistic of expression across an entire category. Empirical p-values and false-discovery rate (FDR) estimates were computed from 10000 permutations. The gene category GO:0016460 'Myosin II' was significantly underexpressed in adenocarcinomas ($p = 0.0012$, FDR = 0.055), while GO:0000786 'Nucleosome' was overexpressed relative to normal samples ($p = 0.0016$, FDR = 0.055). Survival was associated with genes in GO:0005643 'Nuclear Pore' ($p = 0.0001$, FDR = 0.005) with 20 of 30 probesets increasing and 10 decreasing in expression with increased survival. These results illustrate a direct approach for testing differential expression across a gene category and provide novel evidence regarding the involvement of cellular processes in lung cancer development and patient outcome.

Unequal expression assay as a rapid screen for candidate tumor suppressor genes in schwannomatosis. *M.T. Webster, K.E. Larson, M. MacCollin.* Neurology, Massachusetts General Hospital, Charlestown, MA.

Neurofibromatosis 2 (NF2) and schwannomatosis (SCH) are related genetic disorders characterized by the occurrence of multiple schwannomas. Mutations of the *NF2* tumor suppressor gene (TSG) are the molecular events causing disease in NF2 patients, and have also been identified as somatic events in tumors from SCH patients. Linkage and LOH studies have excluded the *NF2* gene as the cause of SCH, and narrowed the *SCH* candidate region which includes a group of genes centromeric to *NF2* on 22q. Since most mutations in TSGs are truncating in nature, we developed a rapid gene-screening assay sensitive to the disproportionate degradation of mRNA harboring truncating mutations. To analyze patients diagnosed with SCH we amplified single nucleotide polymorphisms (SNPs) located in transcribed regions of candidate genes to compare expression of alleles in genomic DNA and cDNA derived from EBV transfected lymphoblast lines. Allelic expression of the *NF2* gene was used as a control. Two *SCH* candidate genes were tested, *CRKL* and *GNAZ* in nine non-founder SCH patients and 4 NF2 patients as controls. Three SCH patients and one NF2 patient were informative for a SNP in the 3' untranslated region of the *CRKL* gene, and all showed equal expression of alleles. Four SCH patients and one NF2 patient were informative for a SNP in exon one of *GNAZ*. Interestingly all showed unequal expression of the cDNA alleles compared to DNA, including the NF2 patient. Subsequent exon scanning of *GNAZ* failed to show molecular alterations outside of the SNP used for screening which was present in SCH, NF2, and normal controls. As expected, NF2 patients showed unequal expression of alleles in the *NF2* gene while expression in SCH patients remained equal. This work illustrates the utility of unequal expression assays in rapidly screening candidate TSGs and excludes both *CRKL* and *GNAZ* as SCH TSGs. We will continue to apply this method in scanning for candidate TSGs located in the *SCH* region.

Retrofitting of an X centromere-based minichromosome with a BAC using Cre/loxP system. *T. Kaname*^{1, 2}, *K. Yanagi*¹, *K. Naritomi*¹, *K. Mann*², *C. Farr*³, *C. Huxley*². 1) Dept Medical Genetics, Univ Ryukyus, Nishihara, Japan; 2) MRC Clinical Sciences Centre, Imperial College London, Hammersmith campus, London, UK; 3) Dept Genetics, Univ Cambridge, Cambridge, UK.

Mammalian artificial chromosomes (MACs) are a potentially useful tool for gene therapy applications as they should allow long-term maintenance of the therapeutic DNA without integration. Minichromosomes derived by telomere-directed truncation of a human chromosome are particularly attractive as a tool for gene transfer because of their mitotic stability. We have established an efficient system for introducing a whole BAC clone including an intact gene unit onto a minichromosome based on the human X chromosome. The use of mutant *loxP* sites with Cre recombinase and direct selection for the retrofitting event led to a high efficiency of correctly retrofitted clones. The 155-kb BAC containing the intact human *HPRT* gene was correctly retrofitted onto the minichromosome in DT40 cells. The *HPRT* gene is expressed from the minigene at approximately the same level in both of these clones. This system allows one to introduce any gene or gene cluster which can be cloned as a BAC into the minichromosome for gene delivery.

Alterations of gene expression pattern in testicular biopsy from a patient with *DAX-1* mutation. *A.L.Y. Pang*¹, *M.M. Martin*², *D.H. Bellan*¹, *A.L.A. Martin*², *O.M. Rennert*¹, *W.Y. Chan*^{1,2}. 1) Laboratory of Clinical Genomics, NICHD/NIH, Bethesda, MD; 2) Department of Pediatrics, Georgetown University, Washington, DC.

Dax-1 is required for spermatogenesis in the mouse. In man *DAX-1* gene products are necessary for normal testicular development and maturation. A patient with the *DAX-1* gene carrying a 11-bp deletion manifested X-linked adrenal hypoplasia congenita (AHC) and hypogonadotropic hypogonadism (HHG). In order to understand the genetic mechanisms of these abnormalities, the pattern of gene expression of the testicular tissue was analyzed using microarrays. Total RNA was extracted from culture cells derived from a testicular biopsy of the patient at 13 years of age. Expressed genes in the culture cells were profiled using Affymetrix HG-Focus GeneChips. The gene expression profile obtained was compared with those from two normal human testicular fibroblast cell lines obtained from ATCC. Among the ~8000 genes examined, 95 displayed 3- or more folds of change in expression levels between patient and normal cells. These differentially expressed genes could be separated into several biological activity groups. Most notably, the comparison expression analyses indicated growth factor genes such as *INTERLEUKIN 1* and *8*, *CHEMOKINE (C-X-C MOTIF) LIGAND 1*, *LEUKEMIA INHIBITORY FACTOR*, and *DIPHThERIA TOXIN RECEPTOR* were significantly downregulated in the testicular cells of the patient. On the other hand, upregulation of expression of genes responsible for prostaglandin biosynthesis (*ALDO-KETO REDUCTASE FAMILY 1, MEMBER C3* and *PROSTAGLANDIN I2 SYNTHASE*) and cell adhesion (e.g. *C-TYPE LECTIN*, *SUPERFAMILY MEMBER 2* and *COLLAGEN, TYPE XV, ALPHA 1*) was observed in the *DAX-1* mutant cells. Other members of the *ALDO-KETO REDUCTASE FAMILY 1*, as well as *FRIZZLED HOMOLOG 7* and *SECRETED FRIZZLED-RELATED PROTEIN 1* and *4* were also increased. These results provide leads for further investigation into the molecular changes that give rise to the clinical symptoms and signs manifested by patients with mutated *DAX-1*.

Evolutionary conservation of regulatory and coding sequences of the pituitary-specific transcription factor,

PROP1. *R.D. Ward*¹, *M.C. Cho*¹, *R.H. Lyons*², *E.M. Rubin*³, *S.J. Rhodes*⁴, *L.T. Raetzman*¹, *T.P.L. Smith*⁵, *S.A. Camper*¹. 1) Dept. Human Genetics, University of Michigan, Ann Arbor, MI; 2) Dept. Biol. Chem., University of Michigan, Ann Arbor, MI; 3) DOE JGI, Walnut Creek, CA; 4) Dept. Biology, IUPUI, Indianapolis, IN; 5) USDA/ARS, Meat Animal Research Center, Clay Center, NE.

All vertebrates have pituitary glands composed of specialized hormone-producing cells. The individual hormones are evolutionarily conserved, although their function varies across the classes of Animalia. Even prochordates such as *Ciona* have pituitary-like hormones, suggesting that genetic regulation of pituitary organogenesis may be conserved among the phylum Chordata. The first known pituitary-specific gene in hierarchy encodes PROP1, a paired-like homeodomain transcription factor. *PROP1* mutations are the most common known cause of multiple pituitary hormone deficiency in humans. Mice homozygous for the spontaneous Ames dwarf mutation or the targeted null allele are excellent models for the human disease. We compared the sequence of the PROP1 gene in five primates, several orders of mammals including species of Rodentia, Carnivora, and Artiodactyla, and related vertebrates such as fish and chicken. A phylogenetic analysis using parsimony supported the orthologous nature of the sequences. Alignment of large regions of genomic sequence from four species and VISTA analysis revealed the presence of several highly conserved noncoding sequences (CNS) near the PROP1 gene. Studies in transgenic mice confirm that one of these is functionally important; it confers a dorsalized expression pattern in the developing pituitary gland. Phylogenetic footprinting across several species implicates specific DNA binding sites in regulation of PROP1 expression. In conclusion, evolutionary comparison has proven to be a valuable approach to understanding regulation of *Prop1*, the key gene for pituitary organ development in vertebrates.

Large scale identification of polymorphisms in Korean population. *B. Oh¹, J-K. Lee¹, H-J. Ryu¹, J-J. Kim¹, J.Y. Lee¹, H. Kim¹, H-Y. Jung¹, G-M. Ryu¹, I. Koh¹, C. Park¹, B. Han¹, J-S. Seo², H.D. Shin³, K. Kimm¹.* 1) Geonmic Epidemiology/Bioin, Natl Genome Research Inst, Seoul; 2) Macrogen Inc., Seoul; 3) SNPGenetics Inc., Seoul.

Genetic variation plays an important role in the multigenic diseases as well as monogenic diseases. Among diverse types of genetic variation the single nucleotide polymorphism (SNP) comprises more than 90%. More than 10 million SNPs have been estimated to be present in human and up to 9 million SNP were so far available in public SNP databases. The analysis of the SNP data has suggested that there are significant differences among populations in terms of SNP pattern. Moreover several issues about how much they are real, what spectrum of the SNP allele frequency distribute on each population and how much the SNPs are representative have been raised. To address these questions, 134 genes in 5q31-33 region have been sequenced to identify SNPs using 24 unrelated Korean individuals and 1,692 SNPs are identified. Among these SNPs 292 SNPs identified from 29 genes have been analyzed. 38% of the SNPs are not found in public database yet, while 67.9% among the novel SNPs have allele frequencies less than 0.1. These results suggest that still more effort should be made to discover SNP to serve as tools in genetic studies of diseases. Ethnic comparison of 27 SNPs reveals that 67% of the SNPs show more than 0.1 difference in terms of allele frequency between Korean and Caucasian, inferring that haplotype map will be significantly different between these. More analysis for the SNPs will be discussed.

Program Nr: 1598 from the 2004 ASHG Annual Meeting

Characterization of Human Variation Resources at the NIGMS Human Genetic Cell Repository. *L. Toji, D. Coppock, P. Bender, C. Beiswanger, J. Beck.* Coriell Cell Repositories, Coriell Inst Med Res, Camden, NJ.

The resources for study of human variation in the NIGMS Human Genetic Cell Repository include a set of panels from diverse populations around the world, the Polymorphism Discovery Resource (PDR), and extended panels of African-Americans, Caucasians, Chinese Americans, and Mexican Americans and recently, in cooperation with NHGRI, panels of cell lines from the International HapMap Project which includes the CEPH population from Utah, USA, the Yoruba people of Ibadan, Nigeria, the Han people of Beijing, China, and Japanese from Tokyo. Lymphoblastoid cell lines and DNA have been prepared for each of the samples in these panels. As part of the routine quality control procedure to verify individual samples in the Repository, the identity of each DNA sample in these panels has been confirmed using a set of six highly polymorphic microsatellite markers. The cumulative profiles for each marker for the existing panels have been compared; the similarities and differences between all of the panels will be discussed along with data on the frequency of the COII/tRNA(Lys) intergenic 9-bp mitochondrial DNA deletion in these populations. In addition, extensive numbers of SNPs have been reported for many of these samples. A review of the availability and extent of SNP data for these panels will be presented. Information about these resources may be found at <http://ccr.coriell.org/nigms>.

Optimal Multiplexing Schemes for 48-plex SNP Genotyping. *Z. Jiang, A. Reyes, R. Oda, J. Mariana, M. Jackson, M. Dobbs, S. Boyer.* Biomedical Research Division, Beckman Coulter, Fullerton, CA.

One of the fruits of the Human Genome Project is the discovery of millions of DNA sequence variants in the human genome. The majority of these variants are single nucleotide polymorphisms (SNPs). Accurate and fast genotyping of SNPs is of significant scientific importance in areas such as linkage/association studies, pharmacogenetics, forensics, and other areas of genetic research. Primer extension, the gold standard technology for SNP genotyping, provides a robust solution at a highly- multiplexed level. The development of multiplex assays in our laboratories involved designing primer sets for both PCR* and primer extension, and examining various combinations of those primer sets and different reaction components under different thermal cycling conditions. In this work, we studied algorithmic approaches to maximizing the multiplexing rate of 48-plex SNP assays and created a primer design engine to provide an efficient tool for assay design. A set of 48 unique sequences was identified and utilized to associate the 48-plex SNP genotyping assays with an oligonucleotide hybridization microarray platform. A standard chemistry protocol based on assays for over one thousand SNPs in the 48-plex format was established. A total of 1152 SNPs were studied on 96 CEPH/Utah family DNA samples from 8 members of 12 families. At 48-plex levels, these SNPs were divided into 24 marker panels: 4 C/A polymorphism panels (192 SNPs), 4 T/A panels (192 SNPs), 4 C/G panels (192 SNPs), 4 T/G panels (192 SNPs), 4 G/A panels (192 SNPs), and 4 T/C panels (192 SNPs). Our results demonstrated over 70 % first pass assay design success, greater than 95% genotyping success rate, and data accuracy of over 99%. This protocol could be applied directly to screen millions of SNPs at a high success rate without further assay optimization. We believe this newly developed technology provides a cheaper and faster solution for automated SNP genotyping with scalable throughput capacity, high assay robustness, and excellent data accuracy. * The PCR process is covered by patents owned by Roche Molecular Systems, Inc. and F. Hoffman La Roche, Ltd.

Program Nr: 1600 from the 2004 ASHG Annual Meeting

Synergistic effects of glycerol in multi-temperature gel electrophoresis dramatically increase the efficiency of SSCP. *K. Li, W. Song, J. Chen, J. Feng, S.S. Sommer.* Dept Molecular Genetics, City of Hope, Duarte, CA.

Single strand confirmation polymorphism (SSCP) is widely used in mutation scanning. To increase detection efficiency of SSCP, a variety of electrophoresis conditions have been evaluated, including glycerol and multi-temperature gel electrophoresis. Mutations in the Factor IX were utilized to optimize conditions. In an initial blinded analysis, nineteen of nineteen mutations were detected with two gel conditions. A pair of generic conditions was then applied to the analysis of the Factor VIII from 48 patients with hemophilia A. In this second blinded analysis, 47 of 47 sequence changes were detected. By loading segments from multiple exons within a lane, it is routinely possible to analyze about a 1,000 segments in a conventional slab gel, which scans a half megabase of sequence (20 segments x 50 lanes per gel, can be analyzed from duplex genomic DNA). We are applying the method to the ABI-377 florescent sequencer, which has the potential to increase throughput by an additional factor of five. While newer technologies capture the imagination, the combination of throughput and high detection efficiency (2.5 megabases analyzed per 2 gels analyzed by the ABI-377) offers a high throughput, low cost approach for scanning for unknown mutations. Throughput may be increased further by capillary electrophoresis.

The characterization of the clinical significance of genetic variants detected in *trans* with known deleterious mutations based upon obvious biallelic phenotypes. *T. Scholl, C. Schwensen, B.C. Hendrickson, K. Eliason, A.E. Deffenbaugh, B. Leclair, C.A. Frye, B.E. Ward, T. Judkins.* Myriad Genetic Laboratories, Inc., Salt Lake City, UT.

A novel method to improve information about genetic variants detected during clinical mutation testing is presented. The approach relies on biological conditions where biallelic mutations induce obvious phenotypes or embryonic lethality. Under these conditions, genetic variants detected in *trans* with known deleterious mutations must be polymorphisms or hypomorphic mutations that convey reduced risk of disease. *BRCA1* was selected to model this approach because testing over 70,000 North American patients has identified over 1,400 genetic variants in this gene. Evidence from extensive clinical testing and mouse transgenic models supports the conclusion that biallelic *BRCA1* mutations induce embryonic lethality. Furthermore, the alleles of *BRCA1* are described by a few prevalent haplotypes, which supports the genetic phasing of variants intrinsic to this method.

Haplotype pairs were assigned to 25,095 anonymous specimens from hereditary breast/ovarian cancer families using SNPs detected during full sequence clinical testing of *BRCA1*. A total of 504 from 1048 genetic variants detected in these specimens could be assigned to one or more haplotypes. There were 21 occurrences of different variants of uncertain clinical significance in *trans* with known deleterious mutations in this dataset. It is likely that these variants convey reduced cancer risk or are benign polymorphisms. From a total of 655 patients that carried these variants in the entire specimen set, there were 352 patients for whom one of these 21 genetic variants was responsible for a test report with clinical uncertainty.

This approach requires large datasets where compound heterozygotes for low prevalence variants and deleterious mutations are found. Present trends of increased genetic testing that involve whole-gene screening should support the application of this technique.

Reducing variability and improving workflow in the collecting, transporting and processing of blood samples for genomic DNA purification using the PAXgene Blood DNA System. *G. Tiller¹, D. Groelz², E. Sittart², C. Lenz², B. Walter-KimmerleZurawinski³, J. Zurawinski⁴.* 1) Div Med Gen, DD2205MCN, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Research and Development, QIAGEN GmbH, Hilden, Germany; 3) Strategic Marketing Department, PreAnalytiX, Hombrechtikon, Switzerland; 4) Regional Marketing Department, QIAGEN Inc, Valencia, CA.

The PAXgene Blood DNA System provides an easy-to-implement, standardized method for collecting human whole blood samples and purifying genomic DNA. Blood samples are collected in PAXgene Blood DNA Tubes containing a unique additive that maintains sample integrity for DNA purification. Collected blood samples can be stored for up to 14 days at room temperature*, or for longer at lower temperatures. PAXgene Blood DNA Tubes are integrated with the PAXgene Blood DNA Kit, which uses a standardized DNA purification protocol. This protocol was developed to minimize the number of procedural steps and streamline the workflow. The buffer-based protocol minimizes carryover of RNA and protein. The use of a single processing tube per sample reduces the possibility of sample mix-up. The purified DNA is of high yield and quality, and is suitable for use in a range of downstream applications.

*DNA yields may be reduced if tubes are stored at 25C for 14 days or longer.

Proofreading genotyping assays mediated by high fidelity *exo* DNA polymerases. *J. Zhang*¹, *K.T. Yao*², *L.L. Chen*¹, *J.R. Pardinas*³, *D.F. Liao*¹, *K. Li*⁴, *S.S. Sommer*⁴. 1) SNP Institute, Nanhua University, Hengyang, China; 2) First Military Medical University, Guangzhou, China; 3) The Miami Project to Cure Paralysis, University of Miami School of Medicine, Miami, FL; 4) Dept Molecular Genetics, City of Hope, Duarte, CA.

It has been recognized for more than three decades that polymerase fidelity varies according to the presence of proofreading activity mediated by its internal 3' to 5' exonuclease. Polymerases with proofreading function possess high fidelity for DNA replication both in vivo and in vitro, but this well-known class of polymerases has been almost completely neglected in mutation detection in the postgenomic era. The obstacle facing *exo*⁺ polymerases for single nucleotide polymorphism (SNP) detection could be bypassed by the primer-3'-termini modification. This hypothesis has been well tested with the employment of three types of modified allele specific primers with: 3' labeling, 3' to 5' exonuclease-resistance, and 3' dehydroxylation. Accordingly, three new SNP assaying methods have been developed to carry out genome-wide genotyping taking advantage of the enzymatic properties of *exo*⁺ polymerases. One of the three SNP assays, the on/off switch mechanism can be used to discriminate bases upstream of the 3' terminus and thus defines a new concept in de novo sequencing technology. These new mutation detection assays are widely adaptable to a variety of platforms, including multiwell plate and microarray technologies. Application of *exo*⁺ polymerases to genetic analysis, and especially SNP assays, may accelerate the pace of personalized medicine.

Mitochondrial energy metabolism in the klotho KO mouse. *Y. Akita¹, K. Hirata¹, N. Povalko^{1,2}, J. Nishioka¹, K. Ishida¹, M. Nishimura¹, C. Mitsumasa¹, Y. Koga¹.* 1) Pediatrics and Child Health, Kurume Univ. School of Med., Kurume, Fukuoka, Japan; 2) Laboratory of Inherited Metabolic Disease, Research Center for Medical Genetics, RAMN, Russia.

The klotho KO mouse (KKO), a model of premature aging, is characterized by a short lifespan, infertility, arteriosclerosis, hypogonadism, skin atrophy, osteoporosis and emphysema. KKO begin to show growth retardation and become inactive gradually at age of 3 to 4 weeks, and usually die prematurely by age of 8 to 9 weeks. There are several studies of KKO in endocrinology of calcium metabolism and regenerative vascular abnormalities, however, no studies focused on the mitochondrial energy metabolism have been reported before. In the present study, we examined the mitochondrial energy metabolism to investigate the relationship between mitochondrial functions and aging seen in the KKO. We performed histopathological and biochemical analysis of KKO at age of 7 to 8 weeks. Muscle pathology showed a mild variation in fiber size and was smaller diameter than those in wild-type mice. COX stain showed decreased level of enzymatic activities called focal COX deficiency. On electron microscopy, mitochondria were decrease in number and showed abnormal shape in femoral and cardiac muscle. Entire respiratory enzyme activities including Complexes I, II, III, and IV were normal in muscle, however those in kidney were profoundly decreased. Oxygen consumption of isolated mitochondria from kidney suggests that KKO was markedly impaired mitochondrial respiration at the age of 7 weeks. Our results suggest that the disruption of klotho gene causes mitochondrial dysfunction and abnormal energy homeostasis in kidney seen in KKO. The present study showed that function of klotho gene is important to modulate the mitochondrial bioenergetics for the maintenance of mitochondrial homeostasis in mouse.

A rapid microarray based whole genome analysis for detection of uniparental disomy. *O. Altug-Teber¹, A. Dufke¹, S. Poths¹, U.A. Mau-Holzmann¹, M. Bastepe², L. Colleaux³, V. Cornier-Daire³, T. Eggermann⁴, G. Gillissen-Kaesbach⁵, M. Bonin¹, O. Riess¹.* 1) Medizinische Genetik, Universitätsklinikum ,Tübingen,Germany; 2) Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, USA; 3) Hôpital Necker-Enfants Malades, Paris, France; 4) Institut für Humangenetik, Universität Aachen, Germany; 5) Institut für Humangenetik, Universitätsklinikum, Essen, Germany.

To date, uniparental disomy (UPD) with phenotypic relevance is described for different chromosomes. It is likely that additional not yet identified UPD phenotypes exist. Due to technical difficulties and limitations of time and resources molecular analyses using microsatellite markers are only performed in cases with specific phenotypic features. To investigate the feasibility of microarray technology in identifying UPD we carried out a whole-genome UPD screen using GeneChip Mapping 10K Array (Affymetrix) with more than 10,000 single nucleotide polymorphisms (SNPs). Six families, each having an offspring with an initial diagnosis of complete or segmental UPD, were genotyped according to manufacturers instructions. Genotype calls for each SNP were generated with GeneChip DNA Analysis Software 2.0. Clustered biallelic markers homozygous for one allele in the offspring and homozygous for the other allele in the parent who is not involved in UPD were identified as informative markers indicating UPD in the offspring. In two cases with complete UPD (paternal UPD15, maternal UPD7) and in three cases with segmental UPDs (paternal UPD2p with maternal UPD2q, paternal UPD11p and paternal UPD20q) we identified 47, 84, 65, 104, 31, and 13 informative markers, respectively. The accompanying reduction to homozygosity across the chromosome or chromosomal region indicated isodisomy due to a somatic error. In the case of complete maternal UPD15, clusters of homozygous and heterozygous SNPs across chromosome 15 indicated a meiotic error. Since our results demonstrated the presence of UPD as expected and revealed clues about the mechanisms of UPD formation, we conclude that array based SNP genotyping is a fast, cost-effective and reliable approach for whole-genome UPD screening.

A genome-wide functional SNP association study of rheumatoid arthritis. V. Carlton¹, S. Schrodi¹, A. Chokkalingam¹, H. Alexander¹, K. Ardlie², M. Chang¹, J. Catanese¹, D. Leong¹, V. Garcia¹, L. McAllister¹, A. Lee³, E. Remmers⁴, L. Criswell⁵, M. Seldin⁶, D. Kastner⁴, C. Amos⁷, J. Sninsky¹, P. Gregersen³, A. Begovich¹. 1) Celera Diagnostics, Alameda, CA; 2) Genomics Collaborative, Inc, Cambridge, MA; 3) North Shore-LIJ Research Institute, Manhasset, NY; 4) NIH, Bethesda, MD; 5) University of California, San Francisco; 6) University of California, Davis; 7) University of Texas, Houston.

In order to identify non-HLA genetic risk factors for rheumatoid arthritis (RA), we performed a genome-wide, gene-centric, case-control association study (475 cases and 475 individually matched controls) using single nucleotide polymorphisms (SNPs). We tested DNA quality by individually genotyping 87 SNPs from candidate genes/regions, then assembled the DNAs into 32 pools (18-70 individuals per pool stratified by clinical phenotype) and genotyped over 21,000 putative functional SNPs [nonsense, missense, splice site, and transcription factor binding site (TFBS)] in approximately 10,000 genes. To confirm association, all SNPs that show allelic association ($p < 0.05$) are then tested in an independent replication set (840 RA cases in 463 families and 926 individually matched controls stratified into 40 pools). To date >900 SNPs have been tested in the replication study and replicated SNPs ($p < 0.05$ in both studies) have been individually genotyped in both sample sets. The correlation of allele frequencies between individual and pooled genotyping was extremely high and multiple SNPs have been replicated, including numerous SNPs within the HLA region, a missense SNP in a hematopoietic-specific protein tyrosine phosphatase *PTPN22* (p -discovery < 0.0007 , p -replication $< 6E-08$; Begovich et al 2004), a SNP that potentially affects a TFBS in a glutamate receptor (p -discovery < 0.03 , p -replication < 0.02) and a missense SNP in a gene of unknown function on 17q21 that appears to be expressed primarily in T cells (p -discovery < 0.003 , p -replication < 0.008). These results support the proposal that genome-wide association studies, focusing on functional SNPs, are a powerful method for deciphering the genetic basis for complex disease.

Program Nr: 1607 from the 2004 ASHG Annual Meeting

Gene expression profiling of microdissected human breast cancer cells from formalin-fixed paraffin-embedded sections using microarrays. *L. Ding, R. Raja, R. Salunga, S. Chu, E. Cheung, M. Ghosh, M. Erlander.* Arcturus Bioscience, 400 Logue Avenue, Mountain View, California 94043.

Surgical tumor biopsies are commonly preserved as Formalin-Fixed Paraffin-Embedded (FFPE) blocks. Enabling high-throughput gene expression analysis of FFPE samples using microarrays will revolutionize the way tumors are diagnosed and treated. However, since the macromolecules in FFPE tissues are cross-linked, efficient extraction and isolation of RNA with quality adequate for microarray analysis from such samples poses a challenge. We have recently developed and optimized a novel process that integrates efficient isolation of total cellular RNA from FFPE sections, linear amplification of isolated RNA, and synthesis of labeled cRNA for microarray analysis. We have also designed custom oligonucleotide arrays that optimize microarray performance of such samples. We have compared matching frozen and formalin-fixed samples to study the fidelity of gene expression ratios derived from formalin fixed samples and demonstrated that microdissected cells from FFPE sections can be used to study native expression level of genes, and that replicate microdissections of pure tumor cell populations can be utilized to generate highly reproducible expression profiles. Further, we have successfully utilized this platform to identify molecular signatures from breast cancer biopsies, suggesting application to clinical analysis.

Program Nr: 1608 from the 2004 ASHG Annual Meeting

Ultra-high Density Microarray-based SNP Genotyping. *K. Jones, J. Huang, K. Cole, J. Zhang, V. Troung, W. Wei, J. Chen, G. Liu, J. Tom, M. Shapero.* Affymetrix, Inc., 3380 Central Expressway, Santa Clara, CA.

The emerging role of single nucleotide polymorphisms in clinical association and pharmacogenetic studies has created a need for high-throughput genotyping technologies. Synthetic DNA microarrays are an ideal format for high throughput genotyping because they are capable of generating data for >50,000 SNP markers in a highly parallel fashion. The principle challenge is to reproducibly present a subset of the genome to an array such that accurate allelic information is obtained. Kennedy et al. (2003, *Nature Biotechnology*, 21, 1233) and Matsuzaki et al. (2004, *Genome Research*, 14, 414) recently described a methodology termed 'whole genome sampling assay', or WGSA, which utilizes restriction enzyme digestion and PCR to convert genomic DNA into a form that is amenable to highly multiplexed amplification using a single generic primer. This method has been used to genotype 117,000 SNPs in the 30 CEPH trios that are part of the HapMap population collection. We compared approximately 22,000 markers, that had been genotyped in both the HapMap project and using WGSA, in the 90 CEPH individuals. Over 99.6% of the approximately 2,000,000 individual genotypes were called with a concordancy of 99.7%, thereby demonstrating the highly accurate nature of the method. Improvements to the process include the use of 5 um features, which allows for tiling of 250,000 SNPs per array, and the use of alternative restriction enzymes which impacts both the complexity of the target and maximizes the number of SNPs within the target. Lastly, we will present a statistical analysis which will allow one to predict SNP distribution prior to WGSA screening.

Fine mapping of candidate regions for human narcolepsy with high density markers. *M. Kawashima¹, T. Ikuta², G. Tamiya², H. Hohjoh¹, T. Juji³, Y. Honda⁴, H. Inoko², K. Tokunaga¹.* 1) Dept Human Genetics, Tokyo Univ, Tokyo, Japan; 2) Department of Molecular Life Science, Tokai University school of medicine, Kanagawa, Japan; 3) Japanese Red Cross Central Blood Center, Tokyo, Japan; 4) Sleep Disorder Clinic of Seiwa Hospital, Tokyo, Japan.

Human narcolepsy is considered to be a sleep disorder that is affected with multiple genetic and environmental factors. A genetic factor strongly associated with the disorder has been found in the human leukocyte antigen (HLA) region: HLA-DRB1*1501-DQB1*0602 haplotype. As a tool for finding susceptibility regions other than HLA, a genome-wide association study using about 25,000 microsatellite markers with pooled DNAs was performed. The subjects investigated in this study were all Japanese living in the Tokyo area. Allele frequencies in patients and controls were estimated from heights of the peaks detected by an automated sequencer (ABI 3700) with GeneScan software. After the 1st and 2nd screening, 327 microsatellite markers showed differences by mean of at least one statistical method of which forty microsatellite markers were in HLA region due to linkage disequilibrium with HLA-DR, DQ genes. The associations were confirmed with individual samples (cases: 95, controls: 95), and 14 markers still showed statistical differences. Three markers showed strong associations in the analysis using all the available samples (cases: 228, controls: 420, $p < 0.001$). Then, the three candidate regions were subjected to high-density mapping using additional microsatellite markers and were narrowed down to 40-100kb. For one of the candidate region, fine mapping using SNPs with the average distance of 5kb was performed for further narrowing down. As a result, two SNPs close to the microsatellite marker showed stronger associations than the microsatellite marker ($p < 0.0002$). In the region, no known genes but 3 predicted genes were reported in database.

Genotyping over 100,000 SNPs on a Pair of Oligonucleotide Arrays. *R. Mei¹, S. Choudhry², H. Matsuzaki¹, H. Tang³, H. Loi¹, H.-J. Tsai², S. Dong¹, N. Ung², J. Law¹, H. Matallana², N. Battle², W. Rodriguez⁴, S. Narzarrio⁴, J. Casal⁴, G. Marcus¹, S. Walsh¹, M. Shriver⁵, K. Jones¹, E. Ziv², E. Burchard².* 1) Dept Research & Development, Affymetrix, Santa Clara, CA; 2) University of California San Francisco; 3) Fred Hutchinson Cancer Center; 4) University of Puerto Rico; 5) Penn State University.

Single nucleotide polymorphisms (SNPs) are emerging as the marker of choice for a broad spectrum of genetic analyses, and in particular the study of complex human diseases. Here we present a high throughput genotyping platform that uses a one primer assay to genotype over 100,000 SNPs per individual on a pair of oligonucleotide arrays. The selection of SNPs was based on computer predictions of restriction fragments that are likely to contain the SNPs, and further driven by strict empirical measurements of accuracy, reproducibility and average call rate. We estimated call rates > 99%, reproducibility is > 99.99% and accuracy, as measured by inheritance in trios and concordance with the HapMap Project, is > 99.7%. Average inter-marker distance is 23.6 kb, and 92% of the genome is within 100 kb of the SNPs. Average heterozygosity is 0.30, with 105,511 SNPs having minor allele frequencies > 5%. We used the SNP arrays to perform a whole genome admixture mapping experiment for asthma susceptibility loci among Puerto Ricans that are known to be an admixed group with European, African and Native American ancestry. Recently admixed populations such as Puerto Ricans offer potential benefits in association studies since markers informative for ancestry may be in linkage disequilibrium across large distances. We genotyped 30 Native American, 30 West African and 42 European American individuals on the SNP arrays to identify ancestry informative markers which were further used for an admixture mapping study that included 165 Puerto Rican asthmatics with severe asthma (defined as FEV1 < 80% predicted) and 165 matched controls to identifying genes for asthma-related traits in Puerto Ricans. We propose that this novel technology is a promising approach for efficient admixture mapping for complex traits.

Program Nr: 1611 from the 2004 ASHG Annual Meeting

Extracting SNP genotypes from Affymetrix GeneChip DNA Analysis product for analysis. *J. Salit, P. Bonnen, J. Friedman, M. Stoffel, J. Breslow, Affymetrix.* The Rockefeller University, New York, NY.

An integral part of any genotyping effort is to prepare the data for analysis. At The Rockefeller University as part of the on-going genome-wide SNP genotyping of the Kosrae population we have built a software application that extracts data from the Affymetrix GeneChip DNA Analysis product. Using the licensed, object-oriented Java version of the Affymetrix Software Development Kit (SDK) we have created an application with a simple user-interface for converting and filtering the SNP genotype data to text files. This interface allows the user to select the output file formats, the samples to export, and the chromosomal regions that will be used to filter the SNPs. In keeping with the Java environment AffymetrixSNP marker objects are created from the Affymetrix annotation files to hold marker information like chromosomal location and the mapping of SNP calls to nucleotides. RUSubject objects store the personal attributes of each sample like gender and parents as well as a collection of AffymetrixGenotype objects that store each genotype call and know how to format that call for different export options. A CHPReader knows how to get the contents of an Affymetrix CHP file and extract the SNP genotype calls for the sample associated with that CHP file. These and other objects work together with the Affymetrix SDK to bridge the pipeline between genotype data generation and analysis by creating the analysis input files.

Testing the Centurion GeneChip Technology as a Platform for Genotyping 100,000 SNPs. Z. Xue¹, L.P. Briley¹, S.A. Shouse¹, K.M. Long², M.G. Moore², K.L. Nangle², D.P. Yarnall¹, J.D. Briley¹, D.D. Kelly¹, D.Z. Zaykin¹, K.G. Au³, A.C. Gatherum¹, M.G. Ehm¹, S.L. Chissoe¹, A.M. Saunders¹, N.K. Spurr¹, E.H. Lai¹. 1) Discovery & Pipeline Genetics, Glaxo Smith Kline, RTP, NC; 2) Bioinformatics, Glaxo Smith Kline, RTP, NC; 3) Genomic & Proteomic Sciences, Glaxo Smith Kline, RTP, NC.

The Affymetrix GeneChip Mapping 100K Set is a pair of oligonucleotide microarray chips that offers the ability to generate more than 100,000 SNP genotypes simultaneously for one subject from 500 ng of genomic DNA at a cost of ~\$0.01 per genotype. We tested the pre-production technology called Centurion as a method for genotyping 100,000 SNPs at once. In this pilot study, 30 CEPH subjects and four duplicates were genotyped on the chips in 3-4 weeks. An average of more than 111,500 SNP genotypes were called per subject. Genotypes from four duplicate samples typed on different chips were greater than 99.99% concordant. In this small Caucasian sampling, there were approximately 8,100 SNPs that were out of Hardy-Weinberg equilibrium ($p < 0.001$) and about 10% of the SNPs were monomorphic. While additional testing is necessary and currently underway, the GeneChip Mapping 100K Set has the potential to be a fast, accurate, cost-effective means of genotyping 100K SNPs at once.

High Stability Vectors for Cloning Trace Amounts of Unstable DNA. *H. Burrell, R. Godiska, M. Patterson, D. Mead.* Lucigen, Middleton, WI.

Large sections of eukaryotic, viral, and microbial genomes are refractory to cloning with conventional host-vector systems. This apparently unclonable DNA results in cloning gaps, rearranged sequences, or a complete inability to clone particular regions, especially those that are AT-rich or encode toxic peptides. Most plasmid vectors induce transcription and translation of inserted fragments, which is responsible for much of the DNA instability. The pSMART series of transcription-free cloning vectors were developed to alleviate these problems. The utility of these vectors was demonstrated by stably cloning several classes of substrates that were unstable or unclonable in conventional vectors, such as:

- Telomeric repeats and other AT-rich fragments from *Pneumocystis carinii*.
- >10 kb clones of *Tetrahymena thermophila* genomic DNA(75% AT).
- Toxic regions of the mouse hepatitis virus genome.
- cDNAs from a fish cardiac muscle library.
- Strong promoters from phage lambda.

Additional methods were developed to clone trace amounts of DNA from uncultured viruses and environmental phage. Unidentified base modifications have been accommodated by these methods, as the genomes of previously unclonable marine bacteriophage and several unculturable bacteria have been cloned. Nearly undetectable amounts of Inoue-Melnick virus were cloned and sequenced using these methods. Further improvements are being undertaken to clone genomic DNA and cDNA from single cells.

The entire mitochondrial DNA analysis of 9 MELAS patients with an A3243G mutation. *I. Kaori¹, Y. Akita¹, N. Povalko^{1,2}, K. Hirata¹, J. Nishioka¹, M. Nishimura¹, C. Mitsumasu¹, Y. Koga¹.* 1) Pediatrics and Child Health, kurume university school of medicine, Kurume, Fukuoka, Japan; 2) Laboratory of Inherited Metabolic Disease, Research Centre for Medical Genetics, RAMN, Russia.

MELAS (Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes), one of the subtype of mitochondrial disorders, is caused by the mutation of mtDNA (mitochondrial DNA). Investigating all the pathogenic mutations or polymorphisms of mtDNA which affects biochemical functions is important to consider the genotype-phenotype correlation in each patient at molecular level. We have analyzed 9 MELAS patients who were diagnosed clinically, muscle-histochemically, and genetically. The mitochondrial DNA was extracted from the blood or muscle biopsy specimens from patients using previously described methods. We have analyzed the entire sequence of mtDNA by described methods. The complete mitochondrial genome was amplified by long-PCR method in 7 overlapping fragments using 14 primers and followed by the ExoSap-IT treatment (USB Corporation, USA), and CEQ Dye Terminator Cycle Sequencing kit (Beckman Coulter, Inc.). The sequences were assembled in a contig using the program DNASIS Pro (Hitachi Software Engineering Co, Ltd, Japan) and the resulting contig was aligned to the Cambridge sequence. We have also analyzed any base change by designated a primer-set and suitable restriction enzyme using PCR-RFLP methods. All MELAS patients have an A3243G mutation in the mitochondrial tRNA^{Leu}(UUR) gene. We have found 13 mtSNPs in Non-coding regions, 10 in ribosomal regions, 2 in tRNA regions (including A3243G), and 47 in protein-coding regions. Among 9 MELAS patients, one has a heteroplasmic nonsense mutation in the COX II gene in addition to the A3243G. This patients showed denovo mutation according to the genetic analysis in the family members and showed more severe clinical phenotype among our MELAS patients. We have successfully constructed an Automated Sequence of the entire mitochondrial genome, and found 72 mtSNPs in 9 MELAS patients rapidly and effectively.

Re-sequencing as a precise method for estimating SNP allele frequencies in pooled DNA. *V. Kodavali¹, A. Northup¹, S.A. Bacanu², J. Wood¹, P. Levitt³, K. Mirnics⁴, D.A. Lewis⁵, B. Devlin², V.L. Nimgaonkar¹.* 1) WPIC, Univ Pittsburgh, Pittsburgh, PA, USA; 2) Department of Psychiatry, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 3) John F. Kennedy Center for Research on Human Development and Department of Pharmacology, Vanderbilt University, Nashville, TN 37232, USA; 4) Department of Psychiatry, University of Pittsburgh, School of Medicine, E1453 Biomedical Science, Pittsburgh, Pennsylvania 15261, USA; 5) Department of Psychiatry, University of Pittsburgh, 3811 O'Hara Street, W1651 BST, PA 15213, Pittsburgh, USA.

To evaluate re-sequencing as a tool for estimating allele frequencies from pooled DNA samples, we measured peak heights from re-sequencing traces. Twenty six known SNPs were initially genotyped in pools from 200 controls and 200 patients with schizophrenia (frequencies of less common SNP alleles: 1.75% - 50%). These estimates were compared with frequencies determined from individual genotypes of the same samples using an accurate allele-specific extension method based on the ligation reaction (Illumina Inc.). There was a highly significant correlation between the two methods for individual SNP allele frequencies ($r = 0.984$, $p = 0.001$, $n = 26$ SNPs, 52 pools), as well as case-control differences ($r = 0.958$, $p = 0.001$, $n = 26$ comparisons). The standard deviations (SD) for quadruplicate assays were comparable to other methods for pooled genotype assays (mean 0.018, range 0 - 0.109). SD values for separately prepared pools using 50 samples were comparable to the larger pools, when 10 SNPs were analyzed separately (mean 0.018, range 0.005 - 0.076). The re-sequencing method provides a reliable, economical, single step process for surveying genomic regions, detection of SNPs and estimation of allele frequencies. Pooled DNA samples thus provide a precise method both for detecting SNPs and for estimating their frequencies in large cohorts. By obviating the need for genotype assays, it also provides economy.

Identification of rare β -thalassemia mutations and Hb South Florida by genomic sequencing in the Malay, Chinese and Indian ethnic group in Malaysia. *J.A.M.A. Tan¹, P.S. Chin¹, Y.C. Wong¹, K.L. Tan¹, E. George², L.L. Chan³.*

1) Department of Molecular Medicine, University of Malaya, Kuala Lumpur, Malaysia; 2) Department of Clinical Laboratory Sciences, Faculty of Medicine and Health Sciences, University Putra Malaysia; 3) Department of Pediatrics, University of Malaya.

Malaysia's population of 22.7 million comprise of Malays 47.2%, Chinese 24.9%, Indians 7% and other races 13.9%. Beta-thalassemia is common in the Malays and Chinese with a heterozygous carrier rate of about 4.5%. Five common β -globin mutations present in the Chinese - FS 41/42 (-CTTT), IVS2-654 (C-T), -28 (A-G), CD 17 (A-T) and FS 71/72 (+A) - account for 92% of β -thalassemia. Four rare β -mutations at CD 26/Hb E (G-A), CD 15 (G-A), Cap (+1) (A-C) and -29 (A-G) account for a further 4% of β -thalassemia in this race. In the Malays, three β -globin mutations at CD 26/Hb E, IVS1-5 (G-C) and IVS1-1 (G-T) account for 73% of β -thalassemia while six other β -mutations at FS 41/42, IVS2-654, FS 8/9 (+G), CD 17, CD 19 (A-G) and Cap (+1) account for a further 12% of the identified mutations. Thus, using the ARMS and Gap-PCR, rapid and specific confirmation of β -globin mutations can be identified in 96% and 85% of the Malaysian Chinese and Malays respectively. Genomic sequencing of a 904 bp region of the β -globin gene (294 bp upstream of the Cap site to 113 bp downstream of the IVS2-1 site) was carried out to identify the uncharacterized β -alleles. Six rare β -globin mutations and one hemoglobin variant were confirmed: in the Malays - FS 16 (-C), IVS1-1 (G-A), IVS2-1 (G-A), -86 (C-G), Hb South Florida (CD 1, G-A); in the Chinese - FS 27/28 (+C), CD 43 (G-T, 2 patients) and in the Indians -88 (C-T). These rare β -mutations had been reported in very low frequencies (3%) in different ethnic groups/populations, except for -88 (observed in the American Blacks at 21.1%). Hb South Florida does not cause any significant clinical problems and has been previously reported only once in a Caucasian family. In heterozygotes, Hb South Florida has been reported to be present in levels of 12-20% and about 20% of the protein is acetylated at the NH₂ terminus of the β -chain.

From large-scale RT-PCR cloning to identification and characterization of alternative splicing. *J.Q. Wu, S. Hulyk, A. Garcia, Y. Yuan, A. Sneed, C. Kowis, E. Fuh, K. Haeberlen, I. Yakub, J. McPherson, P. Gunaratne, R.A. Gibbs.* Human Genome Sequencing Ctr, Baylor Col Medicine, Houston, TX.

Alternative splicing plays a major role in the production of diversity in the human proteome. Alternative splicing patterns have served as prognostic markers and drug targets in human diseases including cancer. Although analysis of expressed sequence tag (EST) and microarray data has provided useful information about alternative splicing, it can not be determined whether the splicing of multiple variable regions with an individual transcript is coordinated. Only sequencing full length cDNA can resolve these cases. In previous publication, we have described a genome-wide RT-PCR cloning pipeline to collect full-length cDNAs. This pipeline also allows us to capture novel splice variants: about 50% of subclones generated from our pipeline have sizes different than the corresponding Refseq transcripts. We searched for the subclones that have end sequences matching the targeted genes. This resulted about 2000 subclones that are potential splice variant. We have full-length sequenced 133 subclones, and observed 42 deletion clone and 18 insertion clone. In order to confirm the alternative splicing events, junction specific primers have been designed for 41 potential splice variants and the corresponding Refseq transcripts of each gene. About 35% novel splice events were verified by RT-PCR and direct sequencing. In order to explore the biological significance of the alternative splicing events, we selected genes implicated in cancer, such as WISP1, to characterize their relative expression level in cancer tissues to adjacent normal tissues by quantitative real-time PCR. Alternatively spliced transcripts show cancer type specific up- or down- regulation. Our results implicate the variation of protein domains potentially influences protein function, and the ratio of alternative transcript / Refseq transcript may underlie the cancer mechanism.

Program Nr: 1618 from the 2004 ASHG Annual Meeting

Resequencing of 2.5 MB of the ENCODE region in 48 individuals from 4 ethnic groups. *I. Yakub, H. Arredondo, S. Doyle, J.Q. Wu, A. Hodgson, L. Lewis, X. Wei, D. Muzny, D. Wheeler, J. Belmont, R. Gibbs.* Human Genome Sequencing Center, Baylor Col Medicine, Houston, TX.

As part of the International HapMap project, the Human Genome Sequencing Center at Baylor College of Medicine has resequenced a 2.5 MB of the ENCODE region in 48 individuals from 4 different ethnic groups consisting of Caucasians, Yorubans (Nigeria), Chinese and Japanese. The 2.5 MB region consists of five 500 KB segments on chromosomes 7p15.2, 8q24.11, 9q34.11, 12q12 and 18q12.1. In order to span this entire 2.5 MB region using 750bp amplicons, we designed 8340 primers to generated 4170 amplicons. Using a multiplex (6-plex) PCR strategy, we carried out 66,720 PCR reactions and setup 400,320 sequencing reactions to resequence all 48 individuals. To meet these needs, we established a re-sequencing pipeline that includes large-scale primer design, automated PCR and sequencing reactions in 96-well and 384-well formats, data management tools and automated data-analysis and SNP detection software. The data obtained from this study is allowing us to determine the smallest haplotype blocks in this region and give us an estimate of the SNP density needed to obtain an accurate haplotype map of the genome. We will also be able to determine the amount of variation in this region among different ethnic groups, frequency of rare variants- both synonymous and non-synonymous and SNP density in relation to gene structure. A subset of the novel SNPs discovered in this study will be further genotyped in 270 individuals from the four different ethnic groups.

Genotyping performance of whole genome amplified DNA derived from genomic DNA templates of variable quantity and quality. *A.W. Bergen^{1,2}, Y. Qi², K. Haque², M. Beerman², C. Glaser², I. Barrow², J. Hartwell², R. Welch², M. Garcia-Closas¹, P. Castle¹, N. Rothman¹, S. Chanock^{1,2}.* 1) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 2) Core Genotyping Facility, NCI, Bethesda, MD.

The promise of whole genome amplification (WGA) is that genomic DNA (gDNA) need not be a limiting factor for molecular genetic analysis. We evaluated the performance of commercially available MDA WGA protocols using gDNA derived from lymphoblastoid cell lines (N=27), buccal cells from cytobrushes (N=20), and buccal cells from expectorated mouthwash (N=48 matched irradiated and unirradiated samples) to provide both non-degraded and degraded gDNA inputs. An input range of 1-100ng of gDNA into WGA was used. Analysis of wgaDNA was performed using three DNA quantification methods and N=15 STR and N=49 loci SNP genotyping assays performed in duplicate on every gDNA and wgaDNA sample for N=17,632 STR and N=104,486 SNP genotypes attempted. These analyses of wgaDNA were designed to characterize the yield and composition of the wgaDNA, genotyping completion and concordance rates, and the samples and assays that failed to produce genotypes from wgaDNA. Relative amounts of double-stranded and human-specific wgaDNA increased with increasing gDNA input. Genotyping performance of wgaDNA was significantly reduced compared to that of gDNA. For example, non-degraded gDNA STR/SNP completion rates were 100%/99.7%, and STR completion rates were more severely affected (95% or 64%) than SNP completion rates (96% or 81%) by reduced gDNA quantity and quality (1ng non-degraded or degraded gDNA, respectively). Increasing amounts of gDNA template improved wgaDNA genotyping performance, though not optimally for wgaDNA derived from degraded gDNA. Reduced wgaDNA genotyping performance was primarily due to the increased variance of allelic amplification, resulting in LOH or increased undetermined genotypes. Other variables affecting wgaDNA genotyping performance included increased %GC content and WGA reagent source. Optimal genotyping performance of wgaDNA was not obtained without at least 10ng of non-degraded gDNA template.

Comparison of buccal cell collection methods on DNA yield and quality. *J. Chang, K. Heard, C. Sanders, G. Satten, K. Steinberg, M. Gallagher.* CDC, Atlanta, 30341.

Buccal cell collection is a noninvasive, economical, and convenient means for obtaining DNA for clinical and research studies. However, unlike whole-blood specimens, buccal swabs yield varying amounts and quality of DNA. We evaluated DNA yields from buccal swabs collected by two methods. With method 1, study participants used cytology brushes to self-collect buccal swabs. Participants then placed the swabs in the manufacturers plastic storage tube and mailed them to us. With method 2, nurses either collected or supervised the self-collection of buccal swabs by participants using cytology brushes. The nurses sprayed the collected swabs with alcohol. No significant differences existed between the average total DNA yields of two groups, although 10.6% of the self-collected samples had a concentration 0.1 ng/L, while none of the nurse-collected samples were below this concentration. To further evaluate the quality of DNA in these samples, we performed microsatellite analysis of D7S1797 and D13S317 in triplicate on 109 nurse-collected and 113 self-collected buccal swabs. All 109 of the nurse-collected specimens were successfully amplified in triplicate for both microsatellite markers; the replica results were 100% concordant. In contrast, only 101 of the 113 self-collected specimens were positive for both microsatellite markers in all three replicate reactions. Of the 101 repeat-positive specimens, 10 yielded discordant results due to allelic dropout: 6 had discordant D13S317 results, 1 had discordant D7S1797 results, and 3 had discordant results for both microsatellite markers. DNA concentrations 0.1 ng/L were strongly associated with amplification failures and allelic dropout ($p=2 \times 10^{-7}$, D7S1797; $p=7 \times 10^{-7}$, D13S317). One of the major differences between the two collection methods was the alcohol treatment of the swabs in the nurse-collected group. This treatment may serve to reduce bacterial growth that may cause DNA degradation. Although collection of buccal swabs by mail is convenient and economical, poor-quality specimens may have a significant effect on downstream applications. Thus, the method of collection should be carefully considered.

Program Nr: 1621 from the 2004 ASHG Annual Meeting

TaqMan-based Real-time Quantitation of MicroRNAs. *C. Chen, D. Ridzon.* Genomics R&D, Applied Biosystems, Foster City, CA.

We developed a new quantitative real-time assay for mature microRNAs (miRNAs) that employs the specificity of ligation, and the sensitivity and accuracy of standard real-time 5' nuclease assays. A total of 24 miRNA targets were successfully designed and tested. Ct values were highly correlated to the input target quantity ($R^2 = 0.998$) over six orders of magnitude. The level of miRNA expression ranged from 0 to 4,814 copies per cell in seven different tissues or cell lines from human and mouse. Of 24 miRNAs examined, mir-16 is the most abundant, particularly in the thymus. Similar patterns of miRNA expression were observed in human and mouse. These results are consistent with previously published Northern data. In addition, no effect of background genomic DNA on quantitation was found. In summary, this TaqMan-based real-time quantitation of miRNAs is fast (~3 h), specific, accurate, and sensitive, allows for high-throughput screening of all possible miRNAs, and can be performed from as little as 1 ng of total RNA. Possible applications of this new technology include the validation of *in silico* predicted miRNAs and miRNA profiling in tissue or cell samples within or between species.

A Whole Genome Quantitative Association Study Using Data from the HapMap Project. *J.C. Engert¹, L.J. Oksanen², M. Lemire², B. Ge², S. Gurd², D. Shah¹, T.J. Hudson^{1,2}, T. Pastinen².* 1) Depts Medicine & Human Genetics, McGill University, Montreal, PQ, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, PQ, Canada.

We have performed a large-scale survey of quantitative variation that is associated with specific haplotypes that have been determined by the HapMap project. The single nucleotide polymorphism (SNP) alleles from the Utah portion of HapMap project were scored from the lymphoblast cell lines (LCLs) of 30 CEPH trios. Thus, if we examine quantitative traits in the unrelated parents of these trios (the exact cell lines from which was derived the HapMap data), our experiments are the equivalent of performing a whole genome association scan in 60 individuals. Our criteria for quantitative trait selection included stable, well characterized traits, that are preserved in lymphocytes. We believe that these cells can be an appropriate cell model for a variety of human metabolic systems. Approximately 600,000 SNPs are now available from the HapMap project for genomewide studies with approximately 400,000 having an allelic frequency of at least 0.025. Our initial experiment was to examine the mRNA level of the low density lipoprotein receptor (LDLR) as a quantitative trait. We have previously demonstrated heritability of mRNA levels in pedigrees from CEPH families. In addition, one of the key responses to statin treatment is an increase in LDLR and this response has been shown to be preserved in lymphocytes. We will present data from baseline LDLR as well as after statin treatment. Combining the detailed genetic information provided by the HapMap from human cell lines with biomedically relevant quantitative phenotypes collected from these same cell lines will demonstrate great utility. This approach should identify many new candidate genes/regions and this technique should be applicable to many complex traits and their associated biochemical pathways.

High-throughput genetic, epigenetic and gene expression analyses of cancers using an integrated BeadArray technology. *J. Fan¹, M. Bibikova¹, E. Wickham¹, E. Chudin¹, J. Yeakley¹, L. Zhou¹, D. Barker¹, M. Chee¹, Z. Lin², J. Floros², N. Thomas², Y. Wang², C. Seifart³, M. Kostelec⁴, J. Modder⁴, T. Downs⁴, J. Wang-Rodriguez⁴.* 1) Illumina, Inc, San Diego, CA; 2) Penn State University, Hershey, PA; 3) University of Marburg, Germany; 4) VA San Diego Healthcare System, San Diego, CA.

We have developed a versatile BeadArray technology for high-throughput genomic analysis in large populations. The arrays are made of beads located in microwells of optical fiber bundles or silicon slides. Both formats support multi-sample analysis with the optical fiber bundles formatted into a matrix that matches a 96-well microtiter plate and the silicon slides divided into discrete sites compatible for loading multiple samples on to a single silicon slide using a multi-channel pipette. A series of cancer studies are conducted on this system: (1) 1152 cSNPs derived from 377 cancer related genes are genotyped with paired gDNA and RNA isolated from 96 lung cancer tissues and 30 cancer cell lines. As a result, a comprehensive genetic and allele-specific expression profile is created. In addition, a targeted LOH and gene amplification analysis is carried out at these genes, coupled with a genome-wide scan using 4600 highly polymorphic SNPs. (2) DNA methylation status is monitored for 375 CpG sites located in the promoter regions of 143 genes in 104 lung cancer and normal samples. Multiple squamous cell carcinoma specific and adenocarcinoma specific methylation markers are identified ($P < 0.001$) and further validated in an independent sample set ($N=46$). (3) Expression profiles of 512 candidate genes are generated for 240 formalin-fixed, paraffin-embedded prostate carcinomas and 60 benign hyperplastic prostates with at least 5 years of clinical follow up, and are used to identify specific molecular markers that correlate with the following clinical parameters: tumor type and grade, organ confined disease vs. locally advanced tumors, therapeutic response and overall prognosis. These projects should help correlate genetic, epigenetic and gene expression profiles to the most important clinical parameters in a large set of clinical samples.

Identification of disease susceptibility genes using the CEQ 8800 Genetic Analysis System. *E. Hayashi*¹, *H.-C. Chi*², *S.K. Boyer*², *D.W. Still*¹. 1) Department of Horticulture/Plant & Soil Science, California State Polytechnic University Pomona, Pomona, CA; 2) Biomedical Research Division, Beckman Coulter, Inc., Fullerton, CA.

Whole-genome scans have proven to be a powerful and efficient method to identify diseases caused by single genes using microsatellite and single-nucleotide polymorphism (SNP) analyses. However, the majority of diseases are effected by complex *gene x gene* and *gene x environment* interactions. The mapping of such factors is complicated by the population structure of the sample populations and spurious associations can easily be made. In genome-wide association studies it is necessary to test at least thousands of SNPs because of the limited amount of linkage disequilibrium in the human genome. Further, because of the difficulties attributed to mixed populations and the inability to control environments in human population studies, alternative approaches to mapping human diseases have been developed. These include the mapping of quantitative trait loci (QTL) on genetically distinct organisms, such as mice and rats. The aim of QTL analysis is to detect linkage between the phenotypes and genetic markers and to assign levels of significance to each detected QTL. Most often SNPs and microsatellites are used in these studies, but other marker technologies can be used as well. The CEQ 8800 Genetic Analysis System is capable of generating a variety of data that can be used to map QTLs associated with phenotypes. We present data using a model organism and discuss several approaches by which marker scaffolds can be utilized to facilitate identification of QTLs and determine the conservation of the QTLs in non-model organisms in comparative genomic studies.

A quality control platform for spotted 70-mer microarrays. *M. Hessner*¹, *L. Meyer*¹, *V. Singh*², *T. Zahrt*², *X. Wang*¹.
1) Dept Pediatrics/Endocrinology, Medical College of Wisconsin, Milwaukee WI; 2) Dept Microbiology/Molecular Genetics, Medical College of Wisconsin, Milwaukee WI.

Spotted 70-mer arrays offer potentially greater specificity and an alternative to laborious use of cDNA libraries. Since microarray fabrication is a considerable source of data variance, we previously directly tagged cDNA probes with fluorescein allowing for prehybridization visualization and development of array quality control (QC) thresholds. Likewise, labeling of oligonucleotide probe sets could offer the same benefits, however, this practice is currently cost-prohibitive. Therefore, a *Staphylococcus aureus*-derived, fluorescein-labeled tracking oligonucleotide, was added at low-molarity into the printing buffer to allow indirect monitoring and optimization of fabrication variables for rat and *Mycobacterium tuberculosis*-specific oligonucleotide arrays. The tracking oligonucleotide did not effect hybridization efficiency or introduce ratio measurement bias in hybridization data. Linearity between the mean log Cy3/Cy5 ratios of genes differentially expressed from arrays either possessing or lacking the tracking oligonucleotide was observed ($R^2=0.90$, $p<0.05$). There were also no significant differences in Pearson's correlation coefficients of ratio data between replicates possessing (0.72 ± 0.07), replicates lacking (0.74 ± 0.10), or replicates with and without (0.70 ± 0.04) the tracking oligonucleotide. ANOVA analysis confirmed that the tracking oligonucleotide introduced no bias. Titrating target-specific oligonucleotide (40 μ M to 0.78 μ M) in the presence of 0.5 μ M tracking oligonucleotide, revealed a fluorescein fluorescence inversely related to target-specific oligonucleotide molarity, making tracking oligonucleotide signal useful for quality control measurements and differentiating false negatives (synthesis failures and mechanical misses) from true negatives (no gene expression). Therefore, a slide qualification strategy, as well as putative array and spot acceptance criteria have been developed. Finally, this novel, inexpensive, approach is useful for more sophisticated post-hybridization applications including automated image analysis and data filtering.

DNA isolation and amplification from Formalin Fixed, Paraffin Embedded Tissues. *K.E. Jones¹, A.A. Camargo², P. Simpson³, R. Deadman¹.* 1) GE Healthcare, Piscataway, NJ; 2) Laboratory of Molecular Biology and Genomics, Ludwig Institute for Cancer Research, So Paulo, Brazil; 3) The Breakthrough Toby Robins Breast Cancer Research Centre, Institute of Cancer Research, London, England.

Large scale genetic analysis studies require the availability of large amounts of genomic DNA. Patient tissues are frequently preserved in formalin and embedded in paraffin for long term storage and ease of transport. However, genomic DNA extracted from these sources is limited in quantity and poor in quality, making it insufficient for whole genome analysis. Current DNA extraction methods generally yield short DNA fragments and it is only possible to PCR amplify regions of less than 1 kb from the extracted DNA. PCR-based whole genome amplification methodologies such as degenerate oligonucleotide primed PCR (DOP-PCR) have not provided an adequate solution to the problem. Recently, an alternate approach has been introduced. Genomic DNA is amplified by multiple-primed linear amplification using the highly processive, strand displacing enzyme Phi29 DNA polymerase. This poster will describe an evaluation of genomic DNA extraction methods from paraffin embedded formalin fixed tissue and amplification using Phi29 DNA polymerase.

Studying human populations using 100,000 genome-wide SNPs on synthetic DNA microarrays. *G. Kennedy¹, M. Cao¹, M. Kennedy¹, M. Taub²*. 1) Genomics Collaborations, Affymetrix, Santa Clara, CA; 2) Department of Statistics, UC Berkeley, Berkeley, CA.

We used a recently described genotyping technology (Kennedy et al. 2004) to rapidly genotype >116,000 SNPs (including 2,334 SNPs on the X chromosome) in a variety of human and ape DNA samples. We constructed haplotypes using Merlin (Abecasis et al. 2003) and studied recombination patterns in 3-generational CEPH families. We found larger recombination fragment lengths and higher variability on the X chromosome (mean=41 Mb + 57Mb) than on autosomes (mean=24 Mb + 28 Mb) but found no major differences in fragment length or variability between males and females. We calculated Wrights F_{st} statistic, a measure of population structure, for SNPs in three human populations (Caucasian, Asian and African-American). When comparing African and non-African populations we found evidence for significantly increased F_{st} values on the X chromosomes relative to the autosomes. In contrast, we found no statistically significant difference in F_{st} values between X and autosomes for the two non-African populations. We assigned ancestral alleles to 69,500 SNPs by genotyping chimpanzee and gorilla DNA on the human microarrays. LD analysis indicates that many of the high- F_{st} SNPs on the X chromosome are located in blocks consisting of non-ancestral alleles that have achieved high frequency. These data suggest that large regions on the X chromosome may have undergone selection and are consistent with the hypothesis that migration of Caucasian and Asian populations out of Africa may have been accompanied by a population bottleneck or other demographic event(s). Genotyping using high-density microarrays provides a rapid and facile method for determining allele frequencies in various populations and for studying recombination patterns at high resolution in pedigrees.

A novel method for genotyping the angiotensin 1-converting enzyme insertion/deletion polymorphism utilizing the MGB™ Eclipse system and dissociation curve analysis. *D. Koontz, S. Nikolova, M. Gallagher.* CDC, Division of Laboratory Science, NCEH, Molecular Biology Branch, Atlanta, GA.

Angiotensin I-converting enzyme (ACE) is important in blood pressure regulation and electrolyte balance, and its influence on the susceptibility to coronary heart disease is being extensively studied. The insertion/deletion (I/D) polymorphism in intron 16 of this gene accounts for much of the interindividual variability of plasma ACE concentration. To date, the most commonly used methods for genotyping this polymorphism involve conventional PCR, nested PCR, or PCR-RFLP followed by gel-based fragment size analysis. These methods are labor intensive, require a large quantity of DNA, are prone to mistyping, and are not easily automated for studying large numbers of samples. We have developed sensitive insertion-specific and deletion-specific assays using the MGB™ Eclipse probe system (Epoch Biosciences) with subsequent dissociation curve analysis to accurately and reliably detect all three genotypes (DD, ID, and II). This hybridization-triggered fluorogenic probe system utilizes a minor groove binding ligand that forms hyperstabilized duplexes with complementary DNA. The reaction occurs in a single well, uses nanogram amounts of DNA, and requires only endpoint analysis of results. We analyzed DNA from three CEPH families to demonstrate consistency with Mendelian inheritance. In addition, the assays were performed on 50 anonymized DNA samples from volunteers and 90 samples from the Coriell Polymorphism Discovery Resource designed to reflect the diversity in the human population (European American=27%, African American=27%, Mexican American=13%, Native American=6%, Asian American=27%). No significant deviation was found in expected genotype distributions when compared with other reports. All results were found to be 100% concordant with conventional PCR. Here we present a rapid, sensitive, and accurate nongel-based method which, unlike similar assays involving the use of SYBR Green dye, is highly specific with the use of gene-specific probes. The method is easily adapted to any automation platform for the analysis of the ACE I/D polymorphism in large sample populations.

A NOBLE SNP TYPING METHOD BASED ON DNA COMPUTING. *N. Nishida*¹, *K. Hirayasu*¹, *M. Takasu*¹, *A. Suyama*², *K. Tokunaga*¹. 1) Department of Human Genetics, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, Japan; 2) Department of Life Sciences, The University of Tokyo, 3-8-1 Komaba, Meguro-ku, Tokyo, Japan.

As a consequence of Human Genome Project and SNP discovery projects, a number of SNPs, which include susceptibility SNPs for common diseases, have been revealed. There has been a great urge to develop a highthroughput SNP typing method with high accuracy and low cost. Here, we show a noble SNP typing method based on DNA computing. In the DNA computing based analysis, we prepared internal codes which we call DNA coded numbers (DCNs). DCNs have optimum properties in physical and chemical aspects so as to execute each DNA computing process precisely. DCNs consist of three parts; named SD, D1 and ED. SD and ED are commonly prepared at both edges over all DCNs and are used for common priming sites in PCR. D1s are different among DCNs and are used to identify SNPs of interest. During the SNP typing by DNA computing, the information of genotype is converted to one of DCNs by one to one manner using oligonucleotide ligation assay. After the encoding reaction from genomic information to DCNs is accomplished, PCR is executed to increase the signal intensity and then SNP genotype is read out by detecting the type of DCNs using capillary array. There are some advantages in DNA computing based method. To use the same set of well-designed DCNs enables us to perform SNP typing with high accuracy. Oligonucleotide ligation assay, engaged in the encoding reaction, enables us to execute multiplex SNP typing. The same set of DCNs is universally used for all types of application such as gene expression profiling and SNP typing, ensuring low cost analysis of genomic information.

Novel genes associated with risk and age-at-onset in Parkinson disease identified through iterative association mapping. *S.A. Oliveira, Y.J. Li, X.J. Qin, S. Züchner, M.A. Nouredine, M.A. Hauser, T. Skelly, S. Ebersviller, M.A. Pericak-Vance, J.M. Vance.* Duke Center for Human Genetics, Duke University Medical Center, Box 2903, Durham, NC.

We previously reported genetic linkage for age-at-onset (AAO) in Parkinson disease (PD) to a region on chromosome 1p (LOD=3.41). To identify the gene(s) associated with AAO and risk in this region, we first tested genes derived from the genomic convergence approach (genes significantly differentially expressed in the substantia nigras of PD cases versus controls which map to the chromosome 1 linkage region). Association mapping was the next step, but has potentially very high costs. To minimize these costs, we performed what we term iterative association mapping, where we first genotyped single nucleotide polymorphisms at an average distance of 100 kilobases over a 20 megabase region under the AAO linkage peak and then gradually increased the density of markers (50 kb, then 25 kb, etc) as needed to identify areas of significant association. Our data set consists of 284 multiplex families with 574 affected and 641 unaffected individuals. The average AAO \pm SD of affected individuals is 59.9 \pm 12.7 years (range: 14-90 years; 58.3% males). After correction for multiple testing, we identified several polymorphisms significantly associated with AAO in PD.

Using dbSNP to Maximize the Success of Custom Arrays for the Illumina Bead Lab SNP Genotyping Platform.

E.W. Pugh¹, R. Ingersoll¹, P. Boyce^{1,2}, G. Ingersoll³, M. Farkas¹, J. Pettengill¹, C. Bark¹, I.A. McMullen¹, T. Templeton¹, S. Carney¹, J. Gearhart¹, K.F. Doheny¹, Y.Y. Tsai¹, C. Boehm¹, J.L. Goldstein¹, L. Watkins¹, A.F. Scott¹.
1) Institute of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Illumina, San Diego, CA; 3) Genetic Software Innovations, Cicero, NY.

The SNP Center provides high throughput SNP genotyping using the Illumina Bead Array technology. Most projects have required the development of custom panels of SNPs. We hope to identify criteria for the selection of SNPs most likely to succeed using information available from dbSNP. We present preliminary performance data from 5229 SNPs. Validation status information was obtained from dbSNP.

Success and Quality of SNP Assays by dbSNP Validation

		----- All SNPs -----			Polymorphic SNPs--	
Validation	n	%polymorphic	%monomorphic	%fail	%called	50%_GC Score
no info	131	48.85	6.11	45.04	99.61	0.73
frequency	146	54.11	2.74	43.15	99.49	0.74
cluster	226	62.83	4.42	32.74	99.51	0.78
doublehit	1316	81.61	1.52	16.87	99.69	0.78
Hapmap	3410	87.27	1.09	11.64	99.88	0.80

The proportion of failing assays decreased with increasing levels of validation present in dbSNP. Markers with better validation were also more likely to be polymorphic. For polymorphic assays, the average call rate and 50th percentile GenCall Score, a measure of genotype quality, increased slightly by the validation type of the SNP, but these differences were not statistically significant.

Genome-wide identification of functional non-coding elements by digital analysis of chromatin structure. *P.J.*

*Sabo*¹, *M. Hawrylycz*¹, *R. Humbert*¹, *J. Wallace*¹, *A. Kohli*², *Q. Li*², *M. Yu*², *M. McArthur*¹, *J. Stamatoyannopoulos*¹. 1) Dept. of Molecular Biology, Regulome, Seattle, WA; 2) Div. of Medical Genetics, Univ. of Washington, Seattle, WA 98195.

Comprehensive identification of sequences that regulate transcription and other chromosomal processes is one of the major goals of genome biology. We developed a novel stochastic methodology - Digital Analysis of Chromatin Structure (DACS) - for comprehensive, genome-wide mapping of DNaseI hypersensitive sites (HSs) and associated cis-regulatory sequences *in vivo*. We used 19-20bp genomic DNA tags to localize individual DNaseI cutting events in nuclear chromatin, and analyzed >250,000 tags from erythroid cells. DACS tags can be accurately and comprehensively (>99%) mapped to the human genome without the aid of a restriction site scaffold, providing base-pair resolution. We applied a quantitative algorithm to discriminate statistically significant tag clustering over small genomic intervals, and show that such clusters identify active chromatin elements corresponding to both known and novel functional elements. A unique feature of DACS is that it permits unbiased evaluation of the chromatin accessibility of sequences from disperse genomic loci at a sensitivity heretofore not obtainable. We observed repeated tagging of specific regulatory sequences far in advance of other well-described elements. This suggests the existence of a discrete hierarchy of chromatin accessibility in the nucleus, compatible with physical compartmentalization. An *in silico* simulation confirmed that DACS could be extended to effect localization of the majority of DNaseI hypersensitive sites (and hence classical cis-regulatory sequences) in the human genome, without requiring a separate molecular validation step for each element. Overlaying a comprehensive cis-regulatory map on emerging genetic variation data has the potential to accelerate greatly discovery of functional non-coding polymorphisms that underlie inter-individual variability in gene expression and quantitative traits.

Program Nr: 1633 from the 2004 ASHG Annual Meeting

Multiplex genotyping of 384 to greater than 100,000 SNP loci per DNA sample on the BeadArray platform. *M.R. Shen, D. Campbell, W. Chang, J. Chen, D. Doucet, F. Steemers, C. King, J. Musmacker, H. Ren, K. Kuhn, M. Chee, J.-B. Fan, K. Gunderson, A. Oliphant.* Illumina, San Diego, CA.

SNP genotyping is increasingly the technology of choice across a broad spectrum of genetic studies, including candidate gene and fine-mapping studies, family-based linkage, and high-resolution, genome wide association scans. To accommodate the variety of study designs, there is a need to efficiently span a wide range in the numbers of SNP loci interrogated and samples processed. Therefore, we developed a highly flexible array-based platform that enables SNP genotyping at a broad range of multiplex levels. We also developed two genotyping assays with complementary capabilities. The GoldenGateTM assay uses a universal array and can accurately process hundreds of samples each day. The assay generates a multiplex pool of up to 1,536 SNP-specific PCR amplicons, each of which contains a different hybridization sequence complementary to one of 1,536 universal capture sequences on the array. Because universal capture sequences are designed into the oligos, no changes to the array are needed for new assays. To date, over 250,000 highly accurate GoldenGate SNP assays have been developed as part of the International HapMap Project (www.hapmap.org). The WGG assay is described in an accompanying abstract (Steemers et al, submitted). The Whole Genome Genotyping (WGG) assay is optimal for genotyping many thousands to hundreds of thousands of SNPs at a time, and can also accommodate a wide range in the number of samples. The WGG assay does not use PCR and can directly analyze genomic DNA of mammalian complexity. Therefore, for practical purposes, there is no limit on multiplexing. This capability is unique among SNP genotyping assays. Together, the GoldenGate and WGG assays allow study designs to use as few as 384 to well over 100,000 SNPs. Both approaches provide robust, highly accurate genotyping with excellent call rates. Details of the implementation of the two assays will be described, including the process flow logic and examples of how key parameters can be varied to accommodate different studies.

Sequence-specific localization of functional non-coding elements in vivo by quantitative chromatin profiling. *J. Stamatoyannopoulos¹, M. Hawrylycz¹, R. Humbert¹, J. Wallace¹, M. Yu², M. McArthur¹, M. Dorschner¹*. 1) Dept. of Molecular Biology, Regulome, Seattle, WA; 2) Div. of Medical Genetics, University of Washington, Seattle, WA 98195.

Identification of functional non-coding elements that regulate transcription and other basic chromosomal processes is a major goal of genome biology. Localization of functionality to specific sequences is a requirement for genetic and computational studies. Here we describe a generic approach - Quantitative chromatin profiling (QCP) - that uses quantitative, high-resolution analysis of in vivo chromatin structure over an entire gene locus to effect rapid and precise localization of cis-regulatory sequences and other functional elements. To demonstrate the sensitivity and specificity of QCP, we analyzed ~330kb of human genome sequence from 7 diverse gene loci and cleanly delineated a spectrum of classical elements including enhancers, promoters, insulators, and locus control regions. QCP provided exceptional sensitivity (100%) and specificity (>99.6%) for validated functional elements within these loci. In addition to defining the core regions of many elements with greater resolution, QCP also demonstrated the ability to identify novel elements in heavily-explored genomic territory such as the beta- and alpha-globin loci, the T-cell receptor-alpha locus, and the X-linked photoreceptor locus. We show further that analysis of genetic variation within elements identified by QCP can be used to determine the role of specific regulatory sequences in modulation of a model quantitative phenotype. Systematic, high-throughput, high-resolution identification of functional non-coding sequences surrounding candidate genes for major common disorders should significantly expand our knowledge of regulation of these genes and simplify the search for genetic variation affecting quantitative traits.

Assessment of a novel flow-through porous microarray for the rapid analysis of gene expression profiles. *Y. Wu¹, P. de Kievit¹, L. Vahlkamp¹, D. Pijnenburg¹, M. Smit¹, P.J. Boender¹, C. Ingham¹, A.K. Raap², A.B. Chan¹, R. van Beuningen¹.* 1) PamGene International BV, s-Hertogenbosch, The Netherlands; 2) Department of Molecular Cell Biology, Leiden University Medical Center, Leiden, The Netherlands.

A novel microarray system that utilizes a porous aluminum-oxide substrate and flow-through incubation was developed for rapid molecular biological testing. To assess its utility in gene expression analysis, we determined hybridization kinetics, variability, sensitivity and dynamic range of the detection using amplified RNA. To show the feasibility with complex biological RNA, we subjected Jurkat cells to heat shock treatment and analyzed the transcriptional regulation of 23 genes. We found that trends (regulation or no change) acquired on our platform are in good agreement with data obtained from real-time quantitative PCR and Affymetrix GeneChips. Additionally, our results demonstrate a linear dynamic range of 3 orders of magnitude and accelerated hybridization kinetics (10-fold compared to conventional microarrays). The minimum amount of transcript that could be detected in 20 l volume is 2-5 attomol, which enables the detection of 1 in 300,000 copies of a transcript in 1 g of amplified RNA. Hybridization and subsequent analysis are completed within 2 hours. Replicate hybridizations on 24 identical arrays with two complex biological samples revealed a mean coefficient of variation (CV) of 11.6%. This study shows the potential of flow-through porous microarrays for the rapid analysis of gene expression profiles in clinical applications.

High Throughput SNP Genotyping for the Human Haplotype Map. *L. Ziaugra¹, J. Moore¹, H. Nguyen¹, A. Lochner¹, M. Faggart¹, M. Goyette¹, R. Barry¹, E. Stahl¹, M.J. Daly², D. Altshuler^{1,3}, S.B. Gabriel¹.* 1) The Eli and Edythe Broad Institute of Harvard and MIT, Cambridge, MA; 2) Whitehead Institute, Cambridge, MA; 3) Harvard Medical School and Massachusetts General Hospital.

The Broad Institute contribution to production genotyping for the International HapMap Project is focused on chromosomes 4q, 7q, 18p and Y, representing about 9% of the human genome. The initial goal of the Hap Map is to successfully genotype 1 SNP with a minor allele frequency $\geq 5\%$ every 5 kb throughout the genome; this milestone will be met by the end of 2004. As of June 2004, we have successfully genotyped 54,552 SNPs in our allocated regions. In evaluating our success against the goal of the 5kb map, we find that approximately 70% of 5kb bins in our allocated regions are complete. Recent additions to dbSNP will be used to help meet our goal. The genotyping group at the Broad Institute has successfully implemented two production scale genotyping platforms to generate data for the Hap Map project: the Sequenom MassArray platform and the Illumina BeadLab. In total we have generated over 7 million genotypes for the Hap Map, about 60% through Illumina and the remainder on Sequenom. Our conversion rate for SNPs on Sequenom is 83%, with a call rate of 99.3%; on Illumina it is 86% and 99.5%. We find similar estimates of genotyping accuracy on the two platforms (99.3% - 99.8%) as assessed by rates of segregation errors and discrepancies in duplicate genotyping. In addition we have completed two externally reviewed Hap Map QA/QC exercises in which data is compared across 10 different Hap Map genotyping centers. In an exercise to assess SNP conversion rate on a random collection of SNPs and genotyping accuracy as compared to a true consensus genotype, the conversion rate for the Sequenom platform was 77% and the accuracy was 99.5%, comparable to other groups. Results of the second exercise to assess accuracy of genotypes already submitted to Hap Map database are pending. Overall we have demonstrated that both platforms can achieve success in terms production data generation and high quality for large-scale genotyping projects. Hap Map data can be obtained via <http://www.hapmap.org>.

Multiple copies of genes are located at segmental duplications that flank the 8p23 inversion variant [inv(8)(p23)] on human chromosome 8p23.1. *N. BOSCH*¹, *Ll. ARMENGOL*¹, *X. ESTIVILL*^{1,2}. 1) GENES AND DISEASE, CENTER OF GENOMIC REGULATION, BARCELONA, BARCELONA, Spain; 2) Experimental and Health Sciences Department, UPF, PRBB, Barcelona, Catalonia.

Genomic architecture of regions containing segmental duplications is of primary importance for the understanding of genomic changes associated with clinical alterations. The genomic organization of the human chromosome 8p23.1 is of special interest due to the presence of clusters of low copy repeats flanking this region. This organization increases the vulnerability of the region to suffer different rearrangements such as the polymorphic inversion found in 26% of the general population, among other rare chromosomal rearrangements. An in-silico analysis of the 8p23.1 region (6Mb in build34) has been performed using Repeatmasker and Pipmaker. This two software packages are a powerful tool to recognize sequences present in more than one copy. Among other multiple-copy genes, we identified 24 copies of a gene coding for the hypothetical protein Q8NF61, from which only five copies are found in the current annotation. On the most proximal part of 8p23.1, twenty-two copies are distributed in 4 clusters of 6, 5, 8, and 3 copies and other two copies are located on the distal part of 8p23.1. Southern blot and PFGE analysis has been performed in order to assess the existence of copy-number and structural polymorphisms in the general population. The complex organization of the different copies of this gene could play a role in the susceptibility of the 8p23.1 region to suffer rearrangements. Comparative studies of this region between human, mouse and rat genomes have revealed several breaks of synteny between these species, with segmental duplications present at the breakpoint regions of the 8p23.1 rearrangements. Furthermore, these segmental duplications contain a large number of genes suggesting that this genomic region could be under positive evolutionary pressure. These findings strongly support a fundamental role of segmental duplications in the evolution of the architecture of this chromosomal region.

Searching for copy number polymorphisms in recently duplicated regions in the human genome. *L. Feuk, T. Tang, J. Cheung, S.W. Scherer.* Department of Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Canada.

Our analysis of the most recent build of the human genome sequence shows that ~4.3% of the genome is duplicated (using a 5kb and 90% similarity cut-off). Duplication events are important in the evolution of chromosomes and seem to be an ongoing process in the human genome. The aim of the present study is to investigate recently duplicated genes in the genome to determine to what extent gene copy number polymorphism exist in the human population for these genes. A survey of the literature of known gene copy number variants indicate that many such variants are located in regions of segmental duplication. We have compiled a list of candidate genes based on analysis of segmental duplication regions. All genes located completely within duplicated segments were first generated. These genes were then analyzed for their longest open reading frame and preserved intron-exon structure. A comprehensive list of 250 recently duplicated genes with no frameshift or stop codon mutations and with open reading frames highly similar or identical to the paralogous gene was created. Using paralogous sequence variants (PSVs) it is possible to differentiate between the expression of gene copies. Allelic ratios, as well as DNA quantification methods are used to indicate copy number changes for the regions investigated. To date, 35 genes that are represented as two or more copies in the genome sequence have been investigated. PSVs were tested in 10 individuals as well as in a cell line with uniparental homodisomy. Of the 35 genes, nine did not show any evidence of duplication, and may represent errors in the genome assembly. 20 genes were duplicated in all individuals, and six showed a pattern of variation indicative of copy number polymorphism. Further studies are now being performed to verify the copy number variants and link copy number changes to expression of the genes.

High frequency of mosaicism among neurofibromatosis type 1 (NF1) patients with microdeletions caused by somatic recombination of the JJAZ1 gene. *H. Kehrer-Sawatzki¹, L. Kluwe², C.A. Sandig¹, M. Kohn¹, K. Wimmer³, U. Krammer⁴, A. Peyrl⁵, D.E. Jenne⁶, I. Hansmann⁷, V.F. Mautner².* 1) Human Genetics, University of Ulm, Ulm, Germany; 2) Laboratory for Tumor Biology and Development Disorders, Department of Maxillofacial Surgery, University Hospital Hamburg-Eppendorf, Germany; 3) Department of Medical Biology, Medical University Vienna, Austria; 4) Department of Pediatrics, Medical University Vienna, Austria; 5) St. Anna Childrens Hospital, Vienna, Austria; 6) Department of Neuroimmunology, Max-Planck-Institute of Neurobiology, Martinsried, Germany; 7) Department of Human Genetics and Medical Biology, Halle/Saale, Germany.

Detailed analyses of 20 sporadic patients with NF1 microdeletions revealed an unexpected high frequency of somatic mosaicism (40%). 16 of these deletions were identified by a screen of unselected NF1 patients. None of the 8 mosaic patients exhibited mental retardation and facial dysmorphism usually associated with NF1 microdeletions. Our study demonstrates the importance of a general screening for NF1 deletions regardless of the phenotype. In mosaic cases, the proportion of cells with the deletion ranged from 91-100% in leukocytes but was much lower in buccal smears. Thus the analysis of other tissues than blood is recommended to exclude mosaicism in patients with NF1 microdeletions. Further our study reveals breakpoint heterogeneity. The classical 1.4-Mb deletion was found in 13 patients. These type-I deletions encompass 14 genes and have breakpoints in the NF1 low-copy repeats. We identified a second major deletion type that spans 1.2-Mb and includes 13 genes. This type-II deletion was found in 8 of 21 patients (38%) and is mediated by recombination between the JJAZ1 gene and its pseudogene. Seven of the 8 mosaic deletions are of type-II while only one was of type-I. Therefore, the JJAZ1 gene is a preferred target of mitotic non-allelic homologous recombination. While type-I deletions occur interchromosomally during meiosis, type-II deletions are mediated by mitotic intrachromosomal recombination. Thus NF1 microdeletions acquired during mitosis differ from those occurring in meiosis and are caused by different mechanisms.

Correlation of Gene coding region length with human chromosome. *C.M. Malcom¹, J.E. Paschall², G.J. Wyckoff².*
1) Dept Anthropology, Univ Chicago, Chicago, IL; 2) Mol. Bio. & Biochem, U. Missouri-Kansas City, Kansas City, MO 64110.

In mammals, several characteristics, including breadth and pattern of expression, substitution rates and level of functional constraint, are shared among positionally linked genes (Duret and Mouchiarud 2000; Malcom et al., 2003). One factor that has been overlooked in previous studies, however, is gene length. We sought to examine the relationship between positional linkage and the length of gene coding regions. We began with a set of more than 15,500 human genes for which information on the length of the complete coding sequence was available. We compared the central tendencies and distributions of gene coding region length among chromosomes. Although to our knowledge there is no literature to suggest that gene lengths vary significantly among chromosomes, our analysis showed several significant differences in both mean gene length and distributions of gene lengths. Kolmogorov-Smirnov tests showed that approximately 24% of all pairwise chromosomal comparisons yielded significant differences, demonstrating that gene lengths vary across chromosomes. In an effort to put this finding into the perspective of previous results regarding gene properties across chromosomes, we compared the resulting matrix of pairwise differences to the matrix of differences among chromosomes with regard to evolutionary rates from our prior published work (Malcom et al., 2003). The two matrices showed a positive correlation by the Mantel test (p-value = 0.06). To probe this result further, we examined the number of PFAM (Protein Families, Sanger Institute, UK) domains within genes and the length of domains within genes to determine whether or not these also vary across chromosomes. Our results suggest that domain identity within genes may in part explain the linkage between evolutionary rate and gene length in humans. This suggests that any genome-wide study may need to take into account the underlying genomic terrain when significance of genome-wide results is interpreted; differences in gene length, gene number, and evolutionary rate across chromosomes may complicate straightforward analyses of gene properties.

Constructing a Full-length Gene Map of Human Chromosome 7. *Y. Ren¹, J. Zhang¹, K. Nakabayashi¹, J. MacDonald¹, J. Cheung¹, J. Skaug¹, S.W. Scherer^{1,2}.* 1) Dpt.of genetics, The Hosp. for Sick Children, Toronto, ON; 2) Dpt. of Molecular and Medical Genetics, Univ. of Toronto, ON.

Chromosome 7(Chr.7) accounts for about 5% of the human genome and based on a first-generation annotation it contains near to 158 million base pairs of DNA and 1900 gene units. We have been updating the website <http://www.chr7.org/> regularly by adding manually curated genomic and clinical data to provide both the scientific and medical research communities with the most reliable resource for Chr.7. To generate the most complete gene map of Chr.7, we have been using computer-based annotation in conjunction with extensive laboratory experimentation. Partial genes are, in our definition, transcriptional units with an incomplete ORF (missing the start or stop codon). Annotating partial genes will provide information on candidate genes for positional cloning and genotype-phenotype projects and facilitate many studies of Chr.7. We are currently attempting to obtain additional sequence information for the 51 partial genes that we have determined currently reside on Chr.7 by performing (1) 5- and 3-RACE and RTPCR to obtain longer cDNA, (2) Connecting adjacent annotated structures (eg. EST clusters and predicted genes) by PCR to provide evidence for continuity between them at the transcript level (3) RTPCR to confirm gene structures predicted by comparative DNA sequence analysis. Three examples are listed. First, Mus AK033957 and Mus AK041451 are mRNA sequences that are orthologous to the human PGR14 gene. We mapped putative new human exons by comparing the mouse sequence with the human genomic sequence and amplified the remaining regions of the human PGR14 gene by RTPCR. Second, we connected AK027618 and AK075525 by RTPCR and confirmed that they are derived from the same gene. Third, we combined human_THC1646891 and human_THC1667560 with Y19188 and found that this transcript is a PCLO-related gene. All experimental data is submitted to an annotation track in the Chr.7 database so it is available for public viewing. Once completed gene structures are established the resulting information is submitted to GenBank and the Human Genome Organization Nomenclature group for standardization.

Progress in the HapMap-ENCODE project: a comprehensive dataset to guide analysis for the Hap Map. S.B.

Gabriel¹, J.C. Barrett², R. Barry¹, P. deBakker¹, M. Goyette¹, J. Moore¹, H. Nguyen¹, R. Onofrio¹, D. Richter¹, E. Stahl¹, L. Ziaugra¹, A. Motpetit³, T.J. Hudson³, M.J. Daly², D. Altshuler^{1,4}. 1) The Broad Institute, Cambridge, MA; 2) The Whitehead Institute for Biomedical Research; 3) McGill University; 4) Harvard Medical School and Massachusetts General Hospital.

By the end of 2004, the Haplotype Map of the Human Genome will reach a major milestone - the successful genotyping of one SNP (MAF > 0.05) every 5kb throughout the genome in 270 DNAs from four population samples (CEPH, Yoruba, Japanese and Han Chinese). While this initial product will provide a rich resource to support genetic association studies, a detailed understanding of the relationship between SNP density and efficiency of tag SNP picking requires a gold standard dataset in which complete SNP ascertainment and highly accurate genotyping are performed over large and representative segments of the genome in substantial sample sizes. The HapMap ENCODE project was designed by the HapMap Project to address this need, and we will present our contributions to data generation and analysis of this public resource.

In total, ten ENCODE regions, each 500kb, are being studied. SNPs are being discovered by resequencing 48 of the HapMap samples and all SNPs (in dbSNP or newly discovered) in each region are being genotyped in the full set of 270 HapMap samples. We present data on SNP discovery, genotyping, dbSNP comparison, and LD analysis. Key observations already obtained based on initial data in the CEPH population (at a density of one SNP / 600 bp) include the following. First, dbSNP already contains >75% of common sites (>10%) found by resequencing of 16 individuals. Second, at a SNP density of 1/600 bp, 88% of the genome falls into haplotype blocks (as defined by Gabriel et al, Science, 2002), with an average block size containing 41 SNPs and spanning 22kb. We use this dense data to evaluate the performance of the initial HapMap spacing of 5kb, and show that an updated plan for a genome-wide HapMap at 1/kb density will increase the efficiency and power of tag SNPs selected from HapMap.

Different Algorithms Predict Similar Haplotype Block Structures. *A. Indap*¹, *P. Tonellato*¹, *G. Marth*², *M. Olivier*¹.
1) Med. College of Wisconsin, Milwaukee, WI; 2) Boston College, Chestnut Hill, MA.

Several computer algorithms have been developed to partition genomic sequence into haplotype blocks. These approaches use different assumptions and it is unclear whether the resulting block patterns are specific to the algorithm used. To date, no comprehensive resequencing data for extended genomic intervals are available for large numbers of independent chromosomes to compare the performance of algorithms. We simulated 1000 50-kb haplotypes via the coalescent and compared the effects of SNP density, minor allele frequency (MAF), and the number of ascertained chromosomes on the performance of two partitioning algorithms, MDBlocks and HapBlock. Individual samples were generated by bootstrapping using different SNP density (all markers, 1kb, 3kb, 5kb, 7kb), MAF (all markers, >1%, >5%, >10%, >15%), and sample size (24, 48, 96 chromosomes). Across all datasets, HapBlock infers a greater number of blocks of smaller size. On average, MDBlocks inferred blocks were 1.6 times larger than HapBlock results and contained 1.7 times the number of SNPs. Across bootstrap samples, 95% of blocks inferred by HapBlock were completely contained in blocks inferred by MDBlocks. All block boundaries inferred by MDBlocks were within 1-3 SNPs of the boundaries inferred by HapBlock. This suggests that HapBlock primarily subdivides blocks inferred by MDBlocks into smaller units, but the overall underlying pattern remains the same. Next, we compared shifts in block boundaries when sampling conditions (SNP density, MAF, number of chromosomes) were altered. Regardless of the algorithm, we identified smaller blocks when SNP density was increased, or SNPs of lower MAF were included. However, the average number of blocks inferred increased for the HapBlock algorithm as more chromosomes were included for analysis, but decreased for MDBlocks. Our results show that block partitioning methods are sensitive to SNP density, MAF, and sample size, but the resulting haplotype block patterns are highly similar for the two algorithms. We will present additional data for other algorithms and larger genomic intervals to assess the congruence of algorithms and sensitivity to sampling parameters.

Large scale SNP-based haplotype analysis of the human chromosome 1p that had identified rheumatoid arthritis susceptible variants in PADI4. *T. Kawaguchi¹, H. Kawakami¹, R. Yamada², A. Sekine³, K. Yamamoto², Y.*

Nakamura⁴, T. Tsunoda¹. 1) Lab. Medical Informatics, SNP Research Center (SRC), The Institute of Physical and Chemical Research(RIKEN), Yokohama, Kanagawa, Japan; 2) Lab. Rheumatic Diseases, SRC; 3) Lab. Genotyping, SRC; 4) Res. Gr. Personalized Medicine, SRC.

Case control linkage disequilibrium mapping is one of strongest strategies for common disease-associated gene discoveries. Last year we successfully identified a rheumatoid arthritis (RA)-associated variants of PADI4 in human chromosome 1p36 as a part of large scale survey of whole genome with 70442 SNPs in or close to gene-encoding regions selected from JSNP database (<http://snp.ims.u-tokyo.ac.jp/>). Here we characterize LD and haplotype of 1p. Chromosome 1p spans 120Mb (>3.8% of whole genome) and contains 1125 genes (>5.1% of total genes). 50Mb of the region (41%) encodes gene. We genotyped a total of 93 RA affected Japanese for 3766 SNPs in the region. These SNPs reside on 648 genes, thereby encompassing 58% of currently identified genes in this region. Average density of SNPs was 0.03 SNP per 1Kb in total and 0.06 SNP per 1Kb for 39Mb of gene structured regions. Pairwise LD index was calculated and identified about 270 blocks (35Mb; 30% of the region) with average length being 130Kb. About 20Mb (almost 60% of the whole blocks) of the block segments correspond to gene-encoding region, and about 40% of the gene-encoding regions was within blocks. We applied SNPHAP to phase haplotypes for the LD blocks and haplotypes were successfully inferred for all the LD-blocks. Each LD-block consisted average of 8 common (>1%) haplotypes. Haplotype-tagging SNPs were identified for LD-blocks, and the total number of tagging SNPs was about 1200 (more than 30% of SNPs in blocks).

By applying case-control association tests with these SNPs, disease-associated SNPs were identified and further biological evaluation supported the finding. Identification of the association between PADI4 haplotypes and RA could validate the large scale LD mapping strategy as one of useful tools for the identification of common genetic disorders. TK and HK contributed equally to this work.

Interethnic variability of ERCC2 polymorphisms. *C.R. King¹, J. Yu^{1,2}, R. Freimuth¹, H. McLeod^{1,2}, S. Marsh^{1,2}.* 1) Departments of Medicine, Genetics, and Molecular Biology and Pharmacology, Washington University School of Medicine, Saint Louis, Missouri 63110; 2) Siteman Cancer Center, Washington University School of Medicine, Saint Louis, Missouri 63110.

ERCC2 plays an important role in DNA repair by eliminating bulky DNA adducts produced by platinum agents during the Nucleotide Excision Repair pathway. Several studies have associated polymorphisms in ERCC2 with response to platinum therapy, lung cancer risk, and DNA repair capacity. We examined polymorphisms and haplotype structure of ERCC2 in 95 European, 95 African, and 95 Asian individuals. SNPs (ERCC2 -9164 AT, -1989 AG, -516 GA, 468 CA [Arg156Arg], 1737 CT [Val579Val], 2133 CT [Asp711Asp], and 2251 TG [Lys751Gln]) were mined and mapped using Golden Path, PolyMAPr, and Promolign. Genotyping was performed using PCR and Pyrosequencing. Of seven SNPs identified, the synonymous cSNP at codon 579 could not be confirmed in our populations. There was a clear difference in variant allele frequencies between populations. Variant allele frequencies ranged from 0 to 0.47 in the European population, 0.05 to 0.72 in the African population, and 0 to 0.47 in the Asian population. There were also significant differences in haplotype structure between populations. Of 18 haplotypes, four were common to all three populations. In Europeans and Asians, the most common haplotype was found at 43% and 47%, respectively, while at 0% in Africans. The most frequent haplotype in Africans (53%), was found at 5% and 0% in Europeans and Asians. Our results highlight the interethnic variability of allele and haplotype frequencies in ERCC2. A more comprehensive analysis of ERCC2 would help to clarify the role of polymorphisms with lung cancer risk, DNA repair, and chemotherapy response. This work was supported by the NIH Pharmacogenetics Research Network Grant U01 GM63340.

Fine Mapping and Positional Cloning of Asthma-Related Loci on 5p. *T. Kurz¹, S. Hoffjan¹, G. Hayes¹, N. Cox², K. Deichmann³, C. Ober¹.* 1) Department of Human Genetics, University of Chicago; 2) Department of Human Genetics, Medicine, University of Chicago; 3) Department of Pediatrics, University of Freiburg.

Asthma is a complex phenotype influenced by multiple genes and environmental factors. To identify susceptibility loci, we conducted a genome-wide screen for asthma and related phenotypes in the Hutterites. Markers on 5p13 showed evidence for linkage to bronchial hyperresponsiveness (BHR) with the marker D5S1470 (likelihood ratio (LR) χ^2 $p = 0.0019$) in the Hutterites. At this locus, there was also overtransmission of the 177 bp allele ($p = 0.0061$). Fine mapping of this region was conducted in a sample of 693 Hutterites by typing 75 SNPs in 23 genes across a 31 cM region that included D5S1470. SNPs in 2 genes close to D5S1470 (NPR, ADAMTS12) were associated with BHR ($p = 0.041$ - 0.0037) and SNPs in 3 more proximal genes (PRLR, LIFR, PTGER4) were associated with atopy ($p = 0.042$ - 0.00017). Only the associated alleles in NPR and ADAMTS12 were on the same haplotype as the 177 bp allele. To determine whether SNPs in 1 or more of the associated genes explained the evidence for linkage with D5S1470, we stratified our sample by the presence of the associated 177 bp allele at D5S1470 and each of the 3 proximal loci. The LR χ^2 was reduced from 9.65 to 1.25 when individuals with the associated alleles at both LIFR and PTGER4 were excluded, indicating that nearly all of the linkage was explained by SNPs in LIFR and PTGER4. To replicate these results, we genotyped 56 SNPs in 19 genes in outbred cases (231 asthmatics, 196 atopics) and 270 random controls from Germany. In this sample, SNPs in PTGER4 were associated with asthma ($p = 0.008$) and SNPs in LIFR and NPR were associated with atopy ($p = 0.004$ and 0.04 , respectively). These combined data suggest that this region harbors multiple susceptibility loci, with 1 close to D5S1470 and at least 1 more proximal, that influence asthma, BHR and atopy in the Hutterites and outbred Germans. Supported by HL66533.

Molecular and genealogical analyses of 8765delAG, a BRCA2 founder mutation in high-risk French Canadian families. *H. Vézina², F. Durocher¹, L. Houde², M. Dumont¹, M. Tranchant¹, L. Gobeil², J. Simard¹, INHERIT BRCA_s.*
1) Cancer Genomics Laboratory, CHUL Research Ctr, CHUQ, Laval University and; 2) Département des sciences humaines, Université du Québec Chicoutimi, Québec, Canada.

The Quebec population contains about 6 million French Canadians who are descendants of the French settlers who colonized Nouvelle-France between 1608 and 1765. These founders account for the major part of the contemporary French Canadian gene pool. The goal of the present study is to gain a better understanding of the role of settlement patterns and demographic history in the spread of the most frequent BRCA2 mutation in our cohort of high-risk French Canadian breast/ovarian cancer families, and to identify the founders who are the most likely to have introduced the mutations. We therefore performed extensive haplotyping analysis of 15 microsatellite markers surrounding the BRCA2 locus and spanning 9 cM on chromosome 13, in 76 carriers of the 8765delAG mutation from 26 families. A highly conserved haplotype is observed for 8 of the 15 markers genotyped. However, in 9 families, among the five most telomeric markers three are different and could thus represent another haplotype. Ascending genealogies of one carrier individual per family (n=26) and of controls (n= 78) were reconstructed using the BALSAC-RETRO genealogical database. These genealogies have an average depth of 11 generations. A number of 15 068 distinct ancestors were identified in the carriers group. Among these, 19 ancestral clusters showed an elevated higher probability of including the founder couple. However, unlike the BRCA1 founder mutation R1443X, for which the founder couple with the highest probability of having introduced the mutation in the Quebec population was identified, no such couple seems to emerge from genealogical analyses, suggesting that either the 8765delAG mutation was introduced more than once, by two separate founders, or that there was a single introduction followed by a recombination event, leading to two different haplotypes. Analyses are currently underway to verify these two hypotheses.

Molecular haplotyping by linking, emulsion PCR: Analysis of PON1 haplotypes and phenotypes. *J.G. Wetmur, M. Kumar, L. Zhang, C. Palomeque, S. Wallenstein, J. Chen.* Box 1124, Mount Sinai School of Medicine, New York, NY.

Linking PCR and emulsion PCR have been combined to create minichromosomes preserving haplotype content. Genomic DNA was dispersed in an emulsion such that less than one template would be found in any aqueous-phase droplet. Four primers were included to amplify separately two linked polymorphic loci. The external primers were present in excess. The internal primers were partially overlapping in sequence and contained 5 biotins. After breaking the emulsion, unlinked duplexes were removed easily on streptavidin-coated magnetic beads. Because the external primers were present in excess, single-stranded unlinked extension products were present that were still capable of subsequent and undesired linking PCR. These contaminants were capped by primer extension on overlapping, complementary 3-phosphate-blocked oligonucleotides. Haplotypes of the minichromosomes were determined by allele-specific real-time PCR. This procedure is robust and requires no additional expensive instrumentation. Human paraoxonase-1 [PON1] is an HDL-associated enzyme with several polymorphisms common to all ethnicities. Promoter polymorphisms are known to affect transcription. L55M may affect PON1 lifetime. Q192R affects substrate specificity. In a population of 390 women of mixed ethnicities for whom we have previously determined genotypes, we determined molecular haplotypes for the double heterozygotes for -909/ L55M (N=95), -909/Q192R (N=80) and L55M/Q192R (N=95). PON1 enzymatic activities were determined in plasma using phenylacetate as well as paraoxon as substrates. The ratio of the activity with these two substrates depends strongly on the Q192R polymorphism. We observed a strong dependence of this ratio on the -909/Q192R haplotype, reflecting increased relative transcription of either Q192 or R192 depending on the linked promoter polymorphism. These results demonstrate the power of molecular haplotype analysis for relating phenotype to genotype. This work was supported by grants from the NIEHS.

A Gene Entrapment Strategy that Generates Homozygous Mutations In Vitro. *S.L. Donahue, H.E. Ruley.*
Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, TN.

The worldwide effort aimed at sequencing the human and mouse genomes is nearly complete, however sequence data alone has not yielded significant insight into identifying gene functions or the relevance of genetic mutation to disease. Thus, practical, genome-wide strategies to characterize gene functions have been developed. Gene entrapment strategies have been used to disrupt genes in murine embryonic stem cells to generate loss-of-function mutations for studies in whole animal models. The primary constraint of this technology, however, is that only one allele is interrupted upon retroviral vector insertion into a random genomic locus. Homozygous gene interruptions are obtained from breeding mice that possess germline heterozygous vector insertions, an undertaking that is ultimately prohibitive for analysis of whole libraries of gene trap cells. Additionally, this issue has restricted the use of gene entrapment technologies in somatic cells. To circumvent this problem, we hypothesized that exposing cells to agents that induce genetic recombination could promote the conversion of heterozygous mutations to homozygous mutations. Several agents that induce homologous recombination were analyzed for their ability to induce loss of heterozygosity (LOH) at the site of retroviral vector insertion in multiple clones obtained from a mouse embryonic stem cell library. While several agents increased LOH at the site of retroviral vector insertion, N-methyl-N-nitrosourea (MNU) was found to increase the rate of LOH by 80-115-fold in all clones examined. Southern blot analysis confirmed that the resulting cells had homozygous mutations at the site of retroviral vector insertion. Furthermore, functional assays performed on a clone with heterozygous interruption of *Xrcc5* showed that the gene product was absent in homozygous mutant cells following MNU treatment. This data shows that this is a powerful tool that can be used to create homozygous mutations in vitro. Additionally, the high rate of conversion and feasibility of this approach suggests that it could be applied to somatic cells to identify genes responsible for various cellular phenotypes.

Effect of menopause on gene expression profiles of circulating monocytes. V. Dvornyk¹, Y.Z. Liu¹, Y. Lu¹, H. Shen¹, J. Wilde¹, T. Conway¹, R.R. Recker¹, H.W. Deng^{1,2}. 1) Osteoporosis Research Ctr, Creighton University, Omaha, NE; 2) Hunan Normal University, China.

Natural menopause is the most important physiological event in female life. It influences general health and functions of various organs and tissues due to profound biochemical and metabolic changes, which are established risk factors. Circulating monocytes are a key element of the immune system. They are major target cells for systemic effect of hormones and actively participate in tissue remodeling by serving as the precursors of various cell types and/or producing cytokines. We analyzed gene expression of circulating monocytes using Affymetrix HG-U133A GeneChip, containing probes for 14,500 genes. The monocytes were isolated from whole blood of 15 women aged 47-55 (7 pre- and 8 postmenopausal). We identified 47 differentially expressed genes ($p < 0.001$). They belong to the various functional categories, including cell signaling and signal transduction (9 genes), transcription regulation (2), apoptosis (1), immune response (4), and others (31). Most of them (36) were downregulated in postmenopausal women. Some of these downregulated genes may be of potential importance for postmenopausal health problems. For example, the EXT1 gene is important for bone metabolism and has putative tumor suppression function. Another gene is FKSG2, an inhibitor of apoptosis. It may contribute to the increased number of monocytes as compared to the premenopausal women, and, subsequently, elevated number of osteoclasts. The placental growth factor gene (PGF) belongs to the family of VEGF-related proteins and may be related to the cardiovascular problems after menopause. STAT1 mediates the expression of a variety of genes, which is thought to be important for cell viability in response to different cell stimuli and pathogens. Among the upregulated genes, SCA7 has been recognized as contributing to retinal degeneration. Another gene of interest is CXorf12, which is located in X chromosome. Its function is unknown. This is the first *in vivo* microarray study of menopause in humans. It demonstrates the prospects of microarrays in genetic dissection of menopause and menopause-associated disorders.

Novel BXSB lupus-susceptibility candidate genes identified by microarray analysis of overlapping chromosome 1 congenic mice. *M.E.K. Haywood, S.J. Rose, M.J. Lees, B.J. Morley.* Rheumatology Section, Eric Bywaters Centre, Faculty of Medicine, Imperial College, Hammersmith Campus, Du Cane Road, London, W12 0NN, United Kingdom.

The BXSB mouse strain is an important model of the glomerulonephritis seen in Systemic Lupus Erythematosus (SLE). Linkage studies have identified several disease-susceptibility intervals, however, the identity of the genes in these intervals remains unknown. Congenic mice represent a defined genetic resource in which the disease-associated interval is bred onto a non-disease prone background strain. In order to identify the lupus-susceptibility genes, we have performed microarray analysis using a series of chromosome 1 congenic lines with partially overlapping intervals. These mice develop specific and limited aspects of the parental disease, permitting phenotypic dissection and the isolation of the contribution of each locus to the overall disease. The genetic difference between each of the lines and C57BL/10, the non-diseased background strain, was less than 5 percent. To ensure that putative disease genes were not arbitrarily rejected, a relatively low fold change in expression levels was studied and the results mapped back to the congenic lines. Simultaneous comparison of the four congenic lines allowed the identification of expression differences associated with specific aspects of disease. Thus we have identified a number of novel SLE candidate susceptibility loci including *Marco*, *Gas5*, *Twist* and *Cd84*, and we have confirmed the identify of *Ifi202* as a disease candidate in the BXSB strain. Sequence analysis of these genes has revealed promoter polymorphisms which may underlie the expression differences that we have confirmed with QRT-PCR. Furthermore, the combination of the microarray results with the different phenotypes of these mice has allowed the identification of a number of expression differences that do not map to a congenic interval, but may be involved in specific disease pathways, notably *Clqb* and *Pawr*.

A comparative genomics approach to SNP-hunting in large genes. *N.S. Wratten¹, J. Simone¹, CH. Chiu¹, L.M. Brzustowicz^{1,2}.* 1) Dept of Genetics, Rutgers U, Piscataway; 2) Dept of Psychiatry, UMDNJ-NJMS, Newark.

Several independent studies have found linkage between chromosome 1q22 and schizophrenia. In this region we found evidence of significant LD between schizophrenia and markers within the *CAPON* gene. A mutation screen of the *CAPON* coding region did not identify any schizophrenia-associated changes in our pedigrees, which indicates that the causative mutation(s) are located in regulatory sequences. The *CAPON* gene extends over 300 kb but only 1.5 kb is exonic and the regulatory sequences are unknown. The large size of *CAPON* poses difficulties common to all association studies of large genes. Firstly, which sequences should be chosen for identification and typing of markers, since a region of this size is expected to contain ~1,500 SNPs? Secondly, how does one overcome the statistical cost of testing multiple SNPs in a moderate-sized sample? Therefore, to facilitate identification of the schizophrenia-associated mutation we took a comparative genomics approach. Regions conserved between primates and rodents are likely to be functional and may have a regulatory role. Targeting these regions for SNP identification has two advantages: The amount of sequence and the number of SNPs to be tested is vastly decreased and those SNPs identified potentially affect function so may increase our chances of testing a causative mutation. Twenty-one conserved sequence blocks were identified, covering 13.8 kb or 3.5% of the entire *CAPON* region. The average block length was 570 bp and each block consisted of at least 10 identical sequences of 15 bp or more. If these blocks are functional we would expect them to be more conserved than other non-coding sequences and indeed comparing verified SNPs in dbSNP there was on average 1 SNP/638 bp and 1 SNP/1057 bp in the entire region and conserved region respectively. We have begun to identify SNPs in the conserved regions for typing and LD analysis. In conclusion, by using comparative genomics we have decreased the size of target sequences more than 10-fold. Our approach should help save time, resources and alleviate problems arising from multiple testing in the identification of disease-associated regulatory mutations.

Self calibration and joint modeling of high throughput genotype data. *S. Ramachandra¹, M. Pratt¹, D. Holden¹, J. Marks¹, A. Spoonde¹, E. Rusman¹, R. Sating¹, A. Diamond², SNPlex Genotyping Program.* 1) Applied Biosystems, Foster City, CA; 2) EnVision Systems LLC, San Diego, CA.

Throughput advances in gene expression and genotyping platforms create qualitatively new challenges in data analysis while at the same time suggesting powerful new approaches to analysis. Typically these platforms operate closer to fundamental limits than their predecessors due to small reaction volumes and higher multiplexy. These factors combined with close physical proximity result in data that have increased susceptibility to covariance effects including varieties of crosstalk and process variability. We present a general approach in which large blocks of data (e.g. plate, run, microarray) are analyzed simultaneously by means of optimal self-calibration. The quantity and inherent redundancy in these data sets allow one to determine much more detailed and accurate parameterization of systematic noise sources than previously possible with serial analyses. The benefit of this analysis is twofold; first, these systematic noise sources can be quantified and tracked, providing much more detailed feedback on instrument and process variables, and second, the systematic variance in the data can be removed producing cleaner data that is less susceptible to error. Application of this methodology to Applied Biosystems high throughput SNPlex genotyping data illustrates these benefits.

SNP genotyping in pooled DNA: an efficient and reliable screening tool for genetic association studies. *L. Wang¹, E. Hauser¹, W. Kraus^{1,2}, C. Haynes¹, J. Rose¹, S. Edgerton¹, L. Huang¹, S. Gregory¹, P. Goldschmidt^{1,2}, J. Vance¹.* 1) Center for Human Genetics; 2) Department of Medicine and Division of Cardiology, Duke University Medical Center, Durham, NC.

Using single nucleotide polymorphism (SNP) at high density for association analyses has been limited by the cost of SNP genotyping for the large number of subjects required. DNA pooling is an affordable alternative. Single base-pair primer extension, followed by denaturing high-performance liquid chromatography (PELC), is a potential tool to genotype SNPs in DNA pools. However, previously it required estimation of a standard correction factor (k) for each SNP, significantly reducing its potential usefulness. We first demonstrated that in association studies k can be eliminated, and then investigated this modified PELC method in an ongoing study on susceptibility genes for coronary artery disease (CAD). Individuals were first grouped based on their CAD index (CAD_i), a validated angiographical measure of the extent of CAD. Groups included 299 young affected (age \leq 55, $CAD_i > 32$), 163 older affected (age $>$ 55, $CAD_i > 74$), and 199 controls (age > 60 , $CAD_i < 23$). DNA pools were made of approximately 100 individuals each, except for older affected. Thirteen SNPs were chosen from a region previously linked to CAD. Modified PELC was used to estimate allele frequency in the DNA pools and each pool was measured three times. To compare with the PELC estimation of allele frequency, each pooled individual was also genotyped using Taqman Allelic Discrimination Assay. In comparison to the allele frequencies obtained via individual genotyping, we found that the average error in using PELC to estimate allele frequency differences between DNA pools was 0.0080.006. In addition, subsequent SNP association analyses, based either on individual genotype data or pooling results were in complete agreement. Using the modified PELC, the reagent cost was approximately 10 cents per SNP per sample under our experimental conditions. We conclude that SNP genotyping in DNA pools using our modified PELC procedure is a cost-efficient and reliable alternative for screening complex diseases for SNP association.

A novel DNA diagnostic method for point-of-care genetic testing: competitive allele-specific short oligonucleotide hybridization with enzyme-linked immunosorbent assay (CASSOH-ELISA). *Y. Matsubara¹, S. Kure¹, M. Hiratsuka², A. Ebisawa², M. Mizugaki², Y. Suzuki¹, Y. Aoki¹.* 1) Dept of Medical Genetics, Tohoku Univ Sch of Medicine; 2) Dept of Clinical Pharmaceutics, Tohoku Pharmaceutical Univ, Sendai, Japan.

With our growing knowledge on the association of genetic polymorphisms and individual variations in drug responses, there has been an increasing promise of personalized medicine. Individualization of drug therapy through genetic testing would maximize effectiveness and minimize risk of medication. In this context, it is important to perform point-of-care genotyping in clinical settings, rather than sending out specimens to a centralized DNA diagnosis laboratory. To date, numerous methods to detect a single nucleotide substitution have been reported. However, these methods require either cumbersome laboratory procedures or high-tech instrument for high-throughput analysis. None of these procedures are readily performed in local clinical laboratories. We previously reported a novel DNA diagnostic method for detecting SNPs using competitive allele-specific short oligonucleotide hybridization (CASSOH) with immunochromatographic strip (*Hum Mutat*, 22:166-172, 2003). The discrimination of a one-base mismatch is achieved by employing unusually short oligonucleotide probes (~10-mer), which would reduce the re-association of mismatched hybrid by a factor of two, providing unsurpassed reliability and reproducibility. We have further devised the method to incorporate enzyme-linked immunosorbent assay (ELISA) for the final detection step, which enabled multiple mutation detection. Starting from 0.5 l of whole blood, genotyping is completed within two hours without sophisticated high-tech equipment or technical expertise. Special ELISA chips have been fabricated so that there is no need for disposing buffer waste, ensuring minimal handling procedures. The method (CASSOH-ELISA) has been successfully applied to the detection of clinically important SNPs in drug metabolism, such as mitochondrial 1555AG, TPMT*3C, and NAT2*5/*6/*7. Our method would facilitate point-of-care genetic testing with potentially diverse clinical applications.

Age-related Alteration of Mitochondrial DNA Copy Number in Leukocytes of Patients with MELAS or MERRF Syndrome. *W. Cheng¹, C. Liu^{1,2,3}, Y. Chen¹, C. Tsai¹, C. Lee⁴, Y. Ma⁴, Y. Chang⁴, B. Wang⁵, Y. Wei⁴.* 1) Vascular and Genomic Research Center, Changhua Christian Hospital, Taiwan; 2) Department of Neurology, Changhua Christian Hospital, Taiwan; 3) Department of Neurology, Chung Shan Medical University and Chung Shan Medical University Hospital, Taiwan; 4) Department of Biochemistry and Center for Cellular and Molecular Biology, National Yang-Ming University, Taiwan; 5) Ctr Medical Genetics, Changhua Christian Hospital, Taiwan.

Mutation of mitochondrial DNA (mtDNA) may affect the copy number of the mitochondrial genome in patients with mitochondrial disease such as MELAS and MERRF syndromes. In this study, we investigated age-related alteration of mtDNA copy number in leukocytes of patients with MERRF or MELAS syndrome. Forty-eight Taiwanese patients including fourteen families with MELAS and seventeen patients including four families with MERRF were recruited. A total of four hundred and eighty-four healthy subjects were enrolled as control. The 4,977 bp deletion and copy number of mtDNA in the leukocyte were determined by PCR. The results showed that the average proportion of 4,977 bp-deleted mtDNA and copy number of mtDNA in leukocytes of patients with MELAS or MERRF syndrome were significantly higher than that of healthy subjects below 30 years of age ($P < 0.05$). By contrast, the average mtDNA copy number in leukocytes was decreased dramatically in patients with MELAS or MERRF syndrome above age 40 ($P < 0.05$). The frequency of occurrence of 4,977 bp deletion and the proportion of mtDNA with A3243G or A8344G mutation in patients with MELAS or MERRF syndrome were found to correlate with the degree of mtDNA depletion in leukocytes. These findings indicate that the mtDNA copy number of leukocytes is increased in early life but is decreased at advanced age of the patients with MELAS or MERRF syndrome. We thus suggest that mtDNA depletion may also occur in affected tissues and play an important role in the pathophysiology and disease progression of the MELAS and MERRF syndromes, respectively, at the later stage of mitochondrial diseases.

Ingenotyping - an highly efficient approach to generate gene targeted mouse and rat models. *J. Laufs, R. Sedlmeier, T. Peters, U. Huffstadt, S. Wattler, M. Nehls.* Ingenium Pharmaceuticals, Martinsried, Bavaria, Germany.

Mouse and rats are the model of choice for *in vivo* studies of gene function but the development of knockouts and allelic variants, i.e. hypo and hypermorphs, is time consuming and costly. The generation of mouse models is dominated by gene targeting through homologous recombination, which requires sophisticated ES cell manipulation and chimera production. No such standard procedure for the development of targeted rat models is available despite some first success in nuclear cloning of rats from unmodified somatic cells. In order to make rat and mouse models with genetic alterations readily available to the scientific community, we developed a patented technology (named INGENOtypingTM) based on gene-saturating chemical mutagenesis. We first applied INGENOtypingTM to generate a pre-set library of mutagenized murine sperm that represents multiple alterations in every mouse gene. Currently somatic DNA and corresponding sperm samples of more than 15,000 mice derived from a well-controlled chemical mutagenesis process using ENU have been archived and can be screened for mutations in any gene of interest within days. Together with the subsequent extremely efficient *in vitro* fertilization, the adult heterozygous carriers are available within 3-4 months. This approach has now been adapted to rats for the industrialized production of gene targeted rat models. ENU mutagenesis in our hands has resulted in more than 220 identified mouse mutations which are to a large extent null but also hypomorphic and hypermorphic alleles. The process and examples of ENU derived mutant mouse lines will be presented.

Differential gene expression analysis in trisomy 21 and normal fibroblasts with the same genetic background. *S. Deutsch*¹, *R. Lyle*¹, *S. Gagos*¹, *M. Moggi*², *C. Baldo*², *S. Dahoun*¹, *B. Bricarelli*², *S.E. Antonarakis*¹. 1) Department of Medical Genetics, University of Geneva, Switzerland; 2) Laboratory of Human Genetics, Galliera Hospital, Genova, Italy.

Individuals with trisomy of chromosome 21 (Hsa 21) or Down syndrome (DS) are affected by a wide range of phenotypes, most of which are only present in a subset of patients. It is not clear how the presence of an extra copy of Hsa 21 leads to DS phenotypes, nor which factors are involved in the phenotypic variability. It is hypothesized that dosage imbalance of Hsa 21 genes either directly or through non-Hsa 21 genes leads to the molecular pathogenesis of this disorder. Genes or pathways involved in DS phenotypes remain to be identified. In order to study the consequences of Hsa 21 trisomy to the transcriptome, and to identify dysregulated genes potentially involved in DS pathogenesis, we have analysed gene expression differences in fibroblasts from normal and trisomic individuals using the Affymetrix technology. A common problem with this type of studies is that unrelated individuals have a large amount of polymorphic gene expression variation not associated to the disease status. To overcome this problem we have adopted 3 different strategies: I) We used cell lines from monozygotic twins, that were discordant for trisomy of Hsa 21. We confirmed the monozygotic status using microsatellites, and performed microarray hybridizations in triplicate. II) We isolated 100% 46, XY clones and 100% 47, XY + 21 clones from an individual mosaic for trisomy 21. Triplicates for each type of clone were used. III) We used fibroblasts from 4 trisomic individuals and 3 normal individuals (unrelated) for microarray analysis. Genes observed to be dysregulated in at least 9 out of 12 possible pairwise comparisons were considered potential candidates. We are currently integrating the data from all experiments using different statistical approaches (GCOS, RMA, transcription module analysis) to identify genes and pathways commonly dysregulated. Our results will give further insights into the molecular consequences of supernumerary chromosomes and possibly suitable candidate genes for involvement in the pathogenesis of DS.

The transcriptome of X-linked recessive myotubular myopathy (XLMTM) muscle. *D. Sanoudou*^{1,3}, *A. Buj-Bello*², *T. Burlison*³, *C. Pierson*³, *J. Laporte*², *J.L. Mandel*², *A.H. Beggs*³. 1) IIBEAA, Athens, Greece; 2) IGBMC, Illkirch, France; 3) Genetics Division, Children's Hospital, Harvard Medical School, Boston, USA.

XLMTM is one of the more severe congenital myopathies. It presents neonatally with profound hypotonia, respiratory distress, major feeding difficulties, absent tendon reflexes and often with dysmorphic features. Pathologically, both fast and slow muscle fibers are affected, with the nucleus centrally located and surrounded by a mitochondrial, glycogen or membranous rich rim. Mutations of the XLMTM gene (MTM1), which encodes a lipid phosphatase called myotubularin, have been found in over 300 families to date.

Using Affymetrix whole genome arrays we analyzed skeletal muscles samples from 7 XLMTM patients versus 7 age-matched unaffected individuals, and 5 Mtm1-knockout (M-KO) versus 5 wild type mice. Data were processed by a combination of bioinformatic approaches including Significance Analysis of Microarrays (thresholds: fold>2 and <5% false discovery rate) and fold change analysis. The most significant changes were consistent across both species including over-expression of 1) cell surface receptor linked- and intracellular- signalling genes, supporting the hypothesis that myotubularin regulates extracellular signaling leading to subsequent effects on muscle function; 2) cell proliferation and muscle development genes, consistent with evidence of muscle regeneration; 3) transcription and phosphate metabolism related genes, pointing to a highly active transcriptional response to MTM1 mutations in skeletal muscle with implications for protein modification. Limited inter-species differences likely represent secondary or species-specific effects of myotubularin mutations, such as over-expression of fibrotic response genes in humans and TGFbeta signalling pathway genes in mice. Despite evidence for aberrant oxidative enzyme activity no significant transcriptional changes were seen for other energy metabolism-related genes.

These data shed light on the molecular pathways of XLMTM development and further validate the M-KO mouse as a representative disease model for future molecular and therapeutic target studies.

In-silico assessment of the impact of single nucleotide polymorphisms in the regulatory regions of human genes.
P. Beaulieu, M.-C. Th  berge, H. B  langer, S. Langlois, M. Lariviere, J.-F. Lefebvre, D. Gehl, D. Labuda, D. Sinnett, Genome-Quebec Regulatory Genetics Consortium. Hemato-oncology, Ste-Justine Hospital, Montreal, Quebec, Canada.

Current efforts to identify functional DNA variants were essentially oriented towards single nucleotide polymorphisms (SNPs) found in coding regions of candidate genes since they have direct impact on the structure and function of the affected proteins. Abnormal expression of finely regulated genes could also lead to disequilibria in different metabolic pathways and/or biological processes. Thus investigation of SNPs in the regulatory regions (rSNPs) of candidate genes should improve our knowledge on complex diseases aetiology. We provide here an in-depth in silico characterization of over 1500 rSNPs found in the 2 kb region upstream of the transcription initiation site of more than 170 genes. We assessed the rSNPs density, repartition of the rSNPs over the 2 kb region, inter-SNP distances, as well as the representation of rSNPs in sequence features such as DNA repeats, dinucleotides including CpG islands as well as human-mouse conserved regions. We evaluated the potential of each SNP to disrupt or create putative transcription factors binding sites. Finally we looked at the distribution of rSNPs with respect to the Gene Ontology (GO) classification and found that genes within some certain GO categories had a distinct rSNPs density suggesting that sub-groups of genes might be more or less prone to variability. The putative functional rSNPs are being validated with a combination of approaches including gene reporter and gel mobility shift assays. This in-silico characterization of rSNPs coupled with experimental validation will improve our knowledge on the structure and mode of actions of regulatory regions, and thus provide crucial informations about how to build better predictive models of functional rSNPs. This work is supported by Genome-Quebec/Canada.

Single Nucleotide Polymorphism (SNP) Detection on Microarrays using Ligase Detection Reaction (LDR) and Gold Nanoparticle Reporters. *P. Fortina¹, F. Cao¹, K. Delgrosso¹, P. Patel¹, K. Scott¹, D. Graves², S. Surrey².* 1) Department of Medicine, Thomas Jefferson University, Philadelphia, 19107 PA; 2) Department of Chemical and Biomolecular Engineering, University of Pennsylvania, 19104 Philadelphia, PA.

Microarrays designed for single nucleotide polymorphism (SNP) discrimination usually are based on hybridization of fluorescently-labeled target to probes immobilized on a substrate. Here we demonstrate a novel and sensitive multiplex approach based on barcode microarray technology and gold nanoparticle reporter detection. Reactions involve solution-phase ligation of 2 perfectly templated oligonucleotides, which have different barcode-capture sequences at each end: one to bind a complementary surface-bound probe and the second to bind a complementary solution-phase oligonucleotide target containing a nanoparticle at the other end. In this scenario, one array-bound barcode is needed to capture the normal sequence and a second to capture the mutant or variant sequence. Array capture of either results in a common barcode sequence available for hybridization to a solution-phase oligonucleotide with a bound nanoparticle. Detection then is achieved by silver enhancement resulting in deposition of Ag on the surface of the nanoparticles, enabling scanometric detection to define location of the gold nanoparticles on an array. Attachment of a dye close to the surface of the nanoparticles via linkage to the oligonucleotide also affords detection after silver enhancement by dye fluorescence or by surface-enhanced Raman spectroscopy (SERS). Genomic DNA with known Inflammatory Bowel Disease (IBD) and Haemochromatosis (HFE) gene SNPs were analyzed using this method. Results show the 5 SNPs (3 IBD SNPs and 2 HFE SNPs) were detected successfully using the universal gold nanoparticle detector. By comparing this method with fluorescence-based hybridization, it is anticipated that much higher sensitivity and selectivity can be obtained, indicating that it could be a promising candidate for next-generation biodiagnostic technology.

A Universal Approach to Study Human Disease Genes. *S. Nidtha¹, R. Bennett², K. Poulter¹, R. Fang¹, R. Nutter¹, P. Baybayan¹.* 1) Applied Biosystems, Foster City, CA; 2) Genetics, Children's Hosp, Boston, MA.

Identification of mutations in human genes to determine the genetic basis of diseases is a challenge. With the availability of the human reference sequence, genetic variation in populations is being studied using a combination of methods such as sequencing, dHPLC and SSCP. Each of these methods has advantages, however extensive optimization is required in order to generate accurate data. Sequencing is a preferred method of choice to discover and confirm genetic variation. Researchers who have chosen to sequence their gene of interest have to invest considerable amount of time testing the primers they designed. To eliminate the time consuming step of designing, optimizing and validating PCR primers for human disease genes, Applied Biosystems has developed VariantSEQ[®] Resequencing System. Detecting genetic variations in humans by resequencing has been made simple by this system since it can be easily integrated into any sequencing pipeline. The system takes advantage of the automated capillary electrophoresis platform, as well as reagents and SeqScape v2.1.1 software for mutation detection and report generation. The universal PCR condition and sequencing protocol allow researchers to: 1. Study disease genes with dense mutation spectrum and polygenic diseases 2. Study larger cohorts and therefore conclusions drawn may be more statistically significant. Variations in sequences known or suspected to exist in the human genome can be detected easily and cost effectively. We describe here a new tool for mutation and SNP discovery that is easy to integrate and takes advantage of DNA sequencing, which is a widely accepted.

Comparison of mutation detection in the HEXA gene by dHPLC with endonuclease cleavage. *A. Proos^{1,2}, C. Vaughan^{1,2}, G. Watts^{1,2}, R. Wenzel^{1,2}, C. Jensen^{1,2}, B. Edmonds^{1,2}, L. Burnett^{1,2}.* 1) Laboratory and Community Genetics, Pacific laboratory Medicine Services(PaLMS), Royal North Shore Hospital, St Leonards, Australia; 2) Kolling Institute of Medical Research, Northern Clinical School, University of Sydney, Royal North Shore Hospital, St Leonards, NSW, Australia.

Aim: To compare mutation detection by denaturing high performance liquid chromatography (dPHLC) with the Surveyor endonuclease cleavage method and HPLC detection.

Method: DNA from a pool of enzyme-defined Tay-Sachs disease carrier or inconclusive samples from the Australian population were amplified for each HEXA gene exon. Fragments were hybridised to form heteroduplexes and analysed by

a: dHPLC at optimum melt temperature for each exon;

b: endonuclease cleavage of mismatches followed by sizing by HPLC at 50 deg celsius. Sequence variations detected by atypical or changed peak patterns by each method were confirmed by DNA sequencing.

Results: For each sample the unique peak patterns observed by dHPLC and the calculated fragment sizes after cleavage are shown and discussed. The advantages and disadvantages of each methodology are also discussed.

Evaluation of automated SNP discovery software and its application in the HapMap ENCODE Project. *D.J.*

Richter¹, J.C. Barrett², R. Barry¹, P. de Bakker^{1,4}, M. Goyette¹, J.M. Moore¹, H. Nguyen¹, R.C. Onofrio¹, E. Stahl¹, L. Ziaqura¹, A. Montpetit³, T.J. Hudson³, M.J. Daly^{1,2}, D. Altshuler^{1,4}, S.B. Gabriel¹. 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) Whitehead Institute, Cambridge, MA; 3) McGill Univ. Health Ctr., Montréal, Canada; 4) Harvard Medical School and Mass. General Hospital, Boston, MA.

Existing software for automated SNP discovery in diploid resequencing data requires manual review to achieve high sensitivity and specificity, which is rate-limiting for large-scale applications. We developed a novel algorithm, PolyDhan, and validated its performance in comparison to and combination with PolyPhred. To determine rigorously and objectively the false positive and false negative rates, we evaluated performance on a large resequencing data set (100 Mb of total sequence: 2.5 Mb in each of 40 individuals) by genotyping all SNPs found, as well as those already in dbSNP, as part of the HapMap ENCODE Project. To our knowledge, no previous evaluation of SNP discovery efforts has integrated SNPs discovered by resequencing with objective verification by genotyping and comparison to dbSNP.

We find that both PolyPhred and PolyDhan perform extremely well on the data set, although each individual program misses some true SNPs, and the lower SNP quality categories in PolyPhred have high rates of false positive calls if not manually reviewed. The combination of the two programs, however, is able to produce very high quality results without human review: we detected over 3,000 novel SNPs (in addition to 2,500 already in dbSNP) with a false positive rate of 7.3%, and, in comparison to confirmed SNPs from dbSNP, a false negative rate of 9.3%.

We also find that 67% of novel SNPs with frequency over 5% are already in dbSNP build 119; that figure rises to 80% for SNPs over 25% frequency. In addition, 89% of novel SNPs showed $r^2 > 0.5$ to an existing SNP in dbSNP build 119. These data underscore the increasing completeness of dbSNP (which now contains 8.8 million SNPs) for choosing a dense collection of SNPs for comprehensive genetic association studies across the genome.

Prevalence of Y chromosome deletions in a Tunisian population of non obstructive azoospermic and oligozoospermic men. *S. ROMDHANE IBALA¹, M. AJINA¹, M. GRIBAA¹, H. ELGHEZAL¹, A. AMOURI², M. ZAOUALI³, A. SAAD¹.* 1) Laboratory of Cytogenetic and Biology of Reproduction, CHU F. HACHED, Sousse, Tunisia; 2) Laboratory of Cytogenetic, Institut Pasteur of Tunis, Tunis, Tunisia; 3) Laboratory of Physiology, Faculty of Medicine, Sousse, Tunisia.

Microdeletions of the long arm of human Y chromosome are associated with spermatogenic failure and have been used to define three regions (AZFa, AZFb and AZFc) that are recurrently deleted in infertile males. Our Objective is to determine the prevalence of microdeletions within the AZFa, AZFb, AZFc subregions in Tunisian patients with idiopathic azospermia or oligozoospermia. One hundred and fifteen patients with idiopathic nonobstructive azospermia (n=58) or oligozoospermia (n=57), have been screened for microdeletion of the long arm of chromosome Y. Those, whose infertility was related to known hereditary, constitutional cytogenetic abnormalities, endocrine or obstructive causes were excluded. Blood and semen samples were obtained from all of the patients. We performed for every one semen analysis. we measured FSH, LH, and testosterone levels and performed karyotype analysis. We looked for microdeletions using 2 multiplex PCR with 7 pairs of primers directed to Y-specific STS genomic markers from the three Y chromosome AZF regions. Overall, 3 of the 115 infertile patients tested exhibited deletion of the Y chromosome, 2 of them being azospermic and 1 extreme oligozoospermic. All patients presented a normal karyotype and deletions were confined to the AZFc region, involving the DAZ locus. In contrast no deletion was detected in AZFa or AZFb. The frequency of Y chromosome microdeletion in our sample (2,6 %) is in the lower limit of the frequencies reported by the literature. This confirms that the frequency may be affected by population structures in different geographical regions. In conclusion we confirm that deletion of the AZFc region of the Y chromosome is the most frequent molecularly defined cause of spermatogenic failure. AZFc deleted men are candidates for ICSI, since in most cases spermatozoa or mature spermatids suitable for the procedure can be recovered from semen or from testis biopsies.

High-throughput Detection of Regulatory Polymorphisms in Candidate Genes Relevant to Common Diseases.

M.C. Theberge, S. Bourgoïn, P. Beaulieu, S. Langlois, H. Belanger, D. Gehl, D. Labuda, D. Sinnett, Regulatory Genetics Consortium. Hopital Sainte-Justine, Universite de Montreal, Montreal, Quebec, Canada.

Understanding genetic variation is critical to reveal the causes to complex diseases and therapeutic responses. Until recently, the emphasis was on the detection of single nucleotide polymorphisms (SNPs) in the coding regions of candidate genes because of their direct effects on the structure and function of the affected proteins. However, transcription factor binding sites lying in the 5 regulatory regions might be disrupted by a SNP leading to changes in expression levels of finely regulated genes. Unfortunately, little is known about the nature and the prevalence of SNPs in the regulatory regions (rSNPs). Thus, investigation in rSNPs of candidate genes should increase our knowledge of the aetiology of complex diseases. This study aimed at identifying the rSNPs in hundreds of candidate genes, selected based on the possible implication of their protein product in cardiovascular diseases, inflammatory disorders, cancers and therapeutic responses. The regulatory regions, arbitrary defined as a 2kb genomic segment upstream of the transcription initiation site, were screened by dHPLC for the presence of SNPs in a population panel of 40 individuals from different ethnic background. In this report, we have screened the regulatory regions of over 190 genes (380 kb of genomics DNA/individual). The nature and position of the rSNPs was confirmed by sequencing. We found the presence of 1554 distinct rSNPs, equally distributed throughout the 2 kb region. Only 20% of these rSNPs have previously been described in public databases such as DBSNP, HGBASE and HGMD. In silico analysis has led to the identification of 77 rSNPs (5%) in conserved regions as well as 1165 rSNPs (75%) affecting predicted binding sites of transcription factors. The functional importance of these rSNPs is being assessed by a combination of methods (gene reporter and gel shift analysis). The detection and validation of rSNPs are relevant to biomedical research by providing a valuable set of targets for discovery of genes related with diseases and therapeutic responses. This work is supported by Genome-Quebec/Canada.

Transcriptional deregulation by adenovirus E1A in human tumor cells: reprogramming of tumor cells to less malignant phenotypes. *J. Dorsman*¹, *A. Teunisse*², *H. Verdurmen*¹, *T. Plug*¹, *D. Rockx*¹, *R. Verheijen*¹, *A. Van der Eb*³.
1) Gynaecological Oncology, VUmc, Amsterdam, The Netherlands; 2) Molecular Cell Biology 1, LUMC, Leiden, The Netherlands; 3) Toxicogenetics, LUMC, Leiden, The Netherlands.

The adenovirus 5 (Ad5) E1A protein can reverse the transformed phenotype in a wide range of human tumor cells and can suppress primary human tumor growth. E1A apparently interferes with oncogenic pathways by its ability to reprogram transcription in human tumor cells. To get more insight which genes are deregulated by E1A in human tumor cells, Affymetrix expression array studies were performed analysing a glioblastoma model system. T98G cell lines which stably express the 12S Ad5 E1A gene were compared with cell lines generated by transfection of the same vector but lacking the E1A gene. The E1A-expressing cell lines do not give rise to any colony formation in soft agar, whereas the control cell lines efficiently form colonies under the same conditions. In agreement with previous studies, an up-regulation of genes involved in the heat shock response was observed. In addition, other groups of co-regulated genes are found, including the down-regulation of a group of genes coding for metalloproteases and of genes involved in xenobiotic metabolism. The Affymetrix data were validated with LightCycler PCR. Subsequently, bioinformatic approaches were used to identify transcription factor binding sites enriched in up- or down-regulated promoters respectively. We found, that the down-regulated promoters were enriched for AP1 elements. This finding is in agreement with the already known negative effects of E1A on AP1. Also other elements not previously associated with E1A were found. The implications of these findings are discussed.

A minimization entropy-based algorithm for modeling bipartite motifs with application to PXR/RXR binding sites. *C. Bi^{1,2}, C. Vyhldal¹, J.S. Leeder¹, P.K. Rogan^{1,2}*. 1) Children's Mercy Hospital, Schools of Medicine and; 2) Computer Science and Engineering, University of Missouri-Kansas City.

We developed a new algorithm for discovering bipartite cis-regulatory patterns based on Shannon's entropy minimization principle and applied to a set of known PXR/RXR binding sites. A bipartite module is an independent functional unit on the upstream of a regulated gene and recognized by a protein binding complex such as PXR/RXR heterodimer. We assume that two proteins (PXR and RXR) cooperatively bind to the module with constrained spacers. The heterodimer binding controls the expression of co-regulated genes such as CYP3A4, which is involved in detoxification of drugs and xenobiotics. A bipartite model built to simulate a bipartite module has two components, left and right motifs and the associated gap penalty function. The goal is to maximize the total information content which can be reduced to minimize the total Shannon entropy. We used Monte Carlo strategy to greedily search the multiple alignment space and find an optimal solution to the bipartite pattern problem. The algorithms were implemented in C++/Perl and successfully applied to finding homogeneous and bipartite motifs using a set of PXR/RXR protein binding sites. We built the models for different motif widths and validated them based on the relative binding strength of the testing sequences. Based on the regression models, we computed the correlation coefficients (r) and Akaike information criterion (AIC) for each model. The best model is the one with the smallest AIC values. Among the best bipartite models are 7<3>7 (7 bps on left and right half-sites with dominant spacer of 3 bps), 8<2>7 and 9<2>7 ($r > 0.83$). The results support our hypothesis that PXR and RXR transcription factors cooperatively bind to two adjacent motifs with variable spacing.

CEPH cell lines are representative of the American Caucasian population: implications for pharmacogenetics.

M.A. Meucci, S. Marsh, H.L. McLeod. Molecular Oncology, Washington University, St. Louis, MO.

A better understanding of genetic influences on drug response is needed to improve the identification of patients that will either benefit or be harmed by therapy. If an adequate sample size is collected, the quantity of available DNA may not be adequate for a comprehensive analysis. CEPH cell lines are a collection of immortalized lymphoblastoid cells from multiple generations of large families. They have previously been critical for genome mapping, and have been used by the International Haplotype Mapping project and by SNP consortium. They have been used to identify QTLs associated with transcriptional control, apoptosis after irradiation and recently have been used to identify cytotoxicity after cancer chemotherapy. There is no data on how representative CEPH cell lines are for genetic variants of pharmacogenetic significance. Genotype and allele frequencies of twenty-eight variants in fifteen clinically relevant genes were analyzed in germ-line DNA from 95 European-Americans and 95 Africans, and 80 CEPH cell lines of American Caucasian origin. The results demonstrate that allele frequencies for the twenty-eight polymorphisms are not significantly different ($p > 0.05$), between the CEPH cell lines and the European germ-line DNA. The Spearman rank value for the comparison between the CEPH and European allele frequencies is 0.954 with a 95% CI of 0.899-0.979. We have demonstrated that CEPH cell lines of American Caucasian origin do not significantly differ in allele frequency compared to the European germ-line DNA. The Spearman rank value for the comparison between the CEPH and African allele frequencies is 0.554 with a 95% CI of 0.181-0.787 demonstrating that, as expected, CEPH cell lines of American Caucasian origin will not provide a high level of prediction for African DNA analysis. It can be stated that in research involving a reference population, the relevant population equivalent CEPH cell lines can be substituted as an ideal DNA resource without compromising quality for quantity, providing pharmacogeneticists with a renewable resource for association, population, and functional analysis of clinically relevant polymorphisms.

Physical Mapping of the Proximal p Arm of HC21. *E. Miller¹, L. Chen¹, E. Becka¹, R. Ganith¹, A. Hohmann¹, E. Hood¹, M. Bozovsky¹, C. Holmes¹, M. Cummings², J. Doering¹.* 1) Loyola Univ Chicago; 2) Univ. of Illinois, Chicago.

Centromeric and other heterochromatic regions, which comprise 10-15% of the human genome, are not included in the completed sequence. We are constructing a detailed physical map of the centromere and p arm of HC21 as a model for the organization of such regions. Our previous work found that proximal 21p has a number of low copy number repeat sequences (LCNR) also found in the centromere of HCY. The linear order of these elements on the proximal p arm of HC21 strongly resembles that on HCY. We have sequenced six of the LCNR from HCY (KFC11, KFC37, KFC43, KFC52, 64b, YIII.1). BLAST results indicate that three of these elements (KFC11, KFC37, KFC52) are contained in the human chAB4 duplicon. The chAB4 duplicon is ~86kb long and composed of a chAB4 DNA segment adjacent to a 48bp satellite array of variable length, followed by an NF1-related pseudogene. Work by others suggested that the chAB4 duplicon normally occurs as two adjacent copies with a palindromic organization. However, our mapping studies show that the chAB4 duplicon is not in a palindromic organization on either HC21 or HCY. The organization of the chAB4 duplicon and adjacent LCNR appears to be the same on HC21 and HCY, which clarifies an unsequenced HCY centromeric region. The chAB4 duplicon and adjacent LCNR are located in the 21-II region of the proximal p arm of HC21. This region is composed of a complex array of monomeric alphoid DNA along with SINES, LINES, and other satellite DNA. Comparing the sequences of the duplicon and adjacent LCNR on HCs 21, Y, 22, and 17 indicates copies of these sequences on different chromosomes share at least 90% sequence similarity. It also indicates that chAB4 may be part of an even longer ~200kb duplicon. LCNR corresponding to ~63kb of the chAB4 duplicon are also present on the distal p arm of HC21. A segment of ~13kb of the duplicon is also found in HC21q adjacent to the D21Z1 alphoid array. Thus various portions of the duplicon have apparently moved independently in the genome. LCNR located in the proximal p arm of HC21 will allow construction of a contiguous map of ~5Mb that links 21-II to the centromeric D21Z1, and joins the p arm to the q arm.

Program Nr: 1671 from the 2004 ASHG Annual Meeting

Copy Number Variation in the Human Alpha Defensin Genes *DEFA1* and *DEFA3*. *P.M.R. Aldred, E.J. Hollox, J.A.L. Armour.* Genetics, Univ Nottingham, Nottingham, United Kingdom.

Human defensins are small cationic peptides that form part of the innate immune system, acting against a variety of bacteria, fungi and also some viruses. To date, a cluster of six human alpha defensins has been identified on chromosome 8p23.1. *DEFA1-DEFA4* are expressed in neutrophils and neutrophil defensins appear to have some anti-HIV activity. *DEFA1* and *DEFA3* differ by a single amino acid change and the corresponding genes have been shown to vary in copy number between individuals. Here we use Multiplex Amplifiable Probe Hybridisation (MAPH), Pulsed-Field Gel Electrophoresis, Southern Blotting and ratios from restriction fragment digest assays to investigate the extent of this copy number variation in the general population. The results show that diploid copy number of *DEFA1* can range from three to nine copies with four to six being most common. The diploid copy number of *DEFA3* was found to range between zero and four copies with most individuals having one or two copies. 18/145 samples were found to lack the *DEFA3* gene, corresponding to a previous report that approximately 10% of people lack the *DEFA3* peptide. Current work is moving on to study the relationship between genomic copy number and expression levels of *DEFA1* and *DEFA3* by comparing ratios from restriction digest of cDNA products with those from genomic DNA.

Interleukin-10 -1082 G/A polymorphism and Risk Of Bronchopulmonary Dysplasia (BPD). *R. Baier, J. Loggins, K. Yanamandra.* Dept Pediatrics, LSU HSC, Shreveport, Shreveport, LA.

IL-10 expression is affected by a single nucleotide polymorphism (SNP) located at position -1082 (G to A). The A allele is associated with lower IL-10 production. Low IL-10 production has been linked to the development of BPD. Thus, the IL-10 -1082 SNP may be a genetic risk factor for the development of BPD. The IL-10 -1082 SNP was determined in 294 (235 African-American, 56 Caucasian and 3 Hispanic) mechanically ventilated VLBW infants at risk for BPD. The incidence of the A allele in our population was 0.62. Thirty-nine (13.3%) infants were GG, 146 (49.7%) were GA and 109 (37.0%) were AA. There were no significant differences between genotype groups with respect to ethnic origin, gender or need for surfactant replacement therapy. AA infants were slightly more mature and of greater birth weight than GA infants (27.0 0.2 wks vs. 26.30.2 wks; $p < 0.05$: 94022 gms vs. 88218 gms; $p < 0.05$). There was no significant effect of the IL-10 -1082 SNP on mortality or development of BPD. However, the AA/GA genotypes was associated with a reduction in risk for the combined outcome of BPD or death (18/38 vs. 80/256; $p = 0.049$).

Outcome	GG (n=39)	GA (n=145)	AA (n=110)	p
Early Death	6 (15%)	14 (10%)	8 (7%)	0.340
Total Mortality	8 (21%)	20 (14%)	15 (14%)	0.536
BPD	11 (34%)	30 (23%)	22 (23%)	0.366
Death or BPD	18 (46%)	46 (32%)	34 (31%)	0.189

The IL-10 -1082 G/A SNP may influence mortality and or the development of BPD in ventilated VLBW infants.

(XY)_mX_n repeats are a common, variable, and evenly distributed polymorphism. *T. Hefferon, D. Cutler, G.R. Cutting.* Inst Genet Med, Johns Hopkins, Baltimore, MD.

While studying the *CFTR* gene, we discovered that a variable TG dinucleotide tract immediately adjacent to a variable T mononucleotide tract displayed a unique form of co-variation. Nucleotides at the interface of TG and T repeat tracts were found to be highly susceptible to point mutations, G>T or T>G, that resulted in simultaneous changes in repeat number of both tracts. To determine if other examples of these repeats exhibited similar variation, we scanned the genome for loci that conformed to the pattern (XY)_mX_n, where m ≥ 5 and n ≥ 5 and identified 41,294 loci. On the other hand, we discovered only 2,930 examples of (XY)_mZ_n tracts. We then determined the distribution of (XY)_mX_n repeats across the human genome. The most abundant group, (TA)_mT, contained 15,110 examples with a mean of 5.3 ± 3.0 per megabase, or roughly one per 200 kb. To determine the extent of variation at (XY)_mX_n loci, we sequenced DNA samples from 18 individuals of diverse geographic origin at randomly selected sequences representing all purine/pyrimidine combinations of di- and mononucleotide tracts ((TG)_mT (n=5), (TC)_mT (n=5), (TA)_mT (n=3), (GC)_mG (n=2), and (GA)_mG (n=3)). Evidence of mutation occurring at the interface of the di- and mononucleotide tracts was observed in all groups except (GC)_mG. The extent of polymorphism varied amongst the combinations, and was highest in (TG)_mT and (TC)_mT, each of which contained an average of seven different alleles in our sample of 36 chromosomes. In addition, sequencing of the *CFTR* (TG)_mT locus in twenty-two chimpanzees revealed two variants, which differed from one another by a mutation at the interface of the two tracts. (XY)_mX_n repeats thus represent a unique form of genetic polymorphism that is both widely distributed and highly informative, and which has potential applications to linkage, mapping, and evolutionary studies.

Program Nr: 1674 from the 2004 ASHG Annual Meeting

A significant portion of false single nucleotide polymorphisms may not be revealed by large-scale validation. *M.J. Luo, X.F. Cui, D.M. Frikker, M.A. Azaro, H.Y. Wang, I.V. Tereshchenko, G.H. Hu, H.H. Li.* Dept. of MGM/The Cancer Inst of NJ, UMDNJ, 195 Little Albany St, New Brunswick, NJ 08903.

More than 10 million single nucleotide polymorphism (SNP) submissions have been received by the public databases. Large-scale effort is being made to validate these genetic markers. Our recent study indicates that a significant portion of false SNPs may not be revealed by the commonly used validation methods. In order to evaluate the limitations associated with the conventional validation methods, 2357 SNPs were selected and reevaluated with three different new approaches, gel electrophoresis, single-sperm test and population analysis. It was found that 4.4 % of these SNPs were not real and may be attributed to paralogous sequence variants. Among the 4.4% false SNPs, 30% may not be revealed by the commonly used validation methods. We also showed that the accuracy of genotyping method could be limited by unknown polymorphisms in the primer or probe regions. Approximate 0.35% of typing errors can be attributed to this problem. The present study indicates that no method alone could identify all false SNPs and SNPs in the databases should be used with caution even if those have been validated. Some of the measurements on SNPs quality present in the database, such as DoubleHit, may not be very meaningful. Gel electrophoresis after PCR amplification is an efficient method for primary and rapid screening. For a high level of accuracy in SNP selection, combined methods should be used.

Functional polymorphisms in the putative promoter region of the human equilibrative nucleoside transporter 1 gene. *S.N. Myers*^{1,3}, *J.D. Roy*^{2,3}, *R.K. Goyal*^{1,3}, *R.E. Ferrell*^{2,3}. 1) Pediatric Hematology/Oncology & Bone Marrow Transplantation, Children's Hosp of Pittsburgh; 2) Department of Human Genetics; 3) University of Pittsburgh, Pittsburgh, PA.

Induction chemotherapy regimens containing cytosine arabinoside (ara-C) and anthracyclines result in 80% complete remission rate in childhood acute myeloid leukemia (AML) but their cure rate is about 35 - 50%, one of the lowest of all childhood cancers. Understanding the factors that contribute to emergence of chemoresistant leukemic cells is crucial to improving treatment outcome in children with AML. Ara-C is the most active anti-metabolite for inducing remissions in AML. Human equilibrative nucleoside transporter 1 gene (hENT1) may play a significant role in determining outcome of AML therapy because it transports Ara-C into leukemic blast cells and is down-regulated in resistant blast cells. We resequenced 1.6 Kb of the 5'-flanking region of hENT1 (SLC29A1) in 48 unrelated individuals and identified four haplotypes comprised of single nucleotide polymorphisms (SNPs) at positions -1345C/G, -1050G/A, and -706G/C. TRANSFAC analysis predicted that -706G/C would alter consensus transcription factor binding site sequences. Expression of reporter gene luciferase was analyzed in the COS-1 cell line transfected with the luciferase vector pGL3-BASIC containing the 1621 bp region spanning from -2 to -1622 of the hENT1 upstream sequence with the wild type CGG sequence, or one of the CAG, GAG, or CGC variants. The expression of luciferase increased by 105% in the CAG ($p < .0001$) and 52% in the CGC variant ($p < .0001$), as compared to the CGG wild type haplotype. A 5% increase from the CGC haplotype was not significant. These data suggest that the CAG and CGC haplotypes of the hENT1 upstream region may influence hENT1 expression and be functionally relevant. We are currently genotyping a cohort of 94 Caucasian individuals of mixed European ancestry at these loci for haplotype frequency distribution. Additional experiments are underway to test the significance of this variation in hENT1 gene in a large group of children treated on ara-C based cooperative clinical trials.

Comparison of whole genome amplification methodologies and sources of biological sample for high-throughput SNP genotyping. *J.W. Park*^{1,2}, *T.H. Beaty*¹, *P. Boyce*³, *A.F. Scott*^{2,3}, *I. McIntosh*². 1) Epidemiology, Johns Hopkins University, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 3) Center for Inherited Disease Research, Baltimore, MD.

The amount of genomic DNA required for extensive genetic analyses may exceed that available, especially for stored samples. Development of methods for whole genome amplification (WGA) circumvents this problem. Two such methods, multiple displacement amplification (MDA) and OmniPlexTM technology, were compared to determine the efficiency and accuracy of amplification measured by SNP genotyping using the Bead Array method on 1,260 markers in 18 unrelated individuals. The success rate of genotyping from amplified DNA by MDA (GenomiPhiTM, Amersham) was lower than that from un-amplified DNA (90% vs. 98.9%) but higher than any other WGA method (64.1%~88.6% for OmniPlexTM with or without 7-deaza-GTP, & TempliPhiTM). The number of mismatches between pre-amplified and amplified DNA extracted from whole blood was lowest for GenomiPhiTM and highest for OmniPlexTM with 7-deaza-GTP as an additive (0.21% vs. 1.33%, $p < 0.01$) among four different WGA methods. The efficiency and accuracy of MDA was also compared on a refined 1,228 SNP panel using different sources of genomic DNA (whole blood, buccal swab, and dried blood spot) from the same individuals. Amplification of DNA from buccal swabs was both less efficient and less accurate than from whole blood (97.6% vs. 99.5% and 0.35% vs. 0.06%, respectively) but superior to DNA from dried blood spots despite the use of 3 independent extraction methods (31.2%-90.3% success rate, 14.5-44.9% mismatches). The low efficiency and accuracy of amplification when using DNA extracted from dried blood spots as template may be due to its low molecular weight, since sheared genomic DNA (< 20kb in length) also gave high rates of SNP genotype mismatches and low efficiency. In conclusion, MDA represents an efficient method to maximize DNA resources from whole blood and buccal swabs.

A simple PCR-RFLP method to type the G1162A renin gene SNP (formerly *BgII*) and its frequency in a Mexican population. *L.L. Valdez*^{1,2}, *F. Mendoza-Carrera*^{1,2}, *H. Montoya-Fuentes*¹, *F. Rivas Jr.*³, *F. Rivas*¹. 1) Western Biomedical Research Center, Instituto Mexicano del Seguro Social; 2) Graduate Studies Program in Human Genetics, Universidad de Guadalajara, Guadalajara, Jalisco; 3) School of Medicine, Universidad de Colima, Colima, Mexico.

Renin is the main rate-limiting enzyme in the renin-angiotensin system (RAS) cascade that leads to the production of angiotensin II. The enzyme and its gene (REN), located at 1q32, are candidate underlying factors in essential hypertension and cardiovascular disease. *BgII*, one of the most commonly investigated REN polymorphisms, has been studied either by Southern-blot or PCR. Previously published PCR techniques involved long amplicons (3.9 kb) or used less-than-ideal primers, and misidentified the precise SNP location. In this report, a new PCR procedure to type REN *BgII* polymorphism is presented. Newly designed primers: 5' ATAATAACAGTACCTACTTGATG 3' (F), 5' CTACAGTCTTAATGAATCACTT 3' (R) were used. Acrylamide electrophoresis disclosed either a single- (allele A, 537 bp) or two-band (allele G, 371+166 bp) pattern per chromosome after *BgII* digestion. Sequencing demonstrated this polymorphism is located at nucleotide position 1162. DNA samples from 129 non-related volunteers were typed following the present PCR-*BgII* protocol. This group of healthy mestizo adults living in Guadalajara is an admixed population with 56% Spanish component. Allele frequency was 0.30 G and 0.70 A, and genotype frequencies 15/129 (11.6%) G/G, 48/129 (37.2%) G/A, and 66/129 (51.2%) A/A. Frequencies are in agreement with Hardy Weinberg expectations ($\chi^2=1.79$, 1 df, $p>0.05$). Allele distribution in this study is similar to that observed in Caucasian populations (range 30-39%). Since this RFLP shows a worldwide diversity (6 to 48% allele G), population-specific data for human REN SNP G1162A must be considered to study RAS in normal and diseased groups. The method here presented is reliable, simpler, and less expensive than previously developed ones.

Cost-benefit and high-throughput method for polymorphism validation. *H.-C. Yang¹, C.-H. Lin², C.S.J. Fann¹.* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Genetics, Yang-Ming University, Taipei, Taiwan.

Using dense SNP markers to locate disease susceptibility genes of complex disorders becomes a mainstream of fine mapping. However, only polymorphic SNP markers provide statistical power to assess LD. The public-domain genetic databases only provide partial information of polymorphism for populations of various ethnic backgrounds. Hence, validation of polymorphism for the studied ethnic group is always essential prior to initializing a large-scale genotyping experiment.

In this paper, we employ DNA-pooling approach based on the platform, MALDI-TOF mass spectrometry (Sequenom), to achieve rapid and economic polymorphism validation. Variation inherent in DNA pools is controlled by replications. To evaluate the performance of the proposed strategy, we carry out an experiment with 185 SNPs located in HLA region of chromosome 6. The SNP information is published in Walsh et al. (2003). Based on our previously collected normal samples consisting of 3400 individuals residing in Taiwan, 630 individuals are selected randomly and their genomic DNA is pooled together. For each SNP, sixteen observations from four replicates for each combination of two PCR amplification and two chips are analyzed. On the other hand, 95 individuals are also chosen randomly from the normal samples and genotyped individually for confirmation purpose.

Firstly, we compare the allele frequencies from our individual genotyping experiment and Walsh et al's experiment which is contributed by European-descent CEPH families. The discrepancy of different ethnic groups reflects on the inconsistent patterns of polymorphism. Twenty-one SNPs out of 185 SNPs cannot be validated suggests a misclassification rate of 11.35% for the two ethnic groups. Secondly, based on our proposed method, we find high consistency in terms of polymorphism validation between our DNA-pooling and individual genotyping studies. The sensitivity is 93.29% and specificity is 100%. These results suggest that using DNA pooling is cost-benefit and information-retained compared with individual genotyping in polymorphism validation.

A comparative study of the neighboring-nucleotide biases on single nucleotide polymorphisms in the mouse and human genomes. *F. Zhang*¹, *Z. Zhao*^{1,2}. 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 2) Center for the Study of Biological Complexity, Virginia Commonwealth University, Richmond, VA.

A comprehensive understanding of single nucleotide polymorphisms (SNPs) in the human, mouse and other model organisms is essential to unravel the genetic basis of phenotypes, functions, and diseases. The substitution patterns at polymorphic sites and the sequence context in a local environment of SNPs reflect the mutability of the sequence and, therefore, are important for studying the molecular mechanisms of the mutation and the genome sequence evolution. In this study, we first analyzed the neighboring-nucleotide composition of 469,455 biallelic SNPs in the mouse genome and then compared the results obtained from 8,043,656 human SNPs. These data were obtained from NCBI's dbSNP database and represented the largest public collection of SNPs at present (dbSNP build 121, released in June 2004). As in humans, large neighboring-nucleotide biases relative to the genome- or chromosome-specific average were observed in mice at the immediate adjacent sites. For all substitutions, the biases for A, C, G, and T were 0.12%, 2.90%, 0.69%, -3.71%, respectively, at the immediate adjacent 5' site and -3.87%, 0.75%, 2.98%, 0.14%, respectively, at the immediate adjacent 3' side. The biases decreased by increasing distance from the substitution site. An examination of the six categories of substitution revealed the different patterns for transitions and transversions. For transitional substitutions, we observed the large biases on nucleotide C at the nearest 5' site and G at the nearest 3' site, reflecting the strong influence of the hypermutability of dinucleotide CpG in the mouse genome. The patterns of neighboring effects on transversional substitutions were complex. In both genomes, the probability of a transversion increased with increasing A+T content of the two immediate adjacent sites. In conclusion, the bias patterns for the neighboring nucleotides in the mouse and human genomes were essentially the same; however, the extent of the biases was remarkably less in mice.

Analyzing individual BioGeographical ancestry and admixture structure in human populations. *I. Halder¹, R. Mei², E. Parra³, J. Akey⁴, M. Shriver¹*. 1) Dept Anthropology, Pennsylvania State Univ, State College, PA; 2) Affymetrix Inc. Santa Clara, CA; 3) University of Toronto at Mississauga, Mississauga, Canada; 4) Fred Hutchinson Cancer Research Center, Seattle, WA.

Understanding genetic variation in populations and how this variation contributes to differences in disease risk among populations is an important area of research. We have typed a panel of 11,555 SNP markers in three resident US populations, (African Americans, Puerto Ricans and European Americans) in an effort to analyze patterns of genetic variability. The first two are considered admixed populations with varying levels of BioGeographical ancestry (BGA), while the European Americans are assumed to be more homogeneous. Putative ancestral populations were chosen from among a panel of twelve world populations typed for the same markers. Using a maximum likelihood based method and a separate Bayesian method we show that individual BGA estimates vary within all groups. Assuming a trihybrid model of admixture between Europeans, West Africans and Native Americans we observed large variations in individual BGA levels in both the African-American and Puerto Rican samples, while the European Americans are more tightly clustered. Additional simulation studies were done to check the reliability of the estimates under the specified model. Simulations further indicate that the choice of ancestral population and its sample size both affect individual BGA estimates.

To test for stratification within the population samples we have used the Individual Ancestry Correlation (IAC) test, where markers are split into two non-overlapping subsets and ancestry is estimated separately with both sets. Correlation between estimates obtained with the different marker sets indicates presence of genetic structure. While both the African-American and the Puerto Rican samples show admixture stratification as expected, we also detected evidence for stratification within the European-American sample. Additional simulations showed that individual BGA estimates differed when only a subset of informative markers was used as opposed to including all markers.

In vivo analysis of p53 protein binding to consensus sites in the p21, GADD45, MDM2, XPC and XPE genes in normal fibroblasts irradiated with ionizing radiation

p21GADD45MDM2XPCXPE. W. Dridi¹, R. Fetni², R. Drouin¹. 1) Dept Pediatrics, CHUS, Quebec, QC, Canada; 2) Cytogenetics, Montreal Children Hospital, Montreal, QC, Canada.

Introduction: As a transcription factor, p53 protein controls the expression of more than 30 genes. P21, GADD45, MDM2, XPC and XPE genes are amongst the most downstream effectors of p53. In the literature, in vitro analysis gives strong evidence that p53 binds to its consensus sequence in these genes. However, only one study has shown in vivo the interaction of p53 with p21 and GADD45 genes in human myeloblastic leukemia cell line (ML-1). **Objective:** To analyze p53 binding in vivo to its consensus sequence on p21, GADD45, MDM2, XPC and XPE genes in normal human fibroblasts following gamma irradiation. **Methods:** Human fibroblasts were exposed to 20 Grays of gamma irradiation. At different time points (0, 1, 2, 4 and 8 hours), cells were treated with either one of the two footprinting agents (DNaseI and UVC were used), DNA was purified, and ligation-mediated PCR was carried out for the p21, GADD45, MDM2, XPC and XPE genes. **Results:** No footprints in MDM2, XPC and XPE genes were observed. Only a weak in vivo footprint was observed at 1 hour on p21 and GADD45 promoters. **Conclusion:** So far, we haven't been able to provide evidence of p53 binding to its consensus sequence under physiological condition. This could suggest that other factors maybe implicated in vivo that are present in ML-1 cell line and absent in normal human fibroblasts.

Searching for candidate genes influencing genetic susceptibility to asbestos-related diseases. *M.A. Pershouse, A. Groves, C. Schwanke, E.A. Putnam.* Biomed & Pharmaceutical Sci, Univ Montana, Missoula, MT.

The exposure of Libby MT residents to asbestos-contaminated vermiculite is well known. The effects of genetic susceptibility on the development of asbestos-related diseases (ARD) are of primary interest. A mouse model of asbestos exposure is being used to determine gene expression responses to various asbestos forms using a small set of known toxic response genes. It is our hypothesis that asbestos-responsive genes will provide a better understanding of response mechanisms and identify candidate genes for polymorphism analysis of DNA from residents exposed to asbestos. C57Bl/6 mice were exposed via intratracheal instillation of tremolite, winchite, and chrysotile asbestos, in addition to saline and wollastonite, a control fiber. Libby asbestos is an amphibole fiber most closely related to winchite. Other fibers were used as closely related controls. 3 months following exposure, mice were sacrificed and whole lungs harvested for microarray analysis. Using an arbitrary cutoff of 1.5 fold change we found 170 out of 1200 genes affected among the three types of asbestos tested. After tremolite exposure, expression of 41 genes escaped the 1.5 fold cutoff. Winchite exposure resulted in 4 genes being filtered to this level. Exposure to chrysotile (the most common asbestos used in industry) resulted in increased expression of 31 genes, and decreased expression of 5 genes. Therefore, using microarray techniques, a list was generated of genes whose RNA expression levels were specifically altered in response to different asbestos exposures. Among the genes altered in winchite exposure are catechol-o-methyltransferase (Comt), Regulator of G protein signaling 7 (RGS7), macrophage receptor with collagenous structure (Marco), and calmodulin 3 (Calm3). Candidate gene expression changes are being validated at the protein level using immunohistochemistry of corresponding tissue sections. These experiments have provided new candidates for genes involved in the asbestos response pathways. These results will be validated by the analysis of polymorphisms in these identified genes in patient samples. Supported by CCR822092.

Automated mRNA splice site mutation analysis by information theory. *V. Nalla¹, P.K. Rogan^{1,2}*. 1) Schools of Computer Science and Engineering and; 2) Medicine, Children's Mercy Hospital, University of Missouri-Kansas City.

We present a software tool to assist in interpretation of non-coding sequence variation in functional elements within human genes. This secure web server analyzes changes in information content at binding sites due to one or more mutations in any catalogued human gene, genome-mapped mRNA or user-defined sequence [<https://splice.cmh.edu>]. Individual information analyses with splice junction binding site matrices detects activated cryptic splice sites, associated splicing regulatory sites and distinguish null alleles from those that are partially functional. Standard gene and mutation nomenclature (HUGO-approved format) are entered using a CGI-based front end supported by backend server. Back-end software verifies the input variant or haplotypes and retrieves the corresponding hnRNA sequences from the reference genome sequence. The software then substitutes either a mutation(s) for the reference sequence and computes the resulting information contents of all preexisting and altered splice sites and/or regulatory sequences. Changes in information content are tabulated and visualized as walker figures showing the binding sites with the sequence. This application has been validated by analysis of ~400 consecutive mutations published in the journal, *Human Mutation*. We confirmed that all of the previous recognized splicing mutations affected splice site strength or activated cryptic splice sites. At least one missense mutation was also classified as a cryptic splicing mutation since it simultaneously abolished a natural splice donor while activating a down stream pre-existing cryptic site. The long term goal is the development of a turnkey system to predict disease severity of splicing mutations.

Isolation and analysis of primate telomeric regions. *Y. Kuroki¹, A. Toyoda¹, T. Taylor¹, T. Itoh², M. Hattori^{1, 3}, Y. Sakaki¹, A. Fujiyama^{1, 4}.* 1) RIKEN Genomic Sciences Center, Yokohama, Kanagawa, Japan; 2) Mitsubishi Research Institute Inc., Chiyoda-ku, Tokyo, Japan; 3) Kitasato University, Sagami-hara, Kanagawa, Japan; 4) National Institute of Informatics, Chiyoda-ku, Tokyo, Japan.

Sequencing of the human genome is considered finished, however some complex regions such as the centromeres and telomeres still remain. Genomic analysis of these complicated structures is important for understanding the biological and biomedical functions of these regions. To elucidate the biological and evolutionary aspects of genomic structure in primate telomeric regions, we have developed a screening system for isolation of telomeric clones. We have constructed resources, such as sheared fosmid/cosmid libraries constructed from flow-sorted human or primate chromosomes or whole-genomic DNA, and technologies to specifically isolate clones containing telomeric motifs at either end of the DNA insert. This methodology has proven quite effective through successful isolation of telomeric clones from human chromosomes, 11, 18, and 21, all of which our group has helped to complete the sequencing of. Unlike the half-YAC cloning technology, which was developed to clone chromosomal ends using yeast cells that have a high host recombination rate, our technology utilizes an F-plasmid based vector which is similar to the BAC cloning system, thereby ensuring stability and a uniform recombination frequency in the host *E. coli* cell. Both ends of the inserted DNA fragment for each isolated clone were sequenced and mapped onto the human genome based on sequence similarity, or through FISH analysis using human or primate chromosomes. In addition, some clones have been completely sequenced and opened to the public. We plan to continue isolating, mapping, and sequencing additional telomeric clones to better understand the aspects of the telomeric and subtelomeric regions. We are also conducting comparative analysis using telomeric clones isolated from other primates and other organisms in order to track the evolutionary paths of each chromosome. This data will help to complete the tiling path for each chromosome, thus improving tools for diagnosis of chromosomal abnormalities.

Genetic investigation of the acute adverse reactions associated with Angiotensin I-Converting Enzyme Inhibitors.

Q. Duan¹, B. Nikpoor¹, G. Molinaro², I.A. Meijer¹, D. Rochefort¹, J. Saint-Onge¹, L. Flury³, J.L. Rouleau², P. Simon⁴, P. Clavel⁵, J. Potier⁶, B. Wehbe⁷, S. Benarbia⁷, J. Marc-Aurèle⁸, M. Cugno⁹, J. Chanard⁵, T. Foroud³, A. Adam², G.A. Rouleau¹. 1) CRN & MUHC Institute, Montreal; 2) Medicine & Pharmacie, Université de Montréal; 3) Medical Genetics, Indiana University; 4) Hémodialyse, CH Saint-Brieuc, France; 5) Hémodialyse, ARPDD & CH Reims, France; 6) Hémodialyse, CH Louis Pasteur, France; 7) Hémodialyse, CH Cornouaille & Laënnec, France; 8) Hémodialyse, Hôtel-Dieu de Saint-Jérôme, Canada; 9) Medicine, IRCCS Maggiore Hospital, University of Milan, Italy.

Angioedema (AE) and anaphylactoid reactions (AR) are acute adverse effects associated with angiotensin I-converting enzyme inhibitors (ACEi), drugs used for the treatment of cardiovascular diseases. Previous reports have documented significantly lower plasma aminopeptidase P (APP) activities in patients with a history of ACEi-induced AR or AE, which correlate with significantly reduced degradation of des-arginine⁹-bradykinin. Given that the incidence of these adverse reactions differs among ethnic groups, we propose that this metabolic anomaly is partially regulated by genetic factors. To determine the genetic basis of variable plasma APP activity, we estimated the heritability of this quantitative trait using the SOLAR (Sequential Oligogenic Linkage Analysis Routines) program. This predicted that 45.6% of the phenotypic variation results from genotypic differences among members of 8 Caucasian families (total of 118 individuals). The 5 largest pedigrees were subsequently used in a genome scan that consisted of approximately 400 microsatellite markers spaced at genetic intervals of 10 centimorgans. Linkage analysis of the genotypes using SOLAR provided LOD scores greater than 1.4 for 5 loci localized on chromosomes 6, 8, 10 and X. Genotyping of these markers in additional families is underway to determine if these represent true or spurious linkage. In addition, screening of candidate genes is ongoing to identify mutations responsible for reduced plasma APP activity and predict susceptibility to ACEi-induced adverse effects.

GENE EXPRESSION PROFILING OF PATHOGENESIS SEEN IN A MOUSE MODEL OF OBLITERATIVE BRONCHIOLITIS. *J. Lande, S. Dalheimer, M. Hertz, R. King.* Department of Medicine and Institute of Human Genetics, University of Minnesota, Minneapolis, MN 55455, United States.

Background: Lung and heart-lung transplantation are effective treatments for many diseases unresponsive to other therapy; however, long term survival of recipients is limited by the development of obliterative bronchiolitis (OB). We have used a heterotopic murine tracheal transplant model of OB to study the immunological and fibroproliferative events associated with this process, using gene expression microarray analyses to profile the different stages of its development. Methods: Four tracheas from BALB/c (isograft) or C57B6 (allograft) mice were heterotopically transplanted into recipient BALB/c mice. Transplanted tracheas were extracted from recipients at day 4 (epithelial loss/regrowth), 14 (immune response) or 25 (fibroproliferation) for whole graft RNA. Five replicates of each graft type/day combination were collected and RNA expression was analyzed using Affymetrix murine 430A arrays. Two-way ANOVA using graft type and day as factors was performed and transcripts with strong statistical significance were further analyzed. Results: 174 transcripts with F test p-values < 0.00001 were visualized using two dimensional hierarchical clustering. Samples clustered into four prominent groups representing both graft types at 4 days, 14 and 25 day isografts, 14 day allografts and 25 day allografts. Cluster analysis indicated a group of 6 genes associated with cell-mediated immunity with relatively high expression in 14 day allografts, 4 genes with relatively low expression in 14 day allografts and 14 genes associated with humoral immunity that were highly expressed in 25 day allografts. The remaining 150 genes indicated a pattern of moderate expression in 4 day grafts, low expression in later allografts and high expression in later isografts. Conclusions: There are clear and reproducible gene expression differences that differentiate isografts and allografts at 14 and 25 days. These expression profiles appear to reflect known processes associated with OB and offer insight into other less well understood aspects of this disease process.

Recent evolution of the most intact retrovirus in the human genome. *J. Lenz¹, D. Heslin¹, A. Ene¹, G. Turner¹, M. Barbulescu¹, M. Su¹, M. Jensen-Seaman², K. Kidd².* 1) Dept. of Molecular Genetics, Albert Einstein College of Med, Bronx, NY; 2) Dept of Genetics, Yale University School of Medicine, New Haven, CT.

Of the many retroviruses that comprise about 8% of the human genome, HERV-K is the most recently acquired in human evolution and is by far the most intact. Since first entering the catarrhine lineage after the catarrhine-platyrrhine divergence, HERV-K appears to have reinfected the human genome continuously until recently.

We asked when the HERV-K proviruses that are in the human genome today originally formed. HERV-K proviruses exist in three forms, relatively intact, full-length viral genomes of which there are about 20 in the human genome today, partial viral genomes, and solo LTRs, a product of intraviral homologous recombination. Using a method to date the time of formation solo LTRs (that far outnumber the full-length proviruses), we estimate that about 100 HERV-K proviruses were fixed in the human genome since the human and chimpanzee lineages diverged. Most of these formed within the most recent 1.2 to 2.7 million years, suggesting that HERV-K has been relatively active during this period of time.

One HERV-K provirus is present at the orthologous positions in the gorilla and chimpanzee genomes, whereas humans contain an intact preintegration site. This provides an excellent example of a locus where the gorilla and chimpanzee genomes are more like each other than like that of humans.

At least 13 of the full-length HERV-K proviruses in the human genome formed after the human and chimpanzee lineages diverged. At least three formed sufficiently recently that they exist allelically with the intact preintegration sites, and each is present in only a fraction of humans today. Many solo LTRs also exist allelically with the cognate preintegration site. One of the proviruses contains full-length open reading frames for all viral proteins. This is the best candidate to be a human genome retrovirus that is capable of reinfected humans today.

The palindromic content of the human genome. *S. Lewis*^{1,2}, *T. Allyn*³, *J. Cheung*¹. 1) Hospital for Sick Children Toronto, ON, Canada; 2) University of Toronto, Toronto, ON, Canada; 3) University of Waterloo, Waterloo, ON, Canada.

True palindromes (comprised of a sequence that is immediately followed by its inverse complement) are hotspots of DNA rearrangement. Under the stress of hypernegative supercoiling, a DNA palindrome can assume an intra-strand paired cruciform structure. Such branched DNA is functionally compromised; cruciformation not only interferes with DNA replication and transcription but also generates a substrate for nucleases and recombinases. Palindromy confers a latent propensity for damage on a DNA sequence, damage that is manifested under some circumstances, though not others.

The study of DNA palindromes longer than about 200bp is impeded by a profound technical barrier which is that such sequences are impossible to clone in *E. coli*. Thus any long, true palindromes that might occur naturally in the human genome are systematically excluded from the sequenced record. We are interested to know whether long, true DNA palindromes exist in human DNA and if so, whether such sequences are associated with pathological DNA rearrangement.

To determine whether long true palindromes exist, we undertook a two-part study. First, we looked for evidence of palindromy by searching the human genome for all instances of palindromes longer than 90 bp. We were able to find 67 putatively palindromic sites, few of which exceeded 100bp. Next we took representative palindromic hits from this computationally-defined collection and tested for their presence or absence among normal individuals. This was achieved by PCR, cloning and DNA sequence analyses.

In brief, inter-individual comparisons show a high level of polymorphism for at least some palindrome-bearing loci. Moreover, different polymorphic forms of the same locus have profoundly different biophysical properties. These studies verify that sites of putative palindromy are not assembly or sequencing errors, but do indeed exist in the human genome. Moreover, the presence of additional "hidden" palindromes is strongly implied by the length cut-off we observed.

Evidence that simple sequence repeats influence the replication time of genes. *M. Regelson*¹, *D. Eller*¹, *Y. Marahrens*^{1, 3}, *S. Horvath*^{1, 2, 3}. 1) UCLA Department of Human Genetics; 2) UCLA Department of Biostatistics, Gonda Center, David Geffen School of Medicine, 695 E. Young Drive South, Los Angeles, CA 90095-7088, USA; 3) Co-directed this work.

Chromatin context determines when a gene replicates in S phase. Genes display a variety of characteristic replication times and transcription factors must cope with the chromatin milieu associated with each gene. Little is known about what is responsible for this diversity. Here we present evidence that SATellite-Related sequences (SARs) and tracts of simple sequence repeats (SSRs), in particular (CA)_n and (ACTG)_n, are increasingly abundant in the regions flanking later replicating genes in *Drosophila* while (CATA)_n tracts are increasingly abundant around earlier replicating genes. Each (ACTG)_n tract, (CATA)_n tract, and SAR influences replication time over a ~100-kb region while each (CA)_n tract influences replication time over ~50-kb. Although these four repeats comprise less than one half of one percent of the "euchromatic genome" in *Drosophila*, they account for ~7% of the variation of gene replication timing and (CA)_n alone appears to influence more than 80% of genes. We propose that SSRs exist to impart heterochromatic properties on basal or default chromatin in order to suppress unwanted transcription and that genes have evolved mechanisms to open up localized regions within this chromatin for transcriptional activation.

The search for genetic modifications of systemic lupus erythematosus through expression profiling of peripheral blood mononuclear cells. *F. Andrade*¹, *S.D. Ghimbovschi*², *D. Alarcon-Segovia*¹, *E.P. Hoffman*². 1) Instituto Nacional de Ciencias Mdicas y Nutricin Salvador Zubiran, Mxico, DF;; 2) Center for Genetic Medicine, Children's Research Institute, Washington, DC.

Systemic lupus erythematosus (SLE) is a complex and heterogeneous disease of unknown etiology, characterized for high titer antibody response against self-antigens. Recent studies have addressed the molecular signatures that characterize lupus during flaring (e.g. the interferon and granulopoiesis signatures). However, it has not been defined whether patients with SLE have a primary defect responsible of these signatures. To define primary immunological abnormalities in SLE, we propose that any functional problem (either genetic or epigenetic) associated with lupus must be detectable independently of whether the disease is active or inactive (i.e. remission). However, the advantage of studying SLE patients in remission is that it can allow dissecting different pathways involved in SLE pathogenesis, in the absence of the inflammatory background caused during flaring. Therefore, to better understand functional mechanisms associated with SLE, we compared the molecular response of PBMCs from SLE patients in remission and healthy individuals, which were exposed to a similar "lupus environment" at different time points: 0, 12, 24 and 48 h. SLE patients were in treatment-free remission for at least a year, having had a severe form of disease in the past. As lupus environment, we used plasma from 2 patients with active SLE not yet treated. In addition, PBMCs were incubated with autologous plasma to define background gene expression. Expression changes were evaluated for the 26,244 genes and ESTs represented on the Affymetrix HG_U133 plus 2.0 GeneChip. Our data suggests that the heterologous plasma from SLE patients in the active stage of the disease have protein factors that induce an activation of the immune system via a cascade of immune response genes (MHC class II-DQ, proapoptotic genes, Ig-lambda, complement C2, interferon-induced proteins, etc.) that yield both common and different activation signature patterns in healthy controls and in SLE patients in remission.

Program Nr: 1691 from the 2004 ASHG Annual Meeting

Examining a Comprehensive System for Fragment-based Applications. *L. Joe, S. Karudapuram, C. Kosman, Y. Lou, T. McElroy, A. Wheaton.* Applied Biosystems, Foster City, CA.

The completion of the Human Genome Project has introduced a new paradigm in complex disease research. With an increasing emphasis on the need to rapidly scan the genome for variations, researchers need tools that will enable discovery and detection of genetic variation in an efficient and highly automated fashion. Since genetic variation can be characterized using a variety of methods it is important that detection and analysis systems are flexible and can easily transition from one application type to the next.

In this study, we describe recent innovations in Applied Biosystems system approach to fragment analysis applications. We demonstrate improved data quality with new matrix and size standards, a highly optimized suite of fragment-specific run modules, and single polymer-array combinations for multiple applications. We also illustrate several software features that improve the overall system flexibility and efficiency, including improved data collection run scheduling and prioritization, multi-application plate support, and increased functionality in analysis software for support of a broader range of fragment-based applications.

Computational prediction of chromatin structure in vivo. *W.S. Noble¹, R. Humbert², J. Wallace², M. Yu³, M. Hawrylycz², J. Stamatoyannopoulos².* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Dept of Molecular Biology, Regulome, 551 N 34th St, Seattle, WA 98103; 3) Division of Medical Genetics, Univ. of Washington, Seattle, WA 98195.

Computational prediction of cis-regulatory sequences in the context of complex genomes has proven to be a major challenge. Focal chromatin remodeling is a general property of human cis-regulatory sequences, which are marked by DNaseI hypersensitive sites (HSs) in vivo[1]. The ability to discriminate HSs from genomic sequences that reside in unremodeled chromatin using a computational algorithm would dramatically facilitate the identification of functional non-coding elements in the human genome. We trained a support vector machine (SVM) classifier[2] using a set of DNaseI HS sequences (n=280) and non-HS control sequences (n=737), and tested the ability of the SVM to predict HSs ab initio in the human genome. We found that the SVM was able to discriminate in vivo HSs with high accuracy (>70%) in the context of both erythroid cells. 89% of the HSs detected in erythroid cells were also found in lymphoid cells, indicating that the SVM was detecting a class of sequence elements that are widely involved in control of chromatin structure, and, by extension, gene regulation. The results provide the first evidence for the feasibility of large-scale computational prediction of chromatin structure in vivo and suggest the existence of common sequence features that dictate chromatin accessibility to the regulatory machinery across the human genome.

Outcome of orthotopic liver transplantation (OLT) in children with inborn errors of metabolism (IEM). *G.L. Arnold, J. DeLuca, R. Bowman.* Div Pediatric Genetics, Univ Rochester Sch Medicine, Rochester, NY.

We reviewed the course of all five patients undergoing OLT for IEM at the University of Rochester School of Medicine and Dentistry. Patient ages/diagnoses included urea cycle disorders (Ornithine Transcarbamylase Deficiency (OTC), male age 18 mos and female age 3 yrs; Argininosuccinate Lyase Deficiency (ASL) age 20 mos), Tyrosinemia Type 1 (Tyr 1) age 6 yrs and Methylmalonic Acidemia (MMA) age 7 yrs. Transplant indications included recurrent episodes of hyperammonemia (urea cycle disorders), suspicious liver nodules (Tyr 1) and recurrent pancreatitis (MMA). The 3 y.o. with OTC received a lobe of a parent's liver; others received cadaver organs. The mean (median) number of inpatient days was: for the year before transplantation 78 (16) days (range 0-197), for the transplant admission 38 (13) days (range 9-86), and for the post transplant year (excluding the transplant admission) 22 (28) days (range 0-41). A complex pre-transplant course tended to predict more post-transplant complications. For the urea cycle patients preoperative intravenous ammonia diverting drugs were stopped on removal of the native liver. Ammonia at the start of surgery ranged from 25-196 $\mu\text{mol/l}$ and was below 40 post-operatively; no further treatment for hyperammonemia was required. The MMA patient was hemodialyzed for 4 hours prior to transplant to reduce abnormal metabolite levels; post transplant both pancreatitis and renal function improved (although mild renal insufficiency persists) as did the lifelong profound anorexia. In the year after transplant, growth percentiles were generally predicted by severity of medical complications. Of interest some patients demonstrated catch up linear/weight growth, and head circumference percentiles increased in the two youngest patients. Developmental delay improved but did not normalize in the two significantly delayed children (ASL and MMA). Overall, parents believed their child's quality of life was improved compared to before the transplant and none regretted the procedure. Risks of OLT must be considered, but the procedure can provide an improved medical and psychosocial quality of life for children having significant IEM.

The C677T mutation in the MTHFR gene follows a clinal distribution within Pakistan. *Q. Ayub, A. Mansoor, S. Rehman, S.Q. Mehdi.* Biomedical and Genetic Engineering Laboratories, Islamabad, Pakistan.

The enzyme, 5,10-methylenetetrahydrofolate reductase (MTHFR) catalyzes the reduction of 5, 10 methylene tetrahydrofolate to 5-methyltetrahydrofolate, the carbon donor for the re-methylation of homocysteine to methionine. The C to T transition at position 677 (C677T) of the MTHFR gene replaces the amino acid alanine with valine at position 222 making the enzyme thermolabile and reducing its activity in the heterozygous or homozygous state, thus causing hyperhomocysteinaemia. The frequency of this mutation in the Pakistani population, that suffers from several nutritional and vitamin deficiencies, is unknown. In this study we examined the frequency of this mutation in 542 Pakistani individuals belonging to 14 ethnic groups. The C to T substitution creates a *HinfI* restriction site and was detected by the Polymerase Chain Reaction-Restriction Fragment Length Polymorphism method. The frequency of the T allele was significantly higher in populations from northern Pakistan (t test statistic =8.585; p=0.019). The highest frequencies were observed in the Hazara (0.34), Kalash (0.27) and Meo (0.28) ethnic groups. Among the southern populations only the Parsi, who are migrants from northern Iran, have a high frequency of the T allele (0.21). The higher frequency of the mutant allele was significantly correlated with longitude (r=0.582; p=0.037) and latitude (r=0.686; p=0.010). The cline appears to be between populations that live in the plains and have plentiful supply of food throughout the year as opposed to those populations that live in the arid mountainous or desert regions of Pakistan. However, the higher frequency of the T allele could also be due genetic drift in isolated populations such as the Hazara, Kalash and Meo. The Hazara have undergone several population bottlenecks in their history and the Kalash have remained isolated in the Hindukush Mountains for centuries. The possibility that these populations could be susceptible to developing hyperhomocysteinaemia and its cardiovascular consequences are major health concerns.

Phenylalanine hydroxylation in patients with classic PKU in response to tetrahydrobiopterin. *O.A. Bodamer, M. Holub, B. Hagerty, A. Muhl, K. Tuschl.* Department of Biochemical Genetics, University Children's Hospital Vienna, Austria.

INTRODUCTION: A significant number of patients with HPA and mild PKU and a limited number of patients with classic PKU have been shown to be responsive to tetrahydrobiopterin (BH4) resulting in decreased plasma phenylalanine levels and increased dietary phenylalanine tolerance. The observed effects were attributed to stimulation of phenylalanine hydroxylase (PAH) by its cofactor BH4.

METHODS AND SUBJECTS: A stable isotope method employing ring D5 phenylalanine, ring D2 and D4 tyrosine was used to measure phenylalanine and tyrosine flux and to calculate whole body phenylalanine hydroxylation (PAHtion) rates before and fifteen hours after an oral BH4 load (20 mg/kg) in three adult subjects with classic PKU and three healthy adults. Dietary phenylalanine intake was kept unchanged.

RESULTS: Plasma phenylalanine levels decreased in all PKU patients: 532, 990 and 1120 mol/l before versus 426, 819 and 924 mol/l after BH4 load while there was no change in the control group. Phenylalanine hydroxylation rates remained unchanged in both groups: 14.2, 9.9, 13.0 versus 15.0, 10.9 and 11.4 mol/kg/h in subjects with PKU and 13.7, 13.5, 8.3 versus 13.8, 14.6, 15.8 mol/kg/h in controls, before and after BH4 load.

DISCUSSION: Although there is no change in PAHtion following a BH4 load plasma phenylalanine levels decreased substantially in subjects with classic PKU. This may be due to increased protein synthesis and/or phenylalanine break down by yet unknown mechanisms. Interestingly absolute PAHtion was similar between PKU and controls but when corrected for plasma phenylalanine levels PAHtion was 5-10 fold lower in PKU. Some of the apparent residual activity of PAH may be in fact due to tyrosine hydroxylation. Although the number of patients and controls studied is limited the results demonstrate that it is feasible to employ a stable isotope method to measure PAH activities in response to a BH4 load.

Functional characterization of a third mitochondrial ornithine transporter gene in the mouse. *J.A. Camacho, N. Rioseco-Camacho, D. Andrade.* Pediatrics, University of California, Irvine, CA.

Redundant genes that can rescue a disease phenotype are potential modifier genes that can influence disease onset, severity and in part be responsible for phenotypic variability. We previously demonstrated that human ORNT2 (HsORNT2), a functional retroposon with 88% identity to human ORNT1 (HsORNT1), can rescue the deficient ornithine transport in cultured fibroblasts of patients with the Hyperornithinemia-Hyperammonemia-Homocitrullinuria (HHH) Syndrome, a disorder of the urea cycle and ornithine degradation pathway. Both ORNT1 and ORNT2 are members of the mitochondrial carrier family (MCF) of proteins and belong to a sub-family of cationic amino acid transporters. We initially screened the mouse database of Expressed Sequence Tags (dbEST) for additional MCF genes that phylogenetically belong to the ORNT sub-family utilizing a conserved amino acid sequence (P29FDT) of mitochondrial ornithine transporters from several species. We identified a mouse EST from Chr12 that has a complete open reading frame (ORF) that is 28% identical to the murine ORNT1 gene. The human ortholog is localized in the q32.2 region of chromosome 14. We tentatively named this gene PFDT2. Both the human and mouse genes have three introns interrupting their ORFs. Northern blotting, PCR and dbEST analysis demonstrated that PFDT2 is predominantly expressed in the CNS with lesser expression in the liver, lung, kidney and heart. This is in contrast to the HsORNT1 and HsORNT2 genes that are predominately expressed in the liver and pancreas. Overexpression (n=3 experiments) of an N-myc-MmPFDT2 construct in cultured HHH fibroblasts rescued the deficient ornithine metabolism of these cells. Immunofluorescence experiments confirmed that MmPFDT2 targets solely to the mitochondria. Our results suggest that the PFDT2 gene codes for a mitochondrial cationic amino transporter that is most likely involved in CNS function and possibly the ornithine degradation pathway.

Identification of new mutations within TATc gene in tyrosinemia type II Tunisian patients. *C. Charfeddine¹, K. Monastiri², M. Mokni³, A. Laadjimi⁴, M. Kairallah⁴, N. Kaabachi⁵, N. Tebib⁵, MF. Ben Dridi⁶, K. Dellagi¹, S. Abdelhak¹.* 1) Immunology, Institut Pasteur, Tunis, Tunisia; 2) Departement of Pediatrics, Hospital of Monastir, Monastir, Tunisia; 3) Departement of Dermatology, Hospital of La Rabta, Tunis, Tunisia; 4) Departement of Ophthalmology, Hospital of Monastir, Monastir, Tunisia; 5) Laboratory of Biochemistry, Hospital of La Rabta, Tunis, Tunisia; 6) Departement of Pediatrics, Hospital of La Rabta, Tunis, Tunisia.

Tyrosinemia type II or Richner Hanhart Syndrome (RHS) is an autosomal recessive disorder characterized by keratitis, palmoplantar keratosis, mental retardation, and elevated blood tyrosine levels. The disease is due to a deficiency of hepatic cytosolic tyrosine aminotransferase (TATc), an enzyme involved in the tyrosine catabolic pathway. The majority of reported cases are found among the Arab and Mediterranean populations probably because of the high rate of consanguineous mating. RHS is characterized by inter and intrafamilial phenotypic variability. A large spectrum of mutations within TATc gene has been shown to underlie RHS. Our aim is the molecular and genetic investigations of RHS in 3 unrelated consanguineous Tunisian families with 7 patients with confirmed biochemical diagnosis for tyrosinemia type II. Families were genotyped with five polymorphic microsatellite markers overlapping the TATc gene. The haplotype analysis revealed that all RHS patients were homozygous for the 5 tested markers. Two haplotypes were observed, suggesting that at least 2 different mutations within TATc gene segregate with these 2 haplotypes. Mutations analyses were performed and two novel missense mutations were identified (C151Y) and (L273P) within exon 5 and exon 8 respectively. Phenotype variability was observed even among individuals sharing the same mutations.

Separation and quantification of branched chain amino acids by LC/MS/MS. *C.L. Garganta, D.J. Czyzyk.* Dept of Genetics, Yale School of Medicine, New Haven, CT.

Maple syrup urine disease (MSUD) is due to deficiency of branched chain ketoacid dehydrogenase. It results in the accumulation of branched chain amino acids and allo-isoleucine, a stereoisomer of isoleucine. Dietary restriction of branched chain amino acids is the mainstay of MSUD therapy and requires frequent monitoring of branched chain amino acid concentrations. To allow collection of blood samples at home, we developed a method to measure branched chain amino acids and allo-isoleucine in blood collected on filter paper.

The amino acids are quantified in a 1/8 inch blood spot by liquid chromatography/tandem mass spectrometry (LC/MS/MS). Samples are extracted with an internal standard solution containing d₈-valine and d₃-leucine in methanol.

The underivatized amino acids are separated on a short C8 column using 25% methanol and 75% 0.1 mM pentadecafluorooctanoic acid. 20% of the column effluent is introduced via the TurboIonSpray into an API2000 triple quadrupole MS/MS. The following transitions were monitored in positive ion MRM mode: 118 to 72 (valine), 126 to 80 (d₈-valine), 132 to 86 (leucines), and 135 to 44 (d₃-leucine). Total run time is 3.5 minutes.

Recoveries were 95-105% across a broad range of concentrations. Interassay coefficient of variation was 5-10%. More than 60 simultaneously collected plasma and blood spot samples were analyzed by amino acid analyzer and this method, respectively. The concentration determined by LC/MS/MS was plotted against concentration measured by amino acid analyzer. The slopes for all 4 compounds were between 0.9 and 1.1 with correlation coefficients >0.95.

This method provides accurate measurement of branched chain amino acid concentrations in blood spot samples. It allows home collection of blood samples for monitoring of MSUD and disorders of leucine metabolism. This testing could also be used in newborn screening labs as a second tier test to eliminate false positive results since the absence of allo-isoleucine completely excludes a possible diagnosis of MSUD.

Neonatal mass screening for hereditary tyrosinemia type I by succinylacetone measurement: The Quebec experience. *Y. Giguere, J. Ruel, N. Belanger, A. Grenier, C. Laberge.* Quebec Neonatal Blood Screening Programme, CHUL du CHUQ, Quebec, Canada.

Hereditary tyrosinemia type I (HTI) is a rare autosomal recessive disorder caused by a fumarylacetoacetate hydrolase (FAAH) deficiency characterized by hepatic failure, renal dysfunction and neurological crisis. The prevalence of HTI is increased in the province of Quebec (1/15000-20000) due to a founder effect in the French Canadian population. Thus, HTI testing is included in the neonatal screening program. During the 1970-1997 period, 2249000 newborns were tested at 3-7 days of life on dried filter paper blood spots for tyrosine (Tyr) level followed by semi quantitative and quantitative (Q) indirect succinylacetone (SA) measurement (-aminolevulinate dehydratase inhibition), and immunoreactive FAAH as the confirmatory test. During that period, 118 cases were detected (HTI incidence = 1/19000), but owing to earlier sampling and increased incidence of breastfeeding, the Tyr cut-off was lowered gradually from 414 to 200 mol/L (7.5 to 3.6 mg/dl), decreasing the discriminating power of blood Tyr. Moreover, since 1996, due to increasing pressure to discharge the mothers and their newborns within 2-3 days after delivery, early Tyr measurement was not sensitive enough as proven in the 5 cases missed (with Tyr 200 mol/L). Since 1998 (1998-2004; 91,7% of sampling performed before 72 hrs of life), we thus modified the testing sequence: 436260 newborns have been tested by semi-Q SA measurement (normal 0.20 O.D.) followed by Q-SA testing (normal 2.5 mol/L) and FAAH as the confirmatory test, Tyr being an auxiliary test. During that period, only 59 (0.02%) neonates showed abnormal results, 36/59 normalized in the repeat sample (0,01% false positive rate), while 23/59 were confirmed by abnormal Q-SA and FAAH, and clinically to have HTI (incidence: 1/15773). No false negative results were reported. Tyr level of cases (n = 23) was 197 77 mol/L, below the 200 mol/L threshold, and 151 51 mol/L in normal newborns (n = 436,201). Thus, since 1998, SA measurement as the initial HTI screening test proved to be highly sensitive and specific despite earlier sampling of neonates.

Wild-type phenylalanine hydroxylase activity is enhanced by tetrahydrobiopterin supplementation *in vivo*: an implication for therapeutic basis of tetrahydrobiopterin-responsive phenylalanine hydroxylase deficiency. S.

Kure¹, S. Sato¹, K. Fujii², Y. Aoki¹, Y. Suzuki¹, S. Kato², Y. Matsubara¹. 1) Department of Medical Genetics,; 2) Department of Pediatrics, Tohoku University School of Medicine, Sendai, Japan.

Phenylketonuria (PKU) is caused by phenylalanine hydroxylase (PAH) deficiency. A phenylalanine (Phe)-restricted diet can ameliorate the effects of high serum Phe on cognitive function. However, Phe restriction is a heavy burden to patients and their families and better therapeutic approaches have been explored. We previously proposed a novel disease entity, tetrahydrobiopterin (BH4)-responsive PAH deficiency, in which administration of BH4 reduced elevated levels of serum phenylalanine (Kure S et al., *J Pediatr*, 1999;135:375-8). Subsequent reports indicate that the prevalence of BH4-responsive PAH deficiency is much higher than initially anticipated. Although growing attention surrounds treatment with BH4, little is known about the mechanism of BH4 responsiveness. An early report indicates that BH4 concentration in rat liver was 5 M where *Km* for BH4 of rat PAH was estimated to be 25 M in an oxidation experiment using a liver slice, suggesting relative insufficiency of BH4 in liver. In the present study, we developed a breath test using [1-¹³C]phenylalanine in order to examine the BH4 responsiveness of normal mouse PAH *in vivo*. The reliability of the test was verified using BTBR mice and its mutant strain lacking PAH activity, *Pah^{enu2}*. BH4 supplementation significantly enhanced ¹³CO₂ production in C57BL/6 mice. Furthermore, BH4 apparently activated PAH activity in just five minutes. These observations suggest that submaximal PAH activity occurs at the physiological concentrations of BH4 normally present in hepatocytes *in vivo*, and that PAH activity can be rapidly enhanced by supplementation with BH4. Thus, we propose that the responsiveness to BH4 in patients with PAH deficiency is due to the fact that suboptimal physiological concentrations of BH4 are normally present in hepatocytes and the enhancement of the residual activity may be associated with a wide range of mutations.

Leukodystrophy in presumed late-onset cobalamin C disease. *C. Thauvin-Robinet¹, G. Couvreur², S. Giraudier³, D. Perrenou⁴, J. Desgres⁵, T. Moreau², M. Giroud², L. Faivre¹.* 1) Centre de Genetique, Hopital d'Enfants, Dijon, France; 2) Service de Neurologie, Hopital General, Dijon, France; 3) Service d'Hematologie-Biologique, Hopital Henri Mondor, Paris, France; 4) Centre de Convalescence et de Reeducation, Dijon, France; 5) Laboratoire de Biochimie specialisee, Hopital d'Enfants, Dijon, France.

Combined methylmalonic aciduria and homocystinuria cobalamin C type are the most common of the inborn errors of cobalamin metabolism. Clinical features occur usually in the first year of life including failure to thrive, poor feeding, hypotonia, vomiting, anemia, hypersegmented neutrophils, thrombocytopenia, mild to moderate developmental delay, microcephaly, and seizures. Only a few cases with late onset are described in the literature. A 39 year-old woman was referred to our unit for the association of progressive neurological deterioration, mental confusion, myoclonia and visual hallucinations. Familial history was unremarkable. Clinical history found normal psychomotor development in childhood but onset at 15 years of age with behavior problems. Pulmonary embolism with hemiplegia, depression and anorexia occurred after delivery at 19 years of age. Seizures were noted at 31 years of age. Workup for causes of neurological deterioration included cerebral MRI showing diffuse leukodystrophy with cortical atrophy and metabolic investigations showing severe hyperhomocysteinemia and low plasma methionine levels in favor of inborn errors of cobalamin metabolism. Urine increased methylmalonic acid levels ruled out MTHFR deficiency. Impaired synthesis of adenosylcobalamin and methylcobalamin in cultured skin fibroblasts was found. Complementation studies are in process, a cobalamin C disease being the most likely diagnosis. The patient was treated by folic acid, betane and hydroxycobalamin, showing partial improvement of the symptomatology. The two families with late-onset cobalamin C disease reported in the literature are reviewed, with a neurological onset between 12 and 16 years of life. These observations show that aminoacids chromatographies should be part of the investigations of unexplained neurological symptoms in adults.

Founder Effect of Phenylketonuria in the Geauga County Amish Settlement of Ohio. *H. Wang¹, L. Nye¹, E. Puffenberger², H. Morton².* 1) Das Deutsch Center (DDC) Clinic for Special Needs Children, Middlefield, OH; 2) The Clinic for Special Children, Strasburg, PA.

Phenylketonuria (PKU) is a metabolic inborn error resulting from a deficiency of phenylalanine hydroxylase (PAH) (EC 1.14.16.1). Over 400 causative mutations have been identified in the past. It seems to be a lower-frequency founder disorder in the Amish population of Lancaster County, appearing less commonly than in the general population. However, here we report that the higher incidence of PKU recently documented in the Geauga County Amish Settlement of Ohio is associated with a founder effect. In this report, 15 individuals with classic PKU were identified from five families. The incidence was greater than 1/1000 in this community. Genealogic analysis showed that all patients could be traced back seven generations to the common ascendants Jeremiah Miller (1817-1890) and Lydia Troyer (1819-1865). DNA was isolated from peripheral blood of four patients in three families in this large pedigree, and the PAH gene was amplified by PCR and then subjected to direct sequencing. We found that all patients were homozygous for the same mutation, IVS10-11 GA. In fact, this is one of the common mutations reported in PKU patients in Europe. As reported earlier, this mutation activates a cryptic splice site and results in PAH protein conformational changes, leading to a non-functional protein. Although we have previously identified this mutation in Mennonite patients, this is the first time we have found it in the Amish population. We are currently in the process of confirming the mutation in all patients. As most PKU patients are compound heterozygotes rather than homozygotes, the cohort of the homozygous patients in this report is highly valuable for further study of the disease from other aspects, such as exploring the role of other genomic factors and environmental factors in the disease phenotypes.

Cobalamin C disease presenting with hemophagocytic lymphohistiocytosis. *S. Yano¹, S. Wu¹, T. Coates², I. Gonzalez³.* 1) Div Medical Genetics, Childrens Hosp, Los Angeles, Los Angeles, CA; 2) Div Hematology/Oncology, Childrens Hosp, Los Angeles, Los Angeles, CA; 3) Dept Pathology and Laboratory Medicine, Childrens Hosp, Los Angeles, Los Angeles, CA.

Patients with methylmalonic aciduria and homocystinuria have defective metabolism of cobalamin to methylcobalamin and adenosylcobalamin. Three complementation groups (cbl C, cbl D, and cbl F) are known in this category. Each cobalamin disease is rare and has autosomal recessive inheritance. The most common one is cbl C disease which is characterized by seizures (often neonatal onset and intractable), developmental delay, megaloblastic anemia, hemolysis, and failure to thrive, in addition to biochemical abnormalities including metabolic acidosis, methylmalonic aciduria and homocystinuria. Hemophagocytic lymphohistiocytosis (HLH) is characterized by infantile onset (80 % of cases occur less than age 1 year) long lasting fever (> 38.5 C, more than 7 days), failure to thrive, hepatosplenomegaly, and anemia as well as characteristic pathologic findings of histiocytes demonstrating phagocytosis of erythrocytes in bone marrow. The Genetic form (Familial HLH, autosomal recessive) and a secondary sporadic isolated form are known: the latter occurs in association with a systemic infection, malignancy or immunodeficiency disorder. Chemotherapeutic agents including cyclosporine and VP-16 are commonly used to treat HLH. It is extremely rare for patients with inborn errors of metabolism to have HLH as one of the clinical symptoms. Four cases of Lysinuric protein intolerance (LPI) have been reported that they fulfilled the diagnostic criteria for HLH (Duval et al., J Pediatr, 1999 134: 236-239). Besides this report, there have been no reported cases of inborn errors of metabolism to have HLH in their clinical courses. We present a case of an infant diagnosed with hemophagocytic lymphohistiocytosis who was later confirmed as having Cobalamin C disease.

Auditory electrophysiology of the *mdx*^{Cv3} mouse shows abnormal latencies which may provide evidence for one basis of cognitive defects found in Duchenne muscular dystrophy. *D.M. Pillers*^{1,2,3}, *J.B. Kempton*⁴, *N.M. Duncan*¹, *S.J. Dwinell*³, *S.M. Rash*¹, *D.R. Trune*⁴. 1) Pediatrics; 2) Ophthalmology; 3) Molecular & Medical Genetics; 4) Otolaryngology - Head and Neck Surgery, Oregon Health & Sci Univ, Portland, OR.

Introduction: Neurosensory electrophysiology is characterized by two major markers: the amplitude of the response to a stimulus, and the time interval until the response peaks. In auditory physiology, this time interval is referred to as the latency, whereas in visual electrophysiology, it is known as the implicit time. We have shown abnormalities in the implicit time of the electroretinogram in the *mdxCv3* mouse model versus the *mdx* which is normal, and sought to determine whether any parallels could be drawn in the auditory pathway. **Methods:** Auditory brainstem response (ABR) audiometry to pure tones was used to evaluate cochlear function. 14 *mdx*, 4 *mdxCv3*, and 13 age-matched control (C57BL/6J and C57BL/10ScSn) male mice were tested. The ABR thresholds to tone-burst stimuli at 4, 8, 16, and 32 kHz were obtained for each ear and statistically compared (ANOVA) for potential group differences. Latencies were determined for wave IV and plotted against intensity. **Results:** Both *mdx* and *mdxCv3* mice demonstrated normal ABR thresholds when compared with controls. However, the latency response curves showed significant differences between the two mouse models. Although the *mdx* curve overlapped with that of the normal mice, that of the *mdxCv3* showed significant shortening of the wave IV latency ($p < 0.05$). **Discussion:** Abnormalities in latency in auditory brainstem response testing can provide evidence for asynchrony in signal processing. Disorders with such asynchrony can be associated with cognitive defects. A subset of patients with Duchenne muscular dystrophy have cognitive defects ranging from dyslexia to mental retardation. Genotype-phenotype correlations in man have shown that 3' DMD mutations, such as that found in the *mdxCv3* mouse, are predominantly associated with the cognitive defects. We speculate that the abnormal latency in the auditory response may provide evidence of a physiologic basis for these cognitive defects.

From deletion to disease: Identification of a novel mutation in the catalytic subunit 1 of the pyruvate dehydrogenase phosphatase (PDP1) gene and demonstration of protein phosphatase regulation. *J.M. Cameron¹, M.C. Maj¹, V. Levandovskiy¹, N. MacKay¹, R. Baumgartner², B.H. Robinson¹.* 1) Dept Metabolism, Hospital Sick Children, Toronto, ON, Canada; 2) Metabolic Unit, Universitäts-Kinderspital beider Basel (UKBB), Postfach, CH-4005, Basel, Switzerland.

Pyruvate dehydrogenase deficiency (PDH; OMIM 312170) is a clinically heterogeneous disorder caused by mutations in the E1alpha, E3 and protein X components. PDH activity is regulated by phosphorylation: it is inactivated by PDH kinase and activated by PDH phosphatase, PDP. Patients have been reported previously that have a reduction in PDH phosphatase activity, but no mutation has ever been identified.

We have identified two brothers with hypotonia, feeding difficulties and delayed psychomotor development with elevated lactate levels. Both patients demonstrated deficient native PDH activity in skin fibroblasts and lymphoblasts. However, activation of the PDH complex using dichloroacetate showed almost normal PDH activity, suggesting there was a possible problem with the efficient regulation of the enzyme complex.

PDP is a dimeric enzyme that consists of a catalytic and regulatory subunit; the catalytic subunit has two isoforms which show differing dependencies to Ca^{2+} ; and Mg^{2+} ;. After sequencing the cDNA of all three genes, we identified a three base pair deletion in the PDP1 gene in both brothers, which was confirmed in genomic DNA.

We have purified human PDP1 and PDP2 proteins and shown them to be active in vitro, and have demonstrated restoration of patient PDH activities after introduction of wild-type PDP1 to fibroblast cell lysates. We are also confirming these findings by gene transfection into intact cells.

Gene expression analysis in the acid sphingomyelinase deficient mouse: Insights into the pathogenesis of Niemann-Pick disease and the identification of new biomarkers. *R. Dhami, E. Schuchman.* Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY.

Acid sphingomyelinase (ASM) deficiency leads to neuronopathic (Type A) and non-neuronopathic (Type B) forms of Niemann-Pick disease (NPD). ASM knockout (ASMKO) mice display neurological and visceral organ defects similar to those documented in human patients, and have been used to investigate various therapeutic strategies. Assessment of therapeutic efficacy, in both humans and mice, is challenged by a lack of knowledge about the mechanisms involved in the development of different tissue pathologies, and by a lack of markers to predict disease severity and progression. To address these issues, we have used oligonucleotide microarray analysis to study differential gene expression in the lungs and brains of ASMKO mice, two important sites of pathology in NPD. The results confirmed the fact that inflammation is an important component of NPD pathogenesis, and also revealed differential expression of several unexpected genes that may provide important clues to the primary pathways involved in NPD tissue injury. For example, in ASMKO mouse lungs the genes encoding several matrix-degrading proteases, including cathepsin K and MMP-12, were elevated. In the brain, expression of the growth hormone gene was markedly increased, while the expression of several other neural-specific genes were decreased. To demonstrate the usefulness of this gene expression data for the identification of possible biomarkers, the serum concentrations of growth hormone, chitotriosidase, serum amyloid A3, and orosomucoid were determined in the ASMKO mice. Both growth hormone and chitotriosidase appear to be good biomarkers of disease progression. Thus, these gene expression analyses have provided valuable information about possible pathogenetic mechanisms in NPD, and identified potential biomarkers that could be used to assess disease progression and therapeutic efficacy.

Canine Mucopolysaccharidosis IIIB: Aspects of Visceral and Brain Pathology. *N. Ellinwood*^{1,4,5}, *L. Verot*², *M.-A. Colle*³, *U. Giger*⁴, *M.T. Vanier*², *M.E. Haskins*⁴. 1) Labo de Thérapie Génique, CHU Hôtel-Dieu, Nantes, France; 2) INSERM U 189 and Fondation Gillet-Mérieux, Lyon-Sud Medical School and Hospital, Pierre-Bénite, France; 3) Labo d'Anatomie-Pathologique, Ecole Nationale Vétérinaire de Nantes, France; 4) Depart's of Clinical Studies and Pathobiology, Univ of Penn, Philadelphia, PA; 5) Depart of Animal Sci, Iowa St Univ, Ames, IA.

Mucopolysaccharidosis (MPS) III comprises a group of severe neuropathic lysosomal storage diseases characterized by a failure of heparan sulfate catabolism. The cause of MPS type IIIB is deficient activity of N-acetyl--D-glucosaminidase (Naglu). Clinically, MPS IIIB is characterized in humans by mild somatic features and severe central nervous system (CNS) deterioration with severe behavioral changes.

Canine MPS IIIB is the only large mammalian model of this disorder. Initial characterization of the model and the normal and mutant DNA sequences have been reported. The disorder is seen in young adult dogs (2-3 years) as cerebellar ataxia. Clinical signs progress from their onset for 1-2 years, before animals require euthanasia. The mutation is an insertion of 45 A residues. It is critical to document the natural history of the disease in this model so as to facilitate evaluation of therapies. Herein, we report on the initial findings in young and aged affected dogs. Examination of tissues from 3-6 month-old affected dogs found distinct lysosomal storage in liver and kidney, but not in the CNS. Biochemical analysis of the CNS from dogs from 3 months to 5.6 years of age has been conducted. Analyses of cerebral grey matter found the proportion of GM2 and GM3 gangliosides (mole%) to have been increased 5 and 3 fold, respectively, compared to normal levels. Increases are evident as early as 3 months of age.

Canine MPS IIIB, an important resource to investigate pathogenesis and evaluate therapies, especially with regard to assessing both the treatment of a large brain as well as the efficacy and safety of therapy over years. Supported by the NIH (RR02512 and RR007063) and The National MPS Society, Inc.

Evidence for Altered Glutamine/Glutamate Synthesis in the SSADH-Deficient Mouse. *K.M. Gibson¹, G.M.I. Chowdhury², A.B. Patel², M. Gupta¹, H. Senephansiri¹, K.L. Behar².* 1) Molecular and Medical Genetics, Oregon Health & Science Univ, Portland, OR; 2) MRRC, Yale Univ, New Haven, CT.

Succinate semialdehyde dehydrogenase (SSADH) deficiency is a rare autosomal recessive inherited defect of GABA catabolism associated with increased gamma-hydroxybutyrate (GHB) and GABA. The murine SSADH knockout (KO) was created to study the pathophysiological mechanisms associated with the human disorder. Neurochemical studies have shown lower brain glutamine in affected patients and KO mice, suggesting altered astroglial/neuronal substrate trafficking. In this study, we infused the astroglial substrate, [2-¹³C]acetate to follow astroglial glutamine synthesis and repletion of neuronal glutamate/GABA in 17-day old KO and wildtype (WT) urethane-anesthetized mice. Mice were infused with [2-¹³C]acetate for 2 hrs (i.p.) using a bolus-variable rate infusion followed by freezing. Concentrations and ¹³C enrichments of amino acids were determined in extracts of cerebral cortex using ¹H-¹³C-NMR. Cortical GABA concentration was greater in KO mice (KO, 12.9 +/- 0.9; WT, 4.7 +/- 0.7 umol/g, P=0.001), whereas glutamate (KO, 9.7 +/- 0.6; WT, 11.3 +/- 1.2 umol/g, P<0.05) and glutamine (KO 3.4 +/- 0.3; WT, 5.7 +/- 0.3 umol/g, P=0.001) were lower. In [2-¹³C]acetate infused mice the steady-state % ¹³C enrichments of glutamine-C4 (KO, 11.2 +/- 0.9; WT, 20.7 +/- 1.6, P=0.001) and GABA-C2 (KO, 3.6 +/- 0.6; WT, 10.6 +/- 0.8, P=0.001) were lower in KO mice, although no differences (P>0.15) were observed for glutamate-C4 or aspartate-C3 enrichment. The combined effect of the lower concentration and ¹³C-enrichment in KO mice suggest that [4-¹³C]glutamine formation from [2-¹³C]acetate was decreased (67%). The steady-state level of [4-¹³C]glutamate was also lower (23 %), although [2-¹³C]GABA was similar between groups. Immunoblotting of glutamic acid decarboxylase isoforms (GAD65/GAD67) revealed a 50% reduction of both in hippocampus, cortex and cerebellum of KO mice as compared to WT animals. These in vivo data provide evidence for reduced astroglial glutamine metabolism in KO mice, yielding new insight into the neurologic abnormalities in both affected patients and KO mice.

Correlation between the age of onset/severity of Hereditary Inclusion Body Myopathy and polymorphisms within the dystroglycan gene. *E. Gottlieb*¹, *C. Ciccone*¹, *D. Darvish*², *S. Naiem*², *P. Savelkoul*¹, *D. Krasnewich*¹, *W. Gahl*¹, *M. Huizing*¹. 1) MGB, NHGRI, NIH, Bethesda, MD; 2) HIBM Research Group, Encino, CA.

Dystroglycan (DG), an integral protein in the Dystrophin-Glycoprotein Complex (DGC) codes for two proteins, and -DG. -DG is a membrane glycoprotein linking the membrane spanning -DG to the extracellular matrix and the cytoskeleton through non-covalent interactions. Functional domains in the DG protein include a transmembrane and dystrophin binding domain in the -DG region, and a mucin-like domain, rich in serine and threonine residues for potential O-linked glycosylation, in the -DG region of the protein. Defects in the DGC cause certain muscular dystrophies, but no human mutations in DG have been reported, despite the identification of many polymorphisms.

Hereditary Inclusion Body Myopathy (HIBM), an adult onset neuromuscular disorder characterized by progressive myopathic weakness and atrophy, caused by defects in *GNE*. *GNE* encodes UDP-GlcNAc epimerase/ManNAc kinase, the rate-limiting enzyme of sialic acid synthesis. We recently demonstrated hypoglycosylation of muscle -DG in HIBM patients, possibly caused by a deficiency of free sialic acid. Severity and age of onset of symptoms vary widely among patients, even those with similar *GNE* mutations and within the same family.

We studied correlations between DG-polymorphisms and symptoms in 32 HIBM patients, mainly of Iranian-Jewish descent. All patients carried C2725G in the 3'UTR, as well as three unreported amino-acid substituting polymorphisms: T488G (D163E), C741G (P248A), and T2611C (V871A), located outside of functional domains or glycosylation sites. Two subjects exhibited G1307A (T436T), located in a potential O-glycosylation site in a conserved area of the mucin-like domain. There was no correlation between this polymorphism and clinical symptoms; one patient had onset at age 31 and wheelchair-bound at age 40, while another had onset at age 22 and walks at age 26. More subjects are needed to draw definite conclusions. In addition, variations in other genes, like laminin-2, and 2,6-sialyltransferase, may influence clinical severity.

The role of metabolic disorders and trace elements in the pathogenesis and treatment of children with autism spectrum disorders. *J. Hou.* Dept Medical Genetics, Chang Gung Children's Hosp, Taoyuan, Taiwan.

The autism spectrum disorder (ASD) is a disease of complex genetic architecture. The underlying etiologies of ASD are heterogeneous and there is no effective treatment till now. When the metabolic consequences of disturbed biochemical pathways or trace elements are well defined, treatment with diet, drugs, or nutritional supplements may bring about a reduction in autistic symptoms. A prospective study evaluating evidence for metabolic etiologies in ASD, as well as for the efficacy of specific vitamin or drug treatments will be presented. We have screened 148 children (88 males, 60 females) who have pervasive developmental disorder with some autistic behaviors. CCDI (Chinese Child Developmental Inventory) study was also performed before and after medical treatment. One hundred normal samples have been prepared for biochemical and genetic comparison. ASD can be associated with fragile X syndrome and several metabolic disorders, therefore laboratory evaluation including tandem mass study for inherited metabolic diseases, and cytogenetic or/and molecular studies for Rett syndrome (MECP2 gene), chromosome anomalies, and fragile X syndrome were performed in each case. Several metabolic defects have been associated with autistic symptoms. These include lactic acidemia, methylmalonic acidemia, hyperphenylalaninemia, hypervalinemia and hyperleucinemia/isoleucinemia. Low blood zinc but high copper levels were found in 75 percent of the patients. The most common chromosomal anomalies were fragile X syndrome (n=15, 13/88 boys, and 2/60 girls). Other co-current anomalies included 47, XY, +m (inv dup 15) de novo (n=3), der(9)t(19;?)(q13.3;?) de novo, and del(2)(2p24). A 6~12-month treatment course with zinc gluconate, vitamin B6 and B12 in these patients showed significant improvement in cognition and social interaction by CCDI evaluation. Those work-ups including metabolic evaluation will distinguish ASD unequivocally from other developmental disabilities. Metabolic disorders and trace elements imbalance may play an important role of the pathogenesis and treatment of children with ASD.

Apoptosis in a mouse model for metachromatic leukodystrophy and the direct role for sulfatide. *J. Liu, C. Regan, T. Rupar.* biochemical Genetics Lab, Child & Parent Resource Inst, University of Western Ontario, London, ON, Canada.

Metachromatic leukodystrophy (MLD) is a progressive neurodegenerative disorder caused by a deficiency of arylsulfatase A (ASA) and is inherited in an autosomal recessive manner. MLD most frequently presents in late infancy and death occurs by about 6 years. ASA hydrolyses the glycolipid sulfatide which is primarily present in myelin. A deficiency of ASA results in the accumulation of sulfatide. The neuropathological characteristics include demyelination, gliosis and formation of metachromatic granules. There is atrophy and the reduction of granule and Purkinje cell numbers in the cerebellum. A knock-out mouse model (ASA KO) of MLD (Dr. V. Gieselmann) has lysosomal sulfatide storage of but does not show the gross white matter changes seen in humans. The mechanism by which sulfatide storage causes the neuropathology of MLD is not understood. The presence and number of cells dying in the murine cerebellum by apoptosis was studied in the ASA KO and control mice by observing DNA fragmentation using the TUNEL stain. The total number of apoptotic cells in mouse cerebellum from 1, 5, 10, 14, 21 and 28 days to 12 months was determined. ASA KO mice had significantly more apoptotic cells after 21, 28 days and 12 months with 50-70% more apoptotic cells in the cerebellum overall and about 80-180% more in white matter. The increase in the number of apoptotic cells was observed in the external germinal layer, molecular layer and internal layer. Sulfatide was tested for its ability to directly induce apoptosis by treating (6.25-25g/ml) primary neural cell cultures from both ASA KO and control mice in vitro with sulfatide or galactocerebroside as a control. Sulfatide induced morphological changes within 1-3 hr and increased the number of apoptotic cells. Galactocerebroside had no effect. Immunohistochemical staining of glial fibrillary acidic protein showed considerable drawing back of cellular processes most prominent in astrocytes. These data indicate that sulfatide may participate directly in the induction of apoptosis and the pathophysiology of MLD in the ASA KO mouse.

Arterial calcifications in adult cystinosis patients post-renal transplant. *K. O'Brien¹, M. Ueda¹, R. Kleta¹, I. Bernardini¹, D. Rosing², A. Ling³, D. MacAvey², W.A. Gahl¹.* 1) SHBG, MGB, NHGRI, NIH; 2) Cardiology Department, NHBLI, NIH; 3) Department of Radiology, NIH.

Cystinosis, an autosomal recessive disorder of lysosomal cystine accumulation, results from mutations in the CTNS gene that encodes the cystine transporter, cystinosin. Renal tubular Fanconi syndrome occurs in infancy, followed by rickets, growth retardation, hypothyroidism, and finally renal failure, which occurs at approximately ten years of age. Treatment with cysteamine decreases cellular cystine levels, retards renal deterioration, and allows for normal growth. For poorly treated patients, renal transplantation allows for survival at least into the third to fifth decades, but individuals experience other, non-renal complications of the disease. We reviewed routine chest and head CT scans on 27 post-transplant cystinosis patients. Thirteen of the 27 patients in our cohort had vascular calcifications, including 11 with coronary artery calcification. One 25-year old man required a 3-vessel coronary artery bypass graft surgery. The finding of vascular calcification was correlated with a history of renal disease, and having lived at least 20 years without cysteamine therapy. Three conclusions emerge from our experience in the long-term evaluation of cystinosis patients and their response to cysteamine treatment. First, cystinosis patients not chronically treated with a cystine-depleting agent experience progressive kidney disease culminating in end-stage renal disease, and the need for dialysis and renal allograft replacement therapy. Long-term oral cysteamine therapy starting in infancy can prevent or delay this outcome. Second, the metabolic disturbances that occur with chronic kidney disease, and with maintenance therapy for renal allografts, predisposes these patients to the premature development of coronary artery and other vascular calcifications. Third, adult post-transplant cystinosis patients should be screened for vascular calcification, which may be a useful non-invasive measure of atherosclerosis and, in some cases, end organ ischemia.

Mutations in genes coding for copper transporting ATP7A and ATP7B in Czech Republic. *L. Pospisilova¹, E. Flachsova¹, Z. Marecek², H. Hansikova¹, I. Halfarova³, R. Bruha², P. Fruhauf⁴, J. Zeman¹, P. Martasek¹.* 1) Department of Pediatrics and Center of Integrated Genomics, 1st School of Medicine, Charles University, Prague, Czech Republic; 2) Internal Medicine 4, 1st School of Medicine, Charles University, Prague, Czech Republic; 3) Department of Pediatrics, Municipal Hospital, Frydek-Mistek, Czech Republic; 4) Faculty General Hospital Prague, Department of Pediatrics, Czech Republic.

Copper plays an essential role in biology as a cofactor for many enzymes. There are two intracellular copper binding P-ATPases in human: ATP7A and ATP7B. Their genes are located on chromosomes Xq13.3 and 13q14.21. ATP7B deficiency causes autosomally-recessive inherited Wilson disease (WD), manifested by low serum ceruloplasmin and accumulation of copper in liver and in brain. The deficiency in ATP7A causes X-linked Menkes disease (MD), resulting in decreased intestinal absorption of copper, low copper levels in serum, and defective distribution of copper in tissues. We report here clinical, biochemical and molecular investigation in family with occurrence of Menkes disease. A boy with clinical symptoms of MD was referred to our hospital at the age of 4 months. Laboratory findings showed low serum copper and ceruloplasmin and low activity of Cu-dependent cytochrome c oxidase (COX) in thrombocytes. Molecular analysis revealed previously not published mutation in gene for ATP7A (Q724X). Mutated protein is truncated, therefore, its function is diminished. Molecular analysis allows genetic counseling and prenatal diagnosis in affected family. In the WD gene, ~ 200 different mutations have been identified. These findings, together with the large size of the gene, complicate the genetic analysis. However, in Central Europe, the H1069Q mutation seems to be present in 40-70 % of analyzed alleles. A group of 74 patients from the Czech Republic, diagnosed with WD, was screened for the H1069Q mutation in the WD gene by RFLP. 17 patients were homoallelic, 27 heteroallelic, and in 30 the H1069Q mutation was not detected. The frequency of mutated allele in our study group, 41 %, is in accordance with its occurrence in Central Europe. Supported by Grant # LN 00A079.

Investigating the role of glycerol kinase (GK) in insulin resistance by microarray analysis in a glycerol kinase knock out mouse. *L. Rahib*¹, *N. MacLennan*², *Z. Fang*^{3,4}, *S. Horvath*^{3,4}, *K.M. Dipple*^{2,3}. 1) Biomedical Engineering; 2) Pediatrics; 3) Human Genetics; 4) Biostatistics, UCLA, Los Angeles CA.

Glycerol kinase deficiency (GKD) is an inborn error of metabolism predisposing individuals to insulin resistance and diabetes mellitus (Gaudet et al., 2000). Peroxisome proliferator-activated receptor ligands are effective therapy for insulin resistance, and induce GK expression in adipocytes (Guan et al., 2002). The purpose of this study was to define the role of GK in insulin resistance by evaluating the changes in gene expression in a glycerol kinase (Gyk) knock out (ko) mouse model. Total RNA was extracted from brown fat from 2 day old Gyk ko and wildtype (wt) male mice. Microarray analysis (Affymetrix mouse 430) revealed 180 genes with differential expression (>1.2 fold) in the ko males compared to wt. Gene sorting demonstrated differential expression of genes in metabolism, transcription regulation, cell death/apoptosis, nucleic acid binding, DNA packaging, carbohydrate metabolism, and differentiation/regulation of proliferation. EASE analysis defined 51 groups with increased and 100 groups with decreased ($p < 0.05$) expression in Gyk ko mice. Expression levels of genes involved in lipid biosynthesis, fatty acid biosynthesis/elongation, glycerophospholipid/phospholipid metabolism were decreased ($p < 0.01$) in the ko mice. While expression levels of genes involved in transcription regulation, oxidoreductase activity, and protein sumoylation were increased ($p < 0.01$). Pathway Assist (Stratagene) analyses confirmed direct and indirect connectivity of GK and the genes involved in transcription regulation and lipid metabolism that were differentially expressed in the microarray. This confirms that GK deletion is integral with other metabolic and transcriptional networks. In conclusion, in a Gyk ko mouse, gene expression levels in categories including lipid metabolism and transcription are modified. Further evaluation of these genes will allow us to understand the role of GK in insulin resistance and diabetes mellitus. Studies of the network of glycerol metabolism in adipocytes will allow better understanding of the relationship between glycerol and glucose metabolism.

Carnitine metabolism in long-chain acyl-CoA dehydrogenase deficient mice. *P. Wood*¹, *N. van Vlies*², *L. Tian*¹, *H. Overmars*², *A. Bootsma*², *W. Kulik*², *R. Wanders*², *F. Vaz*². 1) Dept Genetics, Univ Alabama at Birmingham; 2) Departments of Clinical Chemistry and Pediatrics, Academic Medical Center, University of Amsterdam, The Netherlands.

We investigated tissue acylcarnitines and carnitine biosynthesis in wild type (WT) and long-chain acyl-CoA dehydrogenase deficient (LCAD^{-/-}) mice. We found C14:1 acylcarnitine in all tissues from LCAD^{-/-} mice. Accumulation of acylcarnitines (C9 and C11) in LCAD^{-/-} muscle was also observed, which most likely represents peroxisomal oxidation products of phytanic acid, confirming the role of LCAD in branched-chain fatty acid metabolism. Relevant levels of 3-hydroxy-acylcarnitines were found in heart, muscle and brain in WT mice, suggesting that in these tissues long-chain 3-hydroxyacyl-CoA dehydrogenase is rate limiting for mitochondrial -oxidation. The 3-hydroxy-acylcarnitines were absent in LCAD^{-/-} tissues indicating that, in this situation, the -oxidation flux is limited by LCAD. Additionally, a marked deficiency of acetylcarnitine was observed in LCAD^{-/-} hearts. Furthermore, we investigated the use of the carnitine precursor butyrobetaine (BB) for potential therapy. BB was provided in the water (400mg/L) for 2 weeks and mice were subjected to cold challenge. BB treated males showed greater cold tolerance, while females did not. LCAD^{-/-} mice, both sexes, were carnitine-deficient based on low carnitine levels in serum and heart. BB treatment restored serum carnitine levels in female LCAD^{-/-} mice but not in males, and in both sexes resulted in increased serum concentrations of the long-chain acylcarnitines (C14), indicating that BB induced carnitine production and/or enhanced acylation to carnitine. Despite increased serum carnitine levels in female LCAD^{-/-} mice, they remained cold intolerant. BB treatment in male LCAD^{-/-} mice did not restore carnitine levels but did significantly increase their cold tolerance. It appears that females handle BB differently than males, as shown in LCAD^{-/-} females with BB treatment, displayed high serum and tissue BB values (increased 2-7 fold), whereas the BB levels in male LCAD^{-/-} mice showed no change..

Molecular and biochemical testing for creatine transporter deficiency in an MR population suggests a 1% prevalence. *T. Wood¹, E.H. Rosenberg², A.J. Clark¹, L.S. Almeida², C. Jakobs², S.P. Young³, R.E. Stevenson¹, H. Taylor¹, M.J. Friez¹, C.E. Schwartz¹, G.S. Salomons².* 1) Greenwood Genetic Center, Greenwood, SC; 2) Department of Clinical Chemistry, VU University Medical Center, Amsterdam; 3) Division of Medical Genetics, DUMC, Durham, NC.

Creatine transporter deficiency is an X-linked genetic condition resulting from mutations in the SLC6A8 gene localized to Xq28. Lack of this transporter prevents cellular uptake of creatine and primarily affects normal cognitive function. Affected males present with mental retardation, speech delay, seizures and autistic behaviors. Carrier females may show mild learning problems. Diagnosis can be made via proton MRS studies, an elevated urinary creatine / creatinine ratio, or molecular analysis. A recent study in a European collection of males suspected of having X-linked mental retardation (XLMR) suggested the incidence of the disorder could be as high as 2%. To determine the incidence in a collection of males with non-fragile X mental retardation, we performed a retrospective DNA-based study on 501 males with mental retardation and a prospective urine-based study on 225 males with mental retardation of unknown cause. DNA sequencing of the SLC6A8 coding region identified seven potentially pathogenic mutations: 4 missense, 2 small deletions, and 1 splice site mutation. Testing in 600 normal males did not identify any of these changes. The prospective urine-based study was performed by stable isotope dilution tandem mass spectrometry. One patient out of the 225 males studied was identified with an elevated creatine / creatinine ratio and molecular analysis demonstrated a previously identified p.F408del mutation. A clinical review of all eight patients suggests that seizures can occur later in childhood and the disorder may be slowly progressive in nature. The observed overall incidence of the creatine transporter deficiency of 1.1% (8 / 726) among males with mental retardation of unknown cause is 3-10 times higher than other XLMR conditions except for the Fragile X syndrome and suggests that testing for creatine transporter deficiency should be considered in the initial work-up of males with mental retardation.

Altered splenic gene expression in mice and humans with Gaucher disease. *Y.H. Xu, L. Jia, B. Quinn, G.A. Grabowski.* Dept Pediatrics, Div Human Gen, Children's Hosp Medical Ctr, Cincinnati, OH.

Gaucher disease is an autosomal recessively inherited disease caused by mutations at the acid -glucosidase (GCase) locus (GBA). To understand the molecular pathophysiology of Gaucher disease, global gene expression was examined by microarray analyses of total splenic mRNAs from Gaucher mice and an affected patient. In mice, the progressive mRNA alterations were evaluated in the D409V/D409V point-mutated model. In these mice, RNA microarray analyses consistently identified that 5~9% of genes in inflammatory, signal transduction, transport processes and sphingoglycolipid metabolic pathways showed statistically significantly altered expression. Of these, 48% were up-regulated (2-24 fold) and 52 % were down-regulated (2-50 fold). Among the signal transduction and metabolic transport related genes 30-50% were differentially expressed (up to down or down to up) at the mid/late stages compared to the early stages. In sphingoglycolipid metabolic pathway, three genes [UDP-glucose ceramide glucosyltransferase (Ugcg), -galactosidase 1 (Glb1), and neuraminidase 1 (Neu1)] increased up to 5 fold with age. A similar pattern of mRNA expression was seen in a spleen sample from an adult human with non-neuropathic Gaucher disease. These patterns differed significantly from that in a human Niemann-Pick B spleen. These findings demonstrate a profound potentially characteristic change of gene expression in spleen of Gaucher disease by microarray analysis and suggest that the pathophysiology of GCase deficiency may involve the alteration of multiple gene expression as the disease progresses.

Osteopenia and osteoporosis: previously unrecognized features of Fabry disease. *D.P. Germain¹, K. Benistan¹, S. Perrot², C. Thevenot¹, S. Coulon¹, C. Mutschler².* 1) Dept Genetics, European Hosp Georges Pompidou, Paris, France; 2) Dept Radiology, European Hosp Georges Pompidou, Paris, France.

Background: Fabry disease (FD) is an X-linked inborn error of metabolism due to the deficient activity of alpha-galactosidase, a lysosomal enzyme. While the deposition of uncleaved glycosphingolipids throughout the body is known to have protean clinical manifestations, no data is available regarding the skeletal involvement.

Methods: We prospectively investigated bone involvement in 27 hemizygous males with a mean age of 32 years (range: 16-61 years) affected with classic FD. Bone densitometry was assessed in all patients, using dual energy X-ray absorptiometry (Hologic QDR-4500W).

Results: Bone densitometry examination revealed a statistically significant decrease in bone mineral density (BMD). Using the World Health Organisation (WHO) classification of BMD abnormalities (normal: T score > -1; osteopenia : -2.5 < T score < -1; osteoporosis: T score < -2.5), the following results were obtained at testing lumbar spine and femoral neck : T score normal at both sites : 11% (3/27); osteopenia at one site and normal T score at other site : 33% (9/27); osteopenia at both sites 19% (5/27); osteoporosis at one site and normal T score at other site: 4% (1/27); osteoporosis at one site and osteopenia at other site: 30% (8/27); osteoporosis at both sites 4% (1/27). Eighteen patients had normal glomerular filtration rate.

Discussion: This is the first study demonstrating that FD is associated to an increased risk of developing BMD abnormalities in male patients. Osteopenia and/or osteoporosis were detected in 89% (24/27) of our patients, even in the absence of renal insufficiency. With the emerging enzyme replacement therapies for FD and the hope of increased life expectancy, reduced BMD may become an important symptom to consider. We advise to perform bone densitometry in all FD patients as a baseline assessment in order to assess their risk of pathologic fracture.

ORAL DEFECTS OF BRAZILIAN CASES OF MUCOPOLYSACCHARIDOSIS. *A.C. Santos^{1,2}, A.C. Paula¹, T.P. Delboni¹, D.R. Bertola¹, L.M. Albano¹, L.A. Soares Jr², R. Giugliani³, C.A. Kim¹.* 1) Pediatrics, Instituto da Criança HC-FMUSP, So Paulo, So Paulo, Brazil; 2) Unidadede Odontologia do Instituto Central ,HC-FMUSP; 3) Servio de Gentica Mdica, Hospital de Clinicas de Porto Alegre, e Departamentos de Gentica e Bioqumica da UFRGS.

Mucopolysaccharidoses (MPS) are a heterogeneous group of lysosomal storage disorders caused by the deficiency of enzymes involved in degradation of glycosaminoglycans (GAGS). There are six recognized clinical types. Its pattern of inheritance is autosomal recessive, except for MPS II, which is X-linked. The course is progressive with multisystem involvement, specially skeletal, cardiac, pulmonary and abnormal facies including oral manifestations. We report on 5 Brazilian patients with MPS (1 MPS II, 1 MPS IIIC, 1 MPS IVA, 1 MPS VI and 1MPS VII) with abnormal oral findings. The mean age at diagnosis was 4y2mo (ranging from 1y9mo to 7y3mo) and their current age ranged from 6y to 11y4mo. Parental consanguinity was observed in 2/5 families (40%). All patients presented coarse facies, buccal respiration, limited opening of the mouth due to temporomandibular joint abnormality, drooling, lip enlargement, protruding tongue (macroglossia), hyperplastic gingivitis, ogival palate, abnormally wide teeth and flake enamel. Others findings: anterior open bite, spacing of the teeth, short mandible, dental caries (60%), dentigerous cysts, later eruption of the teeth (40%), sleep apnea, and bruxism (20%). This study alerts for the importance of oral manifestations in MPS. An adequate treatment of the structural and functional oral defects in different types of MPS is recommended by a team of health specialties, to improve the quality of life of these patients.

Correlation between interleukin 6 promoter gene polymorphism and stroke in patients with Fabry disease. G.

Altarescu¹, D. Moore², R. Schiffmann². 1) Genetic Dept, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) Developmental Metabolic Neurology Branch, NIH, Bethesda MD, USA.

Objective: To determine the incidence of the common polymorphism of interleukin (IL)-6 among patients with Fabry disease and ascertain the relationship to the occurrence of cerebral stroke in these patients. **Introduction:** Fabry disease is an X-linked recessive disorder associated with early onset stroke, marked by deep small infarcts as documented on perfusion- and diffusion-weighted magnetic resonance imaging (MRI). A correlation between the IL-6 plasma levels and presence of the 174GC promoter polymorphism with stroke in control populations has been previously shown. **Material and Methods:** Genotyping for the 174GC promoter polymorphism of IL-6 was performed in 51 hemizygotes male patients with Fabry disease and correlated with MRI evidence of white matter lesions. The polymorphisms in the IL6 gene were compared using ANOVA (both parametric and non parametric) for the three genotype groups (G/G, G/C and C/C). **Results:** None of the 9 patients (17.6%) with the G/G genotype had evidence of lesions; the G/C genotype was seen in 20 patients (39.2%) with a mean MRI load of 4.3811.15, and 22 patients had the C/C genotype (43.1%) with a mean MRI load of 355.26557.17; Thus, there was no significant difference between patients who had at least one G allele with regard to evidence of stroke, but both were significantly different from those with the C/C genotype ($p=.001$ and $.002$, respectively). **Conclusions:** The prevalence of the C/C genotype of the IL-6 promoter polymorphism among patients with Fabry disease is greater than in control Caucasian populations, and appears to carry a greater risk for developing white matter lesions on MRI. In that the pro-inflammatory cytokine IL-6 may be released shortly after hypoperfusion of the brain, the interesting question raised by the current study is whether the C/C genotype may be a modifier and/or marker microvascular abnormalities in Fabry disease.

Diffuse Traumatic Brain Injury-Induced Alteration of Mitochondrial DNA Copy Numbers in the Immature Rat Brain. *R. Bai*¹, *T. Chang*², *I. Cernak*³, *A.I. Faden*³, *L. Wong*¹. 1) Inst Molec & Human Genetics, Georgetown Univ Med Ctr, Washington, DC; 2) Neurology and Pediatrics, Children's National Medical Center, Washington, DC; 3) Neuroscience, Georgetown University Medical Center, Washington DC.

Mitochondrial gene expression in liver, heart or skeletal muscle is known to change in response to oxidative stress and age. A new developmental model of diffuse traumatic brain injury (TBI) indicates a difference in bioenergetic response to injury in the early immature brain. We propose to examine this response by evaluating mitochondrial biogenesis in the early immature rodent brain after diffuse TBI. Total genomic DNA was isolated from 7 day old male Sprague Dawley (Harlan) rat brain. The rat pups were injured and sacrificed at 4 and 24 hrs after injury and compared to naives. The mitochondria DNA (mtDNA) copy number for each sample was determined by real-time quantitative PCR (RT qPCR) and normalized to beta 2 microglobulin gene, a single copy nuclear gene. The cortex and subcortex reflect a higher mtDNA copy number. In all regions of the brain examined (cortex, subcortex, hippocampus and cerebellum), the mtDNA copy number decreases acutely 4 hrs post-injury (437 31; 251 31; 192 3 and 10 2; respectively) compared to naives (603 2; 450 98; 278 59; and 73 32). However, by 24 hrs after injury there is an increase (1207 83; 536 46; 217 9; and 97 1) suggesting a compensatory amplification. The cerebellum is most affected at 4hrs post-injury while the cortex has the greatest amplification response at 24hrs post-injury. These results demonstrate that there is an active mitochondrial biogenetic response to diffuse TBI which occurs acutely.

Evaluation of Adrenal Function in Asymptomatic Boys with X Linked Adrenoleukodystrophy Background. *P. Dubey, H.W. Moser, L. Keldiyarova, A. Fatemi, R.O. Jones, L. Bezman, G.V. Raymond.* Neurology, Kennedy Krieger Institute, Johns Hopkins University, Baltimore, MD.

Background: X Linked Adrenoleukodystrophy (X-ALD), is commonly associated with adrenal insufficiency that can be treated to prevent life threatening complications. However, Not many studies have undertaken detailed evaluation of adrenal function in X-ALD. **Methods:** 89 X-ALD boys were studied as a part of a prospective evaluation of Lorenzo's Oil therapy. Adrenocorticotropic Hormone (ACTH) Stimulation test was administered unless known history of Adrenal Insufficiency was present. Baseline ACTH and Cortisol was measured in all patients. Chi2 test of homogeneity used for statistical analyses. **Results:** Mean (SD) baseline age (yrs) was 5.45(4). The Mean (SD) follow-up (yrs) was 4.46(3.01). 88% of X-ALD boys had adrenal insufficiency by last visit, 90% of these were diagnosed with adrenal insufficiency by 10 yrs of age. 85% had baseline adrenal insufficiency, 3% developed it during follow-up. 77% patients first came to attention due to an affected family member, 23% presented with adrenal insufficiency and were subsequently diagnosed with X-ALD. Mean (SD) age of onset of adrenal insufficiency was 4.38(3.59) years, ranging from 8 months to 13 years. Mean (SD) Serum basal Cortisol and ACTH at baseline were 13.69 (6.38) micrograms/dl and 1106.84 (1503) picograms/ml respectively. Basal ACTH was elevated in 37% patients with normal response to ACTH stimulation and normal Basal Cortisol. Greater percentage of patients had normal Basal Cortisol levels in the presence of abnormal ACTH stimulation test and abnormal basal ACTH (93% vs. 6%, $p=0.001$). **Conclusion:** Addison's disease is a prominent cause X-ALD identification besides family screening and occurs early in disease course. Baseline Cortisol may be normal with abnormal ACTH stimulation test, suggesting Addison's Crisis may be precipitated during stress, hence Baseline Cortisol alone is not a good marker of adrenal insufficiency. Patients may maintain normal response to ACTH stimulation test with compensatory increase in Basal ACTH masking clinical expression of adrenal insufficiency, hence require regular and careful monitoring.

Gaucher genotype N188S/RecNciI is associated with myoclonic epilepsy. *L. Kowarz*¹, *O. Goker-Alpan*¹, *S. Banerjee-Basu*², *L. Kinlaw*¹, *R. Schiffman*³, *A.D. Baxevanis*², *E. Sidransky*¹. 1) NSB, NIMH/NHGRI; 2) GTB, NHGRI; 3) DMNB, NINDS; NIH, Bethesda, MD.

Gaucher disease (GD), the inherited deficiency of lysosomal glucocerebrosidase, presents with a wide range of symptoms of varying severity. Significant genetic heterogeneity has been found in a subgroup of patients with type 3 chronic neuronopathic GD who develop progressive myoclonic epilepsy. These patients initially exhibit slowed horizontal saccades, but develop dementia, ataxia and spasticity. The records of 17 such patients were reviewed and 4 ethnically diverse subjects (2M: 2F) with genotype N188S/RecNciI were identified. One patient developed myoclonic jerks at age 5, the others developed myoclonus and then generalized seizures during their teens, and all exhibited prominent ataxia and EEG abnormalities consistent with a global cerebral process. One patient suffered from cognitive decline and one had learning disabilities. In two, the onset of myoclonic seizures preceded the diagnosis of GD. All had mild systemic manifestations of GD; one underwent splenectomy and one received enzyme replacement therapy.

The N188S mutation is rare and has been described as a mild allele producing high residual enzymatic activity. The RecNciI allele is presumed to be a null allele. Molecular modeling using the three-dimensional crystal structure of glucocerebrosidase demonstrated that mutation N188S is located in domain III of glucocerebrosidase, the region containing the TIM barrel forming the catalytic domain. This region is situated between strand 3 and helix 3, and the substitution of a serine does not alter surface charge distribution. N188S, V394L and G377S, all rare mutations associated with myoclonic epilepsy, are located on the outer edge of the active site of the enzyme and, hence, could cause similar alterations in protein function. The association of mutation N188S with the rare myoclonic phenotype in Gaucher disease suggests that N188S might alter local protein structure, binding, and/or post-translational processing, leading to neuronal cell death; it could also have a modifying role on other proteins involved in the pathogenesis of myoclonic epilepsy.

Impaired mitochondrial glutamate transport in autosomal recessive neonatal myoclonic epilepsy. *F. MOLINARI¹, A. RAAS-ROTHSCHILD², M. RIO¹, G. FIERMONTE³, L. PALMIERI³, F. PALMIERI³, N. KHADOM¹, A. MUNNICH¹, P. RUSTIN¹, L. COLLEAUX¹.* 1) INSERM U393, Hopital Necker-Enfants Malades, PARIS, France; 2) Dept of Genetics, Hadassah University Medical Center, Jerusalem, Israel; 3) Dept of Pharmaco-Biology, University of Bari, Bari, Italy.

Early myoclonic encephalopathy (EME) with suppression burst (SB) is an early onset malignant epilepsy syndrome characterized by a burst-suppression pattern of the EEG with bursts of spikes, sharp waves and slow waves, which are irregularly intermingled and separated by periods of electrical silence. The prognosis for EME is poor with no effective treatment and children either die before 2 years of life or survive in a persistent vegetative state. The lack of consistent neuropathological features suggests that etiology may vary from case to case. EME has been reported in nonketotic hyperglycinemia (MIM 605899), propionic acidemia (MIM 606054) and some malformative disorders. However, in most cases, the underlying mechanism of these disorders remains unknown.

Here we report on genetic mapping of an autosomal recessive EME to chromosome 11p15.5 and identification of a missense mutation (Pro 206 Leu) in the gene SLC25A22 (GC1) encoding one of the two mitochondrial glutamate symporters. The mutation co-segregated with the disease and altered a highly conserved amino-acid. Functional analyses showed that glutamate oxidation in patient cultured skin fibroblasts was strongly defective. Further studies in reconstituted proteoliposomes showed defective [14C]glutamate uniport and [14C]glutamate/glutamate exchange by mutant protein.

Intact glutamate metabolism is crucial for amino acid synthesis and oxidation, for ureogenesis and for normal function of the CNS. The identification of mutant GC1 as an etiology of EME emphasizes the unexpected importance of the mitochondrial component of glutamate metabolism in normal brain function, thus opening a novel field in the pathophysiology of EME.

Autism spectrum manifestations in cerebral folate deficiency. *P. Moretti¹, S. Peters², K. Hyland³, T. Bottiglieri³, R. Hopkin⁴, E. Peach⁴, B. Roa¹, C. Bacino¹, F. Scaglia¹.* 1) Mol and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Inst of Metab Disease, Baylor Univ Med Ctr, Dallas, TX; 4) Human Genetics, Cincinnati Childrens Hosp Med Ctr, Cincinnati, OH.

Intracellular folates participate in essential one-carbon transfer reactions. Progressive neurological dysfunction has been described in adults and children with an isolated deficiency of folate in the central nervous system. We report the clinical manifestations and biochemical features of 4 girls and 1 boy with cerebral folate deficiency (CFD). All patients had low cerebrospinal fluid (CSF) levels of 5-methyltetrahydrofolate, the biologically active form of folates in CSF and blood. Red blood cell folate, serum folate, and total plasma homocysteine were normal. All children exhibited psychomotor retardation and seizures with variable response to folinic acid. Three females had manifestations evocative of Angelman syndrome (AS) including facial features, ataxia, and hand flapping. AS DNA methylation studies and *UBE3A* mutation analysis were normal. The fourth female exhibited features of Rett syndrome in the absence of *MECP2* mutations or deletions. Through clinical observations, 4 of these patients demonstrated considerable repetitive behaviors, decreased eye gaze and communication deficits that warranted a formal evaluation for autism using the Autism Diagnostic Observation Schedule and the Autism Diagnostic Interview - Revised. Of the 2 patients formally evaluated thus far (2 children with AS-like features), both met criteria for autism. Regardless of their overall cognitive abilities, these children demonstrated deficits in communication and socialization that mirror those observed in children with idiopathic autism. Formal evaluations are currently being completed with the 2 other females. These findings demonstrate that children with autism and features of AS or Rett syndrome may have abnormalities of CSF folate, expanding the clinical spectrum of CFD. Future studies will determine the general relevance and frequency of these findings and elucidate the molecular mechanisms of reduced CSF folate in these patients.

Dysregulation of the neuronal actin cytoskeleton in identical twins with dystonia as a consequence of a bioenergetic defect. V. Procaccio^{1,2}, M. Gearing³, S. Ono³, CA. Gutekunst⁴, JL. Juncos⁴, A. Davila¹, BH. Wainer³. 1) MAMMAG, Univ California, Irvine, Irvine, CA; 2) Department of Pediatrics, University of California, Irvine, California; 3) Department of Pathology and Laboratory Medicine, Emory University, Atlanta, Georgia; 4) Department of Neurology, Emory University, Atlanta, Georgia.

Actin is a major cytoskeletal protein in neurons, and the dynamics of its assembly affect many aspects of cell motility and membrane turnover, representing a major ATP-consuming process in cells. Actin is co-transported with actin-binding proteins, including ADF and cofilin, that are essential for rapid turnover of actin filaments in vivo and regulated through a phosphorylation process. Recently cofilin has been shown to be translocated into mitochondria, crucial for the initiation of apoptosis. We reported extensive actin aggregation in the brains of identical twins with generalized dystonia and deafness associated with multiple developmental abnormalities. Immunohistochemistry revealed that rod-like inclusions in neocortex and spherical inclusions in basal ganglia were strongly immunoreactive with antibodies to ADF/cofilin. Two-dimensional electrophoresis of brain extracts demonstrated increased phosphorylation of cofilin. DNA microarray studies of mitochondrial gene expression using our Mitochip and real-time quantitative PCR in brain tissues showed increased expression of several genes including actin, cofilin, genes involved in apoptosis and mitochondrial ROS scavenging enzymes in response to increased mitochondrial ROS production. Expression of genes involved in mitochondrial ATP production was down-regulated in brain cortex. Sequencing of the entire mtDNA showed no abnormalities, thus pointing to a nuclear defect in these cases. Because actin reorganization requires ATP consumption, a defect in mitochondrial bioenergetics may perturb cellular ATP levels and alter the phosphorylation state of cofilin. Rod formation in response to mitochondrial stress may be a common pathophysiologic mechanism to protect neurons and conserve ATP by slowing actin filament dynamics.

Fabry disease in children. *M. Ries*¹, *S. Gupta*¹, *D.F. Moore*², *V. Sachdev*³, *J.M. Quirk*¹, *G. Murray*¹, *D.A. Rosing*³, *C.H. Robinson*¹, *E. Schaefer*⁴, *A. Gal*⁴, *J.M. Dambrosia*⁵, *S.C. Garman*⁶, *R.O. Brady*¹, *R. Schiffmann*¹. 1) DMNB/NINDS/NIH, Bethesda, MD; 2) University of Manitoba, Canada; 3) NHLBI/NIH Bethesda, MD; 4) University of Hamburg, Germany; 5) NINDS/NIH, Bethesda, MD; 6) NIAID/NIH, Rockville, MD.

Background: Fabry disease is an under-diagnosed, X-linked multisystem disorder. **Objectives:** To provide quantitative natural history data and novel clinical endpoints for therapeutic trials. **Methods:** We conducted a prospective, cross-sectional case-control study of 25 hemizygous children with Fabry disease (mean age 12.3 years) at the NIH. Main outcome measures were quality of life (Child Health Questionnaire), and sweating as assessed by quantitative sudomotor axon reflex test (QSART). **Results:** Quality of life: Pain scores in patients under 10 years of age were similar to those of a group of children with juvenile rheumatoid arthritis. The mean scores for Bodily Pain and Mental Health (patients 10 years) as well as Bodily Pain (patients 10 years) were lower than controls. QSART: Mean sweat volume in the Fabry group was significantly decreased compared with controls. Renal function, urinary protein excretion, cardiac function and structure were normal in the majority of patients. Patients with over 1.5 percent of normal residual -galactosidase A activity were free of cornea verticillata and had normal Gb3 values in serum and urine. All other children had Gb3 levels comparable to adult patients with Fabry disease. Acroparesthesia and cardiac abnormalities were generally present prior to anhidrosis and proteinuria. Crystallographic mapping of missense mutations identified a peripheral localization in individuals with residual enzyme activity. Mutations associated with left ventricular hypertrophy were localized in proximity to the catalytic site of the enzyme. **Conclusions:** Despite absence of major organ involvement, Fabry disease is already a burdensome disorder in childhood. We have identified important correctable (QSART, quality of life measurement) and preventable outcome measures for future therapeutic trials. Prevention of secondary complications in major organs will be the goal for long-term specific therapy.

Genetic and biochemical features of 18 patients with Pompe Disease. *T. Podskarbi*¹, *H.H. Goebel*², *B.G.H. Schoer*³, *H. Lee*⁴, *Y.S. Shin*⁴. 1) Molecular Genetics and Metabol, Munich, Bavaria, Germany; 2) Dept. of Neuropathology, University of Mainz, Germany; 3) Dept. of Neurology, University of Munich, Germany; 4) University Childrens Hospital, Munich, Germany.

Glycogen storage disease type II (Pompe disease) is caused by deficiency of lysosomal α -glucosidase (GAA), resulting in impaired degradation and lysosomal accumulation of glycogen. The GAA gene has been mapped to chromosome 17q25.2-25.3. Lesions in the gene lead to complete or partial inactivation of the enzyme. The early-onset form of the disease manifests shortly after birth and presents with progressive and generalized muscle weakness. Cardiac and respiratory insufficiency leads to death before 2 years of age. Patient with childhood and juvenile/adult form of the disease present with skeletal muscle weakness and respiratory failure later in life, although some of them show cardiac enlargement. In this report we have comprised biochemical parameters in relation with mutation data in a total of 18 German and Turkish patients (10 females and 8 males), 6 infantile, 2 childhood, 5 juvenile and 5 adult patients. Patients with childhood and juvenile/adult form show a various degree of a residual GAA activity in muscle, fibroblasts and in leukocytes in contrast to the infantile form. Except in one patient with the childhood form we were able to identify mutations of the GAA gene in both alleles of all patients. 7 novel mutations, A237V in exon 4, G293R in exon 5, L355P in exon 6, IVS6-2A>G in intron 6, H568L in exon 12, A611V and R620Q in exon 13 were detected. Among German patients, IVS1-13T>G in intron 1, 525delT in exon 2 and delExon18 are most common, and among Turkish patients c.2741AG>CAGG was most prevalent. The spectrum of the mutations can be correlated with the GAA activity expressed, which again reflects the clinical severity of the disease.

Clinical, biochemical and molecular heterogeneity of branching enzyme deficiency (Andersen disease). *Y.S. Shin¹, M. Vorgerd², H. Lee¹, T. Podskarbi³*. 1) Dept. of Pediatrics, University Childrens Hospital, Munich, Germany; 2) Dept. of Neurology, University Hospital, Bochum, Germany; 3) Molecular Genetics and Metabolism Laboratory, Munich, Germany.

Glycogen storage disease type IV known as Andersen disease or amylopectinosis, is a rare autosomal recessive disorder caused by deficiency of glycogen branching enzyme. The gene for this enzyme is located on chromosome 3q14. Although all forms of GSD type IV are due to aberration of this gene, but their clinical manifestation is extremely variable. The classic form, a severe liver form is characterized by hepatosplenomegaly and progressive hepatic fibrosis in the first 18 months of life, which usually leads to death before the age of 5 years. Patients with a rare nonprogressive variant (a mild liver form) do not develop cirrhosis and survive until adulthood. Patient with the infantile neuromuscular form of the disease may present at birth with severe hypotonia, muscle atrophy, and neuronal involvement resulting in death during neonatal period. In addition to a severe multisystem neonatal form, there are the juvenile form with myopathy and/or cardiomyopathy, an adult neuromuscular form of polyglucosan body disease (APBD) as well as an isolated skeletal muscular form with adult onset have also been reported. The branching enzyme activity is deficient in leukocytes, liver and cultured fibroblasts of the neonatal and infantile liver forms as well as of the cardiac form. About a 10% residual activity can be found in leukocytes among patients with APBD and the mild liver forms. Isolated muscle forms of GSD IV on the other hand show the deficient activity in muscle only and a normal activity in other tissues such as leukocytes, fibroblasts and liver. The molecular study of a German female with APBD revealed a compound heterozygosity for two missense mutations in the branching enzyme gene (R515H, R524Q) and of a Polish boy with the mild liver form for H528R and IVS5+2t>c. Further biochemical and molecular studies of various forms are necessary to understand the marked heterogeneity of the disease.

Mutated *AMN* causes Imerslund-Grasbeck syndrome in a canine model. *Q. He*¹, *M. Madsen*², *E.I. Christensen*², *P. Højrup*³, *H. Vorum*², *S.M. Tanner*⁴, *A. de la Chapelle*⁴, *S.K. Moestrup*², *J.C. Fyfe*¹. 1) Michigan State University, East Lansing, MI; 2) University of Aarhus, Denmark; 3) Odense University, Denmark; 4) Ohio State University, Columbus, OH.

Selective malabsorption of cobalamin (vitamin B₁₂) accompanied by proteinuria, known as Imerslund-Grasbeck syndrome or megaloblastic anemia 1 (I-GS, MGA1; OMIM 261100), is a rare autosomal recessive disorder. In Finnish kindreds, I-GS is caused by mutations in the cubilin gene (*CUBN*), located on human chromosome 10. However, not all patients have *CUBN* mutations; the amnionless gene, *AMN*, which is located on chromosome 14, has been recently identified as another I-GS-responsible gene. Functional study shows that cubilin and AMN forms a tight complex, cubam, to function as a cobalamin-intrinsic factor receptor on the apical membrane of intestinal epithelial cells. We have previously reported a canine I-GS model mapped to a region on dog chromosome 8 that exhibits conserved synteny with human chromosome 14q. We cloned the cDNA of dog *AMN* and found a 33bp in-frame deletion in the *AMN* gene of the affected dogs, by both RT-PCR and genomic PCR. The mutation segregates with the disease in the dog family and is absent in 110 unrelated normal dogs. Deletion of 11 amino acids abolished a putative transmembrane domain, which is potentially important for AMN to anchor on the apical membrane. We also developed antibody against dog AMN and found the AMN protein absent in affected dogs, indicating that the mutant AMN is secreted out of the cells or degraded inside the cells. Thus, canine I-GS is a homologue of one form of the human disease, and provides a novel animal model to study the molecular mechanism of cobalamin absorption, and in a broad sense, receptor biology.

Phenotypic variation among 3 Fabry pts with D231G mutation in a Korean kindred. *H.J Kim¹, H.E. Yim², J.G. Kim³, H.S. Kim⁴.* 1) Medical Genetics, Ajou Univ Col Medicine, Suwon, Korea; 2) Pathology, Ajou Univ Col Medicine, Suwon, Korea; 3) Radiology, Ajou Univ Col Medicine, Suwon, Korea; 4) Nephrology, Ajou Univ Col Medicine, Suwon, Korea.

Fabry dis. is an X-linked lysosomal storage disorder due to α -galactase A deficiency which results in accumulation of glycosphingolipid and leads to multisystem dis. Most of Fabry dis is found to have private mutations in GLA gene and no general correlation between genotype and clinical phenotype has been found to date. We report a Korean family, in which marked phenotypic variation was found among 3 members with D231G mutation. Proband, 37y.o male with end-stage renal disease, was found to have deficient α -galactosidase A activity and D231G mutation of GLA gene. Subsequently, identical mutation was found in two other members of the family; his mother, 62 y.o female who denied any subjective symptoms were found to have proteinuria(2+) and hematuria(2+) and 35y.o asymptomatic brother, showed occasional proteinuria(trace). Renal biopsy of proband showed marked glomerular sclerosis, global or segmental, vacuolated podocytes in non-sclerotic segments, interstitial fibrosis and infiltration of vacuolated histiocytes, tubular atrophy with some vacuolar cytoplasmic change of tubular cells and vascular sclerosis. Renal biopsy of his mother showed mesangial expansion and segmental sclerosis with thickening of capillary walls. Renal biopsy of his brother revealed prominent vacuolar podocytes in glomeruli without glomerular sclerosis or interstitial fibrosis. Characteristic myeloid bodies were easily found in podocytes and tubular epithelial cells. None of three cases showed angiokeratoma, a well recognized clinical characteristics of the dis., however, skin biopsy of the proband showed osmophilic laminated bodies in dermal fibroblasts and endothelial cells, but those of his brother and mother showed no such findings. Identification of mutation in a Fabry dis. pt. should be followed up with pedigree analysis and genetic counselling, in order to provide early Dx. for unrecognized at risk family members, which will lead to early therapeutic intervention for better clinical outcome.

An international, multicenter, longitudinal observational study evaluating the natural history of Mucopolysaccharidosis II (Hunter syndrome). *A. Kimura¹, M. Beck², R. Giugliani³, J. Fletcher⁴, J. Hopwood⁴, Y. Suzuki⁵, E. Wraith⁶, A. Conway¹, J. Lieb¹, S. Hirani¹, J. Muenzer⁷.* 1) Clinical Affairs, Transkaryotic Therapies, Inc, Cambridge, MA, USA; 2) University of Mainz, Mainz, Germany; 3) Hospital de Clinicas de Porto Alegre, Porto Alegre, Brazil; 4) Womens and Childrens Hospital, Adelaide, Australia; 5) Gifu University School of Medicine, Gifu, Japan; 6) Royal Manchester Childrens Hospital, Manchester, UK; 7) University of North Carolina, Chapel Hill, NC, USA.

Mucopolysaccharidosis II (MPS II or Hunter syndrome) is an X-linked recessive disorder caused by the deficiency of the lysosomal enzyme iduronate-2-sulfatase (I2S). MPS II is a progressive, multisystem disorder resulting from the accumulated storage of glycosaminoglycans (GAG). There is no effective therapy for MPS II; however, the safety and efficacy of I2S enzyme replacement therapy (ERT) as a treatment for MPS II is currently being investigated in clinical trials. The literature only contains case studies or data on small groups of patients. To gain a better understanding of the natural history of this disease, a 2-year, multicenter, observational study was initiated. This study will enable a comparison of the progression of the disease in untreated patients vs. patients receiving ERT in the future. Evaluations being performed in the study include medical history, physical examination, hearing and vision testing, ECG, MRI (cerebral & abdominal), urine GAG measurement, joint mobility assessment, pulmonary function tests, 6-minute walk test, intelligence and developmental testing, and an assessment of quality of life. Data will be collected at baseline and at 1 & 2 year visits for each patient. One hundred and eighteen MPS II patients have been enrolled. These patients had a mean age of 11.2 years at enrollment and represented the full range of disease severity. Patient demographics as well as baseline and 1 year data from the study will be presented. This prospectively collected clinical data will provide for the first time quantitative information on the degree and rate of disease progression in a lysosomal storage disorder.

Small neonatal head circumference - A previously unrecognized manifestation in Niemann-Pick disease type C that is useful in a diagnostic score. *E. Passarge*¹, *D. Schmidt*^{1,2}. 1) Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany; 2) University Children's Hospital Zürich, Switzerland.

Objectives: Niemann-Pick disease type C (NPC, MIM 257220), a rare, progressive autosomal recessive neurovisceral disorder due to mutations in either the NPC1 gene or the HE1 gene, respectively, was investigated with respect to early manifestations. Based on the new observation of a small neonatal head circumference a diagnostic score to facilitate an early diagnosis was developed. **Methods:** During a retrospective study of 21 patients the development and clinical course of NPC were examined. The diagnosis of NPC was based on the range of clinical manifestations, the course of illness, histochemical and biochemical data, and in four patients on mutation analysis. Based on a new observation, a reduced head circumference at birth, a diagnostic score (NPC score) was developed, including four other clinical signs of NPC, such as hepatosplenomegaly, prolonged icterus, and muscular hypotonia. The score was applied to patients and compared to an age-matched control group. **Results:** NPC was confirmed in all patients by clinical and laboratory data, and in four patients by molecular genetic analysis. A reduced neonatal head circumference at or below the 3rd percentile was found in 9 of 17 patients with the neonatal and infantile form of NPC compared to an age-matched control group. These patients showed scores indicative of NPC, in contrast to the control group. **Conclusions:** Reduced neonatal head circumference is a hitherto unrecognized manifestation of NPC. Integrated into the known clinical manifestations, we developed a diagnostic score (NPC score) which could facilitate an early diagnosis and avoid unnecessary gene tests.

Novel mutations in the ATP2A2 gene in two families with Darier's disease. *L. Peleg¹, M. Karpati¹, B. Goldman¹, B. Amichai².* 1) Genetic Inst, Sheba Medical Ctr, Ramat Gan, Israel; 2) Dept of Dermatology, Huzot Clinic of Clalit Health Services, Ashkelon, Israel.

Darier's disease (DD) is an autosomal dominant skin disorder characterized by loss of adhesion between epidermal cells and abnormal keratinization. The disease has a world wide distribution with a varied prevalence. Defects in the sarco/endoplasmic reticulum Ca⁺⁺ ATPase type 2 underlie DD. The encoding gene ATP2A2 is positioned on chromosome 12q23-24 and has 21 exons. To date 140 mutations had been identified in familial and sporadic cases of DD. The aim of this study was to identify the genetic defect underlying patients of two Jewish families of Eastern European ancestry: one family included an affected mother and pre-symptomatic healthy twins and the other comprised of six patients out of seven family members. Genomic DNA was extracted from peripheral blood and PCR was carried out to amplify the exons and flanking intron regions of the ATP2A2 gene which were subsequently sequenced. Two novel mutations were identified, one in each family. C391 to T (exon 5), altering arginine 131 to stop codon (R131X) and a change of A530 to C (exon 6) replacing glutamine 177 by proline. Both mutations resulted in restriction site elimination: Taq I and Bsr I for R131X and Q177P respectively. None of the mutations was present in 50 healthy individuals of the same ethnic origin. The mutations are located in the cytoplasmic beta-strand domain which functions as transduction site and is highly conserved.

Longitudinal neuropsychologic and neurologic findings in a mild form of Sly syndrome (mucopolysaccharidosis type VII). *E. Shapiro¹, K.J. Bjoraker¹, L. Charnas¹, S. Simonton², C. Whitley¹*. 1) Dept Pediatrics, Univ Minnesota, Minneapolis, MN; 2) Children's Hospitals and Clinics, Minneapolis, MN.

Sly syndrome, or mucopolysaccharidosis (MPS) type VII, is the rarest of the MPS disorders and results from beta-glucuronidase deficiency. Review of the extant case literature suggests a severe infant form typically presenting with hydrops fetalis and poor outcome, and juvenile forms; a mild form with little disability, and an intermediate form with mental retardation with decline in cognitive function in some cases. **Methods:** When a newborn male infant presented with jaundice and hepatomegaly, a subsequent bone marrow biopsy demonstrated large, toluidine blue inclusions in macrophage cells leading to the early diagnosis of MPS VII. A female sibling was also found to have this condition. We present longitudinal data on the girl with a very mild form and boy with mild mental retardation and somatic abnormalities. Biochemical, genetic, neurologic, neuroimaging, and neuropsychologic follow-up data were collected. **Results:** Physical examination of the boy exhibits mild skeletal abnormalities (e.g., scoliosis), small masses on the bottom of one foot, and segmental hairy nevi. The girl's examination is normal. The boy, age 8 and 13 at evaluations, has stable but impaired IQ (64 and 56 respectively), average face perception, motor coordination, verbal fluency, receptive vocabulary, and behavior; below average attention, achievement, memory, spatial perception, and gross motor coordination. The girl, age 6 and 11 at evaluations, has stable and normal IQ (84 and 92 respectively), average achievement, memory, perception, language, and behavior, and below average attention span, and fine motor coordination. Neurologic and imaging studies were essentially normal for both except effacement of the cervical cord (female) on follow-up. **Conclusions:** No neurodegeneration was noted. These children are not concordant in their phenotype; one mild and one impaired but stable. Their profiles show a familial mild executive dysfunction. Molecular genetic abnormalities (currently in progress) may prove helpful in distinguishing such mild forms of MPS VII from those with other, more severe prognosis.

Presentation of Previously Undiagnosed Inborn Errors of Metabolism to Emergency Departments. *D.L.*

Weiner^{1,5,6}, S.E. Waisbren^{2,5,6}, D. Marsden^{3,5,6}, U.S. Shimizu⁶, S. Albers⁷, B. Taft^{4,5}, H.L. Levy^{3,5,6}. 1) Emergency Medicine; 2) Psychiatry; 3) Genetics; 4) Nursing; 5) Children's Hospital Boston; 6) Harvard Medical School; 7) University Munster, Munster, GA.

Background: Knowledge of characteristics of patients with undiagnosed inborn errors of metabolism (IEM) who present to the emergency department (ED) is critical for appropriate evaluation and often lifesaving management, and may be valuable for assessment of newborn screening programs. **Objective:** To determine whether patients with previously undiagnosed IEMs present to EDs prior to diagnosis and if so, whether they have history, signs and symptoms that should alert the ED physician to the possibility of IEM. **Design/Methods:** Descriptive retrospective chart review. Patients with clinically diagnosed IEM who live in New England were identified by geneticists involved in their care. ED visits and hospitalizations prior to IEM diagnosis were reviewed. **Results:** Information was available on 41 clinically diagnosed patients. Diagnoses included 14 different IEMs, most commonly fatty acid oxidation defects (41%) and propionic acidemia (24%). 30/41(73%) had ≥ 1 ED visit prior to diagnosis, 9/30 (30%) had ≥ 2 visits, up to 4/patient, total 45 visits. Median age at diagnosis was 4.5 mo (3 d to 5.2 yrs). Presenting symptoms, although consistent with IEM, were nonspecific, most commonly lethargy, seizures, tachypnea, apnea, cyanosis, hypothermia, poor feeding, vomiting. History is often remarkable for poor feeding, morning lethargy, developmental delay, hypotonia. Hypoglycemia, acidosis, hyperammonemia, elevated liver transaminases, elevated BUN were common laboratory abnormalities. Critical laboratory studies for evaluation of possible IEM were often not obtained in the ED. Most patients had multiple consults by nongenetic subspecialists prior to evaluation by a geneticist. **Conclusions:** The ED is a site of presentation of the majority of patients with undiagnosed IEM. The possibility of IEM is suggested by history and abnormal laboratory results. ED physicians, as well as primary care physicians and nongeneticist consultants, should be educated regarding recognition and evaluation of patients with possible IEM.

Brain magnetic resonance imaging analysis of a hypomorphic Smith-Lemli-Opitz Syndrome mouse model. *L.S. Correa-Cerro*¹, *J.P. Munasinghe*², *C.A. Wassif*¹, *F.D. Porter*¹. 1) Heritable Disorders Branch, NICHD/NIH, Bethesda, MD; 2) MRI Mouse Imaging facility/NIH, Bethesda, MD.

The Smith-Lemli-Opitz syndrome (SLOS) is a multiple malformation syndrome due to mutation of the 7-dehydrocholesterol reductase gene (*DHCR7*). *DHCR7* reduces 7-dehydrocholesterol (7-DHC) to cholesterol. Common clinical manifestations include dysmorphic facial features, mental retardation, and 2-3 toe syndactyly. Malformations of the brain including callosal abnormalities, Dandy-Walker variant, holoprosencephaly and prominent ventricles. We generated a hypomorphic *Dhcr7*^{T93M/} SLOS mouse model. Phenotypically *Dhcr7*^{T93M/} mice have mild dilatation of the third and lateral ventricles and 2-3 toe syndactyly. Ventricular dilatation was found in 54% of the mice by histological studies at 5 months of age (n=13). This malformation was not observed in newborns or at 2 months of age. We are using magnetic resonance imaging to serially study the development of ventricular enlargement in this SLOS mouse model. An initial study was performed comparing four control and four mutant nine-month-old males. Tissue and ventricular volumes were determined from 3-D reconstructions of fast spine echo images. No significant differences were observed for total brain tissue volume between control (297.26 mm³) and mutant (286.19 mm³) animals. This suggests that ventricular dilatation is not secondary to CNS tissues loss. Two mutant mice showed enlargement of the lateral ventricles (1.9 mm³ and 1.3 mm³) compared to control values (LV=0.470.19 mm³). Future experiments will focus on describing the time course of the development of ventricular enlargement by determining if sterol differences underlie penetrance of this malformation, if water diffusion and T₂ maps can detect parenchymal differences and whether simvastatin treatment can prevent the development of the ventricular enlargement.

Patients with XY Sex Reversal carry mutated SRY with Defective Calmodulin Recognition and Nuclear Import.

*V. Harley*¹, *K. Rimmer*¹, *L. Ludbrook*¹, *S. Kelly*¹, *A. Clayton*², *H. Sim*¹. 1) Human Molecular Genetics, Prince Henry's Institute, Clayton, Australia; 2) Ludwig Institute of Cancer Research, Melbourne, Victoria, Australia.

SRY plays a key role in human sex determination as mutations cause male to female sex reversal as a consequence of complete gonadal dysgenesis. While many SRY mutations affect DNA binding and DNA bending activity it is not clear how others contribute to disease. Four XY females showed reduced SRY nuclear import. In two cases (R133W, R62G), their mutated SRY bound weakly to importin . In two other cases (R75N, R76P), SRY nuclear import was reduced but importin beta binding was normal (Harley et al., 2003, PNAS). This suggests the existence of an importin independent nuclear import pathway. The high mobility group (HMG) domain of SRY has two independent nuclear localization signals (NLS). The N-terminal NLS (nNLS) of SRY and the SRY-related testis factor, SOX9 bind calmodulin (CaM) in vitro (Sim et al., 2003, JBC). Here, we show that a CaM antagonist calmidazolium chloride (CDZ) blocks CaM recognition of SRY both in vitro and in vivo, leading to reduced nuclear import of SRY in treated cells. Fluorescence studies indicate that the conformation of SRY-CaM complex is dramatically different in R75N and R76P mutants. While CDZ reduced nuclear entry of wildtype SRY and the R133W (importin defective) mutant SRY, CDZ had no effect upon the R75N and R76P mutants suggesting that CaM-mediated import is defective in R75N and R76P. Taken together these data suggest that SRY binds CaM during nuclear import and that altered binding leads to reduced SRY nuclear import and sex reversal. This is the second demonstration of a human disease of protein nuclear import, the first being SRY-importin defects, and predicts that defective CaM binding could underlie diseases involving the approximately 100 other HMG box proteins encoded in the human genome.

Clinical outcome of patients who defer hematopoietic stem cell transplantation in favor of enzyme replacement therapy. *C.P. Lorentz¹, C.B. Whitley², S. Grewal², L. Charnas², C. Peters², E.G. Shapiro².* 1) Fairview University Medical Center, Minneapolis, MN; 2) Department of Pediatrics, University of Minnesota, Minneapolis, MN.

Hematopoietic stem cell (HSC) transplantation has become the standard of care for children with the most severe form of mucopolysaccharidosis (MPS) type I, i.e. Hurler syndrome. With the advent of enzyme replacement therapy (ERT), some parents make the informed decision to select low-risk laronidase (Aldurazyme) therapy in lieu of higher-risk HSC transplantation. While ERT may result in longer survival, failure of enzyme to cross the blood-brain barrier will result in progressive neurodegeneration with a deteriorating quality of life. Importantly, the rate of decline in severe MPS I patients without treatment is estimated to be about 20 IQ points per year (1.6 points per month). For example, we saw a 23-month-old female with characteristic facial features, dysostosis multiplex, and elevated urinary glycosaminoglycans. Subsequent mutation analysis found the patient to be homozygous for the Q70X mutation, thus, confirming the classic, severe MPS I phenotype. Although initial psychometric assessment was within normal limits, such patients inevitably decline in cognitive function. After extensive consultation regarding treatment options, emphasizing the distinctions in neurologic efficacy, the parents elected to initiate weekly ERT rather than HSC transplantation. Over the course of 14 months on treatment, the parents appreciated increased limb mobility and some developmental progress. They declined reconsideration of HSC transplantation. Serial evaluations will determine the neurologic outcome, quality of life, and longevity for such individuals. Immediate benefits of ERT may distract parents from considering the inevitable, long-term neurodegeneration that a child will experience. When counseling parents about combined ERT and HSC therapy, this neurodegeneration must be emphasized.

X-linked dominant Conradi-Hünemann syndrome in a male patient due to single gene mosaicism. H.R.

Waterham^{1,2}, *J. Koster*², *M.C.E. Jansweijer*¹, *J.H. Sillevius Smitt*³, *R.J.A. Wanders*^{1,2}, *M. Duran*², *R.C.M. Hennekam*¹. 1) Department of Pediatrics, Academic Medical Center, Amsterdam, The Netherlands; 2) Department of Clinical Chemistry, Academic Medical Center, Amsterdam, The Netherlands; 3) Department of Dermatology, Academic Medical Center, Amsterdam, The Netherlands.

Conradi-Hünemann syndrome, also known as X-linked dominant chondrodysplasia punctata 2 (CDPX2; MIM 302960), is characterized by a bilateral, asymmetric expression of various skeletal and skin abnormalities, including chondrodysplasia punctata (epiphysic stippling), shortening of long bones and ichthyosis. The disorder is caused by a deficiency of the sterol⁸⁻⁷ isomerase due to mutations in the *EBP* gene on chromosome Xp11.22-23. As a consequence of this enzyme deficiency, patients have elevated plasma levels of cholesta-8(9)-en-3-ol but usually normal levels of cholesterol. Since the disorder is recognized almost exclusively in females it has been assumed to be lethal in males. We here report a 24-old male patient initially diagnosed with CDPX2 on the basis of his clinical presentation. The patient is severely retarded, both mentally and developmentally, and has a variety of skeletal (polydactyly, dwarfism, scoliosis, unilateral rhizomelic shortening) and skin abnormalities. Sterol analysis in plasma and cultured skin fibroblasts revealed elevated levels of cholesta-8(9)-en-3-ol. Surprisingly, mutation analysis of the *EBP* gene revealed apparent heterozygosity for a 429delG mutation although the patients karyotype was 46,XY. The different ratios of mutated versus wild-type allele in lymphocyte and fibroblast DNA indicate that the patient is mosaic for a single mutation in the *EBP* gene.

GLUTAMATE CYSTEINE LIGASE CATALYTIC SUBUNIT TRINUCLEOTIDE REPEAT

POLYMORPHISM AND TYPE I DIABETES AGE-AT-ONSET. L. Bekris¹, C. Shephard¹, J. Graham², B.

McNeney², J. Shin², M. Zarghami³, F. Farin¹, T. Kavanagh¹, A. Lernmark³. 1) Environmental Health, University of Washington, Seattle, WA; 2) Statistics and Actuarial Science, Simon Fraser University, Burnaby, B.C; 3) Department of Medicine, University of Washington, Seattle, WA.

Glutathione (GSH) protects against reactive oxygen species (ROS)-mediated cell injury. Glutamate cysteine ligase (GCL), the rate limiting enzyme in the synthesis of GSH consists of catalytic (GCLC) and modifier (GCLM) subunits. Type 1 diabetes (T1D) is an autoimmune disease involving auto-reactive T-cells and ROS, which may cause pancreatic beta-cell destruction. We hypothesized that GCLC may be a susceptibility factor for T1D. A polymorphic GAG trinucleotide repeat (TNR) exists in the 5'untranslated region of the GCLC gene. The aim of this investigation was to determine the frequency of this polymorphism and associations with age-at-onset and islet autoantibodies in a group of new onset 0-34 year old T1D (n=186) and in controls (n=189) from Sweden. Results show: 1) In the T1D, there is marginal statistical evidence for a higher proportion of females when the GCLC TNR 8 allele is present (p-value: unadjusted 0.021, Bonferroni-corrected 0.063) and 2) there is marginal statistical evidence for a higher frequency of the GCLC TNR allele 8 (unadjusted p-value, 0.019, Bonferroni-corrected p-value, 0.057) and for a higher frequency of the GCLC TNR genotype 7/8 (unadjusted p-value, 0.013, Bonferroni-corrected p-value, 0.078) in the younger 0-14 year old T1D than in the 15-34 year old T1D. This study suggests that oxidative stress, due to the GCLC TNR polymorphism may precede type 1 diabetes onset. The GCLC TNR 8 allele and the GCLC TNR 7/8 genotype may be associated with a younger age-at-onset in T1D. Since GCLC TNR 7 and TNR 8 have been reported to be associated with lower GSH levels than GCLC TNR 9 and GSH has been reported to be depleted in T1D we speculate that the GCLC TNR polymorphisms may contribute to T1D risk.

Early epileptic encephalopathy and neonatal diabetes, associated with mutation in ATP-sensitive potassium channel, Kir6.2. *N. Nahi-Buisson¹, C. Bellanne-Chantelot², M. Eisermann³, R. Nabbout¹, N. Bach⁵, S. Nivot⁵, P. Plouin², JJ. Robert⁴, P. de Lonlay¹.* 1) Neuropediatrics, Necker Enfants Malades Hospital, Paris; 2) Molecular Biology Necker Enfants Malades Hospital, Paris; 3) Neurophysiology, Necker Enfants Malades Hospital, Paris; 4) Pediatric Endocrinology Necker Enfants Malades Hospital, Paris; 5) Pediatric Unit, Caen.

Heterozygous activating mutation in the gene encoding the Kir6.2 subunit of the ATP-sensitive potassium (KATP) channel have recently been described as a cause of neonatal diabetes occasionally associated with heterogeneous neurological disorders. We present here a female who presented from birth, feeding problem, developmental delay, and mild dysmorphic features. Intrauterine growth retardation was observed at 28 weeks of gestation. At 3 months of age, she developed neonatal diabetes and a severe epileptic encephalopathy, characterized by epileptic spasms, tonic seizures, and an hypsarhythmic pattern on EEG. Brain MRI, Spectro MRS, and metabolic investigations were normal. Mutation analysis of the Kir6.2 gene (KCNJ11) revealed a C166F missense de novo mutation. Diabetes was controlled by continuous doses of Insulin. Based on in vitro studies, a trial of sulfonylureas is performing, as the antiepileptic drugs were inefficient on the epileptic encephalopathy and the child required high doses of insulin with corticotherapy. The mechanism of this epileptic encephalopathy is still elusive. We discuss several hypotheses, such as the direct role of the activation of the (KATP) channel, a channelopathy with a secondary disturbed excitability of the cortex, or the role of the intrauterine growth retardation in the genesis of this severe epileptic encephalopathy. In conclusion, activating mutation Kir6.2 should be regarded as a possible cause of West syndrome when associated with diabetes. A treatment by sulfonylurea is questionable.

Investigation of Simvastatin Treatment in Smith-Lemli-Opitz Syndrome. C.A. Wassif, L.S. Correa-Cerro, F.D. Porter. NICHD/HDB/NIH, Bethesda, MD.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive, malformation syndrome due to mutations of the 7-dehydrocholesterol reductase gene (DHCR7). DHCR7 converts 7-dehydrocholesterol (7DHC) to cholesterol. As a result of this perturbation, SLOS patients have increased 7DHC levels. Dietary cholesterol replacement is the standard current treatment. Recently attempts have been made to treat SLOS patients with simvastatin in order to reduce the levels of 7DHC both in the periphery and the central nervous system. One study of simvastatin therapy in SLOS patients showed a decrease in 7DHC and an increase in cholesterol. To study the efficacy of simvastatin treatment in SLOS, we have undertaken a multifaceted approach. First, by studying the effects of simvastatin in cell culture, and second, by generating a hypomorphic, viable SLOS mouse model. This was done by "knocking in" a T93M mutation. Mice homozygous for a null disruption (D) of *Dhcr7* die soon after birth. T93M mice were phenotypically normal; however, T93M/D mice had 2-3 toe syndactyly. Sterol profiles of liver, cortex, midbrain, and kidney in both one day old and six weeks old mice showed elevated 7DHC. 7DHC levels were higher in the T93M/D compared to T93M/T93M mice. Treatment of T93M/D mice with simvastatin (10mg/kg/d) for three weeks significantly decreased 7-DHC levels in some peripheral tissues, and decreased 7DHC levels in the cortex. In culture, we have tested 51 SLOS cell lines for their ability to produce cholesterol, and have found a correlation between fractional cholesterol synthesis and severity. SLOS cell lines that have no residual cholesterol synthesis die when treated with simvastatin. Conversely, when cell lines that retain some residual cholesterol synthesis capabilities are treated, 7DHC levels decrease and fractional cholesterol synthesis is increased. Treatment of cells that have been allowed to accumulate 7DHC and then treated with simvastatin show a reduction in 7DHC and a rise in cholesterol. The reduction in 7DHC and the rise in cholesterol levels corresponds to an increase in the levels of the *Dhcr7* transcript. We are continuing to investigate whether increased DHCR7 transcription is mediated by the SREBP pathway or some other mechanism.

Two severe congenital hyperinsulinism resulting from a genome-wide paternal isodisomy and a paternal trisomy combined with a loss of maternal allele. *I. Jiurgea¹, D. Sanlaville¹, J.C. Fournet¹, C. Sempoux², C. C. Bellanné⁴, F. Jaubert¹, F. Brunelle¹, J. Rahier², V. Geromet³, J.M. Saudubray¹, C. Nihoul-Fékété¹, J.J. Robert¹, M. Dunne⁵, J. Feingold¹, M. Vekemans¹, C. Junien¹, C. Gicquel⁶, P. de Lonlay¹.* 1) INSERM U393, Pediatric depart, Hosp Necker-Enfants Malades, paris, France; 2) Department of Pathology, Universit de Louvain, Brussels; Pasteur-Cerba Laboratory; 3) Pasteur-Cerba Laboratory, 95066 Cergy Pontoise Cedex 9; 4) Department of Biology, Hpital Saint-Antoine, Paris, France; 5) Division of Physiology and Pharmacology, School of Biological Science, The University of Manchester, Oxford Road, Manchester; 6) Department of Cytogenetics, Hpital Trousseau, Paris, France.

Focal hyperinsulinism (HI) is caused by a limited somatic event, the loss of maternal alleles in the 11p15 region, responsible for the reduction to homozygosity of a paternally inherited mutation on the ABCC8 or the KCNJ11 gene, coding for a potassium channel. HI can also be observed in Beckwith-Wiedemann syndrome (BWS). We report here two patients with severe HI requiring partial pancreatectomy. Patient 1 had a BWS and patient 2 had a suspected focal HI. In both cases, histology showed a focal unusual aspect of the endocrine tissue. A loss of the maternal allele on all 23 chromosomes was found in the pancreatic lesion and in some leukocytes from patient 1. Paternal isodisomy in leukocytes was confirmed by a 17p13.3 southern blot and rhesus analysis. A paternal trisomy on half of the chromosomes with two genetically different paternal alleles were found in pancreatic lesion of Patient 2. In the other half a loss of maternal allele was observed. In both patients, potassium channels were functional on hyperplastic pancreas and no mutation of ABCC8 and KCNJ11 genes was detected. We want to discuss the role and the mechanism of these rearrangements. In particular they could reduce recessive mutations to homozygosity and/or deregulate the pancreatic expression of imprinted genes located in or outside the 11p15 region, leading to abnormal pancreatic histology and severe hypoglycemia.

Mesenteric mass associated with type III Gaucher disease. *M. Dudek*¹, *W.J. Rhead*², *B. Camitta*², *D. Margolis*², *M. Hernanz-Schulman*³, *B.A. Maxfield*⁴, *G.E. Tiller*¹. 1) Div Med Genetics, Dept Pediatrics, Vanderbilt Univ Sch Med, Nashville, TN; 2) Dept Pediatrics, Med College of Wisconsin, Milwaukee, WI; 3) Dept Radiology, Vanderbilt Univ Sch Med, Nashville, TN; 4) Dept Radiology, Med College of Wisconsin, Milwaukee, WI.

Gaucher disease (GD) is an autosomal recessive lysosomal storage disorder caused by mutations in the gene for beta-glucocerebrosidase. We report an 11 year old Mexican patient with GD type III who developed a mesenteric mass secondary to her disease. She was diagnosed at age 2 years when she presented with organomegaly. She is homozygous for the L444P mutation, and has been receiving enzyme replacement therapy consisting of biweekly infusions of Ceredase or Cerezyme since the time of diagnosis. Chronic problems have included mild developmental delay, growth retardation, abdominal distention, and constipation. At 11 years of age, she presented with severe abdominal pain and no bowel movement for one week. A CT scan revealed a large, multicystic, anterior abdominal mass measuring 11x14cm. At laparotomy, cystic portions were decompressed, but the mass could not be excised due to proximity to the mesenteric vasculature. Histologic analysis of cystic fluid and multiple soft tissue nodes demonstrated Gaucher cells, but failed to identify any neoplastic cells. The patient has been managed postoperatively for four months with stool softeners and weekly infusions of 90u Cerezyme/kg, with decrease in volume of the mass and no progression of symptoms. A similar case has been reported previously (*Ped Radiol* 32:674, 2002). We recommend that patients with GD and chronic gastrointestinal symptoms warrant periodic evaluation, including appropriate imaging studies when indicated.

CNS involvement in Fabrys disease: an image study during 24 months of ERT. *L.B. Jardim^{1,2}, L. Vedolin⁴, C. Cecchin², L. Kalakun², F. Aesse⁴, C. Pitta-Pinheiro⁴, J. Marconato⁴, R. Giugliani^{2,3}.* 1) Department of Internal Medicine, UFRGS, Brazil; 2) Medical Genetics Service, Hospital de Clinicas de Porto Alegre, Brazil; 3) Department of Genetics, UFRGS, Brazil; 4) Department of Neuroradiology, Hospital Moinhos de Vento.

Objectives: To access the neuronal involvement in Fabrys disease (FD) with MRI, MRA and proton MR spectroscopy, during 24 months of ERT. **Methods:** A brain MRI and MRA study of 7 male patients with FD, mean age: 31 y, were performed just before their inclusion in a compassionate use trial with agalsidase-alpha. A standard neurological examination generated a score which varied between zero (normal examination) and 85. Presence and location of gray and white matter (WM) lesions, the presence of vascular occlusion or ectasia at MRA were determined, as well as their relation with age, symptoms and neurological examination. **Results:** (a) Baseline: There were few, previous CNS signs and symptoms. NE CNS scores varied from zero to 3. Three patients showed a widespread pattern of deep WM lesions, mainly in frontal and parietal lobes. (b) Evolution of NE scores in 24 months of ERT: NE CNS scores were all similar, during the period under study. However, two patients presented NE scores significantly different from the others on the 24th month: case 1 had a worse CNS score than others, and case 6, whose NE was completely normal (CI of 95%). (c) Evolution of MRI during 24 months of ERT: At the 12th month, MRI worsened in 2/7 and was stable in 5/7 patients. Patients with progression of WM lesions, mainly in frontal lobes, cases 1 and 2, were related and the eldest of the sample. At the end of 24th month, the MRI of the remaining 5 patients was stable in 3/5, and worsened again in case 1. Finally, WM lesions disappeared in case 6. **Discussion:** MRI seemed to be a better parameter than neurological examination to follow the CNS evolution of FD patients. MRI also showed that, during ERT, WM lesions, although still silent, can progress in some patients, and disappear in others, and that this effect could be related to their ages at the inclusion on ERT.

Support: TKT.

Identification of mutations and short-term experience of enzyme replacement therapy in Korean patients with Fabry disease. *G-H. Kim¹, J-H. Choi², S-S. Kim³, Y. Kim³, H-W. Yoo^{1, 2, 3}.* 1) Med Genetics Clinic & Lab, Asan Medical Center, Seoul, Korea; 2) Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 3) Genome Research Center for Birth Defects & Genetic Disorders, Asan Medical Center, Seoul, Korea.

Fabry disease is an X-linked recessively inherited metabolic disorder, which results from the deficient activity of the lysosomal hydrolase alpha-galactosidase A (-Gal A) leading to the systemic pathologic accumulation of globotriaosylceramide (GL-3). Recent clinical trials have demonstrated that enzyme replacement therapy (ERT) in patients with Fabry disease is effective in both reducing the storage end-product GL-3 and alleviation of symptoms and signs in multi-organ systems. This study aims at characterization of molecular defects of Korean patients with Fabry disease and evaluating the efficacy of ERT during a short-term period. We have identified 10 different mutations of -Gal A in 15 patients from 10 unrelated Korean families with Fabry disease; M42V, E66Q, Q99fs121(c.297_298del), R112C, D231G, D266N, L268fs(c.803_806del), R342X, T412fs(c.1235_1236del), and Y866X. In order to evaluate the effects of these mutations on the -Gal A activity, we constructed E66Q, R112C, and D266N cDNA from a wild type -Gal A. COS-7 cells transfected with these mutant (R112C, D266N) cDNA showed complete loss of its enzyme activities (about 4 and 2 % of wild type-Gal A, respectively), except E66Q with a residual activity (about 30%). Nine male patients and one symptomatic female heterozygote have been on ERT with agalsidase beta (Fabrazyme) at the standard dose of 1 mg/kg every 2 weeks for ranging from 6 months to one year. All patients have shown remarkable reduction of plasma GL-3 level within 3 months after ERT. It has been normalized within 6 months in most cases. However, urinary GL-3 excretion has persisted without significant reduction within 3-6 months after ERT. Renal function remained normal based on serum creatinine levels and creatinine clearance rate. There was no adverse event except infusion-associated fever and chillness. Also, other clinical profiles were monitored during ERT to verify its efficacy.

Haplotype diversity and genetic determinants of the therapeutic response. *R. Sanchez, H. Vasquez, D. Labuda, V. Yotova, F. Costea, E. Levy, D. Sinnott.* Centre de recherche Hopital Ste-Justine, Montreal University, Montreal (Quebec), Canada, H3T 1C5.

The inflammatory bowel disease (IBD) is a complex genetic disorder characterised by at least two major disorders: Crohns disease (CD) and ulcerative colitis (UC). IBD is the most common intestinal disease in Canadian children, with approximately 25% of all cases diagnosed before the age of 20. Different therapeutic approaches are used, 1) combinations of glucocorticosteroids and amino-salicylic acid 2) immunosuppressors drugs (for refractory and steroid-dependent cases) and recently 3) biological drugs such as monoclonal anti-TNF- and IL-10. Genetic factors influence the individuals response to treatment and susceptibility to drug toxicity. Determination of the underlying genetic polymorphisms may be of clinical value in predicting adverse or inadequate response to certain therapeutic agents. In this study we identified genetic variation in candidate genes in order to be able to perform pharmacogenetics investigations in respect to IBD therapeutic responses and toxicity. The candidates genes (TNF-, IL-10, NFB, IKB-, IKAP and MDR-1, MRP-1) are implicated in cellular and molecular pathways involved in the metabolism of commonly administered drugs in IBD patients. Genotypes of childhood cases (n=334) and worldwide population controls were determined by PCR-allele specific oligonucleotide (ASO) hybridization assays. These data were used to determine the haplotype structures and frequencies. The resulting haplotypes are being used for association and/or pharmacogenetic studies. This study will help to increase our understanding of the genetic factors that modify IBD therapeutic response. Supported by VRQ (Valorisation Recherche Qubec).

AAV vector mediated co-expression of FGE with ASA for gene therapy of metachromatic leukodystrophy. T.

Kurai, Y. Takakusaki, R. Kitagawa, M. Yamamoto, S. Hisayasu, Y. Hirai, T. Shimada. Dept Biochemistry & Molec Biol, Nippon Medical Sch, Tokyo, Japan.

Metachromatic leukodystrophy (MLD) is a lysosomal storage disorder caused by a deficiency of arylsulfatase A (ASA). Accumulation of sulfatide results in a variety of neurologic symptoms. No effective therapy is available at this moment. Gene therapy may be an important option for treatment of MLD. It was reported that posttranslational conversion of a cysteine residue to formylglycine is essential for ASA activity. Accordingly, co-expression of formylglycine generating enzyme (FGE) encoded by the sulfatase modifying factor 1 (SMUF1) gene with ASA should be important for mass production of active ASA. In this work, we studied the utility of FGE in gene therapy for MLD. When FGE expression plasmid was cotransfected with ASA expression plasmid into 293, HeLa, and Cos cells, a striking increase of ASA activity was observed. These plasmids were injected into liver of MLD knockout mice using the hydrodynamics-based technique. A synergistic effect of FGE on ASA was also confirmed in both liver and serum *in vivo*. We now generated AAV vectors expressing ASA and FGE. The AAV vectors were pseudotyped with type 1, 2 or 5 capsid and purified by a novel procedure based on the density-gradient centrifugation using iodixanol. The final preparations showed extremely high transduction efficiency both *in vitro* and *in vivo*. Two to three folds enhancement of ASA activity by co-expression of FGE was observed in HeLa cells transduced with AAV vectors. These results indicate that co-expression of FGE with ASA is important for MLD gene therapy. AAV vectors expressing ASA and FGE are useful for further evaluation of gene therapy approaches for MLD.

An Ethnic Specific Polymorphism in Glutamate Cysteine LIgase May Affect Enzyme Activity. *A.S. Willis^{1,2}, T.M. Le², M.L. Freeman³, K.R. Sekhar³, M.S.B. Kennedy¹, S. Dawling⁴, L.J. Roberts⁵, M.L. Summar^{1,2}.* 1) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Dept Pediatrics, Vanderbilt Univ., Nashville, TN; 3) Dept Radiation Biology, Vanderbilt Univ., Nashville, TN; 4) Dept Pathology, Vanerbilt Univ., Nashville, TN; 5) Dept Pharmacology, Vanderbilt Univ., Nashville, TN.

Glutamate cysteine ligase (GCL) catalyzes the first, rate-limiting step in the de novo synthesis of glutathione, an important tripeptide. One of the most important functions of glutathione is the scavenging of free radicals to prevent oxidative damage, which is thought to play a role in many diseases, such as neurodegeneration and cancer. We have previously identified a nonsynonymous polymorphism C1384T in GCLC. The rare allele of this polymorphism changes a conserved proline to serine at position 462 and has only been observed in individuals of African descent. We have undertaken the study of the functional aspects of this polymorphism. Using clones of the coding region of both human GCLC and GCLM, we have expressed both versions of the GCLC C1384T polymorphism in *E. coli*. Western blot demonstrates expression of soluble normal sized GCLC protein. We have optimized an HPLC method for detection and quantitation of -glutamylcysteine, the primary product of GCL as an improvement over our previous method, which monitored production of inorganic phosphate as a result of ATP usage. Using the HPLC method for activity assays, lysates containing human GCL bearing the C allele had increased levels of -glutamylcysteine over lysates in which no human GCL was expressed. However, -glutamylcysteine levels in lysates with GCL bearing the T allele were not increased over background control, suggesting that this version of GCL had little to no activity in this system. We are continuing to explore the effect of the C1384T polymorphism on GCL activity and feel that these findings may be important in a number of diseases where oxidative stress plays a role.

The molecular basis of Gaucher disease in South Africa. *S. Arndt, M. Ramsay.* Division of Human Genetics, National Health Laboratory Service and School of Pathology, University of the Witwatersrand, Johannesburg, South Africa.

Gaucher disease (GD) is a recessively inherited lysosomal storage disorder. The gene responsible for GD is located on chromosome 1q21 and has a highly homologous pseudogene in close proximity resulting in a number of complex mutations due to unequal recombination events. GD occurs at a particularly high frequency in Jewish people of Eastern European ancestry. They share a well-characterized mutation spectrum in the GBA gene, with a large number of point mutations. All these mutations have also been observed in other Caucasian populations around the world, including South Africa. In contrast, very few of these mutations were found in the South African Black GD patients. Seventeen unrelated Black GD patients were studied and 33/34 disease causing mutations were identified. A 3 bp deletion mutation in exon 3 (delta T36) was found in 12/34 (0.353) alleles. This mutation has only been observed in Black patients. In addition, 6/34 (0.177) alleles were identified as the recombinant allele recNciI. Interestingly, 5/17 (0.294) Black patients were compound heterozygotes for the same two mutations. The remaining 13/34 disease causing mutations were missense and nonsense mutations of which seven are novel. Our results have illustrated a different mutation spectrum for GD in South African Black patients, and this information will be used to improve our molecular diagnostic service. Haplotype studies are in progress and preliminary results for two markers (D1S2777 and D1S2140) show complete LD with the frequently observed delta T36 mutation, supporting a founder hypothesis for this mutation. Ethics approval for this research project has been obtained (M030201).

An algorithm for rapid mutation identification in peroxisome biogenesis disorder patients in the Zellweger syndrome spectrum. *S. Steinberg*^{1,2}, *G. Cutting*³, *L. Wei*¹, *L. Chen*³, *A. Moser*^{1,2}, *H. Moser*^{1,2}, *N. Braverman*³. 1) Dept Neurogenetics, Kennedy Krieger Inst, Baltimore, MD; 2) Dept Neurology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Zellweger syndrome (ZS), neonatal adrenoleukodystrophy and infantile Refsum disease comprise the Peroxisome Biogenesis disorder-ZS spectrum (PBD-ZSS). These are severe, multisystemic developmental disorders caused by a failure to assemble peroxisomes. Measurement of plasma very long chain fatty acid levels is the hallmark used for biochemical diagnosis, but a variety of other tests are available. Molecular diagnosis provides a number of tangible benefits over biochemical diagnosis, but the heterogeneity of PBD-ZSS makes mutation identification challenging. These are autosomal recessive disorders caused by defects in 12 different PEX genes. However, the majority of patients (>90%) have defects in one of 5 genes: *PEX1*, *PEX6*, *PEX26*, *PEX12* & *PEX10*. Thus, we devised an algorithm for the systematic molecular analysis of PBD-ZSS patients. Genomic DNA was isolated from cultured fibroblasts from 91 PBD-ZSS not previously studied by complementation analysis. A maximum of 13 PCR amplicons were used for sequence analysis of selected exons from the 5 most common genes. Pathological mutations were identified in 67 (74%) of patients. Overall, 23 novel mutations were identified. This systematic, hierarchical approach to mutation identification provides a molecular diagnosis in about three-quarters of patients and thus is a valuable tool for the diagnostic laboratory.

Defective fuel metabolism in the *Abcd3*^{-/-} mouse is related to inappropriate activation of PPAR. *I. Silva-Zolezzi*^{1,2,3}, *S. Bradley*¹, *D. Valle*¹, *G. Jimenez-Sanchez*^{1,3}. 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) PhD. program in Molecular Biomedicine, CINVESTAV, Mexico; 3) National Institute of Genomic Medicine, Mexico.

There are four known human half ABC transporters in the peroxisomal membrane: ALD, ALDR, PMP70 and P70R, encoded by *ABCD1*, 2, 3, and 4, respectively. Mutations in *ABCD1* cause X-linked adrenoleukodystrophy, function and disease associations of the other three transporters are unknown. *Abcd3*^{-/-} mice are viable; have reduced hepatic glycogen; medium chain dicarboxylic aciduria; defective phytanic and pristanic oxidation; and defective non-shivering thermogenesis. We postulated that PMP70 contributes to the peroxisomal transporter of branched fatty acids. In the absence of PMP70, phytanic and pristanic acids accumulate, leading to inappropriate activation of PPAR, in turn activating fasting fuel homeostasis (FFH). This hypothesis is supported by our demonstration of increased hepatic expression of PPAR targets in *Abcd3*^{-/-} mice. To further analyze the molecular mechanisms underlying this phenotype, we performed an expression analysis in *Abcd3*^{-/-} livers and controls with Affymetrix U74Av2 microarrays. We found expression changes (EC) in at least 50 genes PPAR regulated genes, including those we previously observed by Northern blot. In total, we found EC in 209 genes including 93 with an increased and 116 with a decreased EC over controls. We classified the genes by biological process according to Gene Ontology: 40 (19%) were related to lipid metabolism, including genes related to fatty acids anabolism and catabolism, formed the largest group, most showing an increased EC; 28 (13%) were related to the immune response (IR), most (22) with a decreased EC consistent with the known anti-inflammatory role of PPAR. To evaluate the physiological relevance of the altered expression of IR-related genes, we are currently testing inflammation on *Abcd3*^{-/-} mice. These results support our hypothesis that the severe metabolic phenotype of *Abcd3*^{-/-} mice is related to inappropriate PPAR activation leading to FFH activation and emphasize the profound and widespread consequences that can occur in a monogenic defect.

Correlations of genotype-phenotype in Fabry disease. *L.W. Lai, Y.H. Lien.* Department of Medicine, University of Arizona, Tucson, AZ.

Fabry disease is an X-linked recessive disease caused by mutations in the α -galactosidase A gene. Molecular diagnosis of Fabry disease is important for genotype-phenotype correlations, early diagnosis, and detection of carrier status. Genomic PCR and RT-PCR sequencing of α -galactosidase A were performed in patients from 16 unrelated Fabry families. Five novel mutations (R301G, Y222X, T410A, M42L, and L286P) and 10 previously reported mutations (P40S, S65T, R112C, R112H, N215S, R301Q, R220X, R227X, 777delA, and 1188delC) were identified. One mutation previously diagnosed as a missense mutation S65T, was found to be a splice-site mutation (IVS1-1GC) resulting in an insertion of 14 bp and a frameshift stop at codon 106. For 30 individuals at risk, Fabry disease was diagnosed in 5 males and carrier status in 12 females. Structure-functional analysis of missense mutations predicted that P40S affects active site; N215 affects glycosylation site; T410A may affect phosphorylation site; and M42L, R112C, R112H, R301G, R301Q and L286P cause misfolding. Genotype-phenotype correlations are: M42L, N21S, R301G and R301Q correlate with atypical variant of Fabry disease, while the rest correlate with classic Fabry disease. The M42L mutation is associated with renal variant as the index male patient developed ESRD at age of 70 without other Fabry stigmata. Other unique clinical manifestations were found in two males with severe lymphedema (R227X and 777delA), one male with transient complete heart block at age of 80 (R301Q), one female with FSGS and renal failure in spite of a benign missense mutation N215S, and one female with RPGN responsive to cytotoxic therapy (R301Q). Our findings indicate that molecular diagnosis of Fabry disease has important clinical values in identifying Fabry patients and carriers, and predicting prognosis based on genotype-phenotype correlations. Sequencing both genomic DNA and mRNA provides complete molecular information and avoids genotype misdiagnosis. Furthermore, chemical chaperons are currently developed as a potential therapy specific for patients with missense mutations, which cause protein misfolding. Molecular diagnosis will be useful for identifying such patients who may benefit from chaperon therapy.

Infantile and Juvenile-onset Glycogen Storage Disease type II in a Druze Kindred from Northern Israel:

Genotype Phenotype Correlation. *H. Mandel*¹, *C. Shochat*², *S. Korem*², *L. Sanas*², *O. Mesika*¹, *R. Gershoni-Baruch*¹, *D. Bercovich*². 1) Metabolic unit, Department of Genetics, Rambam Hospital, Technion Faculty Medicine, Haifa, Israel; 2) Department Human Molecular-Genetics, Pharmacogenetics, Migal-Galilee, Biotechnology Center, Kiryat-Shmona, Israel.

Objective: To characterize the phenotypes of patients with glycogen storage disease type II (GSD II) in a Druze kindred from northern Israel and correlate them with genetic defects. **Background:** GSD II is an autosomal recessive disease caused by deficiency of lysosomal acid alpha-glucosidase (GAA). It occurs in different clinical forms and manifests biochemical and genetic heterogeneity. **Methods:** We performed clinical, biochemical and genetic study including 17 patients, from 5 families in one kindred. DNA samples were collected from members of 4 generations including 5 patients, 10 obligatory heterozygotes, and 50 family members. We screened the 20 exons of the GAA gene using denaturing high performance liquid chromatography (DHPLC) and sequenced fragments with different chromatograms. **Results:** Three phenotypes were identified: *Type 1*. Infantile, early-onset, rapidly progressive cardiomyopathy, skeletal myopathy, and death prior to age 1y; *Type 2*: Similar to type 1, but prolonged survival till age 3y; *Type 3*: Juvenile-onset, after age one year, slowly progressive skeletal myopathy without cardiac symptoms. Two missense mutations were identified: a novel A1651G (D404N) at exon-8, and a previously described T1505C (L355P) mutation in exon 6 (reported as associated with infantile type). Three patients whose parents are carriers of D404N mutation had phenotype type 1. Of 3 patients, homozygotes for the L355P, two had type 2, and one type 3. Eleven patients who were compound heterozygotes of these two mutations presented all three phenotypes. **Conclusions:** 1) In this kindred no clear correlation between the mutation and phenotype of GSD II was found. 2) A reliable carrier detection can be offered in this kindred. In a community where termination of pregnancy due to severe genetic disease is often not acceptable, a reliable carrier detection before first cousin marriage is planned, could be an acceptable option.

The relationship between genotype and phenotype in Fabry disease. *A. Mehta*¹, *E. Schäfer*², *M. Beck*³, *U. Widmer*⁴, *G. Sunder-Plassmann*⁵, *A. Gal*². 1) Department of Haematology, Royal Free Hospital, London, United Kingdom; 2) Institute of Human Genetics, University of Hamburg, Hamburg, Germany; 3) Department of Paediatrics, University of Mainz, Mainz, Germany; 4) Department of Medicine, University of Zurich, Zurich, Switzerland; 5) Department of Medicine III, Medical University, Vienna, Austria.

Fabry disease is an X-linked disorder caused by a deficiency of the enzyme α -galactosidase A. Accumulation of the enzyme substrate globotriaosylceramide in lysosomes leads to organ failure and premature death. Males with the classic form of the disease typically have undetectable enzyme activity and multi-organ involvement. Some males, however, are less severely affected. More than 250 different mutations in the gene encoding α -galactosidase A (*GAL A*) have been identified in patients with Fabry disease. It has been suggested that mutations leading to complete loss of enzyme function, e.g. by virtue of a premature stop codon, are associated with classic Fabry disease, whereas mutations resulting in amino acid substitutions result in less severe disease. We report an analysis of the relationship between genotype and phenotype in patients in FOS the Fabry Outcome Survey. α -Galactosidase A was found to be concordant in 27 out of 32 families with two or more affected males, suggesting a limited correlation between genotype and enzyme activity. Consistent with this finding, when clinical symptoms, enzyme activity and localization of missense mutations were considered together, a limited correlation was observed between phenotype and genotype. Future analysis of the functional consequences of *GAL A* mutations at the molecular level may help to elucidate further the genotypephenotype relationship in Fabry disease.

Program Nr: 1757 from the 2004 ASHG Annual Meeting

Genetic susceptibility to the toxic effects of thimerosal in inbred mouse strains. *I.K. Mehta, D.W. Kim, J. Gitschier.*
Dept Pediatrics and Medicine & HHMI Univ California, San Francisco, San Francisco, CA.

Thimerosal, a commonly used preservative that is approximately 50% ethylmercury by weight, has been implicated as a potential cause of autism. We hypothesize that genetic susceptibility to mercury toxicity could exacerbate the neurotoxic effects of mercury and potentially underlie the development of autism and/or neurodevelopmental disorders in some cases. To assess the genetic influences in an animal model, we are investigating the effects of thimerosal in a panel of inbred mouse strains (C57BL/6, 129S1/SvIm, BALB/cBy, C3H/He, DBA/2, and FVB/N, NZW, and AJ). To mimic the pediatric timetable of childhood vaccination, we subcutaneously injected mice with thimerosal on postnatal day 7. Of the mouse strains tested, most show susceptibility to the toxic effects of thimerosal, exhibiting death within 1 month post-injection with thimerosal. In contrast, one strain, namely 1291/SvIm, shows significant survival, at least 6 months post-injection. To evaluate the metabolic fate of thimerosal in thimerosal-susceptible vs. thimerosal-resistant strains, thimerosal concentrations were measured in brain, liver, kidney and heart derived from C57BL/6 and 129SI/SvIm mice. In addition, histological analysis of thimerosal injected vs. mock-injected C57BL/6 and 129SI/SvIm mice are being conducted. Preliminary data suggest that these two strains may metabolize thimerosal differently, allowing for a differential survival at lethal doses. We are currently assessing the inheritance pattern for thimerosal resistance and ultimately plan to identify the genetic loci responsible for this trait.

Mutational Analysis of ATP7B and Genotype-Phenotype Correlation in Indian Wilson Disease patients. R.

Prasad¹, S. Kumar², G. Kaur³, B.R. Thapa⁴. 1) Rajendra Prasad, Biochemistry, PGIMER, Chandigarh, India; 2) Sandeep Kumar, Biochemistry, PGIMER, Chandigarh, India; 3) Baburam Thapa, Pediatric Gastroenterology, PGIMER, Chandigarh, India; 4) Gurjit Kaur, Department of Physiology, Government Medical College, Chandigarh, 160032.

Wilson disease (WD) is an autosomal recessive disorder of copper transport. The gene ATP7B responsible for Wilson disease produces a protein, which is predicted to be a copper-binding P-type ATPase, homologous to Menkes disease gene ATP7A. This study was aimed to detect disease-causing mutations and to determine the possible genotype-phenotype correlation. We have analyzed 43 unrelated Indian Wilson disease families, including 43 patients. We have characterized 22 mutations and 6 polymorphisms by SSCP and direct sequencing of all 21 exons. Among them 21 were novel mutations and 5 were novel polymorphisms. Of these mutations, fourteen were insertion/deletion, five were missense, two were splice site and one was nonsense. The frequency of mutations in WD chromosomes were accounted to be 19% in exon 13, 9% in exon 15, 6% in exon 18, 3.4% in exon 8, 12 and 16, 2.3% in exon 4 and 1.2% in exon 7, 9, 11 and 21. The mutations Pro992His, Ile1102Thr, 2997insA, 3031insC were observed in 24% of the WD chromosomes. Four homozygous patients, two for 2977insA, two for 3031insC mutations and twelve heterozygous patients, six for Ile1102Thr, two for Lys910-ter, two for Ala1002Thr and two 3424insC showed entirely different phenotypes. All WD patients demonstrated significantly decreased copper-stimulated ATPase activity, which was fraternized with elevated levels of liver biopsy copper for individual mutation. The identified mutations provided for at least part of the wide phenotypic variation observed in Wilson disease. The mutations were found in the compound heterozygous state together with other mutation and homozygosity was rarely observed.

The prevalence of premature termination codons in Carbamyl Phosphate Synthetase I Deficiency. *M. Summar*^{1,2}, *A. Eeds*², *L. Hall*¹, *M. Yadav*¹, *B. Christman*³, *F. Barr*¹, *M. Ryan*¹, *A. Putnam*¹, *S. Summar*¹, *M. Arvin*¹, *Urea Cycle Disorders Consortium*. 1) Dept Pediatrics/Div Genetics, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Center for Human Genetic Research, Dept Molec Physiology, Vanderbilt Univ, Nashville, TN; 3) Dept Pulmonary Medicine, Vanderbilt Univ, Nashville, TN.

The rate-determining enzyme in the urea cycle is carbamyl phosphate synthetase I (CPSI). CPSI Deficiency (CPSID), characterized by hyperammonemia, is autosomal recessive. Efforts to genotype patients by sequencing gDNA and cDNA have not always resulted in the detection of both alleles at the RNA level, though two mutations are almost always found when sequencing patient gDNA. We hypothesize that alleles not represented in cDNA constructs contain a mutation that results in the instability of that RNA message due to splicing defects and frameshifts that form a premature termination codon and subsequently elicit the nonsense-mediated decay (NMD) pathway. It is estimated that 1/3 of genetic disorders and cancers could be the result of PTC containing transcripts. Accordingly, we have found 24 total and 21 unique mutations in patients with CPSID that result in stop codon formation, 19 of these unique mutations form PTCs, defined as such because they are not present in the last exon. This data was collected from a mutation screen that resulted in the detection of 153 total mutations, illustrating that PTC formation occurs in 15.7% of all mutations determined in our lab to be associated with CPSID. PTCs were generated from point mutations that created a stop codon directly as well as numerous single and multiple base pair insertions and deletions. Some PTC formation also occurred as the result of splicing defects. This data supports the evidence that many genetic mutations do not affect the protein product but rather the processing of the transcript, meaning that mature proteins are not always produced. Examining NMD in a growing number of diseases like CPSID could provide evidence that this is a prevalent mechanism leading to genetic deficiencies. This finding highlights the increasing importance of RNA processing defects in molecular pathology.

The Relationship between UDP-Galactose 4-Epimerase Activity and Galactose Sensitivity in Yeast. *J. Wasilenko, J. Fridovich-Keil.* Human Genetics, Emory University, Atlanta, GA.

Epimerase-deficiency galactosemia is an autosomal recessive disease that results from the impairment of human UDP-galactose 4-epimerase (hGALE), the third enzyme in the Leloir pathway of galactose metabolism. While severe or generalized GALE-deficiency has been reported in a small number of patients, the vast majority of patients have an apparently benign peripheral form of the disease in which impairment is restricted to circulating red and white blood cells. Patients with intermediate forms of hGALE-deficiency have also been reported. Like transferase-deficiency galactosemia, the underlying basis of pathophysiology in epimerase-deficiency galactosemia remains unknown, although a build-up of galactose metabolites has been implicated in both forms of the disease.

We are using a yeast model system to study the functional impact of GALE deficiency. Previously we have demonstrated that yeast that are GALE (*gal10*) deficient will not grow in the presence of galactose, despite the presence of another metabolizable carbon source. Here we have introduced a doxycycline-repressible promoter just upstream of the *GAL10* open reading frame in order to modulate its expression. Growth of these cells in medium containing different levels of doxycycline results in differential GALE expression, and differential galactose sensitivity. By characterizing these yeast, we are therefore able to explore the relationship between GALE impairment, accumulation of galactose metabolites, and growth in the presence of galactose.

The spectrum of mutations in *mut* methylmalonic aciduria and identification of a common Hispanic mutation and haplotype. *K.M. Niles*², *L. Worgan*¹, *J.C. Tirone*^{1,3}, *A. Hoffman*¹, *K. Morgan*^{1,3}, *A. Verner*⁴, *A. Sammak*⁴, *P. Lepage*⁴, *D. Rosenblatt*^{1,2,3}. 1) Department of Human Genetics, McGill University, Montreal, QC, Canada; 2) Department of Biology, McGill University, Montreal, QC, Canada; 3) Department of Medicine, McGill University, Montreal, QC, Canada; 4) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada.

Cobalamin non-responsive methylmalonic aciduria (MMA, *mut* complementation class) is an autosomal recessive disorder resulting from mutations in the methylmalonyl CoA mutase (MCM) gene (*MUT*). In order to better understand the spectrum and ethnic origin of mutations causing MMA, the *MUT* gene was sequenced in 160 patients with MCM deficiency. Genomic DNA was extracted from patient fibroblasts and each of the 13 exons of the *MUT* gene was amplified by PCR and sequenced. Sequence analysis identified mutations in 96% (308/320) of alleles. Both mutations were identified in 152 patients, one mutation in four patients and no mutations in four further patients. 115 different mutations were identified. 82 of these mutations were novel, adding to the 54 *MUT* mutations that have been previously reported. Mutation types identified were missense (61/115, 53%), small deletions and insertions (25/115, 21%), nonsense mutations (19/115, 17%) and splice site mutations (10/115, 9%). Although many mutations were specific to an individual family, ethnic specific mutations were also identified. The previously reported G717V mutation was seen in 44% (12/27) of Black patients and several other mutations (G94V, G623R, T370P, F174S, F573S, G284X) were identified only in Black patients. There were two mutations seen only in Asian patients, G427D and G544X. A novel mutation in exon 2, R108C, was identified in 60% (16/27) of Hispanic patients. Sixty SNPs within a 134 kb region incorporating the *MUT* gene were examined by genotyping. This data demonstrated that the Hispanic patients with the R108C mutation share a common haplotype, distinct from other Hispanic patients and controls. Three other mutations (G94R, insertion A 1023 and A324T) were also seen exclusively in Hispanic patients.

Haplotypes of the Human Acid -Glucosidase Gene: In normal and individuals with Pompe Disease. *R. Pomponio, J. Marino, M. Phipps, R. Palmer.* Clinical Lab Science, Pharmacogenetics, Genzyme Corporation, Framingham, MA.

Mutations in the human Acid -Glucosidase (GAA) gene lead to absent or severely dysfunctional lysosomal Acid -Glucosidase. These genetic defects result in the progressive accumulation of glycogen in various tissues and organs. Attempts at establishing genotype-phenotype correlations through mutation analysis have been made in the study of the Pompe patient populations, but in many cases, individuals from the same family with the same mutations have been found to have discordant clinical progression. Allelic variation, synonymous and non-synonymous has been observed within and between racial and ethnic groups. However, it has always been unclear whether allelic variation and presence of particular mutations correlate to clinical phenotype. Molecular genetic analysis of the GAA gene was carried out for the identification of genetic changes in individuals with Pompe Disease (Glycogen Storage Disease type II). Sequence data was obtained from the study of 19 Pompe patients (15 infantile-onset, 3 late-onset), their parents, and a collection of normal individuals representative of different racial and ethnic groups and a haplotypes were determined based on a panel of 59 SNP markers identified in and between the GAA gene. We present our finding that there are at least 6 major haplotype groups in the normal population which are representative of the racial and ethnic backgrounds studied, as well as other distinct SNPs and haplotypes which serve as the genetic background markers specific for particular mutations.

Mutation of genes involved in CoQ10 biosynthesis pathway in patients with coenzyme Q10 biosynthesis defect and mitochondrial disorder. *J. MOLLET¹, D. SCHLEMMER¹, L. VAN MALDERGEM², A. MUNNICH¹, A. ROTIG¹.*
1) INSERM U393, Hopital Necker, Paris, France; 2) Centre de Genetique Humaine, Loverval, Belgium.

CoQ10 plays a pivotal role in the mitochondrial respiratory chain as it distributes electrons between the various dehydrogenases and the cytochrome segments of the respiratory chain. We have found CoQ10 deficiency in six patients from three unrelated families. In the first two families the non-consanguineous parents had two affected children while parents in the third family were consanguineous. Clinical presentations of the patients differed from one family to another. Patients from the first family presented retinitis pigmentosa, cataract, deafness, renal failure, cardiomyopathy and ataxia. Patients from family two had hypotonia, deafness and Leigh syndrome. Patients from the third family presented neonatal hyperlactatemia and died in the first days of life. Enzymological studies of the respiratory chain showed that quinone-dependent activities (complex I+III, complex II+III, glycerol-3-P cytochrome c reductase) were in the lowest control values whereas all respiratory chain complexes showed normal activities. LC/MS/MS quantification of quinones on cultured skin fibroblasts or muscle revealed a severe CoQ10 depletion in all patients (<15 nmol/g protein, control values 117+45). Ubiquinone is synthesized via a very complicated pathway, most genes of which have been identified in yeast. The human counterparts of these genes have been identified by sequence homology and mapped. We have tested 10 candidate genes encoding enzymes of CoQ10 biosynthesis pathway by studying the segregation of microsatellite flanking markers in the three families. Several genes have been excluded in all families (MVK, FPP, TPRT, COQ3, COQ4, COQ5, COQ8). We identified a homozygous mutation in one of the remaining genes in the patient born to consanguineous parents. This mutation is a one base pair deletion leading to a premature stop codon.

Exclusion of 17 COX subunits and assembly genes in cytochrome c oxidase deficiencies. *E. ZINOVIEVA*¹, *C. BOUCHET*², *S. LEBON*², *J.P. BONNEFONT*², *A. MUNNICH*¹, *A. ROTIG*¹. 1) INSERM U393, Hopital Necker, Paris, France; 2) Service de Genetique, Hopital Necker, Paris, France.

Cytochrome c oxidase (COX) deficiency is one of the most frequent causes of respiratory chain disorder in childhood and is a clinically heterogeneous condition. COX is the terminal electron acceptor of the respiratory chain and is composed of 13 different subunits. Three of them are encoded by mitochondrial genes and the other 10 by nuclear genes. Moreover, several proteins of nuclear origin are required for maturation and/or assembly of these subunits. Consanguinity of the parents in several families or recurrence of the disease is highly suggestive of an autosomal recessive mode of inheritance. We have identified several consanguineous and/or multiplex families with isolated COX deficiency. The clinical presentation was very different among families (encephalomyopathy, cardiomyopathy, Leigh syndrome, fatal and begin infantile myopathies, myoglobinuria) suggesting a genetic heterogeneity. We have tested 17 genes encoding various isoforms of COX subunits as well as 11 genes encoding COX assembly proteins by studying the segregation of microsatellite markers flanking the candidate loci. DNA from the patients only was studied. Non haploidentity and/or heterozygosity at the candidate loci allowed us to exclude 87% of COX subunits genes and 91% of COX assembly genes. Analysis of other candidate genes is currently under investigation. This work suggests that there is no major gene for COX deficiencies among candidate genes tested in our study.

Developing disease stage markers in late-onset metachromatic leukodystrophy. *K. Bjoraker, C. Boys, S. Pongonis, L. Charnas, D. Loes, C. Peters, W. Krivit, E. Shapiro.* Dept Pediatrics, Univ Minnesota, Minneapolis, MN.

Metachromatic leukodystrophy (MLD) is an autosomal recessive lysosomal neurodegenerative disease caused by the deficiency of the enzyme arylsulfatase-A (22q13.31). Sulfatide accumulation leads to progressive demyelination, dementia, and death. Our purpose was to identify disease stage markers (historical, neuropsychological, neuroradiological) in late onset MLD. With the advent of new treatments determination of stage of disease is increasingly important as success depends on early disease stage diagnosis. Methods: 31 subjects (18 females) over age 10 years were evaluated between 1989 and 2004 at the University of Minnesota for consideration of hematopoietic stem cell transplant. Measures: History- age of initial symptom onset, initial psychiatric diagnosis, most recent diagnosis prior to MLD diagnosis, years from symptom onset to psychiatric diagnosis, and years from symptom onset to MLD diagnosis. Neuropsychological: Cognition, attention, verbal memory, visual spatial, language, executive functions. MRI Baseline: Loes Score with a possible score of 0 to 26 (a demerit scale of number of abnormal brain regions). Results: A lengthy period to MLD diagnosis is almost universal and is preceded by ADHD and psychiatric misdiagnoses. Initial diagnosis: 61% had ADHD or mood disorders, 13% had neurological disorder, and none had psychosis or conduct symptoms. In contrast, immediately prior to MLD diagnosis, 75% were diagnosed with psychosis or severe conduct disorders. Symptoms progress from mild/moderate attentional symptoms to severe frontal presentation that includes schizophrenia and severe conduct disorder. Deficits were found in adaptive behavior, verbal memory, and verbal fluency and relative strengths in reading and receptive vocabulary. A significant relationship was found between neurological disease/MRI and specific neuropsychological correlates (attention, verbal memory, visual spatial, perception, math achievement). Conclusion: A pattern of onset of attention and psychiatric symptoms in a previously healthy individual with deficits in memory, attention, and spatial perception signals the need for a thorough medical investigation.

Program Nr: 1766 from the 2004 ASHG Annual Meeting

The Pompe Registry. *B. Byrne*¹, *P. Kishmani*². 1) University of Florida, Gainesville, FL; 2) Duke University Medical Center, Durham, NC.

Pompe disease (glycogen storage disease type II) is a progressive and often fatal muscle disease with a spectrum of severity from early presentation in infants to adulthood. The underlying pathology is a deficiency or dysfunction of acid alpha-glucosidase, a lysosomal enzyme that lysosomal glycogen to glucose within lysosomes. Due to the rarity of the disease, heterogeneity of symptoms, and multiple organ systems affected the collection of patient-level longitudinal natural history data is only possible through a broad effort across many physicians treating the disease. To that end, the Pompe Registry was created to collect patient baseline demographics as well as musculoskeletal, respiratory, cardiac, and GI manifestations over time. Patient data is confidential and de-identified and is available to the treatment center for real time analyses of disease progression. In addition, aggregate data of all patients in the Registry will be available to assess trends in disease states and establish management recommendations. To date, over 25 individual physicians have agreed to participate in the Registry. 5 patients are enrolled. These first patients are highly heterogeneous in their presentation and may be indicative of the continuous spectrum of phenotypes observed in Pompe, which differ in terms of age of onset, extent of organ involvement, and rate of symptomatic progression. The Pompe Registry is an international collaboration that attempts to increase the understanding of this rare disease and, therefore, to potentially improve management.

Glucosamine for the management of behavior in mucopolysaccharidosis type III (MPS III). *J. Clarke, E. Kerr, N. Poplawski.* The Hospital for Sick Children, Toronto, Ontario, Canada.

BACKGROUND: An open-label pilot study in 10 children with MPS III showed treatment with oral glucosamine hydrochloride lead to statistically significant improvements in parental ratings of behaviour. **AIM:** To determine if treatment with glucosamine has a beneficial effect on the behaviour of children with MPS III. **METHOD:** A randomised, double-blind, placebo-controlled study consisting of baseline estimate of mental age, functional independence and behaviour, with repeat assessment of behaviour after 6 weeks therapy with glucosamine or placebo (lactose). Mental age and functional independence were estimated using the Scales of Independent Behaviour-Revised (SIB-R). Behaviour was assessed using the Aberrant Behaviour Checklist-Community (ABC) and the long forms of the Conners Parent Rating Scale (CPRS) and the Conners Teacher Rating Scale (CTRS). **RESULTS:** 32 children have been recruited. Completed data are available for 24 (11F, 13M, mean age 8y 3m, range 4y to 14y8m), 14 with MPS IIIA, 6 IIIB, 1 IIIC and 3 IIID. Prior to unblinding parents were asked what they thought their child received. 10 (42%) thought glucosamine (all reported improved behaviour and 5 requested therapy continue) and 14 placebo (none reported improved behaviour). Analysis of the CPRS divides the children into 2 groups; improved behaviour (N=14) and no improvement (N=10). Improvement in the CPRS shows correlation with the ABC irritability score (11/14, 79% improved) and parental opinion (8/14, 57% improved) but not the CTRS (2/14, 14% improved). **CONCLUSION:** Interim analysis, prior to unblinding, suggests glucosamine may have a beneficial effect on the behavioural disturbance of MPS III. Analysis of the data following unblinding will be revealing. If it confirms glucosamine is beneficial it will pave the way for a new, safe treatment for children with MPS III and behavioural disturbance.

An automated HPIEC system for the diagnosis of the mucopolysaccharidoses. *P.R. Clements, V.J. Muller, M. Fietz, J.J. Hopwood.* National Referral Laboratory, Genetic Medicine, Women's & Children's Hospital, North Adelaide, SA, Australia.

The diagnosis of the mucopolysaccharidoses by enzyme assay is crucial for the correct identification of the MPS subtype as there can be considerable clinical overlap. Measurement of enzyme activity is performed in our laboratory after a urine screen has been used to determine the identity of the stored substrate [1]. Enzyme assays are performed using radiolabelled substrates which are chemically derived from glycosaminoglycans [2-5]. After incubation of the substrate with extracts from patient cells or tissues, substrate and product are separated by an HPLC system with autoinjector. Separation is by fast flow (4mL/min) ion exchange chromatography (HPIEC) using an ammonium sulfate gradient coupled with on-line scintillation detection. The system has a turnaround time of eight minutes per sample. Assays performed routinely in our laboratory using this system include those for MPS types I, II, IIIA, IIIC, IIID, IVA, VI. (Type VII is measured using a fluorogenic substrate while IIIB assay was by fluorogenic substrate or by separation with paper electrophoresis). The system is reliable in sample recoveries, is not labour intensive and provides a rapid and definitive result. Our experience is that the natural substrates provide accurate discrimination between the MPS types. Provision of these tests enables us to act as a single centre for diagnosis of the full range of MPS disorders. A summary of the NRL experience using this system since 1995 includes the diagnosis of 370 cases of MPS and the performance of 91 prenatal tests. 1. Hopwood JJ & Harrison JR (1982) *Anal. The Arg482His mutation in the -galactosidase gene is responsible for a high frequency of GM1-gangliosidosis carriers in a Cypriot village. *T.K. Georgiou¹, G. Stylianidou², V. Anastasiadou², A. Caciotti³, Y. Campos⁴, E.*

Zammarchi³, A. Morrone³, A. d'Azzo⁴, A. Drousiotou¹. 1) Dept of Biochemical Genetics, The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus; 2) Arch Makarios III Hospital, Nicosia, Cyprus; 3) Dept of Pediatrics, University of Florence, Meyer Children's Hospital, Italy; 4) Dept of Genetics, St Jude Children's Research Hospital, Memphis, TN, USA.

GM1 gangliosidosis is a lysosomal storage disorder caused by deficiency of -galactosidase. It is mainly characterized by progressive neurodegeneration and in its most severe infantile form it leads to death before the age of four. The GLB1 gene gives rise to two alternatively spliced mRNAs which encode the -galactosidase and the elastin binding protein (EBP). The diagnosis of two patients with the infantile form of GM1 gangliosidosis and eleven carriers in a small mountainous village in Cyprus prompted us to carry out a study in order to establish the frequency of carriers in the village and identify the mutation(s) involved. Carrier detection was initially based on the measurement of -galactosidase activity in leucocytes. Among 85 random samples from the village, 10 were classified as carriers. Sequencing of the GLB1 gene in a Cypriot patient identified the missense mutation c.1445G>A (p.Arg482His) in the homozygous state. Seven of the ten carriers identified using the enzyme assay were found to carry the same mutation by NspI restriction enzyme analysis. The three individuals who were negative for the c.1445G>A had borderline enzyme results and were probably wrongly classified as carriers. The frequency of GM1 gangliosidosis carriers in this village is approximately 8% (1:12). Northern blot analysis in skin fibroblasts from one patient showed mRNA of normal size and quantity, and expression studies in COS-1 cells showed no enzyme activity. Western blot analysis showed a marked decrease of the 64kDa mature form of the enzyme protein and reduced amount of the 67kDa EBP. Our results indicate that the c.1445G>A mutation, which is responsible for all GM1 gangliosidosis alleles in this Cypriot village, affects the stability of the mature -galactosidase protein.

Program Nr: 1770 from the 2004 ASHG Annual Meeting

The Lysosomal Disease Research Network. *J. Hegland¹, C. Whitley¹, J. Barranger², C. Eng³, G. Grabowski⁴, J. Muenzer⁵, J. OBrien⁶, G. Pastores⁷, E. Shapiro¹, R. Steiner⁸, W. Wilcox⁹, and the Lysosomal Disease Organizing Committee.* 1) University of Minnesota, Minneapolis,MN; 2) University of Pittsburgh, Pittsburgh,PA; 3) Baylor College of Medicine, Houston,TX; 4) Children's Hospital Research Foundation, Cincinnati,OH; 5) University of North Carolina, Chapel Hill,NC; 6) Mayo Clinic, Rochester,MN; 7) New York University, New York,NY; 8) Oregon Health and Science University, Portland,OR; 9) Cedars-Sinai Medical Center, Los Angeles,CA.

A network devoted to promote and facilitate basic, translational and clinical research in lysosomal diseases (LDs) has recently been established. The network is a scalable multi-center consortium of geographically distributed expert medical centers, patient support and corporate partners. The infrastructure, mission and charter were developed through organizational committees; the collaborating medical centers, pharmaceutical and patient support organizations will direct the activities of the network through participation in the Steering Committee and Advisory Board. The network is advised through expertise-oriented councils (ie, Council of: Clinical Investigators; Scientists; Patient Advocates; Industry Representatives and Laboratory Diagnosticians). The first annual scientific meeting was held May 13-15,2004 and provided a multidisciplinary forum to present and discuss basic and clinical research discoveries in LDs, and related treatment, ethical, and quality of life issues. Plans for the next annual meeting (May 19-20,2005) are underway. The network is currently developing longitudinal studies to understand the natural history of LDs and treatment outcomes. Long term network goals include 1)development of an information management infrastructure to encourage integration of shared clinical experience and relevant longitudinal studies in LDs, 2)promotion of programs to train LD clinical investigators, and 3)development of a web site to facilitate professional and public education, timely network communication, and a data entry mechanism. Interested parties are encouraged to become involved (hegla005@umn.edu). Organizational support has been provided by NIH, NINDS and ORD, NS49950.

Decreased Quality of Life in Women With Fabry Disease. *R. Hopkin¹, N. Jansen¹, L. Bailey¹, M. Yi².* 1) Cincinnati Children's Hosp; 2) Univ Cincinnati Med School.

Purpose: Fabry disease is an X-linked lysosomal storage disorder that is known to have a major impact on the lives of affected men. It is not known how significantly Fabry disease impacts the lives of heterozygous women. The aim of this study is to determine if there are significant differences in quality of life between women heterozygous for Fabry disease and women in the general population. **Methods:** The SF-36 was given to obligate heterozygous women identified at lysosomal disease centers in the US and to all members of the FSIG. Participants were recruited based upon family history regardless of symptoms. Over 150 questionnaires were returned. Preliminary analysis of 88 questionnaires has been performed using the RAND scoring system with the WHI as a control population (n>8300). An unpaired t-test evaluated the statistical differences between the two groups. CID value was used to evaluate the clinical importance of differences between the groups where >0.80 represents high impact and >0.50 a moderate effect. **Results:** The difference between each of the mean scores was statistically and clinically significant in all 8 HR-QOL categories with p<.0001. and CID>0.50.

Hlth Meas	WHI	Fabry	CID value
Gen Health	76.7+16.2	42.8+24.2	2.09
Body Pain	77.3+21.8	60.8+27.4	0.76

Conclusion: Women with Fabry disease reported significantly lower quality of life in all 8 areas of functioning (e.g. general health and bodily pain - see table). The quality of life profile more closely resembled that of women with Multiple Sclerosis than the general population. These results suggest that Fabry disease impacts the health of heterozygous women more than previously appreciated, and highlights the need for additional studies to develop treatment protocols for women with Fabry disease.

***C.elegans* has only one alpha-galactosidase A and alpha-N-acetylgalactosaminidase ortholog.** M. Hrebicek, J. Hujova, R. Dobrovolny, D. Holanova, B. Asfaw, H. Poupetova, J. Ledvinova, M. Kostrouchova, J. Sikora. Institute of Inherited Metabolic Disorders, Prague, Czech Republic.

Human alpha-galactosidase A (GAL) and alpha-N-acetylgalactosaminidase (NAGA) are true paralogs sharing a common ancestral gene. Deficiencies of these enzymes cause human lysosomal storage disorders - Fabry (GAL deficiency) and Schindler (NAGA deficiency) diseases. BlastP searches for orthologs of human GAL and NAGA revealed a single *C.elegans* gene (CeGAL/NAGA) with significant homology to both human genes. We elucidated gene organization of CeGAL/NAGA by cDNA sequencing including 3' and 5' UTR. We performed phylogenetic analyses and homology modeling of CeGAL/NAGA based on 3D structure of chicken NAGA. The GAL and NAGA activity measurements in *C.elegans* mixed culture homogenate revealed presence of both enzyme activities. In contrast to other organisms, the GAL activity in the worm was completely inhibited by N-acetylgalactosamine - a NAGA inhibitor. To study the expression of CeGAL/NAGA in *C.elegans*, we created C-terminal GFP fusion of the whole CeGAL/NAGA ORF under the control of its natural promoter. Presence of CeGAL/NAGA-GFP transgene was confirmed at the level of gDNA, cDNA and protein. pH-dependent GFP fluorescence was observed in membrane-bound compartment of coelomocytes only after treatment with concanamycin A and NH₄Cl, a finding supporting lysosomal localisation of the expressed protein. Immunofluorescence detection of GFP fusion protein showed transgene expression in muscle, intestinal cells and vesicular compartments of coelomocytes. RNA interference assays directed against the CeGAL/NAGA have not revealed any abnormal morphological phenotype, however a biochemical phenotype was observed. The activities of GAL and NAGA decreased in a similar manner in interfered worms, usually by tens of percent of activity of controls. The hypothesis of a single ortholog in *C.elegans* was further supported by phylogenetic, homology modeling and biochemical analyses. RNA interference does not lead to a successful model of Schindler and Fabry diseases in *C.elegans*. However, a deletion mutant of CeGAL/NAGA may provide an interesting model relevant for both disorders.

Home enzyme replacement therapy (ERT) with Replagal for Fabry disease (FD) in Nova Scotia. *K. LeMoine, M. West, C. Simms, F. MacLennan.* Medicine, QE II Health Sciences Centre, Halifax, NS, Canada.

FD is a rare X-linked lysosomal storage disease due to deficiency of α -galactosidase A activity (α -gal). Nova Scotia has one of the world's largest FD kindreds with over 66 adults. However as the province is sparsely populated, FD patients may have to travel up to 4 hours by car to receive enzyme replacement therapy every 2 weeks in Halifax, the regional tertiary care centre. Home ERT can be safely delivered either by a visiting nurse or by the patient. We report our experience with both in Nova Scotia over the past for years.

Eight adult male patients (age 27-52, mean 38.6 years) with FD had received ERT (Replagal 0.2 mg/kg iv every two weeks) in a clinic trial (TKT015) for at least 6 months; none had ever had an infusion reaction. Home infusion was carried out on all patients for 18 months by a visiting nurse for 312 treatments. There were no infusion reactions or other problems.

Home self infusion of ERT has been successfully carried out in 2 patients with FD in Nova Scotia. Patients and their support person were trained for 3 consecutive sessions in the hospital by a nurse educator. Skills taught included hand washing, sterile technique, iv tubing and medication preparation, drug administration, detection of adverse effects and safe disposal of medical equipment. Once patients were able to show these skills in hospital, they were sent home to begin home self infusion therapy. A follow up telephone call is made after each infusion of Replagal to identify any issues. To date there have been no adverse events in the two patients trained. Home ERT is well tolerated and less expensive than that given in larger regional hospitals. It is a safe, well-tolerated and convenient way of providing ERT.

Study of Natural History of Juvenile GM2 Gangliosidosis - Analysis of 20 patients. *G. Maegawa¹, M. Tropak¹, D. Mahuran¹, T. Stockley¹, J. Callahan¹, F. Kok², C. Vasques², R. Rosemberg², M. Vainzof², R. Giuglianti³, C. Barros³, M. Burin³, J. Clarke¹.* 1) Div Clin. & Metab. Genetics, Metab. Program, Research Institute, Molecular Genetics Lab., Hospital for Sick Children, Toronto, ON, Canada; 2) Div of Neuroped., Centro do Genoma Humano, USP, SP, Brazil; 3) Medical Genetics Service, HCPA, Porto Alegre, RS, Brazil.

Juvenile GM2 gangliosidosis (jGM2) is a rare neurodegenerative disorder characterized by progressive ataxia, dystonia, pyramidal signs, dysarthria and psychiatric symptoms, caused by lysosomal beta-hexosaminidase A deficiency. We report a study of 20 patients from 14 unrelated families, 13 diagnosed with Tay-Sachs variant (TSV) and 7 with Sandhoff variant (SV). The mean age of onset was 5.5 years (1.5 to 17 years), 11 males and 9 females. The most common symptoms at onset were ataxia and speech problems which were found in all jGM2 patients. Interestingly, the mean of onset of gait ataxia and dysarthria were similar, 7.1 years and 6.9 years, respectively. However, the progression of the dysarthria was faster than the ataxic gait problems (1.8 years from mild to moderate dysarthria against 3.4 years from mild ataxic gait to a moderate ataxic gait needing a device). Psychiatric symptoms, such as psychotic episodes, aggressive or compulsive behaviour and also schizophrenia developed in 11 patients and were more common among SV patients (5/7). Eight patients developed seizures at a mean age of 5 years (2 to 7.5 years). Gastro-intestinal symptoms such as dysphagia, constipation and diarrhea were present in 15 patients (8/13 in TSV and 7/7 in SV). Acroparesthesia (3/7) and hearing problems (3/7) were also more common in patients with SV. Among these 20 patients, five were considered as having an adult-onset of GM2. However a detail inquiry about the childhood of these patients revealed that they had motor signs and even abnormal behaviour during childhood and early adolescence. Therefore they are included at the study. The juvenile form of GM2 is described as homogeneous. However among these patients, we observed considerable clinical heterogeneity in the clinical presentation as well as in the progression of this condition.

A Cross-Sectional Survey Study to Collect Normative Data in Patients with Niemann-Pick B Disease. M.M.

McGovern¹, M.P. Wasserstein¹, R.J. Desnick¹, M. Vanier², B. Bembi³, R. Giugliani⁴, E. Mengel⁵. 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) Centre Hospitalier Lyon-Sud, France; 3) Istituto per l'Infanzia Burlo Garofolo, Italy; 4) Hospital de Clinical de Porto Alegre, Brazil; 5) University of Mainz, Germany.

Niemann-Pick disease Type B (NPD-B) is a lysosomal storage disorder resulting from deficient acid sphingomyelinase activity and the accumulation of sphingomyelin. The clinical phenotype and spectrum of disease manifestations have been described only in a small number of patients. Fifty-nine patients (31 M, 28 F; mean age 22.6y, age range 7 to 65y) with NPD-B underwent comprehensive clinical evaluations. The most common symptoms at diagnosis were splenomegaly (78%), hepatomegaly (73%), and respiratory (20%). Mean liver and spleen volumes were 1.87 and 11.14 multiples of normal. Mean weight and height Z scores were -0.77 and -1.29. Growth retardation was common in children and adolescents. The most common laboratory findings were elevated chitotriosidase (95%), liver function tests [SGOT (51%), SGPT (50%), alkaline phosphatase (43%), and bilirubin (33%)], and IGF-1 binding protein (35%); abnormal fasting lipid profile [elevated triglycerides, (62%), LDL (46%), cholesterol (41%), and low HDL (74%)]; and low platelets (53%) and IGF-1 (35%). Macular haloes or cherry red spot were present in 25% of patients. Most patients underwent both radiographic and pulmonary function evaluations. CXR and HRCT revealed interstitial lung disease (ILD) in 90% and 96% of patients, respectively. The mean DLCO was 60% of predicted (n=43) with a trend for increasing values as the HRCT ILD severity score decreased ($R^2 = 0.1460$, $p=0.0114$). Of the 48 different mutations identified, R608del was the most common (25% of all alleles). In summary, hepatosplenomegaly, liver dysfunction, thrombocytopenia, lipid abnormalities, short stature, and pulmonary involvement are common features of NPD-B, although there is considerable clinical and molecular genetic heterogeneity among affected patients.

The MPS I Registry: Centralised data collection to delineate the natural history and treatment of MPS I. G. Pastores, on behalf of the MPS I Registry Boards of Advisors. NYU School of Medicine, New York, NY.

Mucopolysaccharidosis I (MPS I) is a chronic disorder caused by the deficiency of the lysosomal enzyme -L-iduronidase. The accumulation of glycosaminoglycans (GAG) in many tissues leads to a heterogeneous disease with a clinical spectrum ranging from severe to attenuated. The primary objectives of the MPS I Registry are to characterize and describe the MPS I patient population and evaluate the long-term effectiveness and safety of specific therapies. The MPS I Registry is a voluntary, multi-center observational program established to monitor the outcomes of all patients with a confirmed diagnosis of MPS I. Data will be analyzed to address questions related to diagnosis, disease course, and management. As of April 2004, 53 patients, from Europe, U.S. and Brazil, have been enrolled. The current age of these patients ranges from 5 months to 46.3 years (median age of 6.1 years). The age at diagnosis ranges from prenatal to 26 years (median age of 1.5 years). Sixty-six percent (66%) of the patients were characterized as having the severe form of the disorder. The majority (70%) of the patients are currently on enzyme therapy (Aldurazyme[aronidase]), and the remainder have undergone hematopoietic stem cell transplantation (HSCT) (2%) or not been treated with either approaches (19%). In addition, 9% of the patients have been treated with a combination of Aldurazyme and HSCT. Data are captured on many of the systems impacted by the disease, including CNS, cardiac, respiratory, gastrointestinal, musculoskeletal, ocular, and auditory. Height, weight, head circumference and urinary GAG are part of the recommended assessments. As of June 2004, 96 patients have been enrolled and further analyses are planned. Initially, the MPS I Registry will provide descriptive data on the baseline clinical status of patients, delineating the pattern and severity of disease at enrolment. Over time, the MPS I Registry will utilize longitudinal data to focus on specific aspects relevant to the diagnosis and management of MPS I, with the anticipated overall outcome of improving the management of patients.

The effects of anti-psychotic drugs on adult Tay-Sachs disease and implications for treating associated psychoses.

B.A.J. RIGAT, A. Mocon, R. Geist, D. Mahuran. The Hospital for Sick Children, Toronto, Ontario, Canada.

Adult Tay-Sachs disease (ATSD) is characterized as a deficiency in activity of hexosaminidase A (Hex A) resulting in intralysosomal accumulation of GM2 ganglioside. ATSD and other variants of Tay-Sachs disease exhibit an autosomal recessive pattern of inheritance for mutations of the HEXA gene encoding the α -subunit of Hex A. Psychiatric abnormalities affect approximately 40 percent of ATSD patients and present as the most prominent and impairing symptoms. However, clinical treatment of ATSD with anti-psychotic drugs is controversial. It has been shown that such drugs are lysosomotropic, inducing lysosome lipid storage and enzyme secretion, thereby potentially exacerbating the disease phenotype. We have examined the effects of the weakly basic antipsychotic drugs imipramine, risperidone, olanzapine and quetiapine on various lysosomal enzymes in wild type and ATSD human fibroblasts. Western blots and enzymatic assays of dose-response studies indicate that, relative to a treated patients plasmatic drug concentration, only very high levels of imipramine decrease protein levels and enzyme activity in cells while correspondingly increasing the levels and activity of each in culture media. For all drugs examined, negligible effects were seen with drug concentrations of up to 10 fold times their respective therapeutic levels. For imipramine, we observe the presence of a concentration threshold at approximately 10 mM after which cell death occurs. This suggests the involvement of the lysosomal V-ATPase proton pump in the lysosomotropic effect. We hypothesize that the threshold level corresponds to the concentration of imipramine for which the proton pump can no longer compensate to maintain the functionally necessary low intra-lysosomal pH. We are investigating this hypothesis using concanamycin A, an inhibitor of the V-ATPase pump. Our data suggests that lysosomotropic effects of antipsychotic drugs are only apparent at hyperphysiological concentrations, not at the levels expected in patients' plasma. Therefore, the use of antipsychotic drugs in ATSD patients is unlikely to promote additional lysosomal enzyme secretion and lipid accumulation.

Novel reaction to Fabrazyme in an 8 year old male with Fabry disease: adverse event or natural history of pediatric Fabry? *S. Sastry, A. Ahmad.* Genetics and Metabolism, Children's Hosp of Michigan, Detroit, MI.

Fabry disease (FD) is a lysosomal storage disease caused by a deficiency in α -galactosidase A, which results in accumulation of globotriaosylceramide in vascular endothelial cells. Manifestations of FD include angiokeratomas, acroparesthesias, hypohydrosis, abdominal pain, renal failure, cardiomyopathy and stroke. In 2003, the FDA approved Fabrazyme for the use of enzyme replacement therapy (ERT) in FD. Mild to moderate adverse infusion associated reactions (fevers and rigor) have been reported during or shortly after infusion in adults. To our knowledge, delayed adverse reactions (>24hrs post infusion) have not been reported.

Symptoms of FD are progressive with onset as early as 3 yrs of age in boys. ERT is advocated in symptomatic children to reverse and/or prevent the sequelae of FD. Little information is available on tolerance of infusion in children. We present an 8 yr old male diagnosed at 18 months of age due to a positive family history. Symptoms of headache and overheating following physical exertion; associated with episodes of acroparathesia and hypohydrosis, started at 5 yrs of age. These were mild episodes, well controlled with Acetaminophen or Ibuprofen. ERT with Fabrazyme was initiated at 8 yrs of age. To date, he has had nine biweekly infusions with no adverse reactions during infusion. However, between 24 and 72 hours after his 2nd, 3rd and 4th infusions, he experienced episodes of fever up to 104F with lethargy, severe acroparathesias, headaches, abdominal pain and back pain. Each episode lasted about 48 hours and was significantly more severe than any episode experienced prior to initiation of ERT. There was no associated intercurrent illness or other inciting trigger. No further adverse events were noted during or following the remaining infusions. He now shows improvement in his clinical status with decreased severity and frequency of acroparathesia, increased ability to sweat and improved tolerance to exercise.

We hypothesize that adverse infusion related reactions can occur during and as far as 72 hours post ERT, but may be self limiting.

Gaucher Disease Therapy: Conditional liver expression of acid -glucosidase (GCase) improves visceral, but not CNS disease in mouse models. *Y. Sun, B. Quinn, G.A. Grabowski.* Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Gaucher disease is an autosomal recessive trait and the most common lysosomal storage disorder. A variant Gaucher mouse model (Enron) was created by generating mice with a GCase V394L point mutation (V394L) and a partial deficiency of prosaposin. Enron mice displayed large numbers of storage cells in the liver, lung, spleen and thymus. The major lipid stored was glucosylceramide (GC). To test the organoid therapeutic approach to the glycosphingolipid storage diseases, a tTA-responding human acid -glucosidase (hGCase) transgenic system was introduced into Enron mice. The expression of tTA-hGCase is under the control of liver-enriched activator protein promoter (LAP). RT-PCR analyses showed that hGCase mRNA was present in liver (high level) and lung (low level), and hGCase protein and activity were detectable in liver, lung and spleen. hGCase was at higher level in serum indicating the enzyme was secreted. In the absence of DOX, expression of hGCase reduced the number and size of storage cells and GC accumulation in the visceral tissues. hGCase expression in these mice can be turned off completely with DOX. The pathology became manifest in liver, lung and spleen within two months on DOX. These results demonstrate that high level expression of hGCase and reversed visceral pathologic lesions. The tTA-response hGCase system represents a powerful tool to facilitate evaluation of therapeutic approaches to the Gaucher disease and other lysosomal storage diseases.

Common Hexosaminidase B (HEXB) polymorphisms effect results of enzymatic carrier testing for Tay-Sachs disease. *HD. Vallance, T. Morris, B. Toh, M. Coulter-Mackie.* Pathology, Children's Hospital of B.C., Vancouver, BC, Canada.

Two brothers known to carry the 1278insTATC mutation in the Tay-Sachs (HEXA) gene were found to have normal serum %Hexosaminidase A (%HexA) enzyme activity, above the screening cut off for carrier detection yet in white blood cells (WBC) %Hex A was well within the carrier range. Total Hex and HexB enzyme activities were well below reference range. The biochemical profile was suggestive of combined inheritance of mutations in HEXA and B genes. Sequencing of the HEXB exons revealed that both brothers had 3 HEXB polymorphisms: I207V and 3' UTR delTG (cis) and S62L(trans). The delTG polymorphism has previously been reported to reduce HEXB mRNA. The allele frequencies in the Ashkenazi Jewish (n=72) vs. non-Jewish populations (n=104) were determined: I207V (11%;17%), delTG (13%;11%) and S62L (2.8%;3%) respectively. Given the high allele frequencies of these HEXB polymorphisms we undertook a retrospective analysis of serum (n=12) and WBC (n=11) enzyme results from non HEXB carrier controls and compared them with data from HEXB polymorphism carriers. In serum (n=2) and WBC's (n=1), delTG carriers had HexB levels 40% below the normal mean (P.001). In serum and WBC's, an I207V carrier had normal HexB but a HexA level 20% below the normal mean (P.001) suggesting that this polymorphism impairs formation of functional HexA (alpha / beta heterodimer). Interestingly, a I207V/delTG carrier had normal serum HexA but a 25% reduction of HexA in WBC's (P.001); a similar trend to the brothers described above. In summary, this is the first report of reduced HexA and HexB activities associated with common HEXB polymorphisms. The inheritance of the delTG mutation reduces HexB and has the potential to elevate %HexA. In addition, the combination and interaction of polymorphisms can further affect HexA as seen with I207V / delTG carriers and the reduction in HexA may only be apparent in WBC's and not serum. We hypothesize that this effect could potentially mask carrier status in serum for a HEXA mutation and may explain the normal %HexA in serum but low level in WBC's in the index family. This hypothesis is being tested with a larger sample size. Funded by Garrod Assoc.

A screening study for Fabry disease (FD) using whole blood filter paper technique in renal transplant (Tx) and dialysis patients in Nova Scotia (NS). *M. West¹, J. Medin², K. LeMoine¹, A. Poepl², T. Hewlett³, J. Dhar⁴.* 1) Dept Medicine, Dalhousie Univ, Halifax, NS; 2) University Health Network, University of Toronto, Toronto, Ont; 3) Dept Medicine, Cape Breton Regional Health Centre, Sydney, NS; 4) Dept Medicine, Yarmouth Regional Health Centre, Yarmouth, NS, Canada.

FD is a rare X-linked lysosomal storage disease due to deficiency of α -galactosidase A activity (α -gal). The prevalence of FD is reported as 1:50,000. NS has a large well-defined FD kindred with a prevalence estimated at 1:14,000. All 66 adult FD patients in NS have classic phenotype and uniform genotype A143P; they are descendants of a founder who emigrated from Montbéliard France to NS in 1750. A prospective screening study in NS of all adult patients (18 years old) with a renal Tx or who are on dialysis is being carried out to determine the true prevalence of FD as a cause of end stage renal disease and to look for previously unidentified cases of FD.

All NS dialysis or renal Tx clinic patients were approached for this study. Known FD patients were excluded: 3 renal transplant (2 cadaver and 1 living related donor), 0 dialysis patients. Consent was refused in 12.8%. 706 patients have been screened to date. Filter paper technique with dried whole blood spots was compared with plasma to measure α -gal. A subset of 10 hemodialysis patients had samples drawn pre and post dialysis to test for an acute influence of hemodialysis. Of 549 (77.8%) samples analyzed to date, 4 male hemodialysis patients have low α -gal (0.7%). None of these is known to have FD. No Tx or peritoneal dialysis patients had low α -gal. 2 of 2 tested have normal plasma α -gal; DNA mutational analysis is pending to confirm FD. There was no observed influence of hemodialysis on whole blood or plasma α -gal.

In conclusion, several NS hemodialysis patients with low α -gal were identified consistent with FD in a province-wide screening study; uremic inhibition of α -gal cannot be excluded. Whole blood filter paper technique was comparable with plasma α -gal. Whether the patients with low α -gal have FD requires further study.

-Mannosidase Deficient Mice: A Model of Lysosomal Storage Disease. *M. Zhu*¹, *K.L. Lovell*², *T.L. Saunders*⁴, *J.S. Patterson*³, *K.A. Friderici*¹. 1) Microbiol/Molec Genetics; 2) Neurology/Ophthalmology; 3) Pathobiol/Diag Invest, Michigan State University, East Lansing, MI; 4) Transgenic Animal Model Core, University of Michigan, Ann Arbor, MI.

-Mannosidase is a lysosomal enzyme that is involved in the degradation of Asn-linked glycoproteins in lysosomes. The deficiency of this enzyme causes an autosomal recessive inherited disorder, -mannosidosis. This lysosomal storage disease is characterized by the intracellular accumulation of small oligosaccharides in many cell types. In human cases of -mannosidosis the clinical symptoms, which include mental retardation, hearing loss, frequent infections and behavior disturbance, can be relatively mild and little is known about the pathology. However, in the two ruminant animal models (cows and goats) the clinical presentation is severe at birth with skeletal deformation, neurological deficits and neonatal demise. Pathology includes cytoplasmic vacuoles in many organs and in CNS, and severe myelin deficits in the cerebral hemispheres. To explore and clarify the pathogenesis of this disease and to establish potential therapeutic strategies, we have generated the first mouse model with targeted disruption of the -mannosidase gene by homologous recombination in a mixed C57B6/129J mouse background. Homozygous mutant animals exhibit -mannosidase enzyme deficiency. General appearance and growth of the homozygous mutant mice is similar to heterozygous and wild-type littermates. Morphological characterization of the homozygous mutant animals reveals cytoplasmic vacuolation in neurons as well as visceral organs including thyroid gland, kidney, epididymis, and liver. The morphological lesions resemble those found in the two ruminant models, but with less severe expression. The neuronal vacuolation is selective, with pyramidal cells in the cerebral cortex especially involved. Severe hypomyelination is not apparent. This mouse model might be closer to the human -mannosidosis case; it will be a very useful tool for studying the phenotypic variations in different species and may help to facilitate a potential treatment for lysosomal storage diseases.

Novel *SLC39A4* Mutation in Kindred with Acrodermatitis Enteropathica. *Y. Anikster*¹, *N. Gal*¹, *J. Abu-Moch*³, *G. Paret*², *M. Rubinshtein*², *Y. Bujanover*⁴, *A. Vardi*². 1) Metabolic Disease Unit, Safra Childre's Hospital, Tel Hashomer, Ramat Gan, Israel; 2) Pediatric Intensive care, Safra Childre's Hospital, Tel Hashomer; 3) Kupat-Holim Clinic; 4) Pediatric, Safra Childre's Hospital, Tel Hashomer.

Acrodermatitis Enteropathica (AE) is a rare autosomal recessive disorder affecting early infancy. The triad of dermatitis, alopecia and diarrhea is its diagnostic hallmark. Other common manifestations are mental change, failure to thrive, nail dystrophy and immune system dysfunction. Similar clinical manifestations are observed with zinc deficiency from any cause. Recently, the human gene encoding an intestinal zinc transporter of the ZIP family, *SLC39A4*, was identified as the mutated gene in AE.

We studied a 4-year-old girl who is the first child of healthy first-cousin parents. She was hospitalized for an investigation of congestive heart failure and lymph node enlargement. Low alkaline phosphatase was found in the routine blood test. After a more thorough study of her medical history, we noticed that she was treated with zinc supplements for dermatitis at the age of nine months. Moreover, she has a 13-year-old boy cousin who was diagnosed with zinc deficiency and still has unhealed scars on his face.

DNA was extracted from peripheral blood samples from both children and their parents. Genomic DNA of the patients was then PCR amplified for each exon of the *SLC39A4* gene and analyzed by direct nucleotide sequencing. We identified a novel 1223 C deletion, this frame shift at amino acid A408 created after 76 amino acid, a stop-codon (A483X). This deletion in exon 7 destroyed a BsuR1 restriction site in the mutant amplicon and created a new Aci I restriction site. Using these restriction enzymes, we checked 30 members of this Arab-Muslim genetics isolate and found 17 carriers for this novel mutation.

Our results allow prenatal diagnosis and carrier detection in these large kindred and widen the clinical spectrum of AE.

Creatine Transporter Deficiency. *C. Bellini, M.C. Schiaffino, L. Costabello, U. Caruso, E. Bonioli.* Dipartimento Pediatria, Università Genova, Istituto G., Genova, Genova, Italy.

The patient was born at 40-week (uneventful pregnancy; weight 3370 g). His non consanguineous parents, brother, and sister are healthy. Increasing psychomotor retardation, mild failure to thrive, and recurrent vomiting was observed as of the third month of life. He came to our observation (age 21 months): there was generalized hypotonia and alternate exotropia with right predominance. EEG showed slow diffuse hypersynchronisms with abnormal multifocal spikes. Polygraphic recordings showed diffuse generalized parosistic "bouffes" with simultaneous eye and upper limb myoclonic movements. Cranial CT showed hypodensity of caudal nucleus and cerebral MRI showed a hyperintense signal in the posterior periventricular white matter and in the posterior part of the basal ganglia (T2-weighted images). Hematological, hormonal, and aminoacids in plasma and urine examinations were normal, karyotype (750 band level) and molecular evaluation for FraX and Angelman syndromes were negative. Plasma creatinine levels were persistently low (0.26-0.32 mg/dl). Urinary guanidinoacetate was within the normal range (95 mmol/mol creatinine, controls: 10.3-98.8), while creatine excretion was as high as 3586 mmol/mol creatinine (controls: 6-1208), suggesting a creatine transporter deficiency. The creatine uptake profile (cultured fibroblasts) was significantly different from what found in controls. DNA sequence analysis of the SLC6A8 gene demonstrated a hemizygous mutation in the X-linked creatine transporter gene, consisting of A-G transition in intron 1 (IVS1-2A>G). The patient's mother's DNA was assayed and the same mutation was found (G. Salomons, Amsterdam Free University). Creatine transporter deficiency is an X-linked recessive disorder characterized by mental retardation and severe developmental language impairment. A defect in the X-linked creatine transporter SLC6A8 gene, mapped at Xq28 (OMIM 300352) was identified in 2001. Since then, 7 unrelated families (13 male patients and 13 carriers) with an SLC6A8 deficiency have been reported. Herein, we report an additional patient with creatine transporter deficiency caused by a previously unreported SLC6A8 gene mutation.

Progressive obesity in a patient with fumarase deficiency. *P. Campeau*^{1, 4}, *R. Laframboise*¹, *Y. Giguère*², *B. Piedboeuf*³. 1) Medical Genetics; 2) Medical Biochemistry; 3) Neonatology, CHUL and Laval University, Québec, Qc, Canada; 4) Department of Medical Genetics, McGill University, Montréal, Qc, Canada.

The male proband is the child of a non-consanguineous french-canadian couple with a non-contributory family history. Rapidly after birth the child presented metabolic acidosis, hyperlactacidemia at 16 mmol/l and hyperammonemia at 263 mol/l. He was treated for less than 24 hours with bicarbonates and sodium benzoate and his clinical condition rapidly improved. The child had transitory DIC, renal failure, hepatocellular lysis and seizures. Brain MRI showed cortical and subcortical atrophy, 4 cysts on the lateral sides of the frontal ventricular horns, and a right temporal hygroma. Echocardiography showed atrial septal defect. Urinary organic acids showed constant and significant fumaric acid increase. Amino acids and karyotype were normal as well as PDH complex activity on skin fibroblasts. Fumarase activity in skin fibroblasts was significantly decreased in the cytosolic and mitochondrial fractions, confirming fumarase deficiency (mutations pending to correlate genotype with phenotype). The child was treated with a low protein diet, phenobarbital, lamotrigine, L-carnitine, biotin, thiamine, riboflavin, pyridoxine and ranitidine. He experienced progressive clinical deterioration with gastroesophageal reflux, scoliosis, diastolic dysfunction with ventricular hypertrophy, severe hypotonia and developmental delay. He had frequent infections with secondary neutropenia; immunoglobulin and complement studies were normal. Progressive obesity developed despite a tightly controlled caloric intake. Investigations revealed a normal insulin response, TSH, ACTH, cortisol and lipid profile. The child died from complications of an influenza infection at 7 months. This is the first report of progressive obesity in a child with fumarase deficiency. We hypothesize that an increase in mitochondrial citrate (caused by a block in fumarate conversion and oxaloacetate replenishing by anaplerotic pathways) led to subsequent increases in cytosolic acetyl-CoA and in the synthesis of fatty acids.

Case report of a Long-chain 3 hydroxyacyl-coenzyme A dehydrogenase (LCHAD) deficiency presenting with metabolic acidosis and ketosis. *A. Feigenbaum¹, G. Maegawa¹, S. Olpin², A. Strauss³, J. Callahan¹, N. Poplawski¹.* 1) Clinical and Metabolic Genetics, Metabolic Lab, Hosp Sick Children, Toronto, ON, Canada; 2) Dept. of Clinical Chemistry, Sheffield Children's Hosp, West. Bank, Sheffield, UK; 3) Dept. of Peds and Vanderbilt Children's Hosp, Vanderbilt University, Nashville, TN, USA.

We report a case with a fatty acid oxidation defect (FAOD) who on initial clinical presentation showed ketones. This 7-week old male was born at 35 week gestation who developed sudden onset respiratory distress, gallop rhythm and a 3/6 systolic murmur. Initial labs showed a severe metabolic acidosis, high lactate (18; nl 0-2.4), hypoglycemia, ketones in urine and with normal AST, ALT, GGT, ALP. Echocardiogram confirmed severe dilated cardiomyopathy with a reduced ventricular function. Org. acid (GC-MS) showed very large lactic acid, moderate 2-OH-butyric and 3-OH-butyric acids and trace of acetoacetic acid. Plasma total carnitine was 13.8 (32-84), free carnitine 9.7 (26-60) and Acylcarnitine profile: reported increased C14, C16 and C18 acylcarnitines suggestive of LCHAD deficiency. The fatty acid oxidation flux in fibroblasts revealed significantly reduced activity for both enzymes indicating MTP deficiency. Molecular analysis showed he was compound heter. for 2 mutations in the LCHAD/trifunc. prot. alpha-subunit gene: G2027T in exon 19 leading to a substitution of arginine to lysine. An unreported intronic mutation T+30 was found after exon 6. The Western blot analysis using specific antibodies to both the LCHAD and thiolase revealed markedly low antigen levels, less than 2% of control. He had a persistent hypocalcemia and was diagnosed with hypoparathyroidism needing suppl. calcium and calcitriol. He is on long chain fat restricted diet, carnitine supplementation and has responded well. His cardiac function has normalized in about 3 months and remains stable since. The clin-lab presentation of this case was typical of FAOD however the urinalysis and did show ketones. This is an example of hypoketosis rather than nonketotic hypoglycemia as a presentation of FAOD and if present can mislead the work-up, diagnosis and even acute management.

Molecular and functional studies of OCTN2 (SLC22A) in three patients with mild systemic carnitine deficiency.

*X. Fu*¹, *T.J. Urban*², *K.M. Giacomini*², *S. Packman*¹. 1) Division of Medical Genetics, Department of Pediatrics, University of California San Francisco; 2) Department of Biopharmaceutical Science, University of California San Francisco, CA.

Carnitine serves several physiologic functions that regulate organic acid metabolism and ameliorate organic acid accumulation in disease states. These include mediation of transport of long chain fatty acids across the inner mitochondrial membrane for β -oxidation, and esterification of potentially toxic acyl-CoA metabolites that accumulate proximal to a metabolic block. Carnitine transport into cells is mediated by a high affinity transport protein (OCTN2) encoded by SLC22A5, which is one of a family of organic ion transporters. We recently studied three families with clinical and chemical features consistent with mild systemic carnitine deficiency, and found both synonymous and non-synonymous amino acid substitutions, and mutations in the 3' untranslated region, in SLC22A5 in these patients. Transformed lymphoblasts from all three patients showed reduced carnitine transport activity, to approximately 25% (20.5% to 29.6% of control, $p < 0.05$) and reduced levels of OCTN2 mRNA (10.2% to 16.4% of control, $p < 0.05$). The reduction in activity (and mRNA expression level) of OCTN2 is moderate in comparison to that observed in patients with null mutations in SLC22A5 and is consistent with the patients mild clinical presentation. It is possible that the genetic variants of OCTN2 identified in these patients may lead to the quantitative deficiency in the expression and activity of OCTN2. Studies are underway to identify the genetic determinant(s) of the carnitine deficiency observed in the three patients, which include examining the functional effects of polymorphic mutations in OCTN2 and the role of modifier genes and other multifunctional organic cation transporters on carnitine transport in patients with mild systemic carnitine deficiency. The finding that moderate but symptomatic deficiencies in systemic carnitine levels are associated with a moderate reduction in OCTN2 expression simultaneously represents a previously unrecognized clinical syndrome in pediatric patients and suggests its mechanism.

Acute rhabdomyolysis and hepatic failure: a manifestation of respiratory chain deficiency? *M.T. Geraghty¹, J. Michaud¹, B. Robinson², D. Millington³, N. Lepage¹, P. Chakraborty¹*. 1) CHEO, Ottawa, ON; 2) Toronto Sick Kids, ON; 3) Duke University, NC.

A 4 month old female presented with seizures 1 day after immunizations. She had normal growth and development and no contributory family history. On admission she had a metabolic acidosis with hypoglycemia, hyperammonemia and increased lactate. Blood gases showed pH 7.17, pCO₂ 52.9 torr and HCO₃ 19 mmol/L. Chemistry results were Na 141mmol/L, K 6.5 mmol/L, Cl 104 mmol/L, glucose <0.6mmol/L, NH₄ 741 umol/L and lactic acid 10.5 mmol/L. Urine was negative for ketones. She had biochemical evidence of liver and muscle dysfunction. Over the next 48 hours lactate returned to normal. CK levels peaked at 48 hours (36162 U/L) with severe myoglobinuria. Liver function tests worsened through 48-72 hours; albumin 22 G/L, ALT 8000 U/L with increased PT and PTT. Free carnitine was 39 umol/L and total was 102 umol/L. Acylcarnitine profile was suggestive of a multiple acyl-dehydrogenase defect. Urine organic acids showed lactic and dicarboxylic aciduria only. Plasma amino acids were non specific, with increased ala and gln (1679 umol/L and 1076 umol/L). There were moderate elevations in phe, tyr, met, orn, lys and pro. The child responded to intubation and supportive therapy. Biochemistry normalized over the following seven days. In vitro studies of fatty acid oxidation in fibroblasts were normal. A muscle biopsy taken 6 months after discharge showed enhancement of Gomori trichrome and SDH staining with no ragged red fibres. On electron microscopy there was a normal number mitochondria but these were enlarged with increased and irregular cristae and located in the subsarcolemmal space. Analysis of frozen muscle showed low complex I and III activity (0.49 umol/min/g wet weight; normal 0.5-1.9). The ratio to citrate synthase activity was reduced. Studies in fibroblasts had similar but less striking results. Rhabdomyolysis and hepatic failure have been reported in fatty acid oxidation defects but they have rarely been ascribed to mitochondrial defects. While not conclusive the clinical findings suggest that this child's presentation was due to a respiratory chain defect.

Newborn screening for inborn errors of metabolism by tandem mass spectrometry in China. *X.F. Gu^{1,2}, L.S. Han¹, X.L. Gao¹, J. Ye^{1,2}, W.J. Qiu^{1,2}.* 1) Department of Pediatric Endocrinology and Genetic Metabolism, Xin Hua Hosp, Shanghai Second Medical University, Shanghai, China; 2) Shanghai Institute for Pediatric Research, Shanghai 200092, China.

Objective: The aims of this pilot study were to establish an analysis method of amino acid and acylcarnitine profiles on dry blood filter paper using MS/MS and to screen inborn errors of metabolism in Chinese newborns. **Methods:** From January 2003 to May 2004, 22,700 neonates in Shanghai were tested using dried blood spots at the age of 3 to 10 days. A 3mm disk of dried blood filter paper was punched and extracted with stable isotope labeled internal standards, which involve 12 kinds of amino acids and 8 kinds of acylcarnitine, then derivatized with butanolic-HCL in 65 oven for 15 min. After preparation, the samples were reconstituted with acetonitrile: water 80:20 volume and analyzed by MS/MS (API 2000). The data which were detected by MS/MS were calculated by the software (Chemo View 1.2). The specimens for quality control of Amino acid and acylcarnitine were supplied by CDC of America. The Diagnosis of positive newborns was confirmed by the characteristic clinical symptoms, clinical chemistry tests, loading test, and gas chromatography-mass spectrography (GC-MS) analysis. **Results:** Sixty-six newborns (0.28%) were positive and recalled. Seven of the 66 newborns (1/3243) were confirmed as inborn errors of metabolism, which involved 3 hyperphenylalaninemia (HPA), 2 methylmalonic acidemia (MMA), 2 3-methylcrotonyl-CoA carboxylase defecion (3-MCC). Among these 7 children only 2 MMA newborns had vomiting on clinical. Other 5 newborns had no symptoms. The false-positives rate was 0.26% (59/22,700). **Conclusions:** We established a fast, accuracy and sensitive tandem mass spectrometry method for amino acid and acylcarnitine profiles analysis, more than 30 metabolic diseases including amino acid disorders, organic acid disorders and fatty acid oxidation disorders could be detected. The pilot study shown that the inborn errors of metabolism in newborn were 1:3243 in this study, and all cases detected should be long-term surveillance.

A pilot study of selective screening in high risk children with inborn error of metabolism using tandem mass spectrometry in China. *L.S. Han^{1,2}, J. Ye^{1,2}, W.J. Qiu^{1,2}, X.F. Gu^{1,2}.* 1) pediatric endocrinology, xinhua hospital, shanghai, shanghai, China; 2) Shanghai Institute for Pediatric Research, Shanghai, 200092 China.

The aim of the present study was to establish a dry blood filter paper method for amino acid and of acylcarnitine test using tandem mass spectrometry and application on selective screening in high risk children with inborn error of metabolism. Eight hundred high risk cases with inborn error of metabolism were studied, the samples were from in more than 30 hospitals of all over China in November 2002 to May 2004, there were 520 males and 280 females, the means age was 3.46 years. The patient had at least one of the following symptoms: mental retardation, slowly development, psychology abnormal, muscle hypotonia, jaundice, hepatomegaly, recovery vomiting or convulsion, hypoglycemia, hyperammonemia and lactic acidemia. The blood was collected on filter paper and analyzed by tandem mass spectrometry. The diagnosis was confirmed by characteristic clinical symptoms, clinical chemistry tests or gas chromatography-mass spectrography (GC-MS) in part of cases. Ninety-three patients were positive in our selective screening program, including 55 with amino acid disorders(41 hyperphenylalaninemia, 3 tyrosinemia, 1 homocystinuria, 1 hypermethioninemia, 2 citrulinemia, 2 maple syrup urine diseases, and 5 ornithine transcarbamylase deficiency), 32 with organic acid disorders(16 methylmalonic acidemia, 4 propionic acidemia, 2 isovaleric acidemia, 4 glutaric acidemia, 2 3-methylcrotonyl CoA carboxylase deficiency, 1 3-hydroxy-3-methylglutaryl-CoA lyase deficiency, 2 biotinidase deficiency, and 1 b-ketothiolase deficiency), and 6 with fatty acid oxidation disorders (2 medium chain acyl-CoA dehydrogenase deficiency, 2 carnitine palmitoyl transferase type II, and 2 multiple acyl-CoA dehydrogenase deficiency). Our results indicated the importance of selective screening on high risk patients of amino acid disorders, organic acid disorders and fatty acid oxidation disorders with tandem mass screening. The most of diseases that cause of death and disability represent a preventable by early diagnosis and treatment.

Molecular Basis for Glucose-Galactose Malabsorption In Large Kindred. *D. Kesselman*^{1, 3}, *O. Reish*², *N. Gal*³, *H. Gore*³, *Y. Bujanover*³, *Y. Anikster*³. 1) Bio Resources Engineering, University of Maryland, College Park, MD; 2) Dept Genetics, Asaf Harofe Hospital; 3) Metabolic Disease unit, Safra Children's Hospital, Tel Hashomer.

Glucose Galactose malabsorption (GGM) is a rare autosomal recessive disorder characterized by life threatening diarrhea at infancy. When the intake of the offending sugars is ceased, the diarrhea promptly stops. The diet given to patients with GGM is free of glucose and galactose and supplemented with fructose. A Mutation in the *SGLT1*- the sodium-glucose co-transporter gene, causes a defect in the glucose-galactose transport across the intestinal lining which is responsible for the disease.

We examined three children from two families of Israeli Arab Muslim origin who have a history of GGM and receive the appropriate diet. We performed the breath hydrogen test with D-Glucose and lactose which confirmed the diagnosis for one of the patients. Peripheral blood samples were taken from the patients, their siblings and their parents and DNA was extracted. Genomic DNA of a patient was PCR amplified for each of the 15 exons of the *SGLT1* gene and analyzed by direct nucleotide sequencing.

We identified a C to G substitution at nucleotide 765. This caused a novel missense mutation C255W. Even though this novel mutation is not on one of the 14 predicted transmembrane domains of the SGLT1 protein, the change from sulfur containing cysteine to the aromatic tryptophan along with the segregation in the kindred further support that this is a pathological mutation. This mutation created an *RsaI* restriction site and using the exon 8 amplicon we showed full segregation in these large kindred. Our results allow for prenatal diagnosis and carrier detection in this unique genetic isolate.

Polymorphism analysis of ATP7B related microsatellite DNA haplotype in Wilson disease. X. Liu^{1,2}, Y.F. Zhang^{1,2}, L. Wang¹, X.F. Gu^{1,2}, K.R. Bao¹. 1) Pediatric, Xinhua Hospital, Shanghai, Shanghai, China; 2) Shanghai Institute for Pediatric Research, Shanghai 200092, China.

Objective To explore the distribution and significance of haplotype of microsatellite DNA(D13S314,D13S301 and D13S316) closely related to ATP7B in normal population , WD patients and heterozygotes. **Methods** Using three well characterized short tandem repeat markers of fluorescence labelling (D13S301-D13S314-D13S316), localization and sequence were analysed with Genotype™ software in 71 WD patients and 123 parents. **Results** Based on the analysis of haplotypes of D13 S314,D13S301 and D13S316, 19, 20, and 15 alleles were obtained in 71 patients with WD, 123 carriers and 54 normal persons respectively, size of segments was 134-157bp, 128-156 bp, and 136-154 bp. Heterozygosity was 0.79, 0.82, and 0.23. There was significant difference in distribution of alleles of D13S314,D13S301 and D13S316 makers between WD patients and normal person($P < 0.01$), 4 alleles in D13 S314 maker, 6 alleles in D13 S316 maker. There was 81 haplotypes. 12-6-5, 15-10-5, 6-10-5 and 6-15-5, the commonest haplotypes, accounted for 5.22%, 4.48%, 4.48% and 3.37% respectively. 12-8-5, 12-7-5 and 6-16-5 separately accounted for 2.99%, 13-10-8, 6-13-5, 6-14-13 and 6-9-5 separately accounted for 2.24%. **Conclusion** The complexity of haplotype may be related to the complexity of mutation spectrum of ATP7B. The haplotype analysis of D13 S314-D13S301-D13S316 is one of effective and feasible method, having important significance, in presymptom and prenatal diagnosis of Wilson disease.

Modeling pathogenesis of human glycerol kinase deficiency (GKD) in glycerol kinase (Gyk) knockout mice. *N.K. MacLennan¹, N. Kuwada¹, Y.H. Zhang¹, Z. Fang^{2,3}, S. Horvath^{2,3}, L. Rahib⁴, E.R.B. McCabe^{1,2}, K.M. Dipple^{1,2}.* 1) Pediatrics; 2) Human Genetics; 3) Biostatistics; 4) School of Engineering, UCLA, Los Angeles, CA.

GKD is an X-linked inborn error of metabolism with episodes of metabolic acidosis. We hypothesized that Gyk knockout (KO) mice would be a model for GKD pathogenesis and tested this by biochemical, microarray and Pathway Assist analysis of Gyk KO and wildtype (WT) mice. We confirmed that Gyk KO mice had hyperglycerolemia, elevated plasma free fatty acids and die by day of life (dol) 3-4 (Huq et al Hum Mol Genet, 1997). We determined (iSTAT Portable Clinical Analyzer) KO male mice were acidemic (pH 7.1), had low plasma HCO₃ (15), and were hypoglycemic (30) on dol 3 compared to WT mice (p<0.05). To understand the molecular mechanism of GKD, we performed microarray analyses on liver mRNA (Affymetrix Mouse 430 Gene Chips). Gene filtering identified 237 differentially expressed (>2-fold) genes involved in metabolism, transcription factor activity, signal transduction, transport, DNA binding, protein modification, cell death and cytoskeleton. Real time PCR confirmed differences in Gyk (12% of WT), glycerol phosphate dehydrogenase 2 (35% of WT), and PPAR gamma coactivating factor 1 (234% of WT). EASE analysis identified 56 increased (p<0.01) and 37 decreased (p<0.01) gene categories in Gyk KO mice. Expression levels of members of gene functional groups involved in organic acid metabolism/transport, lipid metabolism, fatty acid/long-chain fatty acid metabolism, and glucose metabolism were increased (p<0.001). Glycerol/glycerol ether metabolism and steroid biosynthesis gene functional group members were decreased (p<0.001). Pathway Assist (Stratagene) analysis confirmed that perturbations of GK affects pathways involved in organic acid metabolism indicating they are part of the same metabolic network. In conclusion, Gyk KO hepatic mRNA levels are altered in a broad range of functional categories, some of which are relevant to the biochemical aberrations in GKD. Investigations of altered gene expression and metabolite flux in the this GKD murine model will provide valuable insights into GKD pathogenesis.

Cholesterol synthesis and brain cholesterol turnover in PKU. *L.S. Merkens¹, W.E. Connor², M. Gillingham¹, C.O. Harding^{1,4}, D. Lutjohann³, K. von Bergmann³, R.D. Steiner^{1,4}.* 1) Dept Pediatrics, Oregon Health & Science Univ, Portland, OR; 2) Dept Medicine, Oregon Health & Science Univ, Portland, OR; 3) Dept Clin Pharm, Rheinische Fredrich-Wilhelms Universitat, Bonn, Germany; 4) Dept Mole & Med Genetics, Oregon Health & Science Univ, Portland, OR.

Phenylketonuria (PKU) is an inborn error of metabolism caused by phenylalanine (Phe)hydroxylase deficiency causing high blood Phe concentrations. PKU treatment is based on a diet restricted in animal protein and, therefore, cholesterol. Phe inhibits HMG CoA reductase (HMGCR). We hypothesized whole body cholesterol synthesis would be higher and brain cholesterol synthesis lower in PKU vs. controls. HMGCR inhibition by phe would be overridden by the low cholesterol diet systemically, but brain would bear the full effect of HMGCR inhibition since dietary cholesterol doesn't reach the brain. Ten children with PKU were compared to 8 controls. Mean plasma Phe was 6 mg/dL at the time of study, indicating good diet adherence. Plasma cholesterol was measured by gas chromatography (GC); plasma lathosterol and 24S-hydroxycholesterol(24S) by GC/MS. Mean plasma cholesterol concentration was significantly lower in PKU vs controls (132 vs 169 mg/dL). Plasma lathosterol/cholesterol ratio, an estimate of total cholesterol synthesis, was increased in PKU. Plasma 24S, an estimate of brain cholesterol turnover did not differ significantly between groups (195 vs 213 ng/dL). Control children showed a trend of higher 24S at younger ages (linear regression $P=.07$). In PKU, 24S showed no change from 4 mo to 4 yr. In conclusion, low plasma cholesterol levels are consistent with lower dietary cholesterol intake in PKU. Whole body cholesterol synthesis is increased in PKU likely due to lower dietary cholesterol intake. Finally, 24S was the same in PKU and controls, but may be lower in younger PKU children. This finding suggests that Phe may inhibit brain cholesterol synthesis during the period of rapid myelination. Reduced brain cholesterol synthesis could play a role in executive function deficits and hypomyelination observed in PKU.

The frequency of sudden early neonatal death (SEND) and fatty acid oxidation disorders in New South Wales, Australia. *J. Mitchell*^{1, 2}, *V. Wiley*¹, *K. Sim*¹, *K. Carpenter*¹, *B. Wilcken*¹. 1) The Children's Hospital at Westmead, Sydney, NSW, Australia; 2) Montreal Children's Hospital, Montreal, Quebec, Canada.

Purpose: Sudden early neonatal death after uncomplicated pregnancy is a rarity. The differential diagnosis includes cardiac causes, trauma, infection and metabolic disease. Of the metabolic disorders, fatty acid oxidation defects (FAOD) are the most likely to present in this way. Among a birth cohort of 545,000, we describe four cases of sudden early neonatal death occurring in the first three days of life, secondary to different fatty acid oxidation disorders.

Methods: Screening for abnormal metabolites in all suspect cases was performed by tandem mass spectrometry using samples obtained for newborn screening. Amongst four neonatal deaths, the dried blood spots from two were taken post-mortem, and the indicative abnormal profiles were confirmed by mutation testing.

Results: The diagnoses were: medium-chain acyl-CoA dehydrogenase deficiency, multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria Type II), and two cases of acylcarnitine-carnitine translocase deficiency. At autopsy, all four had hepatic steatosis. These babies were among a birth cohort screened by tandem mass spectrometry over a six year period (1998-2004). In that cohort we diagnosed a total of 43 cases of FAOD, amongst whom these 4 (9%) suffered neonatal death. We estimate a minimum of 1:60 term neonatal deaths in New South Wales are metabolic SEND, and if only unexpected deaths in the first week were considered this would be much higher.

Conclusions: Although the diagnosis did not alter clinical outcome in these neonates, it did allow for genetic testing in family members and future pregnancies. These cases illustrate the importance of obtaining samples post-mortem on all babies dying unexpectedly and the value of dried blood spots and tandem mass spectrometry in the detection of FAOD. Neonatal death amongst FAOD patients seems more common than previously thought, and FAOD are an important cause of unexpected early neonatal death.

Detection of mutations Q188R, K285N and S135L in GALT gene in Iranian galactosemia patients. N.

Naghibzadeh Tabataba¹, R. Mirfakhraie¹, S. Saki², E. Talachian³, I. Majd¹, M. Housmand¹, F. Mirzajani¹. 1) medical genetics, National Institute of Genetic Engineering & Biotechnology, tehran, Iran; 2) Islamic Azad University, Tehran, Iran; 3) Iran medical science University, Tehran, Iran.

100 unrelated families, clinically suspected to galactosemia, were screened by qualitative measurement of galactose-1-phosphate uridyl transferase (GALT) activity in blood RBCs using Beutler method. Deficient enzyme activity (classical galactosemia) was confirmed in 13 families. All of these 13 families were submitted to the diagnosis of six common mutations in GALT gene including Q188R, K285N, S135L, L195p, X380R and Q169K using PCR-RFLP method which resulted in detection of 46% of the mutated alleles. 6 patients were homozygote for Q188R mutation, while one patient homozygote for S135L mutation and one heterozygote for K285N mutation were detected.

Molecular Characterization of Lesch Nyhan Syndrome in Puerto Rican Family. *P. O'Neill¹, A.S. Cornier², N. Arciniegas³, J. Acevedo⁴, N. Ramirez⁵, S. Carlo².* 1) Genetics Lab, Univ Vermont, Burlington, VT; 2) Genetics Division, Ponce School of Medicine, Ponce, PR; 3) Department of Pediatrics, Ponce School of Medicine, Ponce, PR; 4) Nursing Dept. Univ of Puerto Rico at Arecibo, Arecibo, PR; 5) Orthopedics Dept., Mayaguez Medical Center, Mayaguez, PR.

Lesch-Nyhan (MIM 308000) syndrome is an inherited deficiency of the purine salvage enzyme hypoxanthine-guanine phosphoribosyltransferase (HPRT) characterized by neurologic dysfunction, cognitive and behavioral disturbances, and uric acid overproduction (hyperuricemia). The neurologic findings most closely resemble athetoid cerebral palsy. The most common presenting features are hypotonia and developmental delay, which are evident by three to six months of age. Patients are delayed in sitting; most never walk. Within the first few years, extrapyramidal involvement (e.g., dystonia, choreoathetosis, opisthotonus) and pyramidal involvement (spasticity, hyperreflexia and extensor plantar reflexes) become evident. Patients are cognitively impaired and have behavioral disturbances that emerge between two and three years of age. Persistent self-injurious behavior (biting the fingers, hands, lips, and cheeks; banging the head or limbs) is a hallmark of the disease, clinical manifestations are more evident with less than 1.5 percent of residual activity of the enzyme. Enzymatic residual activity between 1.5 and 8 percent produces phenotypes with mild neurological manifestations or hyperuricemia alone. Being an X-linked disorder (Xq26-27.2) females with the disorder are rare, only five reported (Jinnah et al). We studied a family from the central part of Puerto Rico in which there are three affected male individuals, one affected female and two female carriers. Male patients had been evaluated but did not have a definite diagnosis. The affected female was evaluated due to hypotonia and developmental delay. Metabolic work up that included carnitine profile, urine organic acids and lactate and pyruvate was negative. Patient presented elevated plasma uric acid and started with self injury behavior around 18 months of age. HPRT activity was measured and diagnosis was made. Mutation analysis of HPRT gene is currently being performed.

Function of two alternatively spliced mRNAs from the Xp21 glycerol kinase gene. *R. Ohira*¹, *E.R.B. McCabe*^{1,2}. 1) Depts of Hum Genet; 2) Pediatr, David Geffen Sch of Med at UCLA, LA, CA.

Glycerol kinase (GK) is involved in fat and carbohydrate metabolism and is alternatively spliced. GK phosphorylates glycerol to form glycerol 3-phosphate, which is important in production of glycerol lipids and glycerol ether lipids. An 87 bp insertion corresponding to exon 18 of the Xp gene (*GK+EX18*) was isolated from human fetal brain and testes. The predominant form of GK found in liver lacks exon 18. Our goal was to determine differences in kinetics and localization within the cell for GKEX18 (GK- or GK+). For kinetic studies, Cos7 cells were transiently transfected with GK- or GK+, and GK activity assayed using whole cell extracts. K_m and V_{max} were derived by Hanes-Woolf analysis. K_m for glycerol and ATP were 2.2M and 6.4M for GK- and 2.6M and 12.2M for GK+, respectively. V_{max} for glycerol and ATP were 16,540U/mg and 1,914U/mg for GK-, and 11,752U/mg and 3,167U/mg for GK+, respectively. K_m values for glycerol were not significantly different (P0.05), but GK+ had a higher K_m for ATP (P0.05). GK- had a significantly higher V_{max} for glycerol (P0.05), but lower V_{max} for ATP (P0.05). Fractionation showed that GK+ had very little activity in the cytosolic, some activity in the mitochondrial, and highest activity in the nuclear fraction. However, GK- had the highest activity in the cytosol, and some activity in the mitochondrial and nuclear fractions. Immunostaining was done on Cos7 cells transiently transfected with Flag-tagged GKEX18 and various markers to identify organelles for colocalization studies. GK+ colocalized mainly to the mitochondria, whereas GK- had a more diffuse expression pattern, suggesting specific functions for the two forms. GK+ may be involved with mitochondrial specific processes, like regulating energy metabolism or apoptosis. GK- may have a metabolic function in the cytoplasm, but also may play a specific role in the nucleus as the ATP-stimulated glucocorticoid receptor translocation promoter (ASTP). ASTP enhances nuclear uptake and binding of glucocorticoid receptor complexes in the presence of ATP. Additional research will be required to determine whether ASTP activity is associated with a single GK isoform.

Immunodetection and mutational analyses in 34 patients with enzymatically diagnosed pyruvate dehydrogenase complex (PDC) deficiency. *K. Okajima*^{1,2}, *M.L. Warman*², *K.S. Kerr*¹. 1) CIDEM, Rainbow Babies & Children's Hosp, Cleveland, OH; 2) Departments of Pediatrics and Genetics, Case Western Reserve University, Cleveland OH.

PDC deficiency is a common cause of primary lactic acidemia. In many cases, mutations are found in *PDHA1* (E1) which maps to Xp22. We analyzed *PDHA1* mutations and alterations of PDHA1 protein on immunoblot among 34 patients (21 male, 13 female) who had been diagnosed by enzyme assay. All patients had normal DLAT (E2) and DLD (E3) activity. **Method:** Genomic DNA (or cDNA) was analyzed by PCR (or RT-PCR) and direct sequencing. Immunoblotting of fibroblast lysates from 10 males and 8 females with mutations and 4 males and 4 females without mutations, was performed using an anti-PDHA1 monoclonal antibody and anti-succinate dehydrogenase as a control. **Result:** Mutations were found in 24 of the 34 patients. 15 patients (9 male, 6 female) had point mutations, 7 patients (4 male, 3 female) had small insertions, one male had a small deletion, and one male was a somatic mosaic for a point mutation leading to exon-skipping. Only one point mutation and one insertion were found in multiple families. Among the 10 males with mutations, 6 had normal and 4 had reduced PDHA1 by immunoblot; 4 males without *PDHA1* mutations had normal PDHA1. Among females with mutations, 5 had normal PDHA1 and 2 had reduced amounts of immunodetectable PDHA1. In the latter 2 samples, enzyme activities were very low and cDNA analyses suggested skewed X-inactivation. **Discussion:** In patients at risk for *PDHA1* mutation, we detected mutations in 15 of 21 males and 9 of 13 females. Males without mutations had normal appearing PDHA1 protein by immunoblot, suggesting that hemizygous *PDHA1* mutations were not the cause of their reduced PDC activity. Similar conclusions are difficult to draw in females with reduced PDC activity and an undetectable mutation because large deletions could be missed in heterozygous females using our strategy. Immunoblot analyses are less sensitive than DNA or RNA based methods for finding PDHA1 mutations, since altered protein levels were noted in only 40% of male and 25% of female samples with mutations.

Effect of genetic excess of gamma-hydroxybutyric acid (GHB) and gamma-aminobutyric acid (GABA) brain secretion on sleep. *A. Philippe¹, I. Arnulf², K.M. Gibson³, D. Rabier⁴, P. Beauvais⁵, A. Munnich¹, J.P. Derenne².* 1) INSERM U 393, Hopital Necker-Enfants Malades, Paris, France; 2) Fédération des pathologies du sommeil, Hopital Pitié-Salpêtrière, Paris; 3) Biochemical Genetics Laboratory, Oregon Health Sciences University, Portland; 4) Laboratoire de Biochimie Médicale B, Necker-Enfants Malades, Paris; 5) Service de Neuropédiatrie, Hopital Trousseau, Paris.

Background: Exogenous gamma-hydroxybutyric acid (GHB) increases slow wave sleep in healthy volunteers and reduces daytime sleepiness and cataplexy in patients with primary narcolepsy. Objective: To examine night-time sleep and daytime vigilance in a 13 yr-old girl homozygous for succinic semialdehyde dehydrogenase (SSADH) deficiency, a rare autosomal recessive metabolic disorder that disrupts the normal degradation of gamma-aminobutyric acid (GABA), and leads to an accumulation of GHB and GABA within the brain. Methods: Sleep interview and unattended polysomnography over 48 hours (habituation night, multiple sleep latency tests, and continuous 24-hours in lab recordings). Her mother heterozygous for SSADH deficiency and a 13 yr-old control girl were also interviewed and recorded during the night. Results: During quiet wakefulness, background EEG activity was slow, composed of 7 Hz activity. Sleep symptoms, duration, and architecture (particularly stages 3-4), were within normal ranges for the patient and her mother, but daytime mean sleep latency was short (3 min 42 s) in the patient while spindle indexes were low in the child (11/hr) and in the mother (39/h), compared to 275/h in the control. At the beginning of the second night, a tonic-clonic seizure occurred, followed by a dramatic increase in stages 3-4, representing 338 min or 56 % of the time asleep. Discussion: Our observations suggest that regular GHB and GABA excess causes subtle sleep abnormalities while a sudden event (here an epileptic seizure) possibly responsible for an extra-increase in GABA and GHB, results in increased slow wave sleep.

Transcobalamin II deficiency: an under recognized cause for bone marrow failure in childhood. *C. Prasad¹, K. Corley¹, A.E. Cairney¹, C.A. Rupa^{1,2}*. 1) Department of Pediatrics, CHWO &; 2) Biochemistry and Pathology, CPRI, London, ON, Canada.

We report on 3 affected sibs (Albanian) with Transcobalamin II (TC II) deficiency. The proband presented at 3 months of age with pancytopenia, failure to thrive, and suspected Fanconi anemia. Intensive investigations, and aggressive management with granulocyte colony stimulating factor, erythropoietin, total parenteral nutrition, gastrostomy feeding, repeated platelet and blood transfusions were unrewarding. Bone marrow transplant was being considered when methylmalonic aciduria was detected with no specific abnormalities on plasma and urine amino acids. The plasma B12 levels were normal. There was a previous sibling death due to pancytopenia. Further confirmatory testing on the proband revealed very little synthesis of TC II by cultured fibroblasts in the absence of exogenous TC II (Dr. David Rosenblatt, McGill University). There was adequate synthesis of AdoCbl and MeCbl. A novel mutation homozygous R399X C>T substitution at nt 1195 of cDNA resulted in a premature stop codon. The proband responded very well to Vitamin B12 (~2.5 mg) with complete resolution of symptoms and normalization of growth and development. A third child (girl) was treated with Vitamin B12 from the age of 3 weeks and confirmed by mutation analysis to also have TC II deficiency. She is doing well with Vitamin B12 replacement, which will be continued, for life as for her brother. TC II deficiency is an autosomal recessive disorder. TC II, a plasma globulin is necessary for delivery of cobalamin molecule to the hematopoietic system. The vitamin B12 levels are usually normal. TC II is a member of cobalamin binding proteins in humans that include intrinsic factor, transcobalamin I and a putative protein. The TC II gene is a housekeeping gene, which has a unique 34-nucleotide stretch sequence that is a motif for a transactive transcription factor that regulates expression of epidermal growth factor receptor gene. The availability of an extremely effective B12 treatment should prompt the physicians to consider this diagnosis earlier in the work up of bone marrow failure syndromes in childhood.

Prenatal diagnosis of glycogen storage disease Ia with hot spot mutations screening and 1176 nucleotide polymorphism linkage analysis. *W. Qiu^{1,2}, J. Ye^{1,2}, L.S. Han^{1,2}, X.F. Gu^{1,2}.* 1) Pediatric Endocrinology, Xinhua Hospital, Shanghai, Shanghai, China; 2) Shanghai Institute for Pediatric Research, Shanghai 200092, China.

Objective This study was to obtain a simple, fast and accurate prenatal diagnosis method for glycogen storage disease Ia (GSD Ia). **Methods** Genomic DNA samples were abstracted from the bloods of 2 GSD Ia patients from 2 families, their parents, uncultured and cultured amniocytes of the 2 fetuses. Screening for the 727GT and R83H mutations of glucose 6 phosphatase combined with 1176 nucleotide polymorphism linkage analysis by restriction enzyme analysis were used to make the genetic and prenatal diagnosis of 2 GSD Ia families. Direct DNA sequencing of the corresponding PCR products were used to confirm the found mutations and 1176 nucleotide polymorphism. **Results** The 2 probands of these 2 families were homozygous for the 727GT mutation and their parents were heterozygous for this mutation. The fetus of X family was heterozygous for this mutation and the fetus of L family did not carry this mutation. The 1176 nucleotide polymorphism of the 2 fetuses was different from those of the probands of the 2 families. The prenatal diagnosis of the X family was confirmed postnatally by the biochemical and molecular studies. **Conclusion** Our finding suggest that the screening for the 727GT and R83H mutations by restriction enzyme analysis combined with 1176 polymorphism linkage analysis is a simple, fast and accurate method for gene and prenatal diagnosis for GSD Ia in Chines.

Classic and Duarte Galactosemia in Louisiana: Newborn Screening Detection and Treatment Outcome. R.

Sharma¹, C. Techakittiroj¹, A. Cunningham¹, H. Andersson^{1,2}. 1) Human Genetics, Tulane University Sch of Medic, New Orleans, LA; 2) Departments of Pediatrics, Tulane University Health Science Center, New Orleans.

Galactosemia newborn screening was done in 121,258 infants in Louisiana during June 2002 May 2004 by detecting semiquantitative galactosemia -1-phosphate uridylyltransferase (GALT). A GALT value $<3.4\text{U/gHb}$ was defined as presumptive positive galactosemia and was confirmed by measuring quantitative GALT. GALT $<10\text{mol/g Hb}$ (50% of low normal) was further tested by isozyme or mutation analysis to classify the type of affected galactosemia (D/D, D/G, G/G). There were 64 presumptive positive cases of galactosemia. After confirmatory tests, 8 cases were normal, 30 cases were galactosemia carriers and 24 were affected with galactosemia (2 G/G, 3D/D, 11D/G and 8 no information). The incidence of galactosemia in Louisiana is 1: 4,826 livebirths (including Duarte variant) and 1: 57,920 (not including Duarte variant) compared to the national incidence rate of 1:53,261. All except one case of classic galactosemia were healthy at the time of diagnosis. Some patients had mild GI symptoms such as reflux, constipation, vomiting etc. during lactose containing diet. All affected galactosemia patients, including Duarte variant galactosemia (D/G, D/D) patients were treated with lactose-free diet for at least 1 year. Duarte variant galactosemia patients (D/G, D/D) were challenged with lactose diet protocol by age 1 year. 7 Duarte variant patients were challenged with lactose diet by age 1 year and all passed the test (Galactose-1-phosphate or Gal-1-p $<2\text{mg}/100\text{ml RBC}$). The average Gal-1-p during restriction and after challenge test in these 7 patients was 0.57 and 1.01mg/100ml RBC, respectively ($p=0.08$). 2/7 Duarte patients were challenged at 2 months old because of parental concern; one failed the test (gal-1-p was 12.7 after challenge) and the other one passed and was given unrestricted diet. Treatment of Duarte variant galactosemia from newborn screening has not been standardized. Our preliminary data do not demonstrate pathology in Duarte variant patients. Follow up is needed to determine whether Duarte variant patients develop cataracts or other late sequelae of galactosemia.

High carrier rate for cystinosis in the Ontario Old Order Amish. V. Siu^{1,2,3}, S. Kuepfer³, R. Dewar², C.A. Rupa^{1,2,3}. 1) Dept Pediatrics and Biochemistry, Univ of Western Ontario; 2) Child and Parent Resource Institute; 3) London Health Sciences Centre, London, ON, Canada.

The Old Order Amish (OOA) in Ontario represent a highly consanguineous and conservative population with a genetic background which differs significantly from that of the OOA in Lancaster County, Pennsylvania. In 1825, the founding members began immigrating directly to Ontario from Alsace-Lorraine. Since then, there has been minimal influx of new genes. Currently, there are about 220 married couples in the area, representing a population of about 900. There are only 9 surnames, 8 of which were present in 1859. About half of the families share the same surname, and 25% of marriages are isonymous. Genetic disorders which are common in Lancaster are notably absent in the main OOA settlements in Ontario, while other disorders not seen in Lancaster have been repeatedly observed in Ontario. The mutations causing 3 treatable disorders, cystinosis, cystic fibrosis, and juvenile-onset glaucoma, in Ontario OOA have been identified. Consultation with Amish bishops established that prenatal screening would not be an option, but that newborn screening for presymptomatic diagnosis and treatment would be acceptable. A newborn screening project was initiated. DNA obtained from umbilical cord samples is analysed for the 4 mutations known to be present in the community. Although carrier status is ascertained, this information will not be revealed until the child has reached adulthood. Thus far, 36 babies have been screened, representing about 80% of all newborns, with a distribution of surnames similar to the entire community. No infant was predicted to be affected. None of the couples had a previously affected child. A high carrier rate of 1:5 for cystinosis was found, predicting an incidence of 1:100 for cystinosis. Two newborns were double heterozygotes, one for cystinosis and glaucoma and one for cystinosis and cystic fibrosis. Carrier rate for cystic fibrosis was 1:9 and for glaucoma was 1:18. The extremely high carrier rate for cystinosis suggests that the mutation was present in a founder and has become prevalent due to continued inbreeding and random drift.

Decreased glycogen content in galactose-1-phosphate uridylyltransferase(GALT) -deficient patient cells. *T. Slepak¹, N. Longo², K. Lai¹.* 1) Dept Pediatrics, Univ Miami, Miami, FL; 2) Dept Pediatrics, Univ Utah, Salt Lake City, UT.

In humans, deficiency of GALT produces the disorder Classic Galactosemia. Although newborn screening & a galactose-restricted diet prevent the acute toxicity associated with this genetic disease, long-term complications such as ataxia, verbal dyspraxia and premature ovarian failure persist in some well-treated patients. The pathogenic mechanisms producing dysfunction of multiple organs are unknown. Previously we demonstrated reduced UDP-glucose and some glycoproteins in galactosemic patient fibroblasts (Lai, et al., 2003, Slepak & Lai, 2003).

In animal cells, glycogen is an important carbohydrate reserve that protects the cells against stress factors. Since UDP-glucose is required for glycogen synthesis, we hypothesized reduced UDP-glucose in GALT deficiency impairs glycogen synthesis. We compared the steady state level of glycogen in fibroblasts derived from normal and galactosemic patients. We found 33% or higher glycogen contents in the controls. We, however, did not see a significant difference in the steady state level of ATP in the patient cells. The rate of glycogen depletion also appeared to be the same when these cells were transferred to hexose-free medium. This suggested that the lower glycogen content in galactosemic cells was not resulted from increased consumption, but from reduced synthesis or accumulation.

To determine if decreased uptake of glucose in the galactosemic cells caused the decreased glycogen synthesis, we assayed 3-o-methyl-D-glucose transport in these cells, but found no difference. We later confirmed that the galactosemic cells accumulated 0.3mM galactose-1-phosphate in medium without galactose. The level of UDP-glucose was twice as high in the controls. We concluded that reduced UDP-glucose under GALT deficiency led to decrease glycogen synthesis. As the galactosemic cells perished faster than controls when transferred to hexose-free medium, we propose that the diminished glycogen contents in GALT deficiency may compromise the viability of other cell types under stress conditions.

Haplotype analysis of the region surrounding *CPT1A* in three unrelated Aboriginal kindreds with CPT1 deficiency. A.M. Stier¹, R.J.A. Wanders², L. IJlst², A. Chan³, F. Bamforth³, P. MacLeod⁴, R.J. Thompson⁵, L.E. Seargeant¹, C.R. Greenberg¹. 1) Department of Biochemistry & Medical Genetics, University of Manitoba, Winnipeg, Canada; 2) University of Amsterdam, The Netherlands; 3) University of Alberta, Edmonton, Canada; 4) University of Victoria, Victoria, Canada; 5) Cadham Provincial Laboratory, Winnipeg, Canada.

Carnitine Palmitoyltransferase (CPT) 1 and 2 facilitate the transfer of long chain fatty acids across the outer and inner mitochondrial membranes respectively. A deficiency in the activity of CPT1 may result in hypoglycemia and organ steatosis. A premature Inuit neonate whose mother had AFLP was found to have absent CPT1A enzyme activity and to be homozygous for the CPT1A P479L mutation. CPT2 activity was normal and the child was diagnosed with CPT1A deficiency. The second and third children in this family have had hypoketotic hypoglycemia, are homozygous for the CPT1A P479L mutation and have near zero CPT1A activity. They are also homozygous for a mutation in CPT2 (F352C). A fourth child is also homozygous for both mutations with no discernible phenotype at this time. Fourteen of the 19 extended family members studied were also found to be homozygous for the CPT1 P479L mutation but have never had documented hypoglycemia. Two other symptomatic individuals, a child from an unrelated Inuit family and a First Nations adult male, have also been found to be homozygous for the CPT1A P479L mutation. The sibs and parents in the second symptomatic Inuit family are also all homozygous for CPT1A P479L and asymptomatic. No one in this kindred, nor the First Nations male, are homozygous for CPT2 F352C; therefore this mutation does not appear to be a major contributing factor to the phenotype. Symptomatic individuals in the 3 kindreds were discordant for haplotypes generated by microsatellite genotyping of the region surrounding *CPT1A*, suggesting that the CPT1A P479L mutation either arose more than once or is a very ancient mutation. Whether the *CPT1A* mutation is a benign variant, the true causative mutation or a major factor in the expression of CPT1A deficiency is being investigated in additional prospective and retrospective studies.

Mutations in *OCRL1* occur in patients with renal Fanconi syndrome without congenital cataracts. *S.F. Suchy*¹, *J. Snoops*¹, *R.L. Nussbaum*¹, *R.R. Hoopes, Jr.*², *A. Shrimpton*², *S.J. Knohl*², *P. Hueber*², *B. Hoppe*³, *J. Matyus*⁴, *A. Simckes*⁵, *V. Tasik*⁶, *B. Toenshoff*⁷, *S.J. Scheinman*². 1) Genetic Disease Res Branch, NHGRI/NIH, Bethesda, MD; 2) Dept. of Medicine, SUNY Upstate Medical University, Syracuse, NY; 3) University of Cologne, Germany; 4) University of Debrecen Medical School, Debrecen, Hungary; 5) Children's Mercy Hospital, Kansas City, MO; 6) Clinic for Children's Diseases, Skopje, Macedonia; 7) University Children's Hospital, Heidelberg, Germany.

Lowe syndrome (OCRL) is a rare X-linked disorder characterized by bilateral congenital cataracts, renal Fanconi syndrome and mental retardation. While the renal phenotype can vary in onset and severity, and the diagnosis is compatible with a normal I.Q., bilateral congenital cataracts are considered the hallmark of the disease and the only universal feature. In a study of Dent disease (DD), an X-linked renal tubular disorder associated with mutations in the chloride channel gene, *CLCN5*, 13 of 32 probands meeting strict phenotypic criteria for DD were identified without mutations in *CLCN5*. Linkage in one family to Xq26.3 suggested *OCRL1* as a candidate. Five distinct, previously undescribed mutations in *OCRL1* were found among the 13 DD probands without *CLCN5* mutations. Loss of PIP2 phosphatase activity and absent/reduced *ocrl1* protein in fibroblasts by western blot confirmed that these were disease-causing mutations. In one of these 5 families, an *OCRL1* missense mutation segregated with the phenotype through 3 generations, indicating that either the gene that modifies the phenotype is tightly linked to *OCRL1* or that this specific mutation is responsible for the unusually mild phenotype. These data demonstrate that 1) DD is genetically heterogeneous, 2) defects in *OCRL1* may result in greater phenotypic variability than previously known 3) all patients with mutations in *OCRL1* do not have cataracts and 4) other gene(s) may be involved in the expression of the OCRL phenotype. A study of these patients may allow us to identify gene products and compensatory mechanisms for *OCRL1* deficiency and provide clues as to how to improve function without replacing the *ocrl1* protein.

Increased long chain fatty acid synthesis in SCAD deficient mice. *D. Wong, S. Bassilian, L. Boros, W-N.P. Lee.*
Harbor-UCLA Medical Center Research & Education Institute, Torrance, CA.

In order to gain a better understanding of the pathophysiology of the fatty acid oxidation disorder in short chain acyl-CoA dehydrogenase (SCAD) deficient mice, we studied de novo lipogenesis in the mutant mouse strain BALB/cByJ using the stable isotope tracer D₂O. Both diseased and control mice were fed a low fat diet with drinking water enriched with 6% D₂O for 10 days. Plasma and liver tissue fatty acids were analyzed using gas chromatography/mass spectrometry. Mass isotopomer distribution analysis was used to differentiate between newly synthesized and preexisting fatty acids. Liver weights were similar in both groups. Levels of long chain fatty acids in liver tissue were significantly elevated in SCAD deficient mice compared to control mice--palmitate, 35.34.8 vs. 17.62.6 mg/g liver (p<.0001), stearate, 7.60.6 vs. 6.30.3 mg/g liver (p<.001), and oleate, 25.94.8 vs. 10.12.4 mg/g liver (p<.0001). Most of the long chain fatty acids were derived from new synthesis, which was significantly elevated in SCAD deficient mice compared to control mice--palmitate, 30.14.0 vs. 14.12.6 mg/g liver (p<.0001), stearate, 6.30.6 vs. 4.90.2 mg/g liver (p<.001), and oleate, 16.53.3 vs. 6.01.9 mg/g liver (p<.0001). Similar statistically significant elevations were seen in the total and newly synthesized amounts of palmitate, stearate, and oleate in plasma. The results support the hypotheses that (1) fatty acid synthesis is increased in SCAD deficiency in order to compensate for the energy deficit caused by the lack of complete beta oxidation of long chain fatty acids and (2) increased fatty acid synthesis is an important factor in the development of fatty liver in these animals.

Program Nr: 1809 from the 2004 ASHG Annual Meeting

Biochemical and molecular diagnosis of Alpha-1-Antitrypsin deficiency in Iranian children affected by idiopathic liver dysfunction. *S. Zare Karizi¹, R. Mirfakhraie¹, M. Houshmand¹, T. Zaman², F. Mirzajani¹.* 1) medical genetics, National Institute of Genetic Engineering & Biotechnology, Tehran, Iran; 2) Children medical center, Tehran Medical University, Tehran, Iran.

75 families clinically characterized by idiopathic liver dysfunctions (eg. Cirrhosis and chronic hepatitis and/or respiratory problems such as early emphysema and bronchiectasy) have been referred to our center. Biochemical tests including SRID were performed to determine the enzyme concentration. PCR- RFLP method was used in order to detect the presence of Z and S mutations. Results from molecular diagnosis were compared with 1AT concentration obtained from Serum Radial Immuno Diffusion (SRID). The association of 1AT genotype with serum concentration was also determined.

Tissue-specific expression of alternatively spliced forms of human Xp21 glycerol kinase (GK) gene. *Y. Zhang, B.L. Huang, E.R.B. McCabe.* Depts of Pediatrics and Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA.

GK deficiency (GKD) is X-linked and results from mutation of the gene encoding GK. GK is involved in carbohydrate and fat metabolism, as well as glucocorticoid-glucocorticoid receptor nuclear uptake. There is poor correlation between genotype and GKD disease severity. To investigate the hypothesis that the protein encoded by the GK gene mapping to Xp21 has additional functions that influence phenotype, we examined four alternatively spliced forms of GK mRNA in different human tissues and cell lines: 1) with exon 8A and without exon 18 (GK+EX8A-EX18); 2) with exon 8A and exon 18 (GK+EX8A+EX18); 3) without exon 8A and with exon 18 (GK-EX8A+EX18); and 4) without exon 8A or exon 18 (GK-EX8A-EX18). Reverse transcriptase-polymerase chain reaction (RT-PCR) amplified human Xp21 GK exons 6 to 19 using primers within exon 5 and the 3'-untranslated region, and resulted in distinct products for each mRNA. After TA cloning, dot blot hybridization was performed with probes containing exon 8A or exon 18 sequence. Sequencing of one colony for each expressed transcript for each tissue or cell line confirmed the results. RT-PCR was done on human tissue polyA RNA and on total RNA extracted from cell lines. Human kidney and fetal liver only expressed GK-EX8A-EX18 (transcript 4). G402 cells (human renal leiomyoblastoma) expressed transcripts 1, 2 and 3 but not 4. HepG2 cells (human liver) expressed transcripts 3 and 4, but not 1 or 2. Cell lines SS6-2 (stem cell myotubes) and A549 (human lung) expressed transcripts 2, 3 and 4, but not 1. Human tissues, such as human adult brain, fetal brain, placenta, testes, and cell lines including human fibroblasts, G401 (human kidney rhabdoid tumor), HEK293 (human embryo kidney) and Cos7 (monkey kidney) expressed all transcripts, but with different intensities. We conclude that the four alternatively spliced GK mRNAs are differentially expressed. We speculate that these different expression patterns may indicate specific and possibly divergent functions for the individual isoforms. Genetic and environmental factors that alter these expression patterns in different individuals could influence the phenotypes of individuals with GKD.

Acylcarnitine Profile Alterations in Autistic Patients. *S. Carlo*¹, *N. Arciniegas*², *J. Acevedo*³, *M. Lopez*³, *C. Burgos*¹, *N. Suarez*¹, *R. Oliveras*¹, *V. Franceschini*¹, *A.S. Cornier*¹. 1) Genetics Division, Ponce Sch Medicine, Ponce, PR; 2) Department of Pediatrics, Ponce School of Medicine, Ponce, PR; 3) Department of Nursing, Univ. of Puerto Rico at Arecibo, Arecibo, PR.

Autism is a complex behavioral disorder defined completely on the basis of impairments in social interaction, impairments in communication, and repetitive and stereotypic behaviors. For most children, the onset of autism is gradual; however, but about 30% show regression of milestones specifically speech. Physical examination included a complete dysmorphology evaluation and an examination of the skin (including Woods lamp examination) to look for evidence of tuberous sclerosis complex and NF1. The dysmorphology examination should identify most, if not all, children with chromosomal disorders. Measurement of height, weight, and head circumference to asses appropriate growth was also evaluated. Metabolic samples were taken to evaluate lactate, pyruvate, urine organic acids, plasma amino acids and acylcarnitine profile and Fragile X DNA. We had previously reported elevated lactate and elevated lactate pyruvate ratio in patients with diagnosis of Pervasive Developmental Disorder and Autism. Further evaluation of these patients has shown unspecific elevations in the acylcarnitine profile. In our group of patients mild to moderate elevations of C-4, C-5 and C-10 were reported. We have also observed the same elevations in lactate, lactate-pyruvate ratio and acylcarnitines in patients with diagnosis of Fragile X syndrome. The elevations in the acylcarnitine profile, lactate and lactate-pyruvate ratio raises the possibility of a mitochondrial fatty acid oxidation disorder.

The Effects of Diffuse Traumatic Brain Injury on Mitochondrial Respiratory Complex Activities in the Immature Rat Brain. *B. Cobb*^{1,5}, *T. Chang*^{2,3}, *I.L. Cernak*⁴, *A. Faden*⁴, *L.J. Wong*¹. 1) Institute for Molecular and Human Genetics - Department of Oncology, Georgetown University, Washington, DC; 2) Neurology and Pediatrics, Childrens National Medical Center Washington, DC; 3) Neurology and Pediatrics, George Washington University School of Medicine, Washington, DC; 4) Neuroscience, Georgetown University Medical Center Washington, DC; 5) National Institutes of Health (National Human Genome Research Institute), Bethesda, MD.

Traumatic brain injury (TBI) is a leading cause of death and disability in both adult and pediatric populations. A new developmental model of diffuse TBI indicates different bioenergetic responses to injury in the early immature brain. Therefore, this study examines the respiratory enzyme activities and oxygen consumption rates in the mitochondria in the early immature rodent brain in response to diffuse TBI. Crude mitochondria extracts were isolated from 7 day old male Sprague Dawley (Harlan) rat brain tissue (cortex, subcortex, cerebellum, and hippocampus). The rat pups were injured and sacrificed at 4 and 24 hrs after injury and compared to nave pups. Citrate synthase activity decreased after injury in all four regions of the brain, particularly at 4 hrs post-injury. Comprehensive respiratory chain activity measurements demonstrates increased complex III activity at 4 hours post-injury when normalized to citrate synthase activity. This response is pronounced in the subcortex, cerebellum and hippocampus (3.83 2.31, 1.97 0.89, 2.16 0.04) compared to naves(0.92 0.05, 0.87 0.10, 0.51 0.10) or 24 hrs post-injury (0.97 0.37, 1.32 0.64, 0.3 0.65). These results suggest selective developmental vulnerability of the immature brain in response to injury. Interestingly, complex III is a site of ROS generation. Further studies are underway to investigate the effects of diffuse TBI on mitochondrial membrane potential, ROS production, and ATP production in the early immature brain. .

The mitochondrial DNA G13513A mutation is not a frequent cause of Leigh or MELAS syndrome. *F. Hol, M. Ruiten, M. Siers, C. van den Elzen, H. Scheffer.* Dept Human Genetics, Univ Medical Ctr, Nijmegen, Netherlands.

The G13513A mutation in the mitochondrial complex I subunit gene ND5 has previously been reported in patients with Leigh syndrome, MELAS syndrome and in a single patient with MELAS/LHON-overlap syndrome. Several authors have claimed that this mutation is a frequent cause of MELAS(-like) and Leigh(-like) syndromes (Pulkes et al. 1999; Chol et al. 2003) and that patients suspected to suffer from these syndromes should be routinely tested for this mutation. We selected 300 patients from our records displaying either Leigh-like or MELAS-like symptoms or were shown to have impaired complex I activity in muscle. All subjects were previously found to be negative for common mitochondrial pointmutations at positions 3243, 8344 and 8993. We designed a Pyrosequence assay that allows rapid testing for presence of the G13513A mutation and accurate determination of the level of heteroplasmy. All 300 subjects were tested for this mutation. Only two patients, both displaying a Leigh-like phenotype, were found to be positive. Patient 1 was a male diagnosed to have Leigh syndrome at the age of seven. He was mentally retarded with strabismus, optical atrophy and spastic paresis and he had typical lesions on CT-scan. At age seventeen he developed renal insufficiency for which he needed dialysis. At age 23 he received a hip prosthesis because of cox arthrosis and died shortly after surgery. The mutation was found to be present in muscle (63%) and blood (42%). The second patient is a female diagnosed to have Leigh syndrome at the age of nine. She is now 25 years old and the disease has progressed showing mental deterioration and neurological dysfunction. The mutation was found in muscle (65%) and blood (26%). The mutation was not detected in blood leucocytes of the asymptomatic mother and brother. In conclusion, our results do not support previous statements by others that the G13513A mutation is a frequent cause of Leigh and MELAS (-like) syndromes.

Deficiency in pantothenate kinase 2 in a mouse model for Hallervorden-Spatz Syndrome leads to retinal degeneration and azoospermia. *Y. Kuo*^{1,2}, *J. Duncan*¹, *S. Westaway*³, *H. Yang*¹, *G. Nune*¹, *E. Xu*¹, *S. Hayflick*³, *J. Gitschier*^{1,2}. 1) Univ California, San Francisco; 2) Howard Hughes Medical Institute; 3) Oregon Health and Science University.

Pantothenate-kinase associated neurodegeneration (PKAN, formerly known as Hallervorden-Spatz Syndrome) is a rare but devastating neurodegeneration syndrome, resulting from an inherited defect in coenzyme A biosynthesis. As pathology in the human condition is limited to the inaccessible structures in the CNS, including the retina and globus pallidus, we have generated a mouse knock-out of the orthologous murine gene (*Pank2*). We have discovered that homozygous null mice manifest changes in the eye. Specifically, *Pank2* mice show retinal degeneration with scotopic a-waves and b-waves significantly lower than those of wild-type littermates, decreased cell number and disruption of the outer segment, and reduced pupillary constriction response. The homozygous male mutants are infertile and suffer complete azoospermia, a condition that was not appreciated in the human. In contrast to the human, however, no changes were noted in the basal ganglia by MRI or by histological exam, nor were there signs of dystonia, even following the mice for one year. Dysphagia was also not apparent, although the *Pank2* mice are 20% decreased in weight compared to their wild-type littermates. Immunohistochemistry shows staining consistent with localization of *Pank2* to the mitochondria in both the retina and spermatocyte. In an attempt to elicit a movement disorder, mice were fed on diets deficient in pantothenate acid (B5-depleted) or B5 supplemented (control) diets starting at 5 weeks of age. While wild-type and *Pank2* animals fared poorly, with development of white fur patches, impaired movement and grooming, and decrease in body weights, the *Pank2* mice were more severely affected and died precipitously and simultaneously at 5 months. B5-depleted wild-type animals were sacrificed at 5 months for histological examination. No iron accumulation in the brain, retina or testes was detected, but the testes showed an absence of mature sperm and disorganization in the tubule, similar to the *Pank2* knock-out animals.

Novel mtDNA G3242A and G3244A mutations adjacent to a common A3243G mutation. *M. Mimaki*¹, *I. Nishino*², *I. Nonaka*², *Y. Goto*¹. 1) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, NCNP, Tokyo, Japan; 2) Department of Neuromuscular Research, National Institute of Neuroscience, NCNP, Tokyo, Japan.

Mutations in mitochondrial tRNA Leu (UUR) gene demonstrate marked phenotypic variability, including conditions as diverse as mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). We identified two patients with mitochondrial disorders having a novel mutation in this mitochondrial tRNA gene, a transition at nucleotide position 3242 and 3244, respectively. First patient was a six-year-old girl with typical symptoms of MELAS. Muscle biopsy also showed typical findings of MELAS such as ragged-red fibers (RRF) and strongly SDH-reactive blood vessels (SSV). Total mitochondrial DNA sequencing revealed a heteroplasmic G3242A mutation. Fibroblasts derived from the patient showed complex I deficiency, and the threshold effect on respiratory chain enzyme activities in transmitochondrial cell lines confirmed the pathogenesis of this mutation. Second patient was an eleven-month-old female with lactic acidosis, cardiomyopathy, and renal tubular dysfunction without typical symptoms of MELAS. Muscle biopsy suggested mitochondrial abnormalities but neither RRF nor typical SSV was detected. Fibroblasts derived from the patient showed normal respiratory chain enzyme activities. Sequencing of DNA from muscle and fibroblasts revealed the essentially homoplasmic G3242A mutation, however, it was not detected in blood of her healthy mother, which suggests pathogenicity of the mutation. Although both of these two mutations were adjacent to an A3243G mutation, the most common mutation associated with MELAS, phenotypes of two patients and biochemical effects were quite different. Investigation regarding different effects by the G3244A and G3242A mutations on the phenotypes and similarities shared by the A3243G and G3244A mutations may provide a better understanding of tRNA dysfunction as well as an insight into the complicated issues surrounding the correlation between genotype and phenotype in mitochondrial disorders.

Role of mannose-6-phosphate receptor (M6PR300) in enzyme uptake and glycogen clearance in Pompe disease.

D. Bali¹, A. McVie-Wylie², J. Dai¹, YT. Chen¹. 1) Division of Pediatric Genetics, DUMC, Durham, NC; 2) Pharmacology and Toxicology, Genzyme Corporation, MA.

Pompe disease, a lysosomal glycogen storage disorder resulting from acid -glucosidase (GAA) deficiency, is amenable to enzyme replacement therapy (ERT). MPR300 is necessary for lysosomal enzyme uptake *in vitro*, however it is presently unclear if the same system is involved *in vivo*. We have generated viable tissue-specific MPR300 knockout (KO) mice to investigate this question. To further elucidate the role of MPR300 in recombinant human GAA (rhGAA) uptake and glycogen clearance in Pompe disease, muscle-specific MPR300 KO mice were crossed with GAA KO (Pompe) mice to create double transgenic mice. These mice were administered four weekly doses of 20 or 100mg/kg of rhGAA and sacrificed 3 days after the last dose. Age-matched Pompe mice and mice administered with vehicle were used as controls. Enzyme activity results demonstrated decreased enzyme uptake in the skeletal tissues (quadriceps, gastrocnemius and triceps) and heart of the double KO mice as compared to the Pompe mice (80, 70 and 76 and 50% reduced uptake respectively). Glycogen content data indicated that glycogen clearance in the heart was 77% in Pompe mice as compared to 7% in double KO mice at 20mg/kg dose, although similar glycogen clearance was seen in both mouse models at 100mg/kg dose. In the skeletal muscle, the glycogen depletion was significantly decreased in the double KO mice compared to the Pompe controls (28, 27 and 33% reduction in the double KO mice for the quadriceps, triceps and gastrocnemius respectively, compared to 71, 72 and 74% in Pompe mice). Our data suggests that skeletal muscle and the heart seem to be largely dependent on M6PR for rhGAA enzyme uptake and glycogen clearance *in vivo*, although the heart appears to employ alternative mechanisms for enzyme uptake and glycogen depletion at higher doses of rhGAA besides M6PR. Muscle-specific MPR300 KO mice are an effective animal model to better define the lysosomal enzyme uptake and targeting *in vivo* and this may lead to improvements in ERT currently available for Pompe and other lysosomal storage diseases.

The CPSI T1405N polymorphism is an independent predictor of postoperative pulmonary hypertension in children following congenital heart surgery. *J.A. Canter, M.L. Summar, H.B. Smith, K. Christian, D. Drinkwater, J.L. Haines, F.E. Barr.* Vanderbilt University Medical Center, Nashville, TN.

Pulmonary hypertension (PHTN) is especially dangerous to children following surgical repair of congenital heart anomalies. Added pulmonary vascular resistance, in the setting of decreased right ventricular contractility, creates a perilous low-cardiac output state. Extreme interventions, including inhaled nitric oxide (NO), are required to treat this common complication. In this study, we followed a consecutive cohort of children (N=131) with congenital heart defects requiring open-heart surgery to determine key factors in the development of postoperative PHTN. All children in this cohort had mean pulmonary artery pressure (MPAP) measured by indwelling pulmonary artery catheters placed during surgery. PHTN was defined as a MPAP >20mmHg for at least one hour during the 48 hours following surgery despite pharmacologic intervention. In this cohort, 59% (78/131) children had postoperative PHTN. Age, cardiopulmonary bypass time, and presence of Down syndrome were expected to contribute to this complex phenotype. We also determined the frequency of a well-characterized polymorphism in the CPSI gene, T1405N, that has previously been implicated in the availability of substrate for endogenous NO production. The precursor of endogenous NO is arginine supplied by the urea cycle. CPSI encodes for the enzyme, carbamoyl-phosphate synthetase, which catalyzes the rate-limiting step in the urea cycle. We found a significant difference in the CPSI T1405N polymorphism frequency in patients developing postoperative PHTN compared to those without PHTN (P=0.03). The logistic regression model constructed from these variables (log likelihood = -72.8) revealed that age (OR=0.92, 95% CI 0.87-0.98), presence of Down syndrome (OR=5.24, 95% CI 1.11-24.77) and CPSI T1405N genotype (CC genotype vs. AC genotype, OR= 4.08, 95% CI 1.04-16.04 and CC genotype vs. AA genotype, OR= 5.97, 95% CI 1.54-23.15) were independent predictors of postoperative PHTN. Accurate prediction of susceptibility to postoperative PHTN will likely need to take into account the genetic variation in urea cycle capacity.

GNE enzyme activity in Hereditary Inclusion Body Myopathy. *S. Sparks*¹, *C. Ciccone*¹, *M. Lalor*¹, *E. Orvisky*², *D. Krasnewich*¹, *M.-S. Sun*¹, *M. Dalakas*³, *W. Gahl*¹, *M. Huizing*¹. 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD; 2) NBS, NIMH, NIH, Bethesda, MD; 3) NINDS, NIH, Bethesda, MD.

UDP-GlcNAc 2-epimerase/ManNAc kinase, encoded by *GNE* on 9p12-13, is the bifunctional and rate-limiting enzyme in the biosynthesis of sialic acid. The epimerase converts UDP-GlcNAc to ManNAc and the kinase converts ManNAc to ManNAc-6-phosphate. Mutations in either or both the epimerase and kinase domains of *GNE* cause Hereditary Inclusion Body Myopathy (HIBM), an autosomal recessive disorder characterized by adult-onset, progressive distal and proximal muscle weakness sparing the quadriceps muscles. We employed cultured fibroblasts and a cell-free transcription/translation system to investigate the epimerase and kinase activities of 3 HIBM patients and their individual *GNE* mutations. The cell-free system allows the measurement of GNE activity without influences from other enzymes present in the fibroblasts.

In cultured fibroblasts from HIBM patients, residual epimerase activity ranged from 38% to 83% of normal. However, when the same patient mutations were cloned into *GNE* and the resulting protein translated in the cell-free system, the GNE-epimerase activity was negligible compared to wild type *GNE*. We conclude that fibroblasts contain enzymes, besides GNE, that convert UDP-GlcNAc to ManNAc. Kinase activity in cultured fibroblasts from an HIBM patient with a homozygous 2186T>C mutation was 26% of normal. When this same mutation was cloned into *GNE* and expressed in the cell-free system, the GNE-kinase activity was 28% of normal. This indicates that there is residual *in vivo* kinase activity in HIBM patients, and this activity may be necessary for survival. Further evidence of this is the embryonic lethality of the *GNE* knock-out mouse.

Comparison of GNE epimerase and kinase activity in both systems will help to explain the phenotype of HIBM patients with specific mutations in the epimerase or kinase domains.

Mutation Analysis of 25 Colombian Gaucher Disease Patients using dHPLC: Report of three novel mutations.

M.A. Cabrera-Salazar¹, R.J. Pomponio², O.Y. Echeverri¹, G. Miller³, L.A. Barrera¹. 1) Instituto de Errores Innatos del Metabolismo. Pontificia Universidad Javeriana. Carrera 7 No 43-82 Edificio 53, Lab 305 ABogot - Colombia; 2) Pharmacogenetics- Clinical Laboratory Science, Genzyme Corporation, Framingham, MA 01701; 3) Genetics, Genzyme Corporation, Framingham, MA 01701.

Gaucher Disease is the most common of the lysosomal storage disorders, affecting all ethnic groups. The pathology of this recessively inherited disease arises from the accumulation of glucocerebroside in tissues due to deficient activity of the enzyme glucocerebrosidase (E.C. 3.2.1.45). The glucocerebrosidase (GBA) gene spans a 7.2 kb fragment located on locus 1q21, consisting of 11 exons and 10 Introns. Located 16kb downstream is a highly homologous pseudogene sequence (Horowitz, 1989). Fourteen fragments comprising 11 exons of the GBA gene were analyzed in DNA samples from 25 Colombian patients using denaturing High Pressure Liquid Chromatography (dHPLC). Sequencing of abnormal findings led to the discovery of three novel mutations (595-596delCT, 898delG and N380H in exons 6, 7 and 9 of the GBA gene) with high prevalence among Colombian patients. We have also found the presence of a double mutation (L444P-E326K) in two different families classified as Gaucher Type 1. This mutation was previously reported in one patient with Gaucher type 2.

Identification of Seven Novel Mutations in the Alpha Glucosidase Gene in Argentinian Patients with Glycogen Storage Disease Type II. *N.A. Chamoles¹, R.E. Palmer², R.J. Pomponio².* 1) Neurochemistry Laboratory, Buenos Aires, Argentina; 2) Pharmacogenetics, Clinical Laboratory Science, Genzyme Corporation, Framingham, MA 01701.

Glycogen Storage Disease II (GSDII) is an autosomal recessive disorder caused by a deficiency in acid alpha glucosidase (GAA), the enzyme required to hydrolyze lysosomal glycogen to glucose. In the absence of sufficient quantities of functional enzyme, glycogen accumulates within lysosomes resulting in cardiac and skeletal muscle dysfunction. Disease severity varies among patients and is differentially classified as either infantile, juvenile, or adult, based on age of onset and clinical severity. From 12 Argentinian patients who were diagnosed with various forms of GSDII based on biochemical analysis of GAA function, we have identified 7 novel mutations (236_246del, 377G>A, 1397T>G, 1755-1G>A, 1802C>G, 1978C>T, and 2608C>T). Three different families displayed the g.377G>A allelic variant encoding a truncated form of GAA (p.Trp126Ter), suggesting a high frequency among a subset of Argentinians. Additionally, we identified a single patient presenting with juvenile onset disease who was heterozygous for g.1978C>T encoding for p.Arg660Cys. A previous association with an amino acid substitution at this position (Arg660His) and juvenile disease in two Japanese patients suggests a possible correlation with changes at this amino acid and less severe disease. The identification of novel mutations, as well as supporting evidence for previously identified genotype/phenotype associations, demonstrates the importance of continued mutational analysis in populations from diverse geographic locations.

Mutation and biochemical analysis of patients belonging to the *cbIB* complementation class of vitamin B12-dependent methylmalonic aciduria. *J.P. Lerner-Ellis*¹, *C.M. Dobson*⁵, *T. Wai*¹, *D. Watkins*¹, *J.C. Tirone*¹, *C. Dore*⁴, *P. Lepage*⁴, *R.A. Gravel*⁵, *D.S. Rosenblatt*^{1,2,3,4}. 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Biology, McGill University, Montreal, Quebec, Canada; 3) Medicine, McGill University, Montreal, Quebec, Canada; 4) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada; 5) Department of Biochemistry and Molecular Biology, University of Calgary, AB, Canada.

The *cbIB* disorder is a rare inborn error of vitamin B₁₂ (cobalamin, Cbl) metabolism that occurs due to mutations in the *MMAB* gene, which encodes the enzyme ATP:cobalamin adenosyltransferase. This disorder results in decreased synthesis of the cobalamin derivative adenosylcobalamin (AdoCbl). AdoCbl is required for activity of the mitochondrial enzyme methylmalonyl CoA mutase (MCM), which catalyzes the isomerization of methylmalonyl CoA to succinyl CoA. Deficient MCM activity results in methylmalonic acidemia and methylmalonic aciduria and a susceptibility to life-threatening acidotic crises. Seven mutations in the *MMAB* gene have previously been identified in *cbIB* patients. In this study, we have investigated a panel of eighteen *cbIB* patients. Cultured fibroblasts from all patients had decreased synthesis of AdoCbl from exogenous labeled cobalamin and decreased incorporation of [¹⁴C] propionate into cellular macromolecules, an indirect measure of MCM activity. Diagnosis of the *cbIB* disorder was confirmed in all cases by complementation analysis. Genomic DNA from patients was analyzed for deleterious mutations in the *MMAB* gene. Six novel mutations were identified, and of the seven previously identified mutations, four were found in at least one additional patient. None of these mutations were identified in one hundred control alleles. In total, thirteen mutations have now been identified in eighteen *cbIB* patients.

Identification of 6 Novel Mutations in the Acid Alpha Glucosidase Gene Associated with Infantile-Onset Pompe Disease. *R.E. Palmer¹, J. Abysalh², C. Braithwaite², A. McPhee², L. Smith², L. Atwater², C. Sung², S. Richards², R.J. Romponio¹.* 1) Clinical Laboratory Science, Pharmacogenetics, Genzyme Corporation, Framingham, MA. 01701; 2) Department of Immunology, Genzyme Corporation, Framingham, MA 01701.

Pompe disease (Glycogen storage disease II) is an autosomal recessive lysosomal storage disease resulting from mutations within the acid alpha glucosidase gene (GAA). Patients with Pompe disease accumulate lysosomal glycogen and display a spectrum of disease severities. The most severely affected infantile-onset patients present with generalized muscular weakness and cardiac hypertrophy that lead to death before 1 year of age. We have evaluated a group of 10 infantile-onset patients for mutation status and GAA protein expression and have identified twenty distinct GAA mutations including six that are novel. Patients carrying missense mutations on one or both alleles express varying levels of processed and unprocessed GAA suggestive of some functional heterogeneity. A single patient with two truncating mutations has no detectable protein supporting previous findings that truncated forms of GAA are not expressed. One novel mutation results in loss of the initiator methionine of the protein (g.3G>A). Western blot analysis of protein derived from patient fibroblasts reveals low levels of aberrantly sized products that may represent use of alternative translational initiation sites. This analysis demonstrates that, although over 100 different disease-associated GAA variants have already been identified, continued genotyping efforts yield novel findings that may enhance our understanding of genotype/phenotype associations.

Mutation spectrum of the human ATP7B gene of Korean patients with Wilson Disease. *S-W. Park¹, G-H. Kim¹, H-W. Yoo^{1, 2}*. 1) Genome Research Center for Birth Defects & Genetic Disorders, Asan Medical Center, Seoul, Korea; 2) Department of Pediatrics, Asan Medical Center, Univeristy of Ulsan College of Medicine, Seoul, Korea.

Wilson disease (WD) is an autosomal recessive disorder of copper transport, probably one of the most common inherited metabolic disorder in Korea. The product of WD gene is a copper transporting P-type ATPase(ATP7B). In this study, efforts have been made to identify novel mutations and investigate an allele frequency of each mutation in Korean patients with WD. This study includes 115 unrelated Korean patients diagnosed as WD by clinical and biochemical findings; a low serum ceruloplasmin (<15mg/dL) and increased urinary copper excretion (>100ug/day). Initially, direct genomic DNA sequencing of PCR products of exon 8, 11, and 16 was performed to screen common mutations (R778L, A874V, N1270S) in Korean WD patients, subsequently the exons 10,13,14,15 and other exons were analyzed. If no mutation was found, promoter region was evaluated. We identified 23 different mutations in 115 unrelated Korean patients with WD: R778L, A874V, N1270S, c.2513delA, G1035V, T1029I, L1083F, c.2630-2656del, c.2304-2305 insC, IVS3 +1 G>T, V1106I, M729V, D1267A, C656X, A1168S, G943S, R919G, I1148T, G891D, P992L, G1186S, and T1031A. Among these mutations, seven mutations were novel; C656X, M729V, G891D, V1024A, T1029I, T1031A, V1106I. We characterized molecular defects of the ATP7B gene in only 72% of Korean Wilson patients. The R778L is the most common mutation with 38.7% of allele frequency that is more prevalent than previously reported in Korean patients. The other common mutations are A874V, N1270S and 2513delA. Their allele frequencies are 7.4, 5.6, and 4.0% respectively. Most patients carrying aforementioned mutations are compound heterozygotes, which hinders making a genotype-phenotype correlation. In conclusion, the spectrum of mutations in the ATP7B gene of Korean patients with Wilson disease is very heterogeneous, although the R778L mutation is the most common.

Persistence of 3-hydroxyisovaleryl carnitine in blood spots of infants born to mothers with 3-methylcrotonylglycinuria. *A.A. Basinger, D.M. Frazier, J. Muenzer.* Pediatrics, University of North Carolina, Chapel Hill, NC.

Expanded newborn screening with tandem mass spectroscopy allows detection of additional inborn errors of metabolism in infants, and in some cases, mothers of screened infants. The most common organic aciduria identified by newborn screen (NBS) in North Carolina (NC) is 3-methylcrotonyl-glycinuria, caused by deficiency of 3-methylcrotonyl-CoA carboxylase (3-MCC), an enzyme in the degradation pathway of leucine. Since 1997, 801,744 children have been screened by the NC NBS program and 17 identified with 3-MCC deficiency. A blood spot (BS) 3-hydroxyisovaleryl (C5-OH) carnitine of 2.60 M on initial NBS or 1.36 M on initial and repeat NBS suggests 3-MCC deficiency. In NC, confirmatory testing includes plasma acylcarnitine profile, carnitine, urine organic acids, and biotinidase. Six previously undiagnosed women were identified with 3-MCC deficiency after their infants had positive NBS and negative confirmatory testing. Infants of affected mothers had initial BS C5-OH carnitines of 6.312.61 M and repeat values of 5.381.81 M, similar to infants with confirmed 3-MCC deficiency (5.023.71M). BS C5-OH carnitine increased in 4/9 children of affected mothers between the initial and repeat NBS. Elevated BS C5-OH carnitines persisted in three infants up to 2 months. Mothers' levels of BS C5-OH carnitine were 8.12-33.0 M. Four mothers reported good general health. One had chronic joint pain and fatigue that responded to supplemental carnitine and a protein-restricted diet. One reported occasional episodes of emesis with mild illnesses and after high-protein meals. Proposed mechanisms for persistence of BS C5-OH carnitine in infants of affected mothers include delayed maturation of 3-MCC or intracellular retention of C5-OH carnitine. Of 23 infants identified with elevated C5-OH carnitine on initial and repeat NBS, 6 (26%) were infants of mothers with 3-MCC deficiency. The addition of a maternal BS acylcarnitine profile to confirmatory testing would allow prompt differentiation between infant and maternal 3-MCC deficiency.

Cerebral complications and treatment of Cobalamin C deficiency. *V. Cunningham¹, P. Laoprasert¹, M. Matthews¹, T. Bottiglieri², K. Hyland², S. Stabler¹, S. Zeisel³, C. Freehauf¹, J. Van Hove¹.* 1) Depts of Pediatrics, Pathology and Medicine, Univ of Colorado Health Sciences Ctr, Denver, CO; 2) Institute of Metabolic Disease, Baylor Univ Med Ctr, Dallas, TX; 3) Dept of Nutrition, School of Medicine, Univ of North Carolina, Chapel Hill, NC.

Cobalamin C disease is a disorder of vitamin B12 metabolism with methylmalonic (MMA) aciduria and homocystinuria. Current treatment with parenteral hydroxycobalamin (OH-Cbl), oral betaine and folate improves biochemistry and neurologic outcome but in infants mental retardation is still frequent. Here we explored reasons for this poor outcome. A 2 week old male presented with hard-to-control seizures, methylmalonic aciduria, and hyperhomocysteinemia. Fibroblast studies confirmed cobalamin C deficiency. A gyral cortical malformation was identified on EEG, MRI, and ictal PET studies and he underwent partial frontal cortex resection for seizure control. Pathology showed cortical dysplasia with severe neuronal migrational defects. We did not identify previous literature reports of cortical migrational defects in this disorder. Without such extensive studies these malformations may be under-recognized. Initial therapy of OH-Cbl 1 mg/d (285 g/kg/d) IM, and betaine 200 mg/kg/d reduced serum MMA from 21,455 to 1595 nmol/l (normal 73-271) and homocysteine from 140 to 21 mol/l (normal 4-12). Maintaining betaine but increasing OH-Cbl up to 5 mg SC daily did not further reduce serum MMA and homocysteine. CSF analysis on initial therapy showed elevated MMA 23,299 nM (normal 73-271), and homocysteine 1238 nmol/L (normal 32-79), but reduced methylfolate 31 nmol/L (normal 40-187) and choline 1.27 mol/l (normal 1.4-2.2), indicating inadequate biochemical control behind the blood-brain-barrier. Options for improvement of cerebral biochemistry may include folinic acid and choline substitution, and higher OH-Cbl doses. On added choline 125 mg/kg/d and folinic acid 5 mg/d, and on 1 mg/d (178 g/kg/d) OH-Cbl and 135 mg/kg/d betaine, CSF showed increased MMA 73,315 nM, decreased homocysteine 697 nmoles/L, and improved methylfolate 182 nmol/L. Such strategies should be explored to improve cerebral biochemical control and neurologic outcome.

Branched chain amino acid metabolites in plasma and urine acylcarnitine analyses. *S.E. McCandless¹, P.E. Minkler², M.K. Stoll², C.L. Hoppe^{2,3}*. 1) Center for Human Genetics, Case Western Reserve University and University Hospitals of Cleveland, Cleveland, OH; 2) Medical Research Service, Louis Stokes Department of Veterans Affairs Medical Center, Cleveland, OH; 3) Departments of Pharmacology and Medicine, Case Western Reserve University School of Medicine, Cleveland, OH.

Two recently identified deficiencies (isobutyryl-CoA dehydrogenase and 2-methylbutyryl-CoA dehydrogenase) involve the metabolism of the branched chain amino acids valine and isoleucine. The markers identified in MS/MS newborn screening programs for these disorders are isomers of C4 and C5 acylcarnitines. Our laboratory uses HPLC/MS to resolve and identify these and other isomeric acylcarnitines that can't be resolved by MS/MS. We use standardized solutions of isobutyrylcarnitine (IB) and 2-methylbutyrylcarnitine (2-MB) to generate multiple point standard curves, allowing quantitation of IB and 2-MB in patient samples. Initially, the normal range was defined by samples from a small number of normal adult volunteers. We now present data from accumulated samples showing the range of values seen in patients referred for evaluation (presumably most with some clinical indication). IB was found in roughly half of the plasma samples (range 0 to 2.15 mol/L, 97th %ile 0.38 mol/L, N=1806), and in 90% of urine specimens (range 0 to 156.3 mol/g creatinine, 97th %ile 39.8, N=1117). None of the samples were from patients known to have isobutyryl-CoA dehydrogenase deficiency, although the definitive diagnosis was not determined in all cases. More samples (88%) had 2-MB in plasma (range 0 to 2.89 mol/L, 97th %ile 0.36, N=1706), while 92% of urine samples had measurable quantities (range 0 to 260.5 mol/g creatinine, 97th %ile 29.9, N=1062). It is important to note that the plasma 2-MB concentration in a patient with known deficiency was elevated, but the value was similar to values seen in individuals on L-carnitine therapy for a variety of other disorders. This study shows that the range of values seen for these metabolites in many of the samples referred to the laboratory is higher than expected based on a small number of normal controls.

Genetic and Genomic Systems to Study Methylmalonic Acidemia (MMA). *C. Venditti*¹, *R. Chandler*¹, *M. Tsai*², *N. Wehrli*², *R. Deering*², *K. Kaestner*², *G. Giaever*³, *H. Kazazian*². 1) GDRB, NHGRI/NIH, Bethesda, MD; 2) University of Pennsylvania, Philadelphia, PA; 3) Stanford Genome Technology Center, Palo Alto, CA.

Nematode, yeast and murine models have been developed to study methylmalonic acidemia. We identified homologues of PCCB, MMAA, MMAB, MMCM, and MMCR in *C. elegans* and cloned them as full-length cDNAs for feeding interference. RNAi directed against MMAA, MMAB, and MMCM caused the animals to produce >30,000 nM methylmalonic acid (MMA) in the incubation media after interference and substrate loading, which corresponded to a 4-5 fold increase over WT. This system can be used to examine chemical and genetic modifiers of propionyl-CoA metabolism and to identify cobalamin metabolic candidate genes using the genomic resources of *C. elegans*. To identify cellular targets of MMA toxicity, we performed chemogenomic profiling using yeast exposed to either three percent or 100 uM MMA. Genes encoding MMA sensitivity loci were identified using whole genome parallel analysis. A diverse set of >50 mutants, corresponding to known or predicted yeast genes, identified potential targets of MMA toxicity. These include proteins involved in vesicle formation, gluconeogenesis, neutral amino acid transport and the glycine cleavage system. Two mutants displayed extreme sensitivity to MMA. One encodes a vacuolar H-ATPase regulatory subunit b that is mutated in a human syndrome of distal renal tubular acidosis and deafness. The other has homology to phosphoglycerate mutase, a key enzyme of gluconeogenesis and glycolysis. These mutants may help understand the perturbation of intermediary metabolism seen in MMA and have allowed a simple yeast growth assay, demonstrating concentration dependent MMA toxicity, to be created. This system will enable yeast genetics to be used to study MMA toxicity. Finally, we have created a mouse model of methylmalonyl-CoA mutase deficiency. The mice display many features seen in the human condition, including massive elevation of MMA in body fluids, and perish shortly after birth. These diverse model organism systems will allow the human condition to be studied using modern genomic and genetic methods, and should facilitate the development and testing of new therapies for MMA.

Molecular analysis of Peroxisome Biogenesis Disorders. *N. Shimozawa*^{1,2}, *T. Nagase*², *Y. Suzuki*³, *N. Kondo*², *R.J.A. Wanders*⁴. 1) Life Science Research Center, Gifu University, Gifu, Japan; 2) Department of Pediatrics, Gifu Univ Sch of Med, Gifu, Japan; 3) Medical Educat Develop Center, Gifu Univ Sch of Med, Gifu, Japan; 4) Dept of Clin Chem and PEDIATR, Univ of Amsterdam, Netherlands.

Peroxisome biogenesis disorders (PBD) are genetically heterogeneous diseases with an autosomal recessive inheritance. We have analyzed the PBD at the molecular level, as the only diagnostic center for peroxisomal disorders in Japan. (1) We identified a total of 32 Japanese PBD patients, those were subdivided into 6 complementation groups (CG). (2) We demonstrated two common mutations: a G89R mutation of PEX26 in all patients from CG-A and a 2 base pair deletion of PEX10 in all patients from CG-B, homozygously. To determine whether the high frequency of these mutations are due to a founder effect, we analyzed SNPs in these genes among the patients and Japanese controls, which suggested that both mutations arose once on an ancestral chromosome in the Japanese population, respectively. (3) So far, 12 different CG of PBD were identified in the world. To date, we have identified a new CG-K of PBD with PEX14 as the defective gene. Human PEX14 rescues the import of a PTS1-dependent as well as a PTS2-dependent protein into the peroxisomes in fibroblasts from a patient with Zellweger syndrome belonging to the CG-K. This patient was homozygous for a nonsense mutation in a putative coiled-coil region of PEX14, Q185X. We showed that the patients fibroblasts lacked PEX14 as determined by immunocytochemical analysis. These findings indicate that there are 13 genotypes in PBD and that the role of PEX14 is also essential in humans.

Glucocorticoid receptor gene polymorphisms: frequencies and impact on ALL outcome. A. Gahier-Rudolf, A. Doreau, D. Labuda, D. Sinnott, A. Moghrabi, M. Krajcinovic. Hemato-oncology dept, Research center, Ste-Justine hospital, Montréal, Canada.

Corticosteroids (CS) modulate a large number of physiological functions that, along with their anti-proliferative effect, explain the wide therapeutic spectrum of synthetically derived counterparts. The acute lymphoblastic leukaemia (ALL) is the most frequent pediatric cancer, whose treatment beside other anti-tumor agents, comprises CS drugs as an important component. However, the response to CS is not always optimal: at relapse, loss of *in vitro* sensitivity to CS is common, whereas various side effects have been also reported. CS exert their action through binding to the glucocorticoid receptor (GR), which then acts as a transcriptional regulator of responsive genes rendering GR polymorphisms potential modulators of CS response. We have previously shown that Bcl I polymorphism in GR locus correlated with overall survival probabilities in childhood acute lymphoblastic leukemia (ALL) while Arg23Lys and Asn363Ser polymorphisms did not seem to play a role. In order to further explore the variability of this gene and its impact on ALL outcome, the regulatory gene region (2 kb upstream of the transcription initiation site) was searched for the sequence variability by dHPLC, followed by direct sequencing. Four polymorphisms comprising C to T, A to C, G to A and A to G base substitutions were identified. Analysis of DNA samples of 174 individuals from a number of populations (Africans, Asians, Amerindians, Middle-Easterners, and European) revealed low frequency (below 1%) for the first two base substitutions. Of interest were a G to A transversion confined only to Africans (2.9%), and an A to G polymorphism with frequencies of 5%, 2.9% and 1.4 % in Europeans, MiddleEasterners and Africans, respectively. The latter polymorphism was subsequently analyzed in 237 children of European descent that were treated for ALL at Ste-Justine Hospital, Montreal. The GG genotype was associated with reduced relapse free survival probabilities ($p=0.03$) indicating its potential for the prediction of recurrent disease (supported by Cancer Research Society and Genome Quebec).

Pharmacogenetic analysis of multiple sclerosis: identification of potential response markers for Glatiramer

Acetate treatment. *I. Grossman*^{1,2}, *N. Avidan*², *C. Singer*^{2,3}, *D. Goldstaub*³, *L. Hayardeny*³, *E. Ben-Asher*², *M. Chemla*², *T. Paperna*¹, *J.S. Beckmann*⁴, *D. Lancet*², *A. Miller*¹. 1) Division of Neuroimmunology and MS Center, Rappaport Faculty of Medicine, Technion, Haifa; 2) Department of Molecular Genetics, Weizmann Institute of Science, Rehovot; 3) TEVA Pharmaceutical Industries Ltd. Kiryat Nordau, Netanya; 4) Service of Medical Genetics, Centre Hospitalier Universitaire Vaudois, Lausanne.

Evidence is accumulating to indicate that response patterns to drugs are at least partly under genetic control. For a disease such as Multiple Sclerosis the evaluation of patients' response to drug treatment may take up to 2 years. During this time a significant deterioration in health may amass. For this reason, a diagnostic tool that will allow the allocation of drugs and their doses, based on objective genetic screening, may have a considerable impact on patient-care and health management. The field of pharmacogenetics is aimed at seeking such solutions by testing the potential associations between genetic markers, such as single nucleotide polymorphisms (SNPs) or their haplotypes, and drug response. In an exploratory study with this future goal in mind, we have genotyped 63 SNPs within 27 candidate genes likely to be involved in the presumed mode-of-action of the Multiple Sclerosis drug Glatiramer Acetate and its clinical response features. DNA samples were obtained from two different clinical trials, each of which was analyzed separately since they involved different populations and primary clinical endpoints. A number of candidate genes were found to be significantly associated with different response definitions. An overlap of associations between the two independent cohorts tested corroborates the robustness of the results. The fact that significant association is found despite the rather limited number of patients and SNPs studied, may indicate that the Glatiramer Acetate drug response is under the genetic control of a limited number of genes, each potentially having a rather pronounced effect. Taken together, our results indicate that the goal of personalized treatment for multiple sclerosis and possibly other autoimmune diseases may be within reach.

The influence of three polymorphisms of thymidylate synthase gene on the TS mRNA levels. *M. Primeau*¹, *M. Krajinovic*^{1,2}. 1) Hemato-oncology dept, Centre de recherche de l'Hôpital Sainte-Justine, Montréal; 2) Pediatrics dept, Université de Montréal; Montréal, Québec, Canada.

Interindividual variability in response to TS inhibitors could be caused by variable levels of thymidylate synthase (TS). A polymorphism in the 5UTR consisting of either two or three 28bp repeats modulate TS mRNA expression. Individuals that are homozygous for the triple repeat (3R) were found to have elevated RNA and protein levels compared with double repeat (2R) homozygotes. The presence of additional USF binding site seems to explain the higher transcriptional activity of 3R allele. A GC polymorphism within the second 28bp repeat element has been recently described. This substitution changes a critical residue in the USF consensus element rendering 3RC and 2R alleles with comparable transcriptional activity, as shown *in vitro*. In addition, a 6bp deletion in 3UTR seems to affect TS mRNA stability, decreasing mRNA levels. With the aim to understand the underlying mechanism of genotype-phenotype correlation in leukemia clinical settings, we analyze the impact of three reported TS polymorphisms on TS mRNA levels. Both normal and leukemia blood cells originating from 48 healthy donors and 32 patients with ALL were analyzed. The genotyping was performed by PCR followed by gel electrophoresis (TS repeat), enzyme digestion (GC polymorphism) or ASO (6bp deletion). TS mRNA levels were assessed by real-time PCR standardized to the expression of 2-microglobulin. The comparison between groups was done by ANOVA. No correlation was found between 3R allele or 6bp deletion and TS mRNA levels in either normal or leukemia cells. To explore the effect of tandem-repeat and GC polymorphisms on TS expression, the genotypes were combined according to the number of USF sites. The individuals whose genotypes contain 3 USF sites tended to have slightly higher mRNA levels ($p=0.08$) compared to those with 2 sites. The difference was seen in ALL samples only. High intra-group variability suggests the presence of additional factors relevant for TS expression.

VKORC1 Haplotypes Predictive for Warfarin Dose. *M. Rieder¹, A. Reiner¹, D. Nickerson¹, D. Blough¹, J. Smith¹, D. Veenstra¹, B. Gage², H. McLeod², C. Eby², A. Rettie¹.* 1) University of Washington, Seattle, WA; 2) Washington University, St. Louis, MO.

Warfarin is the definitive treatment for the long-term prevention of thromboembolic events, but poses considerable dose management problems because of its narrow therapeutic range, ethnic differences in dose requirements and inter-individual variability in dosing. Recently, the pharmacologic target for warfarin, vitamin K epoxide reductase (VKORC1) was identified. We hypothesized that SNPs in VKORC1 may affect the warfarin dose for patients on chronic warfarin therapy. An extended genomic region surrounding the VKORC1 gene (11.2 kb) was resequenced in 186 European American warfarin patients, who were treated to establish a therapeutic warfarin dose, and multi-ethnic controls (119 European Americans, 96 African Americans and 120 Asian Americans). We identified ten noncoding, common SNPs (>5% MAF) and inferred haplotypes in both the European clinical and control cohorts. Five common haplotypes were identified in the European clinical samples and multiple linear regression was used to evaluate their association with daily warfarin dose. Four haplotypes (H1, H2, H7, and H9) were significantly associated ($p < 0.05$) with warfarin dose. Furthermore, these haplotypes were grouped into clades A (low warfarin dose) and B (high warfarin dose), containing haplotypes H1 and H2 (clade A) and H7 and H9 (clade B), respectively. Clade diplotypes (AA, AB, BB) assigned to each patient were also significantly associated with warfarin dose (AA=2.70.8 mg/d, AB=4.91.9, BB=6.22.9; MeanSD). Overall, the proportion of warfarin dose variance explained by VKORC1 clades A and B was 25%. These VKORC1 results were replicated in an independent cohort ($n = 327$) of European American patients. We also identified a haplotype distribution in Asian and African American populations that is consistent with their lower and higher warfarin dose phenotypes, respectively. Prospective genotyping for VKORC1 SNPs and haplotypes may lead to more accurate initial dosing and quicker time to stable anticoagulation, thereby improving the safety, effectiveness, and costs of warfarin therapy.

CYP2B6 Genotype and Nicotine Metabolism. *H.Z. Ring¹, A.M. Valdes¹, D. Katsuyoshi¹, P. Jacob², R. Walton³, G.E. Swan¹, N.L. Benowitz².* 1) SRI International; 2) University of California, San Francisco; 3) University of Oxford.

CYP2B6 metabolizes nicotine and many therapeutic drugs including bupropion. An amino acid changing polymorphism K262R in CYP2B6 has been associated with a higher clearance of bupropion, though its effect on other CYP2B6 substrates remains to be evaluated. In this study, we investigated whether four genetic variants of the CYP2B6 gene (R22C, Q172H, K262R and R487C) were associated with nicotine and cotinine plasma pharmacokinetic measures in 212 healthy Caucasian volunteers (mean age 41.3 years, 72.2% female) in an in vivo nicotine and cotinine metabolism study of adult twins. We observed that the variant genotype at CYP2B6 K262R was associated with significantly higher nicotine clearance (R/R>R/K>K/K, $p<0.008$). Furthermore, compared with 262 K/K subjects, individuals carrying one or two variant 262R allele were also associated with significantly higher cotinine clearance ($p<0.005$) and lower cotinine half-time ($p<0.007$). These differences remained significant after adjustment for non-independence between twins in a pair using a bootstrap procedure. This is the first investigation of CYP2B6 genotype and nicotine metabolism in vivo. Our results provide evidence that the CYP2B6 enzyme plays a role in nicotine and cotinine metabolism and suggest that variants at this gene should be further investigated for their potential role in mediating individual susceptibility to nicotine dependence and tobacco-related diseases. Research supported by National Institute of Drug Abuse grant DA016382. CORRESPONDING AUTHOR: Huijun Z. Ring, Ph.D., Center for Health Sciences, SRI International, 333 Ravenswood Ave., Menlo Park, CA 94025; huijun.ring@sri.com.

CYP1A2*1F allele predicts risk of liver toxicity in children prescribed acetaminophen following surgery. *L.J. Sheffield¹, J.M. Wood¹, L.P. James², J. Roche¹, G.A. Chalkiadis¹, D.J. Venter¹, J.J. Pitt¹, A.J. Davidson¹, N.E. Cranswick¹.* 1) Genetic Health Services Victoria, Intensive Care, Anaesthetics, Cancer Genomics, Clinical Pharmacology, Murdoch Childrens Research Institute, University of Melbourne, Melbourne, Victoria, Australia; 2) Pharmacology and Toxicology, University of Arkansas for Medical Sciences, Little Rock, AR.

Acetaminophen, (paracetamol), is used extremely widely as an analgesic in the community. We show that CYP1A2 alleles predict if there is a risk of liver toxicity on exposure to therapeutic dosages of paracetamol. Overdose of acetaminophen is a well-known cause of liver failure due to hepato-cellular necrosis. Case reports have suggested liver toxicity may occur in some children who have been given therapeutic dosages of acetaminophen. We report a pharmacogenetic study of 95 children given paracetamol for pain relief following surgery. Hepatic transaminases were measured as was the level of 3-(cystein-S-yl)-acetaminophen protein adducts (3-Cys-A). 3-Cys-A adducts are found in the liver and serum of laboratory animals treated with toxic doses of acetaminophen and are a highly specific biomarker of acetaminophen toxicity. The relationship between occult liver toxicity and the individuals genotype was investigated by genotyping for functional polymorphisms of the three CYP450 genes known to be involved in the oxidation of acetaminophen to the reactive metabolite, NAPQI. The polymorphisms tested were CYP2E1*5A, CYP2E1*5B, CYP2E1*6 CYP2E1*7A, CYP2E1*7B, CYP2E1*7C, CYP1A2*1F, CYP1A2*6, CYP3A4*, CYP3A4*18. Only the CYP1A2*1F polymorphism, (CYP1A2 gene), correlated with our measures of liver toxicity. For cases with a value for aspartate aminotransferase (AST) >100 there were 16/82 children who had allele A of CYP1A2*1F and 0/26 with allele C (the wild type) ($p=.03$). When those having an increased level of 3-cys-A were included 20/82 had allele A and 0/26 had allele C ($p=.01$). Children with allele A (polymorphism) were the only ones with measures of liver toxicity, and no toxicity was seen with allele C (wild type). The risk for occult liver damage for patients homozygous for AA was 1 in 3 whilst AC and CC seemed highly protective.

Program Nr: 1835 from the 2004 ASHG Annual Meeting

UDP-Glucuronosyltransferase 2B7 Genotype and Cotinine Glucuronidation. *A. Valdes¹, D. Katsuyoshi¹, P. Jacob III², N.L. Benowitz², G.E. Swan¹, H. Ring¹.* 1) SRI International, Menlo Park, CA; 2) University of California, San Francisco.

Glucuronidation plays a major role in the detoxification of many tobacco toxins and is carried out by UDP-glucuronosyltransferases (UGTs). Cotinine is a major constituent of cigarette smoke. In this study, we investigated the relationship between the UGT2B7 His268Val polymorphism and rate of cotinine glucuronidation in urine in 246 Caucasian and Hispanic participants (mean age 41.9 years, 61.9% female) in an in vivo nicotine and cotinine metabolism study of adult twins. We found that Tyr-Tyr homozygotes at UGT2B7 position 268 had a lower cotinine glucuronide to total cotinine ratio (0.210.01) than UGT2B7-268 His carriers (0.260.01, $p < 0.003$). The difference remained statistically significant after taking into account the non-independence between twins in a pair using a bootstrap procedure. This is the first investigation of UGT2B7 genotype and cotinine glucuronidation in vivo. Our result is consistent with published data indicating a significantly lower glucuronidating rate among UGT2B7-268 Tyr-Tyr homozygotes for other tobacco-specific metabolites (NNAL) in liver microsomes. A reduction in the rate of glucuronidation may cause the accumulation of tobacco toxins in the body and lead to an elevated risk of cancer. Additional studies are needed to further examine the potential role of UGT2B7 genotype in susceptibility to tobacco-related cancers. Research supported by University of California - Tobacco-Related Disease Research Program grant 12KT-0234. CORRESPONDING AUTHOR: Huijun Z. Ring, Center for Health Sciences, SRI International, 333 Ravenswood Ave., Menlo Park, CA 94025; huijun.ring@sri.com.

Effect of genetic polymorphisms in γ -glutamyl carboxylase (GGCX) and microsomal epoxide hydrolase (EPHX1) on vitamin K cycle activity in warfarin-treated patients. *M. Vecsler^{1,2}, E. Gak^{1,2}, S. Almog^{1,2}, R. Loebstein¹, D. Kurnik¹, N. Austerweil^{1,2}, B. Goldman^{1,2}, H. Halkin^{1,2}.* 1) Danek Gertner Institute of Human Genetics and Institute of Clinical Pharmacology, Sheba Medical Center, Tel Hashomer; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv; Israel.

Background: GGCX is responsible for post-translational activation of vitamin K-dependent proteins required for normal hemostasis. GGCX activity is dependent on efficient regeneration of reduced vitamin K by the warfarin-sensitive vitamin K epoxide (KO) reductase (VKOR) complex, in the vitamin K redox cycle. This study investigated the influence of genetic polymorphisms in candidate genes on vitamin K cycle activity and its interrelated sensitivity to warfarin.

Patients & Methods: In 100 patients on warfarin at therapeutic steady state, we analyzed candidate polymorphisms in the genes: *GGCX* (G8762A); two putative components of VKOR complex, *EPHX1* (T612C) and glutathione S-transferase A1 (*GSTA1* T-567G and T-631G), as well as the major warfarin-metabolizing enzyme, *CYP2C9* (*CYP2C9**2 and *CYP2C9**3), and determined their effect on vitamin K cycle activity, expressed as KO/plasma warfarin concentration ratio (KO/W) and on the warfarin sensitivity index (WSI), expressed as the INR/plasma warfarin.

Results: Vitamin K cycle activity was significantly associated with age and *CYP2C9*, *GGCX* and *EPHX1* genotypes (multiple $r=0.53$). *CYP2C9* and *GGCX* showed opposite effects on vitamin K cycle activity. Patients with *GGCX* 8762A containing genotypes presented higher KO/W ratio compared to the G/G wild type genotype (9.211.0 vs. 3.44.6, $p=0.02$). *CYP2C9**2 and *3 containing genotypes were associated with lower cycle activity than the wild type genotypes (2.32.5 vs. 3.44.6, $p=0.01$). WSI was independently and significantly associated with *CYP2C9* and *GGCX* genotype (partial $r=0.30$ and -0.34 , respectively).

Conclusion: These results suggest that common genetic variations significantly affect vitamin K cycle activity and that individual combined genotypes of *GGCX*, *EPHX1* and *CYP2C9* could be considered in the prediction of individual sensitivity to warfarin.

Genetic polymorphisms in microsomal epoxide hydrolase (mEH) component of the vitamin K epoxide reductase (VKOR) complex affect warfarin dose requirements. *R. Loebstein¹, M. Vecsler^{2,3}, E. Gak^{2,3}, N. Austerweil^{1,3}, D. Kurnik¹, B. Goldman^{2,3}, H. Halkin^{1,3}, S. Almog^{2,3}.* 1) Institute of Clinical Pharmacology; 2) Danek Gertner Inst Human Genetics, Sheba Medical Center, Tel Hashomer; 3) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv; Israel.

Background: The dose-response relationship of warfarin is only partially explained by known polymorphisms in the cytochrome P450 2C9 (2C9) gene, responsible for metabolic clearance of the active enantiomer S-warfarin, as well as by age and body weight. We determined the relative influence on warfarin doses of candidate genes of vitamin K redox cycle: mEH and glutathione-S-transferase A1 putative components of the VKOR, and -glutamyl carboxylase (GGCX) gene.

Patients and Methods: We studied the effects of 2C9, mEH, GST and GGCX genotypes, and of vitamin K1 and K epoxide concentrations, on warfarin doses in 100 patients, at stable anticoagulation.

Results: Allele frequencies for 2C9*1, *2 and *3, mEH T₆₁₂C and GGCX G₈₇₆₂A were 76.5%, 12.5% and 11%, 75% and 25% and 70.5% and 29.5% respectively. Warfarin doses differed among the 2C9 (2C9*1, 2C9*2 and 2C9*3) genotypes: 6.3, 5.3 and 3.8 mg/day respectively (p<0.01), with no differences in the other genotypes. Two way analysis of variance examining the effect of 2C9 and each of the candidate genes revealed only mEH to have an effect on warfarin doses: among the 62 patients with 2C9*1 higher warfarin doses were required among the variant homozygotes for the mEH gene 7.52.9 mg/day compared to the heterozygotes 6.54.2 mg/day and the mEH wild type patients 6.02.6 mg/day (p=0.03). Multiple regression demonstrated only age and 2C9 genotype to be associated with warfarin dose requirements with no effect of concurrent medications or mEH genotype. However, logistic regression analysis showed an odds ratio of 3.14 (95% CI: 1.47-6.67) for requiring 7 mg of warfarin/day in the variant mEH patients compared to the wild type.

Conclusions: Beyond the effects of 2C9 genotype, age and weight, variants of the mEH genotype appear to predict warfarin doses 50 mg/week.

Quantitative measurements of succinylacetone in amniotic fluid and plasma using GC/MS: a sensitive approach to prenatal diagnosis and follow up of tyrosinemia type I patients. *D. Cyr¹, G. Villain², R. Giguere¹, C. Auray-Blais¹, B. Lemieux¹, R. Drouin¹.* 1) Medical Genetics, CHUS, Sherbrooke, Quebec, Canada; 2) Biology department, Lille Sciences and technologies University, France.

Tyrosinemia is a genetic disorder caused by a reduced activity of fumarylacetoacetate hydrolase. Succinylacetone (SA), the diagnostic metabolite, derives from the accumulation of fumarylacetoacetate, a toxic molecule. In untreated patients, SA can easily be measured in plasma and urine because the expected concentrations are in the $\mu\text{mol/L}$ range. Due to a founder effect, the province of Quebec has an unusually high prevalence of tyrosinemia cases. Therefore, the quantification of SA in the nmol/L range in amniotic fluid (AF) or blood of patients treated with NTBC becomes very useful. This goal can be attained with a GC/MS assay, using a stable isotope dilution process and a newly and more sensitive electronic impact MS technology. The method utilizes 5- C^{13} -SA as an internal standard (IS) and a three steps sample treatment consisting of an oximation (to protect the keto groups), a liquid-liquid extraction and a tri-methylsilyl derivatization. After a 3l GC splitless injection, we validated the method by recording the intensities of the ions m/z 620 for SA and m/z 625 for the IS to demonstrate the specificity, recovery, limit of quantification and detection, accuracy, metabolite stability and precision of measurements. Our experience suggests that samples must be kept at -80C for a storage longer than a week. The mean overall recoveries of SA, using the liquid-liquid extraction procedure, is 90% 6%, the coefficient of variation is 6% and the limit of detection is 1 nmol/L . Control values in AF revealed a mean of 4 nmol/L (range: not detected (nd)-12 nmol/L); in plasma, a mean of 3 nmol/L (range: nd-6 nmol/L). The utility of this method was demonstrated by quantification of SA in the AF sample of an affected foetus (SA=2102 nmol/L) and in plasma from patients treated with NTBC (mean=26 nmol/L , range: 16-44 nmol/L , n=19). These preliminary results demonstrate that this method is suitable for clinical use and will be enhanced by further urinary testing and inter-laboratory comparative studies.

Conversion of the substrate preference of isovaleryl-CoA dehydrogenase to 2-methylbutyryl-CoA by site-directed mutagenesis. *E. Goetzman, A. Mohsen, K. Prasad, J. Vockley.* Children's Hospital of Pittsburgh, University of Pittsburgh School of Medicine.

The amino acid residues that line the substrate binding pocket of isovaleryl-CoA dehydrogenase (IVD) are conserved in over twenty known and putative IVDs found in GenBank with the exception of an IVD-like sequence from the potato plant (St-IVD-1) that differs at five key residues in the substrate binding pocket. Potato plants possess a second IVD gene (St-IVD-2) with the usual amino acid sequence in the binding pocket. Both proteins are 63% identical to human IVD. Both were expressed in *E. coli* and purified. Recombinant St-IVD-2 showed maximal dehydrogenase activity with isovaleryl-CoA as substrate (K_m of 1.3 M). In contrast, St-IVD-1 was maximally active with 2-methylbutyryl-CoA (K_m of 1.0 M), but had no activity with isovaleryl-CoA. Isovaleryl-CoA and 2-methylbutyryl-CoA are five-carbon branched-chain substrates that differ in the position of the branch. In mammals they are catabolized by separate enzymes, IVD and short/branched-chain acyl-CoA dehydrogenase (SBCAD), which are only 35% homologous. We hypothesized that the five differing residues in the substrate pocket of St-IVD-1 were sufficient to change the preferred substrate from isovaleryl-CoA to 2-methylbutyryl-CoA. Human IVD was mutated to match St-IVD-1 at these five residues and expressed in *E. coli*. The five mutations abolished activity toward isovaleryl-CoA, but the recombinant enzyme could now utilize 2-methylbutyryl-CoA. Thus, a minimal number of substitutions are sufficient to convert human IVD into an SBCAD. Three of these residues (at positions 95, 99, and 103) lie in helix E of human IVD, which forms one side of the substrate pocket, while the other two residues (370 and 374) are located across the pocket near the catalytic base. A mutant human IVD containing only the three helix E mutations was inactive with both substrates while the substrate specificity of a L370M/G374A double mutant was similar to wild-type IVD. These data suggest the three helix E substitutions play the major role in conferring the 2-methylbutyryl-CoA dehydrogenase activity to St-IVD-1.

A viable knock-in mouse model of congenital erythropoietic porphyria. *D.F. Bishop, M.C. Ramirez, A. Shady, R.J. Desnick.* Department of Human Genetics, Mount Sinai School of Medicine, New York, NY.

Congenital erythropoietic porphyria (CEP) results from the markedly deficient, but not absent, activity of the fourth enzyme in the heme biosynthetic pathway, uroporphyrinogen III synthase (UROS). The enzymatic defect leads to the accumulation of uroporphyrin (URO) and coproporphyrin (COPRO) I isomers in erythrocytes, plasma, urine, and feces. Based on the amount of residual activity, the disease phenotype varies from non-immune hydrops fetalis to milder, later-onset cutaneous involvement. A murine model would facilitate the evaluation of various therapeutic strategies, however, the homozygous UROS knockout was an early fetal lethal. Thus, we generated knock-in mice for two UROS missense mutations, C73R and V99A, that result in low enzymatic activity, the purified murine recombinant C73R and V99A enzymes having 0.1 and 2% of wild type enzymatic activity, respectively. These mutations were individually introduced into an ES cell targeting vector containing an 11 kb murine UROS genomic sequence with adjacent silent restriction sites and a *neo* selectable marker. After homologous recombination in SV129 ES cells, germline transmission of both mutations was obtained. The homozygous C73R mouse was an early embryonic lethal, whereas the V99A homozygotes and heteroallelic C73R/V99A mice were viable and fertile. Both V99A/V99A and C73R/V99A mice exhibited prominent erythrodontia, providing rapid identification. Compared to wild-type mice, the fecal URO I and COPRO I isomers were elevated in the porphyric mice 9 to 12-fold and 68 to 84-fold, respectively. In the V99A/V99A mouse, plasma URO I was elevated 6-fold over wildtype, while in the V99A/C73R mouse, plasma URO I increased 34 fold, consistent with the lower residual activity of the heteroallelic CEP mouse. Hematologic indices were normal for both lines and the development of cutaneous lesions is being evaluated. Thus, these mice have the biochemical and clinical phenotype of CEP and provide a model for the evaluation of therapeutic gene and stem cell strategies.

A case of Fanconi Bickel syndrome caused by uniparental disomy of chromosome 3 with hyperinsulinism and hyperammonemia. *T.L. Hoffman¹, E. Blanco⁵, A. Lane⁵, P.G. Parton⁵, D. De León², I. Gadi⁴, I. Krantz¹, R. Santer³, C. Stanley², T. Wilson⁵.* 1) Pediatric Genetics, Children's Hospital of Phila, Philadelphia, PA; 2) Pediatric Endocrinology, Children's Hospital of Phila, Philadelphia, PA; 3) University Childrens' Hospital, Hamburg, Germany; 4) Department of Cytogenetics, Labcorp, Research Triangle Park, NC; 5) Pediatric Endocrinology, State University of New York, Stony Brook, NY.

Fanconi Bickel syndrome (FBS) is caused by mutations in the facilitative glucose transporter GLUT2. Patients with FBS present with hypoglycemia, hepatomegaly, failure to thrive, and renal Fanconi syndrome with vitamin D-resistant rickets. We describe a 2 year old female with FBS characterized by a more severe phenotype than previous reports. Our patient suffered from severe hypoglycemic seizures and required high glucose infusion rate from intravenous dextrose infusion to maintain normoglycemia. She had significant developmental delays with absent speech. Lab analysis indicated hyperinsulinism and mild hyperammonemia, two atypical features not previously seen in FBS. Treatment with diazoxide allowed discontinuation of intravenous dextrose and reduction of glucose infusion rate such that enteral feeds could maintain normoglycemia. Sequencing of genomic DNA indicated that the child was homozygous for a previously described null mutation in GLUT2 (C1213T). Molecular genotyping of the child's parents showed that only the mother was a carrier of the C1213T mutation. Microsatellite marker analysis confirmed paternity and indicated that there was homozygous inheritance of the C1213T allele in the child via maternal isodisomy of chromosome 3. Uniparental disomy (UPD) of chromosome 3 has never been described and represents a novel mode of transmission for FBS. The implications of UPD 3 on the severity of the child's phenotype are discussed.

X-Inactivation studies in Fabry female carriers. *A. Morrone¹, C. Cavicchi¹, L. Carraresi¹, T. Bardelli¹, M.A. Donati¹, D. Antuzzi², R. Parini³, S. Feriozzi⁴, R. Barone⁵, G. Pistone⁶, R. Di Vito⁷, A. Salviati⁸, R. Ricci², E. Zammarchi¹.* 1) Dept of Pediatrics, Azienda Osp Meyer, Univ of Florence, Florence, Italy; 2) Catholic Univ, Rome; 3) S Gerardo Hospital, Monza; 4) Belcolle Hospital, Viterbo; 5) Dept of Pediatrics, Catania; 6) Dept of Dermatology, Palermo; 7) Dept of Nephrology, Chieti; 8) Dept of Neurology, Verona.

Fabry disease is an X-linked lysosomal storage disorder caused by a primary deficiency of α -galactosidase A. Female carriers can be asymptomatic or clinically affected. Because of X-chromosome inactivation, heterozygous females can show normal GLA activity and mutation analysis is the only certain method of detecting female carrier status. We identified GLA gene mutations in 40 females from 21 unrelated families with a positive family history of Fabry disease. Up to now very few studies on X-inactivation have been carried out on Fabry carriers. In order to determine an eventual correlation with clinical manifestations in Fabry carriers, X-inactivation studies were carried out on the peripheral blood DNA of 35 female Fabry carriers. Of these 27 showed clinical signs or symptoms and were classified as manifesting carriers (MC), while 8, with no clinical sign or symptom, were defined as asymptomatic (A). 13 (11 MC and 2 A) showed a random X-inactivation pattern. 16 MC and 6 A, showed a moderately skewed and/or skewed X-inactivation pattern: 14 MC in favour of the mutant allele, 6 A in favour of the wild type allele and 2 MC in favour of the wild type allele but in the latter a possible recombination cannot be excluded. These X-inactivation studies suggest that female carriers with a random, moderately skewed and /or skewed X-inactivation pattern in favour of mutant allele have an increased risk of developing symptoms ($p < 0.001$), while carriers showing a moderately and/or skewed pattern in favour of wild type allele are more likely to be asymptomatic ($p < 0.001$). X-inactivation studies and accurate clinical evaluations could be helpful in predicting the female phenotypes and give useful indications for the therapeutic management of manifesting carriers. TKT Europe 5S and Genzyme Corporation are gratefully acknowledged.

Increased blood brain barrier permeability caused by loss of function of thymidine phosphorylase in patients with MNGIE. *K. Szigeti¹, N. Sule², A.M. Adesina², D.L. Armstrong², G.M. Saifi¹, E. Bonilla³, M. Hirano³, J.R. Lupski¹.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept pathology, Baylor Col Medicine, Houston, TX; 3) Dept of Neurology, Columbia Univ Col of Physicians and Surgeons, New York, NY.

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is an autosomal recessive multisystemic disorder caused by thymidine phosphorylase (TP) deficiency. While the pathomechanism of the secondary mitochondrial dysfunction has been extensively studied, that of the leukoencephalopathy has not been elucidated. We hypothesized that the white matter hyperintensities on T2 weighted MRI images reflect disturbance of blood-brain barrier (BBB) function. We performed immunohistochemistry (IHC) for TP and intracellular albumin in 2 postmortem brain specimens from patients affected with MNGIE and compared them to normal age-matched controls (N=4) and to a patient with FK 506-induced posterior reversible leukoencephalopathy (PRLE), a disease caused by BBB breakdown. TP is expressed in astroglia, endothelial cells, microglia and to a variable degree even in cortical neurons in the human telencephalon in contradistinction to rodents. Albumin IHC disclosed quantitative ($p < 0.01$) and qualitative differences between the MNGIE and control brains. These data indicate that loss of TP function impairs the integrity of the BBB. MNGIE provides a unique opportunity to examine the effects of loss-of-function of TP in the human central nervous system.

Mapping of a new autosomal recessive non-syndromic hearing loss locus to chromosome 5q13. *L. Basel-Vanagaite*^{1,2}, *R. Atia*³, *N. Magal*³, *T. Shohat*^{4,5}, *E. Taub*¹, *M. Shohat*^{1,2}. 1) Dept Medical Genetics, Rabin Medical Ctr, Petah Tikva, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Felsenstein Medical Research Center, Petah Tikva, Israel; 4) Israel Center for Disease Control, Israel Ministry of Health, Tel Hashomer; 5) Department of Epidemiology and Preventive Medicine, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel.

Isolated deafness is a genetically heterogeneous trait. Approximately 80% of genetic hearing loss is non-syndromic. The recessive mode of transmission accounts for approximately 75% of inherited cases of non-syndromic deafness. We have ascertained 5 individuals from a large consanguineous family with profound congenital autosomal recessive deafness. All the affected individuals are otherwise healthy. Following a genome wide screening, linkage was detected to locus D5S424 on chromosome 5, thereby defining a novel deafness locus. Two-point linkage analysis resulted in a maximum lod score of 3.54 ($\theta = 0.00$) for marker D5S424. Recombination events defined a 15 Mb critical region between GATA141B10 and D5S428. Fine mapping and identification of candidate genes are in progress.

Program Nr: 1845 from the 2004 ASHG Annual Meeting

GERON Genotyping a centralized data management and analysis system for genetic linkage and association studies. *S. Bandyopadhyay, J.R. Gibbs, D. Hernandez, J.F. Duckworth, A. Singleton.* Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Building 10, Room 6C103, MSC1589, Bethesda, MD 20892, USA.

The GERON (GEnetics Research ONline) Genotyping data management system provides a repository for the storage and mining of genotype data as well as streamlining the multitude of steps required to perform any type of marker based linkage/association analysis. The system has the capacity to handle polymorphic marker data for family and case-control based genetics research. The database includes current Genethon allele frequency data, fragment sizes for 891 CEPH (Centre d'Etude du Polymorphisme Humain) reference individuals at 10251 unique markers and also enables the user to build their own estimates of allele frequencies based on analysis of ethnicity specific genotyping. The database automatically applies allele offsets based on CEPH genotypes. The database includes dynamic links to UniSTS and dbSNP for marker information, and integrates genetic location data from several different published genetic maps. The system has the ability diagnose and track mendelian errors, perform simple statistical analysis and export to various linkage/association analysis file formats. GERON is available from <http://neurogenetics.nia.nih.gov>.

Haplotypic association spanning the 22q11.21 genes COMT and ARVCF with schizophrenia. *M. Martinez*¹, *A.R. Sanders*², *I. Rusu*², *J. Duan*², *J.E. Vander Molen*³, *C. Hou*², *S.G. Schwab*^{4,5,6}, *D.B. Wildenauer*^{4,7}, *P.V. Gejman*². 1) EMI 00-06, E0006/15932, INSERM EMI 00-06, Evry, France; 2) Center for Psychiatric Genetics, Evanston Northwestern Healthcare Research Institute, and Northwestern University, Evanston, IL; 3) Department of Human Genetics, University of Chicago, Chicago, IL; 4) School of Psychiatry and Clinical Neurosciences, University of Western Australia (UWA), Perth, Australia; 5) Centre for Medical Research, UWA, Perth, Australia; 6) Department of Psychiatry, University of Bonn, Bonn, Germany; 7) Centre for Clinical Research in Neurosciences, UWA, Perth, Australia.

Catechol-O-methyltransferase (COMT) has been implicated in schizophrenia by its function through its roles in monoamine neurotransmitter metabolism and its impact on prefrontal cognition, and also by its position through linkage scans and a strong cytogenetic association. Further support comes from association studies, especially family based ones examining the COMT variant, Val^{108/158}Met. We have studied eight markers spanning COMT and including portions of the two immediately adjacent genes, thioredoxin reductase 2 (TXNRD2) and armadillo repeat deleted in velocardiofacial syndrome (ARVCF), using association testing in 136 schizophrenia families. We found nominal evidence for association of illness to rs165849 ($P=0.051$) in ARVCF, and a stronger signal (global $P=0.0019-0.0036$) from three-marker haplotypes spanning the 3 portions of COMT and ARVCF, including Val^{108/158}Met with Val^{108/158} being the over-transmitted allele, consistent with previous studies. We also find Val^{108/158}Met to be in linkage disequilibrium with the markers in ARVCF. These findings support previous association signals of schizophrenia to COMT markers, and suggest that ARVCF might contribute to this signal. ARVCF, a member of the catenin family, besides being a positional candidate, is also one due to its function, i.e., its potential role in neurodevelopment, which is implicated in schizophrenia pathogenesis by several lines of evidence.

Model-independent linkage analysis and association tests in a group of families with kyphoscoliosis: a comparison between microsatellites and single-nucleotide polymorphisms. *C.M. Justice¹, M.H. Roy-Gagnon¹, B. Marosy², S. Novak², P. Boyce³, J. Pettengill³, K.F. Doheny³, E.W. Pugh³, N.H. Miller², A.F. Wilson¹.* 1) Genometrics Section, NHGRI/NIH, Baltimore, MD; 2) Department of Orthopaedic Surgery, JHU, Baltimore, MD; 3) CIDR, IGM, JHU SOM, Baltimore, MD.

Kyphoscoliosis is an unusual deformity in which a lateral curvature of the spine is seen in conjunction with thoracic hyperkyphosis in otherwise normal individuals. As part of a large collaborative study of familial idiopathic scoliosis, 202 families (1198 individuals) with 2 or more individuals with a lateral curvature ≥ 10 were ascertained and clinically characterized. Seven families (53 individuals) had at least two individuals with kyphoscoliosis (lateral curvature ≥ 10 and thoracic kyphosis >40) documented prior to skeletal maturity. The average degree of lateral curvature for individuals with and without kyphoscoliosis was 48 and 31, respectively. The average degree of kyphosis was 53. A genome-wide screen was performed at the Center for Inherited Disease Research using a modified CHLC v.9 marker set of 391 short tandem repeat polymorphisms (STRPs). Individuals with kyphoscoliosis or scoliosis were classified as affected. Sib-pair analysis suggested linkage to chromosomes 2, 5, 13 and 17. An additional 25 STRPs were genotyped in the candidate regions. The most significant p-values were obtained for chromosomes 5 and 13. To narrow further the candidate regions, 71 SNPs were genotyped in a ~ 10 Mb region of 5p13 using a mass spectrometer. Results were read using SpectroTYPER software (Sequenom). Using a candidate region approach, 145 SNPs (14 candidate genes) on chromosome 13 and 13 SNPs (1 candidate gene) on chromosome 5 were genotyped with SNPs from ABI and read with the Perkin-Elmer ABI Prism 7700 Sequence Detection System. Additional SNPs were genotyped under the Illumina platform. One panel was genotyped for chromosome 5 (.05 Mb density) and another panel for chromosome 13 (.131 Mb density). Results are presented (graphically) and compared for sib-pair linkage analysis and tests of association using only the STRPs, only the SNPs, and the STRPs and SNPs combined for each platform and all platforms combined.

The a-Catenin polymorphisms associated with amyloid levels, are not a strong risk factor for late onset

Alzheimers disease. *D. Avramopoulos¹, M.D. Fallin², S.S. Bassett¹*. 1) Dept. of Psychiatry, School of Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Dept. of Epidemiology, School of Public Health, Johns Hopkins Univ, Baltimore, MD.

A recent study by Ertekin-Taner et al detected a strong association between intronic polymorphisms in the a-Catenin gene (VR22) and the levels of beta Amyloid (A-beta) in Alzheimers disease patients, thus implicating VR22 in the pathogenesis of late onset Alzheimers disease. That study was a follow up to a strong linkage finding by the same group for a quantitative trait locus for A-beta on chromosome 10q, a candidate gene approach that examined VR22 because of its location and functional relevance. We recently reported linkage for Late Onset Alzheimers Disease (LOAD) on chromosome 10q in families of maternal disease origin from the NIMH genetics initiative pedigrees, in a region that overlaps with the QTL described above. Although VR22 lies just outside our linkage interval, we decided to test whether this gene is also a risk factor for LOAD, and whether the presence of the high risk allele is correlated with the observed linkage signal in our pedigrees. We genotyped the two SNPs showing the strongest effect in the Ertekin-Taner study for 182 of the NIMH genetics initiative pedigrees, those that include both affected and older unaffected members. Our analysis did not detect an association or trend. We then genotyped the remaining NIMH pedigrees in order to examine the correlation between the presence of the high A-beta load associated allele and linkage at VR22 using the GIST method and software. No such correlation was detected. Given the failure of two independent tests for the effect of these polymorphisms we conclude that despite their strong association with A-beta loading, they do not appear to have an equally strong effect on the risk for LOAD, and that the gene(s) underlying our linkage signal close to the centromere of chromosome 10 in the NIMH pedigrees remains to be identified.

Mapping of a new locus for autosomal recessive spastic paraplegia. *N. Bouislam^{1,2}, A. Benomar², A. Bouhouche², H. Azzedine¹, A. Durr^{1,3}, A. Brice^{1,3}, M. Yahyaoui², G. Stevanin^{1,3}.* 1) Institut des Neurosciences, INSERM U289-NEB, Paris, France; 2) Laboratoire de Neurogenetique, Hopital des Specialites, Rabat, Morocco; 3) Department of Genetics, Cytogenetics and Embryology APHP, Hopital Salpetriere, Paris, France.

Hereditary spastic paraplegias (HSP) are characterized by progressive spasticity in lower limbs, due to the dysfunction and/or degeneration of the upper motor neuron. It is classical to distinguish between pure and complex HSP. The pure forms present with pyramidal signs (brisk reflexes, Babinski sign, spasticity, motor deficit, +/- sphincter disturbances) often associated with deep sensory loss. Complex forms variably associate numerous combinations of neurological and extra-neurological signs such as ataxia, dysarthria, neuropathy, optic atrophy or retinitis pigmentosa, hearing loss, mental retardation. Molecular studies in HSP have confirmed the heterogeneity at the genetic level and 20 loci have been mapped to date. We have identified a large consanguineous family (11 subjects including 3 affected members) of Moroccan ancestry with pure spastic paraplegia displaying an autosomal recessive pattern of inheritance of the disease. All 3 affected family members had onset of spasticity in the lower limbs between ages 10-15 and required walking aid at ages 26, 38 and 42. A genome wide study suggested linkage to a new locus on chromosome 14. Linkage analysis of 27 microsatellite markers allowed to obtain a maximal multipoint lod score of 3.21. Haplotype reconstruction restricted the candidate region to a 5 cM interval encompassing 10 markers at the homozygous state among the patients. Direct sequencing of the coding exons of two candidate genes was performed but no disease causing mutation was found. This pedigree represents a genetically distinct form of pure and slowly progressive HSP mapped to chromosome 14.

Characterization and homozygosity mapping to 9p24 of a recessive syndrome of nonprogressive cerebellar ataxia and mental retardation in the Hutterite Brethren. *K.M. Boycott¹, J. Parboosingh¹, H.C. Glass², E. Wirrell², J.*

Scott³, K. Davey¹, S. Flavelle¹, A.E. Chudley⁴, A. Bureau¹, D.R. McLeod¹. 1) Dept Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Dept Pediatrics, University of Calgary, Calgary, AB, Canada; 3) Dept Radiology, University of Calgary, Calgary, AB, Canada; 4) Dept Medical Genetics and Biochemistry, University of Manitoba, Winnipeg, MB, Canada.

The Hutterites are an endogamous German-speaking people that originated from the Anabaptist movement during the 16th century. We reviewed and examined 19 Hutterite patients with developmental delay and previously documented cerebellar signs. Patients completed a standard set of investigations, including magnetic resonance imaging of the brain. Twelve Hutterite patients from six interrelated sibships had clinical presentations consistent with Dysequilibrium syndrome (DES), a syndrome of nonprogressive cerebellar ataxia and mental retardation described in a small number of Hutterite patients in the 1980s. Clinical features of our patient group included mild to profound mental retardation, strabismus, pes planus, walking after age six, relatively marked truncal ataxia with limited peripheral ataxia and a static clinical course. Variable features included short stature and seizures. The underlying structural brain abnormalities identified on neuroimaging of Hutterite DES patients are distinct and include hypoplasia of the inferior portion of the cerebellum with absence of the inferior portion of the vermis, partial formation of the primary fissure and cerebellar hemispheres, small pons, and simplification of the cerebral cortex.

The autosomal recessive inheritance of DES and the endogamous nature of the Hutterite population have facilitated homozygosity mapping studies. A genome scan using 400 microsatellite markers at a density of 10 cM identified a region of homozygosity spanning 17 cM and localized the DES gene between 9ptel and D9S286. Candidate genes are currently being evaluated. Identification and functional analysis of the DES gene will provide new insights into cerebellar development.

Analysis of Multiple Polymorphisms in the Serotonin Transporter (SLC6A4) in Autistic and Control Populations. *I.J. Chacon, A.L. Yonan, R. Cheng, E. Cayanis, J.D. Terwilligwe, A.A. Palmer, T.C. Gilliam.* Columbia Genome Center, Columbia University, NY, NY 10032.

Twin and family studies demonstrate a strong genetic contribution to the development of Autism Spectrum Disorders (ASD), yet no risk alleles have been unambiguously identified. We previously reported a genomewide scan to identify autism susceptibility loci in 345 multiplex families (AGRE). The most significant finding was an MLS of 2.83 on chromosome 17q, which increases to 4.41 among a subset of families with only affected males (Stan Nelson, personal communication) and harbors a strong candidate gene for ASD, the serotonin transporter (5-HTT; SLC6A4). Here, we report a survey of the putative functional promoter polymorphism (5-HTTLPR) together with neighboring SNPs in two large ASD samples (AGRE and Risch et al. 1999) and an independent control sample. We noted an interesting trend wherein the 5-HTTLPR variant and SNPs that map within the GC-rich repeat sequence elements of the promoter were difficult to genotype and violated Hardy-Weinberg (HW) equilibrium in both ASD and control populations. Neighboring SNPs that map outside the promoter region were more reliably genotyped and met HWE. Specifically, HW disequilibrium was detected for 5-HTTLPR in the unaffected founders of both autistic populations as well as the controls and three SNPs that lie within the promoter region did not produce reliable genotypes. By contrast, two SNPs localized in the 5' UTR region (rs2020939 and rs2020936) and a third in intron 2 (rs1872924) show conformation to HWE and point to allelic association to ASD. We detect evidence of preferential transmission of an allele of SNP3 (located 26Kb from the 5-HTT promoter) in the Risch autism sample (FBAT ver-1.4.2; Z-score: 2.10, p-value:0.035), and of a haplotype containing this same allele in a preliminary analysis of 170 AGRE pedigrees added to the Risch sample (FBAT; Z-score: 2.23, p-value: 0.026). We will complete this systematic survey of the 5-HTT polymorphisms in and surrounding the promoter region and discuss potential ramifications of these studies for the genetic analysis of autism and other neuropsychiatric disorders.

Linkage Disequilibrium-Based Investigation of Candidate Genes for Developmental Dyslexia in the Chromosome 6p21.3-22.3 Region. *J. Couto¹, K. Wigg¹, Y. Feng¹, B. Anderson², T. Cate-Carter², R. Tannock², M. Lovett², T. Humphries², C.L. Barr^{1,2}.* 1) The Toronto Western Research Institute, University Health Network, Canada; 2) The Hospital for Sick Children, Toronto, Canada.

Developmental dyslexia or specific reading disability (RD) is a complex cognitive disorder, defined as severe difficulty in reading despite average intelligence and adequate opportunity. It affects 3-10% of children and tends to persist into adulthood. RD is heritable, and linkage to several chromosomal regions has been identified. The most replicated finding to date is for linkage in the 6p21.3-22.3 region on the short arm of chromosome 6, although the susceptibility gene(s) in this region has not yet been identified. The objective of this study was to establish a dense set of markers in 6p21.3-22.3, and to fine-map and identify RD susceptibility genes. We investigated 45 SNPs (single nucleotide polymorphisms), in a sample of 180 nuclear families ascertained through children with reading difficulties at school. Diagnosis of RD, as a categorical trait, was made using 3 core tests that assess single-word reading and phonological decoding. Additional quantitative reading and related phenotypes were assessed using tests for the partially overlapping skills that contribute to reading ability. Candidate genes included the genes for cAMP response element like protein 1 (CREBL1) and cyclin dependent kinase 5 (CDK5) regulatory subunit associated protein 1-like 1 (CDKAL1). Using the transmission disequilibrium test, we found significant evidence for association of categorically defined RD to two SNPs in the gene for CREBL1 ($p=0.014$; $p=0.040$) and one SNP in CDKAL1 ($p=0.018$) in the 6p region. Evidence for association was also found to another polymorphism in CDKAL1 for phonological decoding, a quantitative phenotype of RD ($p=0.044$). The two SNPs in each gene are in linkage disequilibrium (LD) with each other, $D=0.884$ and 1.000 respectively. These two positive regions are 10.9 Mb apart and are not in LD with each other. It is likely that one region is an artifact of limited statistical power. We will be able to distinguish between the two as our sample size increases, and we further investigate both regions.

Genetics of autism and the broader phenotype in Iceland: Genome scan for autism and ASD. *R. Fossdal¹, E. Saemundsen², G. Bjornsdottir¹, P. Magnusson³, B. Lauth³, S. Sieberts¹, S. Hreidarsson², S. Thorvaldsson¹, O. Gudmundsson³, J. Thorhallsdottir¹, H. Palsdottir¹, B. Unnarsdottir¹, J. Gulcher¹, H. Stefansson¹, K. Kristjansson¹, T.E. Thorgeirsson¹, K. Stefansson¹.* 1) CNS, deCODE Genetics, Inc., Reykjavik, Iceland; 2) State Diagnostic Counseling Center, Reykjavik Iceland; 3) Department of Child and Adolescent Psychiatry, National University Hospital, Reykjavik Iceland.

The autism spectrum includes a few syndromes with variable severity and age at onset for impaired development of social skills, repetitive behaviors and verbal and non-verbal communication problems. Although autism has a striking genetic component according to twin studies, a number of genome scans and association studies performed in the last decade have not yet led to the isolation of definite autism genes. Additional studies are therefore needed. We have begun a study of the genetics of autism and autism spectrum disorders (ASD) in Iceland that is based on linkage within large extended families. Here we describe the family cohort of 352 individuals with autism or ASD and their relatives. The study includes the systematic phenotypic ascertainment of the unaffected relatives to identify individuals with signs of the broader autism phenotype as judged by their scores on a screening instrument that we have developed, The Development, Social Interaction and Mood Questionnaire (DSIM), and previously described screening instruments (SRS and SCQ). We also describe the genealogical relationships between ASD and psychiatric phenotypes (schizophrenia, BP, depression, and anxiety). The aim of the project is to include the broader autism phenotype in linkage analysis, but here we present the results of the genome scan for autism and ASD probands (170 affected). To ensure a high information content for this scan, all affected individuals, as well as their parents, siblings, and grandparents, have been genotyped with 2000 microsatellite markers. This scan is based on approximately half of the autism-ASD family cohort, and the results provide support for previously published linkage peaks on chromosomes 5p, 15q and Xq. The research is supported by The Simons Foundation.

SNP genomic screening provides further evidence for genetic heterogeneity in essential tremor. *J.R. Gilbert, L. Zhang, S. Knauer, C. Haynes, C. Salzman, M.M. Menold, S. West, J. Stajich, B. Scott, A.E. Ashley-Koch.* Duke University Medical Center, Durham, NC.

We previously conducted a microsatellite genomic screen on a large essential tremor (ET) family (DUK 13001) that was unlinked to published ET loci on chromosomes 2 and 3. Several interesting regions emerged, but because of the moderate size of this pedigree, no conclusive linkage could be established. To aid in the linkage of this family, we conducted a 10K SNP chip genomic screen in this, and 2 other moderately sized ET families (DUK 13041 and DUK 13028). Expected 2pt lod scores for each family, assuming an affecteds only dominant model with a two allele marker, were generated with SIMLINK and were as follows: DUK 13001: 2.0; DUK 13041: 2.3; and DUK 13028: 1.2. Peak 2pt lod scores were obtained for DUK 13001 on chromosomes 3 (lod=1.6), 5 (lod=1.4), 15 (lod=1.6) and 20 (lod=1.4). Regions on all chromosomes except chromosome 3 had also provided positive 2pt lod scores with the microsatellite genomic screen of this family. The region on chromosome 3 did not overlap with the previously reported ET linkage on chromosome 3. For DUK 13041, peak 2pt lod scores were obtained on chromosomes 1 (lod=2.0), 4 (lod=1.7) and 9 (lod=1.7). For DUK 13028, peak 2pt lod scores overlapped regions on chromosome 4 (lod=1.1) with DUK 13028, and chromosome 5 (lod=1.0) with DUK 13041. However, the best evidence for linkage with DUK 13028 was on chromosome 17 with a peak 2pt lod score of 1.5. Because none of the peak regions for families DUK 13001 and DUK 13041 overlap, these data provide further evidence for genetic heterogeneity in ET and suggests that there are additional ET loci that remain as yet unidentified. We are currently characterizing the patterns of LD amongst the SNPs in the genomic screen and performing multipoint analysis to further refine these high-priority regions.

Towards the identification of the anx mutation in the anx/anx murine model for anorexia nervosa. *M. Gratacos, JM. Mercader, M. Ribases, X. Estivill.* Genes and Diseases, Center for Genomic Regulation, Barcelona, Spain.

Anorexia Nervosa (AN) is a complex disorder where both socio-cultural and genetic factors are supposed to be involved. The mutant *anx/anx* is a spontaneous murine model for AN, as mutants are characterized by poor appetite, growth failure, and abnormal behavior such as head weaving and hyperactivity. This model is due to a recessive autosomal mutation, not yet identified, but mapped through linkage analysis close to the Pallidin gene (*Pa*), located at 122,9 Mb in chromosome 2. Several studies on differential gene expression and on neuropeptide distribution have been performed in order to disclose the etiology of this phenotype, but no additional data on the position of the *anx* gene has been published until now. The aim of this study was to map the genetic position of the *anx* gene through the typing of 30 microsatellite markers and covering a region of 30 Mb around the *Pa* gene. The offspring of several experimental crosses of carrier heterozygotes (B6C3Fe-*anx* A/+ a) were analyzed and over 400 meioses are being screened using three multiplex reactions of 10 microsatellites each. Markers were generated from information obtained in databases (DMit markers) and from the available sequence of the mouse genome. Preliminary linkage analysis reveals that the *anx* mutation is located close to position 119 Mb (Tx 119) (lod score 4.5 at a recombination fraction of 0) on mouse chromosome 2. Fine mapping of the *anx* mutation is being performed with SNPs covering the region of synteny between the two parental strains and additional microsatellite markers. Mutation search using dHPLC should facilitate the identification of mutations in candidate genes responsible for the anorexia phenotype in the *anx* model and to identify the mutation causing anorexia, to better understand the mechanisms underlying feeding and body weight regulation, and the genetic factors involved in the development of eating disorders.

A clinical, genetic and neuropathologic analysis of autosomal dominant cerebellar ataxia linked to chromosome 16q22.1 (16q-ADCA type III). *K. Ishikawa¹, S. Toru¹, T. Tsunemi¹, T. Amino¹, H. Fujigasaki¹, M. Sakamoto¹, M. Li¹, H. Tomimitsu¹, K. Owada¹, K. Ishida², M. Gomyoda³, M. Yoshida⁴, Y. Hashizume⁴, I. Kondo⁵, K. Kobayashi⁶, T. Toda⁶, H. Mizusawa¹.* 1) Dept Neurology and Neurological Sciences, Graduate School, Tokyo Medical & Dental Univ, Tokyo, Japan; 2) Dept Neurology, National Matsue Hospital, Matsue, Shimane, Japan; 3) Dept Clinical Laboratory, National Matsue Hospital, Matsue, Shimane, Japan; 4) Dept Neuropathology, Inst Medical Science of Aging, Aichi Medical School, Aichi, Japan; 5) Dept Medical Genetics, Ehime Univ School of Medicine, Onsen-Gun, Ehime, Japan; 6) Dept Post-Genomics and Diseases, Osaka Univ Graduate School of Medicine, Suita, Osaka, Japan.

Autosomal dominant cerebellar ataxia (ADCA) is a group of heterogeneous neurodegenerative diseases showing progressive cerebellar ataxia as a cardinal clinical feature. We mapped families with pure cerebellar ataxia to a 3 cM region in the chromosome 16q22.1 (Nagaoka et al., *Neurology*; 2000). This region was the locus for another ADCA, spinocerebellar ataxia type 4 (SCA4)(Flanigan et al., *Am J Hum Genet*; 1996), which shows prominent peripheral neuropathy. To identify the gene for 16q-ADCA type III, we constructed a physical map of the locus and analyzed haplotypes for newly discovered polymorphic DNA markers in 30 families of 16q-ADCA type III. We have so far narrowed the critical region of the gene into 3.8 megabase (Mb) interval between D16S3043 and D16S3095 in 16q22.1. In addition, we identified specific haplotype that completely segregate with the disease in all families. Clinical features of these families revealed that 16q-ADCA type III has the latest age of onset with benign course compared to any other ADCAs with known gene loci. Neuropathologic analysis on two families revealed that the Purkinje cell undergo characteristic degeneration with increase of presynaptic proteins around atrophic Purkinje cell bodies. Such changes are not seen in any other ADCAs. We conclude that 16q-ADCA type III has distinct clinical and neuropathologic features. Testing the specific haplotype is useful for molecular diagnosis of 16q-ADCA type III.

Replication of Evidence for Modifiers of Age at Onset in Huntington's Disease on 6q23-24 and 18q22: The HD MAPS Study. *J-L. Li¹, V. Wheeler², L. Srinidhi², A. Russ¹, T. Gillis², M. Marcial², L.A. Cupples¹, J.F. Gusella², M.E. MacDonald², R.H. Myers¹, for the investigators of the HD MAPS study.* 1) Department of Neurology, Boston Univ School of Medicine, Boston, MA; 2) Molecular Neurogenetics Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Huntington's Disease (HD) is a fully penetrant, autosomal dominant disorder associated with an abnormal expansion of a stretch of CAG repeats in the first exon of the huntingtin gene. Although repeat size is correlated with the age at onset (AO), and accounts for approximately 70% of the variation in AO, much of this effect is seen in very young onset individuals with very large repeat sizes. AO adjusted for repeat size is strongly heritable suggesting that it has significant genetic modifiers. Our recent whole-genome scan in 629 affected sibling pairs from 295 pedigrees provided suggestive evidence for quantitative trait loci modifying AO at six genomic regions. In the present study, we assessed evidence for linkage in 125 newly recruited sibling pairs from 57 pedigrees (total sample of 352 pedigrees with 754 sibling pairs). Eighteen microsatellite markers were genotyped, three from each of the six linkage loci. We performed a variance components multipoint linkage analysis in the newly recruited and total sample. We also analyzed the subset with CAG repeat size range from 36 to 50 repeats, as the variation in onset age for a given repeat is maximal in this range. Chromosomes 6q23-24 ($p=0.008$), 18q22 ($p=0.05$) showed evidence for linkage in the new sample and in the total sample (LOD=3.74 and 1.41 respectively). Increased evidence for linkage at 18q22 was seen in the group restricted to 36 to 50 repeats (LOD=2.25). These regions contain several interesting candidate genes, encoding proteins with established roles in cell death and nervous system development, including glutamate receptors, apoptosis effectors, transcription factors, and others. Further studies to identify genetic modifiers for AO for HD are underway.

Program Nr: 1858 from the 2004 ASHG Annual Meeting

Permutation linkage analyses identified several novel susceptibility loci for nicotine dependence with the Framingham Heart Study data. *M.D. Li, D. Wang, J.Z. Ma.* Program in Genomics and Bioinformatics on Drug Addiction, Department of Psychiatry, MSC 7792, Univ Texas Health Sci Ctr, San Antonio, TX.

Nicotine dependence is the most prevalent form of drug abuse in the US and throughout the world. Epidemiological studies demonstrated that genetics account for at least 50% of the liability to nicotine dependence. However, there have been very limited linkage studies for this disorder. In this study, we conducted genome-wide permutation linkage analyses on the longitudinal smoking data of the Framingham Heart Study (FHS) to account for the abnormality associated with the smoking phenotype (defined as the number of cigarettes smoked per day). We used empirical thresholds obtained from permutation tests to determine the significance of each genomic region. To minimize environmental effects on linkage analysis results, we organized the longitudinal FHS smoking data from 1970-1988 into four time points. The Haseman-Elston, non-parametric, and variance component methods were used for the analysis. Under the empirical genome-wide thresholds determined specifically for the FHS smoking data, we found four highly significant linkages of nicotine dependence on chromosomes 1, 3, 4, and 13 ($P = 0.001$) and seven significant linkages on chromosomes 7, 8, 9, 11, 16, 17, and 20 ($P < 0.05$). These regions include nine reported previously and two newly detected in this study. These findings strongly indicate that some of these regions may harbor susceptibility loci for nicotine dependence. Further analysis of these positive regions by fine mapping and/or association analysis is warranted. To our knowledge, this study presents the most convincing linkage evidence for nicotine dependence in the field (supported by NIH grant DA-12844).

STRATIFICATION OF AUTISM FAMILIES BASED ON SEX OF AFFECTED CHILDREN IDENTIFIES DISTINCT LINKAGE REGIONS. *B. Merriman¹, J. Stone¹, R. Cantor¹, A. Yonan³, C. Gilliam³, D. Geschwind², S. Nelson¹.* 1) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Neurology, Univ California, Los Angeles, Los Angeles, CA; 3) Columbia University, New York, New York.

Autism Spectrum Disorder (ASD) is marked by a profound bias in the gender of affected individuals. While the prevalence of ASD is estimated at 1/1000 in the general population (Folstein et al 2001), the ratio of affected males to females is 4-10:1 (Miles et al 2000, Frombonne E. 1999). This male bias is consistent across many studies and is more striking in higher functioning individuals with autism. It has been suggested that to produce an affected female requires a heavier genetic load of susceptibility genes (Tsai et al 1983). In order to test if a more homogeneous genetic group could be identified based on sex of the affecteds, we used genome scan data of Yonan et al (2003), and subdivided affected sibling pair families into two groups based on the sex of their affected children; 138 families contained only affected males while 108 families contained at least one affected female. Reanalysis of the genome scan data indicated two regions of the genome highly skewed due to the sex of affected children. First, there was stronger evidence of linkage to 17q11 (MLS 4.7) in families with affected boys only. The chromosome 17q region has been previously implicated by Yonan, et al. The shift in linkage score by sex-stratification is non-random ($p=0.01$). Second, 4q31-q34 was linked in families with at least one affected girl (MLS 2.8, genome-wide $p<0.01$), a region not implicated in the initial genome scan. Further, in the two sex-split scans we observe a highly non-random enhancement of a total of 16 (mostly minor) linkage peaks, as compared to 42 via simulation results ($p\text{-value} = 10^{-16}$), suggesting the presence of 812 additional linked loci. These results support the notion that the genetic variants which predispose to autism may have profoundly different effects in developing male and female brains. Also, the novel analytical methodology we developed applies to linkage analysis of other diseases with gender biases, and other forms of sample stratification.

Haplotype mapping of a risk locus for multiple sclerosis at the telomeric end of the HLA complex. *J.P. Rubio^{1,2}, R. Burfoot¹, M. Bahlo¹, J. Stankovich¹, L. Johnson^{1,2}, H. Butzkueven², N. Tubridy³, M. Marriott², C. Chapman³, B. Taylor⁵, D. Booth⁴, R. Heard⁴, T.P. Speed¹, G.S. Stewart⁴, T.J. Kipatrick², S.J. Foote¹.* 1) Genetics and Bioinformatics, WEHI, Parkville, VIC, Australia; 2) The Howard Florey Institute of Experimental Physiology and Medicine, Parkville, VIC, Australia; 3) The Royal Melbourne Hospital, Parkville, VIC, Australia; 4) The Westmead Hospital, Westmead, NSW, Australia; 5) The Royal Hobart Hospital, Hobart, TAS, Australia.

We have refined an MS susceptibility locus to a 210 kb genomic interval spanning the class I and extended class I sub-regions of the HLA complex. This work follows an earlier mapping study in which we detected the presence of a susceptibility locus independent of the DRB*1501-DQB1*0602 (DR15) association at the telomeric end of the classical HLA complex. To refine the locus, an additional 34 microsatellite markers (47 in total) spanning the HLA complex (D6S299 to D6S291) were genotyped in an expanded cohort of 166 Tasmanian simplex families and 104 control families. Microsatellite-based haplotypes were analysed using a novel algorithm (HAPLO_CLUSTERS), which was designed in-house. Long-range haplotypic association was observed for a genomic segment spanning 5 Mb from D6S2225 (extended class I) to G51152 (class II), and an 865 kb sub-region (extended class I/class I) was selected for fine-scale mapping with 26 SNPs. Haplotype block structure was observed across the region and a support interval ($p < 0.05$) for haplotypic association was detected for a 201 kb genomic segment encompassing the genes for GABBR1, MOG, HLA-F and HCG4. Ten SNPs mapping to the core risk interval were genotyped in an independent cohort of 356 MS simplex families from the Australian States of Victoria and New South Wales, and significant association was observed for the same risk haplotype. In conclusion, we have employed a systematic fine mapping strategy to localise four candidate genes for MS. Our findings also provide evidence for an additional MS risk locus further telomeric in the extended class I region of the HLA complex.

A Western Canadian family with pure autosomal dominant spastic paraplegia maps to the SPG8 locus. P.N.

*Valdmanis*¹, *I.A. Meijer*¹, *A. Lei*¹, *P. MacLeod*², *G.A. Rouleau*¹. 1) Centre for Research in Neuroscience, McGill University Health Centre, Montreal, Quebec, Canada *SPG8*; 2) Children's & Women's Health Center, Vancouver, British Columbia, Canada.

Hereditary spastic paraplegia (HSP) is characterized by a progressive spastic paralysis in the lower limbs. This heterogeneous disorder can exist either in a pure form or a complicated form that is accompanied by other neurological or non-neurological symptoms. *SPG8* HSP is a pure autosomal dominant form of the disease, which has previously been mapped to chromosome 8q23- 8q24 in a Caucasian kindred. Two additional families have been reported, one in Brazil, and another from Britain. Linkage analysis of these families has refined the *SPG8* locus to a 3.4 cM region between markers D8S1804 and D8S1179. We have identified a novel family from British Columbia, Canada, which displays linkage to the *SPG8* locus. Twelve members of this family are affected, nine of whom have had their DNA and clinical information collected. DNA samples have been gathered from ten other family members. Five STS markers were typed spanning from D8S1804 to D8S1128 that formed a haplotype segregating with the disease phenotype. A sixth marker at the upper boundary, D8S586, exhibited a recombination event in an affected family member. Further fine mapping is underway to determine the lower recombinant. The flanking markers currently extend beyond each end of the *SPG8* candidate region; thus the interval cannot be reduced with this family. Clinical features include a spastic gait and lower limb stiffness, typical of pure HSP individuals. The age of onset for affected individuals falls within the fourth and fifth decade. The identification of this large family will help contribute to the elucidation of the *SPG8* gene and provides further evidence for the geographic diversity of HSP *SPG8*.

X-linkage for Parkinsons Disease and Influence of Breakpoints and Recombination Hotspots on Linkage Analysis with Dense Markers: The GenePD Study. *G. Xu¹, A.L. DeStefano¹, J.B. Wilk¹, J. Latourelle¹, R. Prakash¹, J. Maher¹, M. Sun², M.E. MacDonald², J.F. Gusella², R.H. Myers¹, for the GenePD Study.* 1) Dept Neurology, Boston Univ Sch Medicine, Boston, MA; 2) Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School Boston, MA.

Parkinson disease (PD), a late-onset neurodegenerative disorder, is characterized by resting tremor, rigidity, slowness of movement and postural instability. Mutations in four genes parkin, -synuclein, DJ-1, and PINK1 have been identified to cause PD in a minority of families and more than ten PD linkage regions have been reported with the susceptibility genes in these regions still under investigation. Two independent studies show PD linkage on the X chromosome. Here we report X chromosome linkage analysis in 308 families (294 affected sib-pairs) from the GenePD Study, which yielded inconsistent multipoint LOD scores using public recombination frequencies. Analysis of 16 micro-satellite markers (STRs) and 24 single nucleotide polymorphisms (SNPs) generated LOD=3.45 at 65cM (42.65 Mb). However, the addition of two STRs and 11 SNPs at the peak region (42.65 Mb to 44 Mb) for a total 18 STRs and 35 SNPs yielded a reduced multipoint LOD=0.81 at 64cM. We explored the source of the discrepancy and found that the 1.2Mb region from 42.4Mb to 43.6Mb of chromosome X is likely a recombination hotspot. The estimation of the genetic distance based on the physical locations of the markers in the region appears to underestimate the recombination frequency. Underestimating genetic distance with dense markers may bias the linkage analysis, resulting in decreased LOD scores. With the advent of genome wide SNP typing for linkage analysis, it will be important to establish accurate genetic distances between markers in close physical proximity and to pinpoint recombination hotspots. We suggest that linkage analysis with SNP genotypes may be more susceptible to map misspecification than that with traditional STR markers, resulting in inaccurate and reduced LOD scores. This study provides evidence that chromosome Xp11 may be implicated in the susceptibility to PD.

Genome linkage screen for prostate cancer susceptibility loci: a comparison of microsatellites versus single nucleotide polymorphisms. *S.N. Thibodeau¹, J.C. Guenther¹, G.B. Christensen¹, S. Hebring¹, C. Rosenow², C.A. Hilker¹, S.K. McDonnell¹, J.M. Cunningham¹, S.L. Slager¹, D.J. Schaid¹.* 1) Dept Lab Med & Pathology, Mayo Clinic, Rochester, MN; 2) Affymetrix, Inc., Santa Clara, CA.

Prostate cancer is one of the most common cancers among men and has long been recognized to occur in familial clusters. Brothers and sons of affected men have a 2-3 fold increased risk of developing prostate cancer. However, identification of genetic susceptibility loci for prostate cancer has been extremely difficult. Although suggestion for linkage has been reported for many chromosomes, most promising regions have been difficult to replicate. In this study, we compare genome linkage scans conducted by microsatellites versus single nucleotide polymorphisms (SNPs) measured in 467 men with prostate cancer, from 167 families. For the microsatellites, the ABI Prism Linkage Mapping Set version 2 with 402 microsatellite markers was used, and for the SNPs, the Early Access Affymetrix Mapping 10K array was used. Our results show that the presence of linkage disequilibrium (LD) among SNPs can lead to inflated lod scores, and this seems to be an artifact due to the assumption of linkage equilibrium that is required by the current genetic linkage software. After excluding SNPs with high-LD, we found a number of new lod score peaks with values of at least 2.0 that were not found by the microsatellite markers: chromosome 8, with a maximum model-free lod score of 2.2; chromosome 2, with a lod score of 2.1; chromosome 6, with a lod score of 4.2; chromosome 12, with a lod score of 3.9. The lod scores for chromosomes 6 and 12 are difficult to interpret, because they occurred only at the extreme ends of the chromosomes. The greatest gain provided by the SNP markers was a large increase in the linkage information content, with an average information content of 61% for the SNPs, versus an average of 41% for the microsatellites. The strengths and weakness of the microsatellite versus SNP markers are illustrated by the results of our genome linkage scans.

An apparently novel cardiomyopathy syndrome maps to a 40Mb pericentromeric region of chromosome X. *M.A. Aldred¹, C.S. Tan¹, M.M. Williams², L.A. Tyfield², R.C. Trembath^{1,3}, I.D. Young³.* 1) Division of Medical Genetics, University of Leicester, Leicester, UK; 2) Dept. of Molecular Genetics, The Lewis Laboratories, Southmead Hospital, Bristol, UK; 3) Leicestershire Clinical Genetics Service, University Hospitals of Leicester NHS Trust, Leicester, UK.

We describe a family in which 3 male children, identical twins and their maternal cousin, were affected by an apparently X-linked syndromic cardiomyopathy. One twin died *in utero* from structural cardiac anomalies. The surviving twin was noted to have an abnormal pattern of cardiac contraction from birth and died in heart failure aged 5 months. Autopsy revealed left ventricular cardiomyopathy, with left ventricular and atrial dilatation and endocardial fibroelastosis. He was also developmentally delayed and facially dysmorphic. The maternal cousin was similarly affected and died aged 6 years. Metabolic and chromosome analyses were normal. The phenotype was not typical for CMD3A or Barth syndrome and mutation analysis of the G4.5 *TAZ* gene was normal. We then examined X-inactivation patterns at the androgen receptor locus in the boys' mothers. Both showed a completely skewed pattern, with the active X-chromosome being that inherited from their unaffected father, thus strengthening the hypothesis of an X-linked trait. In contrast, their mother, also presumed to be a carrier, showed only a slightly skewed pattern that was within the normal range, suggesting that she might be mosaic for a new mutation. Twenty-four microsatellite markers were typed, with an average spacing of 10cM. Haplotype analysis excluded both *TAZ* and *DMD*, a second X-linked cardiomyopathy locus, and identified a 40Mb pericentromeric candidate interval. Sequence analysis of two functional candidate genes within this region was normal. Further families are now sought to help narrow the critical interval for this male-lethal phenotype and pinpoint the underlying molecular defect.

Comprehensive Heritability and Linkage Analysis for ECG Measurements in Extended Mexican American Families. *U. Broeckel¹, J.T. Williams², A. Matter¹, M.P. Stern², J. Blangero², R.T. Bauer², J.W. MacCluer².* 1) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

A number of genes have been identified for monogenic diseases influencing ECG alterations such as long QT syndrome. However, the genetic mechanisms influencing normal variation in ECG measurements have not been described in detail. The aim of this study was to assess genetic influences on ECG measurements as determined by heritability analysis. In addition, we performed a genome-wide linkage analysis in order to identify chromosomal regions influencing these phenotypes.

During a first survey beginning in 1991 resting 12-lead ECGs were obtained in 943 individuals from randomly ascertained families. Individuals with atrial fibrillation and other pathologic changes such as left bundle branch block were excluded from the analysis. Heritability and linkage analyses were performed using the SOLAR software package. A significant heritability was detected for heart rate as determined by averaged R-R interval ($h^2 = 0.39$), PR interval ($h^2 = 0.32$), QRS duration ($h^2 = 0.40$), and QTc ($h^2 = 0.41$). Subsequent linkage analysis identified a number of regions linked to ECG phenotypes. The strongest evidence for linkage was detected for QTc with LOD = 2.93 at chromosome 2 at position 186cM. Additional signals were detected on chromosome 12 (LOD = 1.2), chromosome 17 (LOD = 1.65), and chromosome 22 (LOD = 1.62). Interestingly, the chromosome 17 locus overlaps with a previously described monogenic form of long QT syndrome (KCNJ2; LQT7). In addition, we identified one single linkage signal for QRS duration on chromosome 15 (LOD = 2.94) at position 139cM.

In conclusion, the most frequently determined ECG measurements show a significant heritable component in extended Mexican American families. Suggestive linkage signals were detected for QTc as well as QRS duration. In addition, we will present further data on the 10 year follow-up ECGs in order to describe the potential heritable components with regard to changes over time.

Mapping Of A Novel Gene For Hypertrophic Cardiomyopathy at Chromosome 1q32. *M. Ismail¹, N. Akhtar², A. Abid¹, S. Khaliq¹, S.Q. Mehdi¹.* 1) Biomedical and Genetic Engineering Laboratories, Islamabad, Pakistan; 2) Department of Cardiology, KRL General Hospital, Islamabad, Pakistan.

Hypertrophic cardiomyopathy (HCM) is a clinically and genetically heterogeneous disease with an autosomal dominant mode of inheritance. It is primarily a disorder of the myocardium, characterized by hypertrophy. In the absence of other conditions such as hypertension, aortic valve stenosis or thyroid disease usually the left ventricle is affected. Recent studies suggest that the prevalence of HCM is about 0.2% in the general population. To date, at least 11 disease-causing genes encoding sarcomere proteins, have been identified. Here we report a three-generation Pakistani family with the history of sudden cardiac death inherited in autosomal dominant manner. The family consists of 7 affected and 11 normal individuals. Linkage analysis was carried out to map the disease-causing gene for this family. Genomic DNA from each individual was genotyped for microsatellite markers for all the known HCM loci. A maximum two point lod score of 4.58 was obtained with marker D1S1660 at chromosome 1q 32.2. The disease region was defined by getting proximal and distal cross-overs with markers D1S1189 and D1S1678 respectively that is approximately 13.06 cM. A candidate gene TNNT2 (cardiac troponin T) present in this region was screened for mutation by heteroduplex analysis and direct sequencing. No disease-associated mutation was found in the TNNT-2 gene. Further investigations are in progress to identify the disease-causing gene for this family.

Linkage and association of the *Growth Hormone Secretagogue Receptor (GHSR, Ghrelin receptor)* gene in human obesity. A.E. Kwitek¹, A. Baessler¹, M.J. Hasinoff¹, M. Fischer¹, W. Reinhard², G.E. Sonnenberg¹, M. Olivier¹, J. Erdmann³, H. Schunkert³, A. Doering⁴, H.J. Jacob¹, A.G. Comuzzie⁵, A.H. Kissebah¹. 1) Medical College of Wisconsin, Milwaukee, WI; 2) University of Regensburg, Regensburg, Germany; 3) University of Luebeck, Luebeck, Germany; 4) GSF Institute, Neuherberg, Germany; 5) Southwest Foundation for Biomedical Research, San Antonio, Texas.

The growth hormone secretagogue receptor (GHSR, ghrelin receptor) plays an important role in the regulation of food intake and energy homeostasis. *GHSR* lies on human chromosome 3q26, within a QTL strongly linked to multiple phenotypes related to obesity and the metabolic syndrome. Because its biological function and location make it an excellent candidate gene, we tested the relationship between common single nucleotide polymorphisms (SNPs) in *GHSR* and human obesity. We performed a comprehensive analysis of SNPs, linkage disequilibrium (LD), and haplotype structure across the entire *GHSR* gene region (99.3 kb) in 178 pedigrees with multiple obese members as well as in an independent sample of the general population (WHO MONICA Study). Analyses included variance component analysis and family-based association tests. The LD analysis revealed a disequilibrium block consisting of five SNPs, consistent in both study cohorts. We found linkage between all five SNPs and BMI and, furthermore, provide suggestive evidence for transmission disequilibrium for the minor SNP-alleles and the two most common haplotypes with the obesity affection status in the family cohort. Replication of these findings in the general population resulted in stronger evidence for association of the SNPs and haplotypes with the disease. To our knowledge, these data are the first to demonstrate linkage and association of SNPs and haplotypes within the *GHSR* region and human obesity. The finding of linkage, together with both significant transmission disequilibrium in families and replication of this association in an independent population, provides evidence that common SNPs and haplotypes within the *GHSR* region are involved in the pathogenesis of human obesity.

Genome Scan for Calcified Atherosclerotic Plaque of the Abdominal Aorta: Evidence for Linkage to Chromosomes 7p and 9q in the NHLBI Family Heart Study. *L.A. Lange¹, J.J. Carr¹, I.B. Borecki², G. Heiss³, C.E. Lewis⁴, J.B. Wilk⁵, S.C. Hunt⁶, J.E. Hixson⁷, D.K. Arnett⁸, E.M. Lange¹, J.H. Eckfeldt⁸, L.E. Wagenknecht¹, for the FHS Investigators.* 1) Wake Forest University, Winston-Salem, NC; 2) Washington University, St. Louis, MO; 3) University of North Carolina, Chapel Hill, NC; 4) University of Alabama, Birmingham, AL; 5) Boston University, Boston, MA; 6) University of Utah, Salt Lake City, UT; 7) University of Texas, Houston, TX; 8) University of Minnesota, Minneapolis, MN.

Calcified atherosclerotic plaque in the abdominal aorta has been demonstrated to predict cardiovascular morbidity and mortality and is associated with other measures of atherosclerosis including calcified plaque in the coronary arteries. The NHLBI Family Heart Study (FHS) recruited large extended families from the original FHS cohort and measured atherosclerotic plaque in the infrarenal abdominal aorta and proximal common iliac arteries with multi-detector CT. Quantity of calcified atherosclerotic plaque was measured by Agatston score, modified to account for slice thickness, and then log-transformed (the value 0.50 was first added to observations of zero). We used variance components linkage analysis, adjusting for age and sex, with 579 microsatellite markers (Marshfield set 10.0) to identify chromosomal regions that may harbor genes influencing atherosclerosis in 415 Caucasian pedigrees (2,337 participants with CT data). The mean age (SD) was 57.3 (13.2) years (range 31 - 93); 55% of the cohort was female. The prevalence of calcified atherosclerotic plaque 0 (and median Agatston score in those with plaque) was 74% (1806) in men and 67% (708) in women. The strongest evidence for linkage was observed on chromosomes 7p21.3 (between D7S2201 and GATA119B03; LOD=2.15) and 9q31.1 (near GGAA22E01; LOD=2.10). A potentially important candidate gene for aortic calcification, IL-6, lies under the linkage peak for chromosome 7. This represents the first genome-wide linkage analysis of calcified atherosclerotic plaque of the abdominal aorta. These results suggest that at least two chromosomal regions may harbor genes associated with the quantity of calcified plaque.

A new locus for autosomal dominant mitral valve prolapse on chromosome 13q. *M. Leyne*¹, *F. Nesta*^{1,2}, *C. Simpson*¹, *R. Levine*^{1,2}, *S.A. Slaugenhaupt*^{1,2}. 1) Center for Human Genetic Research, Massachusetts General Hosp, Boston, MA; 2) Harvard Medical School, Boston, MA.

Mitral valve prolapse (MVP) is a very common cardiac disorder in humans, occurring in approximately 2.4% of the general population. The condition is characterized by systolic billowing of the mitral leaflets into the left atrium, often accompanied by mitral regurgitation. To date, two MVP loci have been identified. The first locus, *MMVP1*, was mapped to chromosome 16p11.2 in 1999 and in 2003 our lab identified a second MVP locus, *MMVP2*, on chromosome 11p15.4. During our MVP studies we identified a single large pedigree containing 46 individuals and excluded linkage of this family to both *MMVP1* and *MMVP2*. Thus, we performed a genome scan using the ABI Prism Linkage Mapping Set v.2 and found linkage of MVP to *D13S265* (NPL = 6.62, $p < 0.004$). We then genotyped additional markers in this region and confirmed the localization of *MMVP3* to chromosome 13q31.3-13q32.1 (NPL 18.41, $p < 0.0007$). The *MMVP3* locus is defined as an 8.2Mb region between the markers *D13S794* and *D13S786*. The current transcript map for the candidate region contains 16 genes and shows synteny to mouse chromosome 14. We are currently using novel methods in order to prioritise and initiate mutation screening of the candidate genes. Our results confirm the genetic heterogeneity of MVP and set the stage for the molecular identification of genes that play a role in the pathogenesis of this common cardiac disorder. Determination of the genetic basis of MVP is important because the disease often manifests clinically in the 5th or 6th decade of life through presentation as a severe cardiac event. Additionally, genetic analysis of MVP provides an opportunity to explore clinical findings that are currently of uncertain significance. Our familial studies have revealed individuals with variations of mitral valve morphology that do not meet standard criteria for MVP but resemble the pattern seen in fully affected family members. The ability to identify such precursor valve morphologies in younger, genetically susceptible individuals could further enhance our ability to evaluate patients at risk of developing fully expressed MVP.

Hemoglobin cluster & erythropoietin receptor genes may be related to red blood cell size and count: genome-wide scans in the Framingham Study. *J-P. Lin¹, C.J. O'Donnell², L. Jin³, C. Fox², L.A. Cupples⁴.* 1) DECA/NHLBI, NIH, Bethesda, MD; 2) Framingham Heart Study/DECA/NHLBI/NIH, Framingham, MA; 3) Center for Genome Information, University of Cincinnati, Cincinnati, OH; 4) Department of Biostatistics, Boston University, Boston, MA.

Hematocrit (HCT) levels are associated with different kinds of vascular diseases and all cause mortality. We carried out genome scans on HCT and hemoglobin (HGB), a correlated trait. The results of the two scans were not similar and no evidence suggestive of linkage was found on the chromosome regions where some important candidate genes are located. Other studies indicated red blood cell count (RBC) and size (MCV, mean cell volume and MCH, mean cell HGB), traits related to HCT and HGB, have even stronger genetic components and worth exploring. Most importantly, RBC count and size are major criteria for anemia and related hematology disease diagnoses. So far, no genome scan has been reported to determine the genetic components on those elements. We carried out 10 cM genome-wide scans on RBC, MCV and MCH in a community-based Caucasian cohort, the Framingham Study, using 330 families with 1144 individuals being genotyped and phenotyped. By variance-component linkage methods implemented in SOLAR, the heritabilities were estimated as 56%, 51% and 51% for RBC, MCV and MCH. On the RBC scan, we found maximum lod 3.2 on chromosome 19, 24 cM. Within this area there lies an important candidate gene, erythropoietin (EPO) receptor. On the MCV and MCH scans, both had a maximized lods on chromosome 11, 9 cM with lods 3.8 and 3.6 (empirical p-value method). Right under the peak area, there is hemoglobin cluster - several -like genes which are important candidates for RBC size. We also found other regions with lods > 1.5 on chromosome 12 for RBC, chromosome 1 for MCV and chromosome 18 for MCH. Our results suggest that gene(s) of hemoglobin cluster may have a major effect on the RBC size, whereas, the EPO receptor may be related to RBC count. Further studies would be worthwhile to determine the relationships between RBC size and count and positional candidate genes.

QTL mapping of heart disease modifiers in a mouse model of cardiomyopathy. *F.C. Noonan-Wheeler¹, K.M. Carlson¹, L. Fernandez², H.A. Rockman², D.A. Marchuk¹.* 1) Molecular Genet and Microbiol, Duke University, Durham, NC; 2) Medicine, Duke University, Durham, NC.

The progression from myocardial hypertrophy to heart disease and ultimately to heart failure is a complex process, involving genetic and environmental factors. Elucidating the genetic components contributing to heart disease has been difficult, due largely to the heterogeneity of human populations. Animal models can overcome this difficulty. Transgenic mice with cardiac-specific overexpression of calsequestrin (CSQ), a Ca²⁺ binding protein, develop many of the phenotypes observed in human heart failure including cardiac hypertrophy, dilation and premature death. We found strain specific differences in cardiac function and survival, indicating the presence of genetic modifiers of the heart disease phenotype. We have taken an unbiased genomic approach to the identification of these modifier genes. Our lab is using a reciprocal backcross strategy to map QTLs in the DBA and AKR strains. CSQ+ DBA mice were bred to wild type AKR mice to produce heterozygous F1 progeny. The CSQ+ F1 mice were backcrossed to generate F1/AKR and F1/DBA mice for the linkage scan. We used three quantitative traits, survival and two measures of heart function, fractional shortening and left ventricular-end diastolic diameter to measure linkage. We have previously reported results from the F1/AKR backcross in which 4 QTLs were mapped (LeCorvoisier et al. 2003). Here we report the results of a genome-wide linkage scan in the backcross to DBA. We identified one locus on chromosome 3 that showed linkage to all three traits and one additional locus linked just to heart function. The chromosome 3 QTL appears to be the same locus that we mapped in a different cross using C57/Bl6 and DBA (Suzuki et al. 2002), suggesting that a homozygous DBA genotype at this locus has a protective effect on heart function. Identification of the genes at these QTLs in the mouse will allow us to study the corresponding human genes in our heart disease population. We will perform association studies with polymorphisms in candidate genes to determine which genes and SNPs are functioning as modifiers of the heart failure phenotype.

Evidence for lipid phenotype loci on chromosomes 3q and 7p in the GENECARD study of early onset coronary artery disease. *S.H. Shah¹, D.C. Crossman², J.L. Haines³, C.J.H. Jones⁴, V. Mooser⁵, C.B. Granger¹, J.M. Vance¹, W.E. Kraus¹, E.R. Hauser¹.* 1) Duke University Medical Center, Durham, NC; 2) University of Sheffield, Sheffield, UK; 3) Vanderbilt University, Nashville, TN; 4) University of Wales College of Medicine, Cardiff, UK; 5) GlaxoSmithKline, Inc, RTP, NC.

Background: Coronary artery disease (CAD) and dyslipidemia have strong genetic components. We hypothesize that incorporating lipid phenotypes increases power to map CAD genes, narrows linkage peaks and identifies subsets for study. **Methods:** The aim of GENECARD is to identify genes for early onset CAD using linkage analysis. We performed quantitative trait loci (QTL) mapping and ordered subset analysis (OSA) on 420 GENECARD families (at least 2 siblings with CAD before age 51 in men, 56 in women) using lipids and 390 microsatellite markers. OSA defines more homogeneous subsets and calculates lod scores after ranking families by mean values of a covariate. This results in an overall lod and a maximum subset lod (the highest lod for subsets of families with most extreme covariate means). QTL mapping used SOLAR variance components analysis. **Results:** Two regions with high lod scores on the overall scan showed increased linkage for CAD using OSA: chromosome 3q (max lod 4.2, overall 2.4 $p=0.02$ in families with lowest total cholesterol (TC)) and chromosome 7p (max lod 3.6, overall 1.2 $p=0.03$ in families with highest TC). QTL mapping showed linkage to chromosome 3q (lod 1.4) for high-density lipoprotein (HDL) to TC ratio, and on chromosome 7p (lod 2.0) for TC. Families comprising the peak on 3q have significantly fewer CAD risk factors.

Conclusions: We found evidence of linkage for early onset CAD to chromosome 3q in families with fewer CAD risk factors, and a QTL for HDL/TC ratio in the same region, possibly due to a concentrated non-lipid-related genetic effect on CAD. The linkage to chromosome 7p in families with the highest TC, corroborated by a QTL for TC, may represent a lipid phenotype predisposing to early CAD. This suggests etiologic heterogeneity in our study, possibly due to differential lipid phenotypes. Candidate genes such as apoD and adiponectin reside near these regions and are being studied.

Principal Component Analysis of Quantitative Trait Loci for Adenovirus Gene Therapy. *S.K. Musani¹, H-G. Zhang², H-C. Hsu², N. Yi¹, D.B. Allison¹, J.D. Mountz².* 1) Section on Statistical Genetics, University of Alabama at Birmingham, Birmingham, AL; 2) Department of Medicine, University of Alabama at Birmingham, Birmingham, AL.

Generation of cytotoxic T-cells (CTL) is the most crucial aspect of the immune response to adenovirus (Ad) gene therapy. Other related, albeit minor responses that occur simultaneously include; changes in the sera levels of interferon gamma (IFN-), tumor necrosis factor alpha (TNF-) and interleukin-6 (IL-6). To better understand the genetic network underlying these simultaneous events, data on the -galactosidase (LacZ) expression in the liver, levels of CTLs and sera cytokines from 20 strains of C57BL/6 DBA/2 (BD) recombinant inbred (RI) mice 30 days post intravenous injection of AdLacZ were analyzed. A number of quantitative trait loci (QTLs) affecting each of these variables individually have been reported before, but because these variables are highly correlated, the present study applied principal component analysis to a genome-wide search for QTLs affecting a combination of the original variables. Principal component analysis classified variation in immune response to Ad gene therapy after 30 days into 2 independent principal components: the first principal component (PC1) extracted information on sera cytokines mainly and the second principal component (PC2) extracted information on LacZ expression and CTL production. Maximum likelihood based interval mapping revealed two QTLs on chromosomes 7 and 9 at positions 57.5 cM and 41.01 cM, respectively, to be significantly associated (LOD2.0) with PC1, whereas five QTLs were significantly associated with PC2, which mapped on chromosomes 12 (23.01 and 31.01 cM) and 15 (29.21, 36.01 and 56.31 cM). These results demonstrate the utility and potential importance of principal component analysis in mapping QTL affecting complex multiple correlated traits.

Program Nr: 1874 from the 2004 ASHG Annual Meeting

Pseudo: A program for fast calculation of empirical p-values for genomewide non-parametric tests of linkage.

J.E. Wigginton, G.R. Abecasis. Department of Biostatistics, University of Michigan, Ann Arbor, MI.

The calculation of genomewide empirical p-values for non-parametric linkage tests continues to present significant computational challenges for many complex disease mapping studies. Once a genome scan is performed, it is common practice to determine significance of lod score peaks using simulation, specifically by repeated linkage analysis of thousands or even millions of datasets generated by gene-dropping to reproduce the underlying null distribution. This empirical distribution can be used to estimate how frequently peaks of similar or greater magnitude occur by chance in data of similar structure. One limitation of this approach is the fact that individual simulations may take hours or days of computational time to complete, making it impractical to perform enough simulations to adequately evaluate significant findings. In these simulation studies, most computational effort is expended in subroutines that compute family-specific z-scores. An efficient method for sampling null genome scans is to pre-calculate family-specific z-scores for a modest number of replicates for each family and then to randomly sample from this pool in order to generate "pseudosimulations". These pseudosimulations can then be used to assign an empirical p-value to the lod score of interest. We have implemented this idea in a new program called Pseudo. Pseudo is able to compute empirical p-values extremely efficiently relative to conventional methods that utilize gene-dropping. While actual time savings will depend on the underlying data set, we have been able to generate 1000 pseudosimulations in an hour using <50M of memory for a data set that previously required 24 hours and 1.5G of memory per simulation, thus realizing a 24,000-fold speed gain while using 30 times less memory. In addition to extremely efficient calculation of empirical p-values for individual affection variables, Pseudo is able to assess significance of multiple correlated affections, produces a graphical summary of results, and provides an estimated variance for empirical p-values. Pseudo is freely available for download on our web site at <http://www.sph.umich.edu/csg/abecasis/Pseudo>.

A genome-wide scan of serum cholesterol level in young-onset hypertension families. *C. Chung¹, C.S.J. Fann¹, C.L. Hsu¹, J.W. Chen², Y.S. Jong³, H.M. Lo³, F.M. Ho³, C.K. Kang⁴, C.C. Chen⁵, H.C. Change⁵, W.H. Pan¹.* 1) Institute of Biomedical Sciences, Academia sinica, Taipei, Taiwan; 2) Cardiovascular Research Center, National Yang-Ming University, Taipei, Taiwan; 3) Tao-Yuan General Hospital Department of Health, Taiwan; 4) Min-Sheng Hospital, Taoyuan, Taiwan; 5) Lin-SHin Hospital, Chung-Li, Taiwan.

Elevated serum levels of low density lipoprotein cholesterol (LDL-C) and cholesterol are important risk factors for cardiovascular disease (CVD), which are well-established intermediate traits that may be influenced more directly by lipid metabolizing genes than clinical CVD end points. To identify the quantitative trait loci influencing total serum cholesterol and LDL-C levels, we conducted genome-wide linkage analyses in 1337 individuals from 245 families of the young-onset hypertension study which was carried out in three Hakka communities located in the northwestern Taiwan. The marker set of deCODE genetics was typed for the study subjects, which defines a roughly 10 cM resolution human index map. Evidence of linkage was assessed with a variance component method using SOLAR software. There was a strong evidence of linkage found on chromosome 6q27 for LDL-C with a LOD score of 3.42 adjusted for sex and body mass index. Other chromosomal regions with highly suggestive evidence of linkages for LDL-C and cholesterol included 8q11 (LOD 2.00), 17q25 (LOD 2.46), and 4p16 (LOD 1.86). Three candidate genes of interest are found in these regions: Apolipoprotein(a) (Lp(a)), Plasminogen (PLG) near 6q27 and Cholesterol 7- α -hydroxylase (CYP7A1) near 8q11. To establish the relevance of Lp(a), PLG, and CYP7A1 for cholesterol, we performed association study using Quantitative (Trait) Transmission/Disequilibrium Test (QTDT) and Family Based Association Test (FBAT) software after genotyping 25 single-nucleotide polymorphisms (SNPs) around three candidate regions. There are two SNPs showed significant association at PLG ($Z=2.47$, $p=0.013501$) and CYP7A1 ($Z=-2.943$, $p=0.003247$), respectively. These results have thereby allowed us to significantly reduce the number of potential candidate regions and to prioritize genes for further mutation screening.

Evidence for a QTL on 12q23 influencing triglyceride and high density lipoprotein cholesterol levels in the

HERITAGE Family Study. *M. Feitosa¹, T. Rice¹, K.E. North², T. Rankinen³, A.S. Leon⁴, J.S. Skinner⁵, J.H.*

Wilmore⁶, J.P. Despres⁷, J. Blangero⁸, C. Bouchard³, D.C. Rao¹. 1) Div Biostatistics, Washington Univ School Medicine, St Louis, MO; 2) Dep Epidemiology, Univ North Carolina Chapel Hill, NC; 3) Pennington Biomedical Res Center, Louisiana State Univ System, Baton Rouge, LA; 4) School Kinesiology, Univ Minnesota, Minneapolis, MN; 5) Dep Kinesiology, Indiana Univ, Bloomington, IN; 6) Dep Health and Kinesiology, Texas A & M Univ, College Station, TX; 7) Québec Heart Institute, Québec, Canada; 8) Dep Genetics, Southwest Found Biomedical Res, San Antonio, TX.

To determine whether a QTL influenced the variation of triglyceride (TG) and high density lipoprotein cholesterol (HDLc) levels, bivariate linkage analysis was employed using 654 makers. Covariate effects of age, sex, hormonal use, smoking, fasting insulin levels and body mass index (BMI) were removed and the residuals were used for SOLAR univariate and bivariate variance component linkage analysis. A maximum genome wide bivariate LOD score of 3.0 was found on chromosome 12q23-q24 (at 108cM) for TG and HDLc in White families (from 99 nuclear families with 606 parent-offspring and 383 sibling pairs). This linkage peak is substantially higher than the univariate linkage at the same chromosome location for each trait (TG: LOD = 1.98, HDLc: LOD = 2.04). The genetic correlations between baseline TG and HDLc were -0.14, for the residual component (r) and -0.33 for the QTL (Q_{TL}). The complete pleiotropy ($Q_{TL} = 1$) and the coincident linkage QTL ($Q_{TL} = 0$) hypotheses were both rejected ($p < 0.001$). In conclusion, these results suggest incomplete pleiotropy for a QTL on 12q23-q24 influencing the plasma levels of TG and HDLc. A putative nearby positional candidate gene is the class B scavenger receptor (SR-BI), which has a high affinity binding for HDLc and mediates selective cholesterol uptake.

A QTL for left ventricular mass on chromosome 12p in American Indians. *H.H.H. Göring¹, V.P. Diego¹, S.A. Cole¹, L. Almasy¹, T.D. Dyer¹, K.E. North², T.K. Welty³, L.G. Best³, R.R. Fabsitz⁴, B.V. Howard⁵, E.T. Lee⁶, S. Laston¹, B. Dyke¹, J.W. MacCluer¹, R.B. Devereux⁷.* 1) Dept. of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Dept. of Epidemiology, University of North Carolina, Chapel Hill, NC; 3) Strong Heart Study Dakota Center, Rapid City, SD; 4) National Heart, Lung, and Blood Institute, Bethesda, MD; 5) MedStar Research Institute, Hyattsville, MD; 6) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 7) Cornell University Medical Center, New York, NY.

Left ventricular mass (LVM) is a clinically important phenotype for assessing the risk of cardiovascular morbidity and mortality. Identification of the genetic factors that influence an individual's LVM may therefore provide crucial knowledge about heart disease and treatment. We have measured LVM (adjusted for height) in participants in the Strong Heart Family Study, a multi-center study of cardiovascular disease (CVD) risk factors in large, randomly ascertained pedigrees of American Indians from Arizona (AZ), North/South Dakota (DK), and Oklahoma (OK). Each individual's phenotype was adjusted for sex and age and normalized prior to analysis. Data from the 3 centers were analyzed separately as well as jointly. 1915 phenotyped individuals from 69 pedigrees in total were included in the analyses, with nearly equal sample sizes from the 3 centers. The heritability of LVM was estimated as 0.38, 0.46, 0.45 and 0.43 in the AZ, DK, OK and combined sample, respectively. Genome-wide variance components linkage analysis yielded a lod score of 3.1 on chromosome 12p (between markers D12S364 and D12S310) in the AZ sample. This finding was replicated with a lod score of 3.1 at the same position in the DK sample. In the OK sample, the lod score at the same position was 0.3. The 3 datasets were subsequently combined. Analysis of the combined sample yielded a lod score of 5.4. No other significant lod scores were obtained in the individual datasets or the combined sample. In summary, our results provide overwhelming evidence for a major locus for LVM, a strong predictor of CVD, on chromosome 12p in American Indians.

Evidence for Ethnic Specific QTLs for CRP levels: The IRAS Family Study. *J.I. Rotter^{1,2}, S. Beck³, X. Guo^{1,2}, C.D. Langefeld³, K.D. Taylor^{1,2}, F-C. Hsu³, L. Wagenknecht³, S. Rich³, M.F. Saad², Y.D. Chen^{1,2}.* 1) Medical Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) UCLA, Los Angeles, CA; 3) Wake Forest University School of Medicine, Winston-Salem, NC.

Increased C-reactive protein (CRP) levels have been reported to predict coronary heart disease, stroke, peripheral vascular disease, and diabetes, and are associated with features of the metabolic syndrome. Family-based studies have shown that plasma levels of CRP are influenced strongly by genetic factors, including variation in the CRP gene itself. As part of the IRAS Family Study, the NHLBI Mammalian Genotyping Service (MGS) performed a 10 cM genome scan on 1520 individuals (Hispanic American (HA): 1135; African American (AA): 567) from 130 families (HA: 88; AA: 42). A variance components approach (SOLAR) was used for analysis on plasma CRP (g/ml) levels (determined by ELISA), with age, sex, and BMI included as covariates to adjust for possible confounding effects. These analyses revealed a potential quantitative trait locus (QTL) on chromosomes 1q21-25 near D1S1589 (LOD=2.66 at 187 cM) and 11p15 near D11S1984/D11S2362 (LOD=2.77 at 6 cM) that contributes to variation in CRP level in the AA sample. Only very modest evidence of linkage to CRP levels in these regions were observed in the HA families (1q21-25 LOD=0.25 and 11p15 LOD=0.13). Interestingly, several studies have reported linkage of type 2 diabetes to the 1q21-25 region and the CRP gene is within 1q23. The strongest support for linkage in HA was on chromosome 4q23-25 (LOD=2.11, 109 cM). This region is rich in immunological candidate genes such as the FCgamma family. When combining the HA and AA data and further including ethnicity as a covariate, the LOD score remained 2.06 on chromosome 1q in the entire sample. In conclusion, there is evidence supporting the existence of QTLs on chromosome 1 and on chromosome 11 that contribute to the variation of CRP levels in AA while HA show linkage to chromosome 4, providing evidence for genetic heterogeneity between the two ethnic groups.

Genetic analysis of HNF4 polymorphisms in Caucasian American type 2 diabetes. *A.M. Bagwell^{1, 4}, J.L. Bento^{2, 4}, J.C. Mychaleckyj^{3, 4}, B.I. Freedman³, D.W. Bowden^{1, 2, 3, 4}.* 1) Molecular Genetics Program; 2) Department of Biochemistry; 3) Department of Internal Medicine; 4) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC.

Hepatocyte nuclear factor 4 alpha (HNF4), the gene for maturity-onset diabetes of the young type 1 (MODY1) subtype of type 2 diabetes mellitus (T2DM), lies within the T2DM-linked region on chromosome 20q12-13 and is therefore a positional candidate for later-onset T2DM. Only a few rare coding mutations have been identified in HNF4, but recent studies suggest that single nucleotide polymorphisms (SNPs) located near the HNF4 alternate promoter P2 are associated with diabetes susceptibility in Finnish and Ashkenazi populations. We genotyped 23 SNPs covering 111 kb which includes the HNF4 gene and tested them for association with T2DM in a collection of 300 Caucasian T2DM patients with end-stage renal disease (ESRD) and 310 controls. In contrast to previous reports of association, our single SNP analysis provided no evidence for association with T2DM, with P-values ranging from 0.06-0.99. However, haplotype analysis of SNPs in two separate linkage disequilibrium blocks, one encompassing the P2 promoter and the second in the exon 4 region of HNF4, identified statistically significant differences in haplotype frequencies between cases and controls ($P < 0.0001$). The haplotype analysis identified two uncommon risk haplotypes (2.36% and 2.24% of chromosomes) in the P2 block and two uncommon protective haplotypes (7.14% and 5.02% of chromosomes) in the exon 4 block that account for the observed haplotypic associations. DNA sequencing did not identify SNPs in P2 or mutations in exon 4. The observed associations with haplotypes in the absence of single SNP associations suggest that a combination of noncoding SNPs may drive the observed associations with the phenotypes. In addition, evidence that other genes in 20q12-13 are associated with T2DM in our subjects suggests that the diabetes phenotype may be due to the contribution of multiple genes. Together, these results suggest that T2DM linked to 20q12-13 is a heterogeneous disease in which different populations may have different T2DM susceptibility loci.

Parametric linkage analysis of type 2 diabetes (T2DM) replicates 2 loci and reveals a pattern of heterogeneity in pedigree-specific analysis. *W. Blaum*^{1,2}, *K. Hunt*², *M.P. Stern*². 1) Institut fuer Humangenetik, Charite Berlin, Germany; 2) Dev of Epidemiology, Univ of Texas Health Science Center San Antonio.

Of the 39 Mexican-American extended pedigrees from the San Antonio Family Diabetes Study we selected for parametric linkage analysis 7 pedigrees in whom an autosomal dominant mode of inheritance for T2DM was suggested. WHO and ADA criteria were used to define T2DM. The 7 pedigrees contained 242 persons of whom 99 were affected by WHO criteria (68 by ADA). 182 subjects were genotyped by CIDR with a set of 382 microsatellites. Four runs of two-point (tpt) analysis (WHO and ADA criteria with and without age-adjustment) were performed using LINKAGE. Regions for which at least two runs showed LODs > 1 and no run contradicted linkage are reported and were selected for parametric multi point (mp) analysis using GENHUNTER2. Markers that met these criteria included D9S1779 (max. tpt LOD: 1.35), D9S1871 (1.13) and D9S2169 (1.43) on chr9p as well as D20S478 (1.09) on chr20. Mp analysis showed a LOD of 1.45 near D9S2169 and of 1.3 near D20S478 in all 7 families. The 2p HLODs (GENHUNTER2) indicate heterogeneity in both regions: 2.1 (=0.53) on chr9p and 1.51 (=0.27) on chr20. We thus examined markers in individual families where at least one tpt run showed suggestive linkage (LOD > 1.9), at least one a LOD > 1, and no run showed a LOD < 0.588 (corresponding to a p-value of 0.05). Of 5 results that met these criteria the most interesting were a tpt LOD of 2.94 (family #2) at marker D9S2169 and of 2.69 at D20S478 (family #9). All flanking markers in these families also showed LODs > 1. In mp analysis family #2 shows a LOD of 2.93 near D9S2169 and family #9 one of 2.44 near D20S478. Results on chr9p replicate previous findings in Mexican-Americans and American-Caucasians while the region on chr20 has recently been linked to T2DM in Finns and Ashkenazim Jews. An interesting positional candidate in the latter region is HNF4 (MODY 1). Our study thus proved useful in the identification of both, susceptibility loci for T2DM and small(er) sets of individuals for whom a further investigation seems promising.

Extended haplotype in the PKLR region on 1q21 is associated with type 2 diabetes. *R.L. Craig¹, Z. Zhang¹, W.S. Chu¹, H. Wang¹, S.C. Elbein²*. 1) Internal Medicine, UAMS, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR.

Type 2 diabetes has been mapped to chromosome 1q21-q24 by multiple laboratories. Pyruvate kinase, a key glycolytic enzyme expressed in liver and pancreatic beta cells, is encoded by PKLR and is located within the linked region. We previously reported an association of 4 SNPs within the PKLR gene with T2DM. To identify the extent of that association, we selected 65 SNPs over a 400 kb region surrounding PKLR from the public database. Only 17 SNPs were polymorphic and could be successfully typed using Pyrosequencing. We initially typed pools of 192 unrelated, non-diabetic Caucasian control individuals and 192 Caucasian individuals with T2DM, and confirmed differences of over 5% in individual samples. We identified 9 additional SNPs that were associated with T2DM ($p < 0.05$) in a population that was expanded from our original report. The associated SNPs extended from 8 kb telomeric to 50 kb centromeric to PKLR, and encompassed at least 4 additional genes. Within this region, all associated SNPs showed strong linkage disequilibrium ($r^2 > 0.75$) and most associated SNPs were in complete linkage disequilibrium. The strongest associations showed p values of 0.007 (OR=1.6) and tagged the extended haplotype. In contrast, only 1 SNP in this region showed neither association nor linkage disequilibrium by r^2 . No association was found when the most strongly associated PKLR SNPs were tested in 260 African American diabetics and 160 African American controls, however. We have confirmed our earlier findings of an association using additional markers and an expanded population. However, extensive disequilibrium will make identification of the causative variant in this region challenging. The lack of association in African American subjects may suggest that the responsible SNP is 5' or 3' to PKLR. Work is in progress to resequence each gene in this region in Caucasian individuals with each haplotype to identify additional variation given the paucity of validated and 2 hit SNPs in the current database.

Examination of candidate chromosomal regions for type 2 diabetes mellitus (T2DM) in Kuwaiti population. *M.M. El-Zawahri¹, M.S. Al-Dabbous¹, M.A. Taha², M. Al-Aroug³*. 1) Dept Biological Sci, Fac Sci, Kuwait Univ, Safat, Kuwait; 2) Dept Statistics & Operation Research, Fac Sci, Kuwait Univ, Kuwait; 3) Alameery General Hospital, Ministry of Health, Kuwait.

Type 2 diabetes mellitus (T2DM) shows multifactorial etiology with strong evidence for many genes interact not only with each other but also with environmental factors. It accounts for approximately 90% of diabetes cases. Kuwaiti population is a small and multiplex families from three main Asian ancestral populations (Saudi Arabia, Iran and Iraq). The rate of consanguineous marriages has reached 54.5% within the Kuwaiti families. The prevalence of T2DM in Kuwaitis is two fold higher than worldwide prevalence average. We genotyped markers in nine chromosomal regions (1q, 2p, 2q, 3q, 5q, 7q, 8p, 9q, and 20q), previously reported as supporting linkage with T2DM, in a panel of 42 large Kuwaiti pedigrees in which diabetes segregates consistent with an autosomal dominant (AD) pattern. Candidate regions on 3q, 5q, 7q and 9q yielded little evidence for linkage. Regions on 1q (MLS=0.96), 2p (MLS=1.11) and 2q (MLS=0.84) gave only suggestive evidence of linkage. While as regions on 8p (MLS=3.71) and 20q (MLS=3.35) gave significant evidence of linkage. These results provide strong evidence to support 8p and 20q as candidate chromosomal regions for susceptibility loci for type 2 diabetes mellitus in Kuwaiti population. In conclusion, linkage evidence provided in this study is particularly important given the evolutionary history of this multiplex Kuwaiti population and its well documented historic contribution ; Kuwaitis have one of the most highest rates of diabetes in the world. This work was supported by College of Graduate Studies, Kuwait University, Kuwait.

Variation in conserved nongenic sequence upstream of dual specificity phosphatase (DUSP12) gene on chromosome 1q21 is associated with type 2 diabetes. *S.C. Elbein^{1,2}, S.K. Das¹, W.S. Chu¹, Z. Zhang¹, S.J. Hasstedt³.*
1) Medicine, Slot LRVA/111J-1, Univ Arkansas Medicine, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR; 3) University of Utah Health Sciences Center, Salt Lake City, UT.

Genome scans in multiple populations spanning 4 ethnic groups have linked chromosome 1q21 to type 2 diabetes (T2DM). We tested 568 SNPs across the 15 Mb linked region and identified a significantly associated ($p < 0.00001$) SNP in pooled DNA. We tested 45 polymorphic SNPs at a mean 4 kb interval over 1 Mb around this SNP and narrowed the associated region to a 50 kb interval encompassing the DUSP12 gene. DUSP12 is expressed in liver and pancreas and was previously shown to regulate glucokinase activity in liver. We screened for mutations in DUSP12 exons, introns, and 2 kb of 5' and 3' flanking regions in 16 cases and 8 controls. We also identified a highly conserved nongenic sequence (CNG) at -8 kb from the ATG start and near the original association. We tested the association of 29 SNPs over 20 kb in 192 Caucasian cases and 192 Caucasian controls, and identified 10 SNPs over 18 kb that were associated with $p < 0.05$. Additional SNPs showed a trend to association. The strongest associations were with a microsatellite within the CNG (-8379) and a SNP at 7581 in the 3' flanking region. The SNPs fell into 5 haplotype blocks defined by D' (confidence intervals). The associated SNPs fell into 2 blocks by D' or 4 bins defined by r^2 . The most associated haplotypes were driven by the CNG microsatellite (-8379) and the 3' (7581) SNP with $OR = 1.7$. Haplotypes of 4-5 markers spanning 3 - 4 bins and 2 blocks showed strong associations with T2DM ($p = 0.0009$ and $p = 0.00015$), with both protective and risk haplotypes. Both the microsatellite and 7581 SNPs were also associated with T2DM in 286 cases and 167 controls of African American ethnicity ($p < 0.02$ for both), but other SNPs were not associated. Furthermore, allele frequencies and associated microsatellite alleles differed from Caucasians. We propose that the 3' (7581) SNP and the CNG variants alter DUSP12 expression and lead to T2DM through altered glucokinase activity in liver and pancreas.

Contribution of CYP19 polymorphisms to the risk of type 2 diabetes stratified by physical activity. C.E.

Engelman¹, T.E. Fingerlin¹, L.K. Moss¹, M.M. Barmada², R.E. Ferrell², J.M. Norris¹. 1) University of Colorado Health Sciences Center, Denver, CO; 2) University of Pittsburgh, Pittsburgh, PA.

Type 2 diabetes mellitus (T2DM) may result from an interaction between genetic susceptibility and environment. A polymorphism in the cytochrome p450 aromatase (CYP19) gene (15q21.1) was found to be linked with T2DM, after conditioning on Calpain-10 (Cox, 1999). In addition, studies have found physical inactivity to be a determinant in T2DM. Despite the importance of both environmental and genetic factors, few studies have examined these factors together. We used the family based association test (FBAT) to look for association of 2 single nucleotide polymorphisms (SNPs) in the CYP19 gene and T2DM in 743 affected Caucasian individuals from 252 families from Colorado. The FBAT allows for missing parental genotypes, and accounts for the relatedness of affected individuals in the analysis. A physical activity history was collected by questionnaire and average METs per week from occupational and leisure activity prior to diabetes diagnosis was calculated. We conducted an analysis overall, and in the upper and lower tertiles of physical activity. In the overall analysis, the Hgal site of CYP19 was associated with T2DM ($p=0.002$) and the rs700518 site showed suggestive evidence for association ($p=0.08$). In the affecteds with high levels of physical activity, the Hgal site was less significantly associated with T2DM ($p=0.03$) and the rs700518 site showed no association ($p=0.46$), results that could be influenced by the reduced sample sizes in each tertile. However, in the affecteds with low levels of physical activity (exposed to the risk of inactivity) the rs700518 site showed significant association with T2DM ($p=0.01$) despite that reduction in sample size. The Hgal site could not be analyzed in the affecteds with lower physical activity due to a small sample size since the 1 (Cys) allele has a frequency of 6%. In conclusion, the CYP19 gene may be associated with T2DM, particularly in individuals with lower levels of physical activity, suggesting a potential gene-environment interaction.

Strong association of intragenic SNPs with type 2 diabetes in the 152 megabase region of chromosome 1q21 in the Old Order Amish. *M. Fu*^{1,2}, *M. Sabra*¹, *C. Damcott*¹, *T.I. Pollin*¹, *S. Ott*¹, *K. Tanner*¹, *J. Wang*¹, *X. Shi*¹, *J. Connell*¹, *B.D. Mitchell*¹, *A.R. Shuldiner*^{1,3}. 1) Dept Med, Div Endocrinology, Diabetes, and Nutrition, Univ Maryland, Baltimore, MD; 2) Division of Endocrinology, the Second Affiliated Hospital, Sun Yat-sen University, Guangzhou, P. R. China; 3) Geriatric Research and Education Clinical Center (GRECC), Veterans Administration Medical Center, Baltimore, MD.

Linkage of type 2 diabetes (T2DM) to chromosome 1q21-q24 has been observed in the Old Order Amish, and other 5 populations. Amish genome-wide and fine-mapping linkage studies revealed evidence for linkage of T2DM and impaired glucose tolerance (IGT) to 1q21 (near D1S2858, LOD = 2.35, P = 0.0008). To positionally clone the T2DM susceptibility gene in the region, we first performed linkage disequilibrium (LD) mapping with SNPs distributed over the broad region of 40 Mb underlying the linkage peak. Additional iterative genotyping of SNPs around positive signals identified three distinct regions associated with T2DM and/or IGT, at 152-153 Mb, 156-161 Mb, and 166-168 Mb. In total, 100 SNPs at inter-marker intervals averaging 40 Kb were genotyped in the 150-153 Mb region in 651 Amish subjects with T2DM (n = 145), IGT (n = 148), and normal glucose tolerance (n = 358). We identified 6 SNPs associated with T2DM, IGT, and T2DM/IGT (P = 0.0006-0.0444) and 4 SNPs associated with IGT and IGT/T2DM (P = 0.0015-0.023). These SNPs were genotyped in an expanded set of 1200 Amish subjects and were found to be significantly associated with glucose area under curve during an oral glucose tolerance test (p = 0.001-0.049), providing additional support for association of the SNPs with glucose homeostasis. The nine significantly associated SNPs were in strong LD (D' 0.9) and formed a haplotype block of approximately 67 Kb. The SNPs were distributed in introns, untranslated regions and within 2 Kb of 7 genes. Association of SNPs to T2DM within the region of high LD has also been shown in Utah Caucasians. In summary, it is likely that more than one gene in the chromosome 1q21-q24 region contributes to T2DM and may reside within a 67 kb region defined by these ongoing LD mapping studies.

Selected Linkage Studies for T2DM to Chromosomes 20, 12 and 17 in Italians. C. Gragnoli^{1,2,3}, E. Milord⁴, J.F. Habener^{1,2,5}. 1) Mol Endocrinology, Mass Gen Hosp, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Bios Health Center, Rome, Italy; 4) Millennium Ph, Inc, Cambridge, MA; 5) HHMI, Boston, MA.

Type 2 diabetes mellitus (T2D) is a common complex trait disorder. Multiple genome scans have identified different loci in linkage with T2D. Loci on chromosomes 12q15 and 20q have been identified in independent studies. A meta-analysis of four genome scans has reported a linkage on chromosome 17p11.2-q22. Not far away from this region lies the glucagon receptor gene (GCR), on chromosome 17q25. The possibility that the linkage on chromosome 17 might include the GCR gene may not be entirely eliminated, given substantial potential variation in loci localization estimates. In a combined French-Sardinian study of GCR gene there is association of Gly40Ser mutation with T2D, confirmed by an UK study but not by other studies. Our goal was to study these selected regions of chromosome 17, 12 and 20 in a group of Italian patients with late/early-onset T2D by microsatellites genotyping (D17S801, D17S937, D17S180; D12S355, D12S1056, D12S1655; D20S887, D20S109, D20S196) and non-parametric multipoint linkage analysis (Merlin 2000-2002/decode map or Marshfield map) with allele frequencies calculated from sib-pairs data. We have recruited from Rome 174 sib-pairs with T2D, 29 sibpairs/families with early-onset T2D and MODY. The linkage analysis at chromosome 17q25 reported a lod score=-0.22 (P=0.8) in the total T2D sib-pairs, a lod score=-0.09 (P=0.7) in the late-onset T2D group and a lod score=-0.31 (P=0.9) in the early-onset T2D group. At chromosome 12q13.1-13.2 in the total T2D sib-pairs identified a lod score=0.03 (P=0.4), a lod score=-0.02 (P=0.6) in the late-onset T2D group and a lod score=0.67 (P=0.04) in the early-onset T2D group. At chromosome 20q13.1 in the total T2D sib-pairs reported a lod score=0.35 (P=0.1), a lod score=0.32 (P=0.11) in the late-onset T2D group and a lod score=0.11 (P=0.2) in the early-onset T2D group. We can exclude in our patient cohort linkage to T2D in the region containing the GCR gene and on chromosome 20q13.1. Linkage analysis in our patient group suggests that chromosome 12q15 might carry a gene causing T2D in the early-onset Italian T2D cohort.

Further evidence of a Quantitative Trait Locus for Body Mass Index (BMI) mapping to Chromosome 10p and subsequent analysis of the positional candidate gene *GAD2* in a large European Type 2 diabetes sibship resource.

*C.J. Groves*¹, *E. Zeggini*¹, *A.T. Hattersley*², *M. Walker*³, *G.A. Hitman*⁴, *S. O'Rahilly*⁵, *M.I. McCarthy*¹, *S. Wiltshire*¹. 1) Oxford, UK; 2) Exeter, UK; 3) Newcastle, UK; 4) London, UK; 5) Cambridge, UK.

Type 2 diabetes (T2D) and obesity are closely related phenotypes. In this study we reanalysed genome scan data from 418 microsatellite markers (mean spacing 9.3cM (H)) genotyped in 573 UK sibships multiplex for T2D, using BMI as the outcome quantitative trait. BMI information, available from 1223 T2D subjects (mean (SD) BMI: males 27.8 (4.3) kgm⁻²; females 29.8 (5.6) kgm⁻²), was log-transformed, adjusted for age and sex, and standardised against a representative sample of 14000 UK subjects to account for selected ascertainment. Analysis was performed using MERLIN-REGRESS to implement a modified Haseman-Elston (HECOM) analysis. The only region demonstrating significant linkage was located at 10p11.2-10q11.3. The maximum LOD score (3.74 @ 42 Mb (NCBI34), pointwise asymptotic $p=1.7 \times 10^{-5}$ between D10S208 - D10S196) reached genome-wide significance (empirical $p=0.0158$), with no other region generating LOD scores 1.18. This same region has shown evidence for linkage to obesity/BMI in seven studies to date. In French families showing linkage to 10p, positive associations were reported with variants in the *GAD2* gene. *GAD2* encodes glutamic acid decarboxylase, an enzyme that has been implicated in the gabanergic control of appetite. However, in the UK families we found no evidence for association between any of these variants (-243 AG: $p=0.8$; +61450 CA: $p=0.5$; +83897 TA: $p=0.5$), or their haplotypes and obesity. In addition, using family-based association analysis (QTDT) we found no evidence that these variants accounted for the 10p linkage signal. These data provide strong, replicative evidence for the presence of an obesity gene on chromosome 10p: however, variation at the *GAD2* locus is not likely to be responsible, and linkage must be due to variation in other genes.

Variants at the CTLA4 gene region are significantly associated with both type 1 diabetes and age at diagnosis in Newfoundland. *M. Liu¹, K.S. Wang¹, M.Y. Lu¹, B. Bharaj¹, H.T. Chen¹, J. Pasternak¹, J.A. Curtis², L.A. Newhook², A.D. Paterson^{1, 3}.* 1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Pediatrics, Memorial University of Newfoundland, St. Johns, Newfoundland, Canada; 3) Department of Public Health Sciences, University of Toronto, Toronto, Ontario, Canada.

Background: Studies have shown that both type 1 diabetes (T1D) and the age at diagnosis of T1D have a genetic component. The CTLA4 gene is an important negative regulator of the T lymphocyte immune response, and is one of the three confirmed candidate loci (IDDM12) for T1D. However, the relation between the CTLA4 gene and the age at diagnosis of T1D is largely unknown. Method: We genotyped eight SNPs and one (AT)_n microsatellite marker which covered about 45 kb around CTLA4 (2q33). Family-based association analysis was performed with FBAT using 538 extended families (including 628 affected individuals) from Newfoundland, where there is a high incidence of T1D. Age at diagnosis was analyzed as a quantitative trait with an upper limit at 18 years old in order to reduce the effect of extreme values. Since all the markers were in strong linkage disequilibrium (LD) with mean D equal to 0.93, haplotype analysis of all possible groups of markers was also performed. Result: For T1D, four markers (3 SNPs and one microsatellite marker) showed significant association ($p < 0.01$) with the lowest p value equal to 0.0016 for allele 120 of the (AT)_n microsatellite marker (allele frequency 0.029). The most significantly associated haplotype ($p = 0.00021$) was a SNP pair rs231728-rs231806 (frequency 0.036) with excess transmission to affected offspring. For the age at diagnosis of T1D, two SNPs rs231806 (allele frequency 0.59) and rs5742909 (allele frequency 0.089) were significant associated with p values 0.0026 and 0.0037, respectively. Haplotype rs5742909-rs3087243 (frequency 0.078) was most significantly associated with age at diagnosis ($p = 0.0013$). Conclusion: Our data showed that the polymorphisms at the CTLA4 gene region were significantly associated with both T1D susceptibility and the age at diagnosis of T1D in Newfoundland population.

Genetic Analysis of Quantitative Lipid Traits in the Genetics of NIDDM (GENNID) Study. *A. Malhotra, J.K. Wolford.* Translational Genomics Research Institute, Phoenix, AZ.

Lipid levels serve as important markers in a number of diseases with high prevalence, including cardiovascular disease, obesity, and diabetes. Although environmental factors such as diet affect lipid levels, familial aggregation and twin studies have suggested the role of genetic factors and heritability estimates have been found to range from 0.3-0.75. The goal of this study was to identify potential genetic determinants of lipid levels in African Americans, Caucasians, and Hispanics from the GENNID repository, a publicly available resource that contains information on families ascertained with at least two diabetic children. There are a total of 350 families corresponding to approximately 1,750 individuals in our study sample. Regression analyses were performed on low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglycerides (TG), total cholesterol, LDL/HDL, and TG/HDL and the data were adjusted for covariates, such as age and gender, significantly related to these values. In a segregation analysis of these traits, two-locus models, in some cases, had higher likelihood estimates than the single gene models, but a mode of inheritance could not be inferred. We performed variance components linkage analysis as implemented in the program Genehunter. In African-Americans, the highest multipoint LOD scores were found for LDL/HDL (LOD=1.9) on chromosome 5p, and cholesterol (LOD=1.73) and LDL (LOD=1.54), both on chromosome 19p. Two-point LOD scores of 0.97 for LDL/HDL, 1.32 for cholesterol, and 1.64 for LDL were observed in these locations. The linked region on chromosome 19, which is approximately 10cM from the LDL receptor and the APOE genes, overlaps with results obtained in at least five independent studies, providing further support that 19p harbors a susceptibility locus. No LOD scores greater than 1.5 for HDL, TG, or TG/HDL were found. We are currently performing variance components linkage analysis using Caucasian and Hispanic genotype data.

Genetic analysis of Type 1 Diabetes in an Isolate Population from South America. *N. Pineda-Trujillo*^{1,5}, *F. Uribe*², *V. Balthazar*³, *F. Montoya*⁴, *J.M. Alfaro*³, *G. Latorre*², *A. Villegas*², *J. Ceron*^{1,2}, *A.F. Perez*^{1,2}, *M. Ospina*¹, *A. Naranjo*¹, *A. Serrano*², *D. Castrillon*^{2,3}, *I. Duque*², *A. Abad*², *C.E. Duque*¹, *G. Bedoya*¹, *A. Ruiz-Linares*^{1,5}. 1) Grupo de Genetica Molecular; 2) Medicina Interna-Endocrinologia; 3) Endocrinologia- Pediatria y Puericultura, from Universidad de Antioquia, Medellin, Colombia; 4) Universidad Pontificia Bolivariana, Facultad de Medicina, Medellin, Colombia; 5) Biology (Wolfson House)University College London, London-United Kingdom.

The most important genetic risk for type 1 diabetes (T1D) is conferred by HLA (IDDM1) and it is believed that this locus interact with others to give the T1D phenotype. We have done two separate studies in samples from Antioquia, a population isolate in North West Colombia. The first study involved a set of three families, where one of them presented with 9 out of 16 affected individuals. This family showed a dominant-like inheritance mode with high penetrance (98.5%) and affected individuals were anti-GAD positive. In addition to evaluate previously reported candidate loci on chromosomes 2 and 11, we also evaluated the rest of these two chromosomes with markers from the Linkage mapping set v.2 (Applied Biosystems). We also evaluated STRs on class II HLA. For chromosomes 2 and 11 negative lod scores (Z) were obtained and for HLA low values were obtained. However, a $Z = 2.8$ was found at theta zero in 2pter for marker D2S319. Haplotypes in HLA were randomly transmitted. In the second study we collected one hundred trios (father-mother-affected child) and evaluated D2S319, IDDM2 and IDDM8 loci. All affected children were tested for anti bodies anti-GAD and only 40% were positive. The most significant Pvalue in the TDT was for D2S319 and for IDDM8 with a value of 0.025. Hph I at IDDM2 with a Pvalue of 0.03. After stratifying according to the antibodies result, Pvalues of 0.03, 0.04 and 0.04 for IDDM8, D2S319 and Hph I respectively were obtained. These results suggest that in this Colombian sample there are important effects of at least these three loci affecting the susceptibility for T1D. Including therefore that the new locus (D2S319) truly exists in 2pter.

Stronger evidence for linkage in type 2 diabetes families with mean age-of-diagnosis 55 years of age. *L.J. Scott¹, W.L. Duren¹, A.U. Jackson¹, T.T. Valle², J. Tuomilehto², R.N. Bergman³, F.S. Collins⁴, M. Boehnke¹.* 1) U. Michigan, Ann Arbor, MI; 2) Nat'l Public Health Inst., Helsinki, Finland; 3) U. Southern California, Los Angeles, CA; 4) NHGRI, Bethesda, MD.

Younger age-of-diagnosis (AOD) UK type 2 diabetes (T2D) families showed greater evidence of linkage for T2D compared to older onset T2D families (Frayling et al., 2003). We examined the evidence for linkage in 441 families with mean T2D AOD 55 years of age (mean AOD =47.75.5) and 295 families with T2D AOD > 55 years of age (mean AOD =59.23.1) from the Finland-United States Investigation of NIDDM Genetics (FUSION) study. Compared to individuals in AOD > 55 families, individuals in AOD 55 families had higher weight at age 30 (74.315.4 vs. 69.611.9 kg, $p < .0001$) and higher fasting glucose at study (10.33.4 vs 9.43.1 mmol/l, $p < .0001$). In a genome-wide T2D linkage scan, the strongest evidence for linkage in AOD 55 families was $MLS=2.81$ on chromosome 11q and in AOD > 55 families was $MLS=1.27$ on chromosome 21p. We asked if the number of autosomal regions with LOD scores greater than a given value was larger than expected by chance in the AOD 55 families by randomly choosing 441 families and rerunning the linkage analysis 10000 times. We did not observe a significant enrichment of peaks with $MLS > 2.5$ (1 observed, .59 expected, $p\text{-value} = .49$) or $MLS > 2$ (1 observed, 1.23 expected, $p\text{-value} = .79$), but we did observe more peaks than expected with $MLS > 1.5$ (6 observed, 2.51 expected, $p\text{-value} = .006$, peaks on chromosomes 6q, 7q, 11q, 12p, 14q, 17p). None of the regions had a higher LOD score in the AOD 55 families when compared to the total sample: chromosome 6q ($MLS=1.84$ vs. 2.66), 11q ($MLS=2.81$ vs. 2.98), 14q ($MLS=1.70$ vs. 2.31). These results suggest there is enrichment for detectable genetic effects in AOD 55 families but that no one locus is strongly enriched in the younger T2D onset group.

Hypertriglyceridemic type 2 diabetes and impaired glucose tolerance/impaired fasting glucose subjects were linked to chromosome 2q in a genome-wide scan - The San Antonio Family Heart study - *J. Sung^{1,2}, K.J. Hunt³, H.H.H. Göring¹, L. Almasy¹, S. Cole¹, T. Dyer¹, J.W. MacCluer¹, M.P. Stern³, J. Blangero¹*. 1) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Department of Preventive Medicine, Kangwon National University, Chuncheon, Korea; 3) Division of Clinical Epidemiology, Department of Medicine, University of Texas Health Science Center, San Antonio, TX.

A search for the genes responsible for type 2 diabetes has been partially successful with some replications. One explanation for the diverse results might be found from properly dissecting the heterogeneous phenotypes. Tryglyceride level is problematic to most diabetic patients, and hard to manage for some even after glycemic control. We performed a genome-wide linkage study to localize possible susceptibility genes influencing hypertriglyceridemic type 2 diabetes. Impaired glucose tolerance (IGT) or impaired fasting glucose (IFG), as well as diabetes in 38 randomly ascertained, extended, Mexican American pedigrees with 961 individuals. Participants were examined at baseline and average 5.1 years later. Diabetes or IGT/IFG was defined by 1) previous diagnosis of diabetes and/or diabetic medication, or 2) exceeding 110 mg/dL of fasting plasma glucose level or 140 mg/dL of postprandial 2-hour glucose level in either of two examinations. There were 351 subjects who met diabetes-related criteria, and 151 of 351 were hypertriglyceridemic ($>2.3\text{mmol/L}$). We performed logistic regression to take the residual of dichotomous traits adjusting for demographic factors, then normalized the residuals. We used multipoint IBD matrices derived from a 10 cM genomic map, and a variance decomposition method (SOLAR). In the final model, dietary factors and medications were considered. Heritability was estimated to be 0.63. The highest multipoint LOD (MLOD) score of 3.49 was found on chromosome 2 at Loc 195 cM for a comparison within the diabetic subjects ($n=351$), and LOD of 2.50 at chromosome 16 Loc 70 cM in total subjects ($n=961$). This chromosome 2 region was proximal to the previous reports for diabetes (245-261 cM). This work was supported by a grant from the NHLBI (P01 HL45522).

Program Nr: 1893 from the 2004 ASHG Annual Meeting

Candidate gene analysis of a T1D susceptibility locus. *T.L. Tabone, G. Morahan.* Genetics & Bioinformatics, The Walter & Eliza Hall Inst, 1G Royal Parade, Parkville, VIC, Australia.

In this study, a novel type 1 diabetes (T1D) susceptibility interval on human chromosome 19p13 was identified. A putative T1D susceptibility gene is proposed to be in linkage disequilibrium to a microsatellite marker, to which a LOD score of 3.3 was obtained from analysis of British multiplex families with T1D.

A positional candidate gene approach was employed to identify the potential causal variant of T1D susceptibility segregating in the multiplex families. Several candidate genes were identified in this region and genomic variants in these genes were sought to test association with T1D susceptibility.

Linkage and linkage/disequilibrium analysis suggest the potential causal variant of T1D in the multiplex families is within a small and genetically well-defined region, facilitating its identification in the near future.

Examination of locational candidate genes in age related macular degeneration. A. Agarwal¹, L.M. Olson², J.R. Gilbert³, N. Schnetz-Boutaud², S. Schmidt³, W.K. Scott³, E. Postel⁴, M.A. Pericak-Vance³, J.L. Haines². 1) Ophthalmology and Visual Sciences, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Center for Human Genetics, Duke University, Durham, NC; 4) Duke Eye Center, Duke University, Durham, NC.

Age-Related Macular Degeneration (AMD) is one of the most significant causes of vision loss in the elderly. There is substantial evidence that genes play a critical role in its etiology. As part of our ongoing genetic epidemiological studies of AMD, we participated in a genomic screen of 391 rigorously diagnosed multiplex families with AMD, identifying several chromosomal locations to be further examined, including 1q25-32, 10q25-26, and 14q11-13. Genes within these regions thus represent locational candidates for further study. We tested five genes on 1q (FIBL-6, OCLM, CRB1, OPTC, REN), two genes on 10q (GSTO1, PRDX3), and one gene on 14q (NRL), additionally selected based on their potential functional role in AMD. A mutation in FIBL-6 has been previously proposed as a causal variant for AMD. We tested multiple SNPs in each gene on two independent datasets. The first consisted of 165 families and the second consisted of 401 cases and 159 examined normal controls. We performed both family-based (single locus: Pedigree Disequilibrium Test [PDT]; multilocus: FBAT) and case-control (Chi-square) analyses. 29 SNPs with minor allele frequencies >0.20 were tested in these eight genes. No significant associations were seen in either dataset for any of the 20 SNPs on chromosome 1q, for the two tested SNPs in GSTO1 on chromosome 10q, or the four tested SNPs in NRL on chromosome 14. Two SNPs in PRDX3 (peroxiredoxin 3, an antioxidant protein) gave nominally significant P values ($p=0.05$, 0.04), but only in the case-control analyses and neither survive correction for multiple comparisons. Thus despite positive linkage information and plausible functional importance, none of these polymorphisms appear to represent a significant risk factor for AMD.

Final steps in identification of the X-linked lethal infantile spinal muscular atrophy (XL-SMA) gene. M.E.

Ahearn¹, J. Ramser², K.O. Yariz¹, D. Dressman³, R.D. Clark⁴, E.P. Hoffman³, A. Meindl², L.L. Baumbach¹. 1) Univ Miami Medical Sch, Miami, FL; 2) Ludwig Maximilians Univ, Munchen, Germany; 3) Children's National Med Ctr, Washington, DC; 4) Loma Linda Univ Sch Med, Loma Linda. CA.

X-linked lethal infantile motor neuron disease (MIM 301830), closely resembles Werdnig-Hoffman disease, with the additional features of early onset or congenital contractures and/or fractures. Fourteen unrelated families have been identified from North and Central America and Western Europe. Of these, nine families have been tested for linkage on the X-chromosome; all families mapped to the same Xp11.3-Xq11.2 region. One family is thought to represent a new mutational event. The cumulative LOD score is 8.71 at $\alpha = 0.0$ at DXS1003. In the past year we have used the ABI Linkage Mapping Set X chromosome markers from the Xp11.3-Xq11.2 region supplemented with additional markers for further linkage analysis. This has not yielded any new recombination events however, new LOD score information has been generated. We are currently using ABI Assay-on-Demand SNPs in this region to further narrow the candidate disease gene interval. Mutation screening through genes in the region has proceeded jointly between University of Miami (UM) and Ludwig Maximilians University (LMU) pursuing complimentary approaches. UM screening has focused on selection and study of candidate disease genes based on presumed protein functions that relate to RNA processing, neuronal or muscle development, cell to cell communication and apoptosis. Growing knowledge concerning the molecular and cellular basis of autosomal SMA is used for selection many of these candidates. At LMU, all cDNAs in the disease gene region are being tested for mutations in XL-SMA samples using high-throughput methodologies. In total, approximately 60 genes within the candidate region have been tested with no mutations found in affected males or carrier females. It is anticipated that we will complete gene screening by October 2004. Our most recent results will be presented. *This study has been generously supported by grants from the MDA, FSMA, Payton's Pals, UM School of Medicine and the Dr. John T. Macdonald Foundation Center for Medical Genetics..*

Linkage heterogeneity in 254 hereditary prostate cancer (HPC) families. *M.D. Badziuch¹, J.L. Stanford², D.M. Friedrichsen², S. Kolb², E.A. Ostrander², M. Janer³, L. Hood³, G.P. Jarvik¹.* 1) University of Washington, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Institute for Systems Biology, Seattle, WA.

The 254 Seattle/PROGRESS HPC families (mean cases/family= 4.45) have previously undergone a 10 cM genome scan by 2-point lod and multipoint NPL analyses. Additional analyses were undertaken to examine potential linkage heterogeneity (het). Model-based 3-point lod scores were assessed for het by the alpha-test. Using the sex specific Marshfield map, the most significant het was with D7S2212/D7S820 at chromosome (chr) 7q21 (lod<0, hlod= 1.59, p-het= 0.007) under a recessive model; the location of a proposed HPC locus (Friedrichsen, 2004). Under a dominant model, D11S2371/D11S2002, chr 11q13-14, gave hlod= 1.58, p-het= 0.01. The differences (d) between pairs of affected brothers' ages or Gleason score (GS) were examined for associations with multi-marker ibd allele sharing, a model free approach (SAGE LODPAL). A >60 cM span on chr 9q21-33 had age-d effects (p < 0.01), peaking at D9S930/D9S934 (lod= 3.07, p= 0.0002). Chr 11q23-24 gave an age-d lod of 2.85, p= 0.0003. GS was known for 266 brother pairs in 94 families and showed d effects on chrs, 2q37 (lod= 2.11, p=0.002), 8q21-23 (2.23, 0.002) and 18q21 (1.81, 0.004). Small d predicted linkage in most cases. Some markers yielding these results were previously associated with number-of-sibs-affected (GAAT1A4/D8S1132) by Goddard, et al (2001) and with GS (D9S930/D9S934) by Witte, et al (2000). As studies suggest many HPC loci, methods robust to het and consistent linkage signals among datasets should be pursued. Small d may be a useful covariate in HPC linkage.

Replication of Linkage and Refinement of *IGAN1* Locus. I. Beerman^{1,2}, A. Gharavi^{1,2}, G. Frasca⁴, A. Amoroso⁴, D. Pirulli⁴, C. N.-Williams^{1,2}, S. Woodford⁵, R. Wyatt⁵, B. Julian⁶, G. Giggheri⁷, F. Scolari⁸, R. Lifton^{1,2,3}. 1) Genetics, Yale, New Haven, CT; 2) HHMI, Yale, New Haven, CT; 3) Medicine, Yale, New Haven, CT; 4) Bologna, Italy; 5) Memphis, TN; 6) Birmingham, AL; 7) Genoa, Italy; 8) Brescia, Italy.

IgA nephropathy (IgAN) is the leading cause of glomerulonephritis worldwide. Though IgAN is a significant contributor to renal failure, little is known about the pathogenesis and there are no effective treatments for this disease.

Familial segregation and ethnic clustering suggest a genetic contribution to IgAN. Genome-wide linkage analysis of 30 multiplex kindreds demonstrated that familial IgAN links to a 6 cM region (*IGAN1*) on 6q22-23. Parametric analysis using a model of dominant transmission with 75% penetrance yielded a peak lod score of 5.6 with 60% of kindreds linked to *IGAN1*. (*Nature Genetics*, 2000 **26**:354-357)

To replicate these findings, we studied an independent cohort of 16 IgAN kindreds (40 affecteds) applying the same phenotypic criteria as previously. We genotyped these kindreds for 25 microsatellite markers encompassing the lod-1 interval. Using the parameters from the initial study, these families yielded a lod score of 1.5 at the initial lod score peak with an alpha of 0.45 (point wise $p < 0.005$) achieving published criteria for significant replication. The significance was also validated by 1000 simulations, yielding an empiric p-value of 0.006.

For kindreds linked to *IGAN1*, identification of additional affected members has the capacity to further test the hypothesis of linkage. We identified a 5th cousin in one such kindred with biopsy documented IgAN. This cousin is separated by 11 meiotic events from the closest affected individuals in the pedigree and shares an 8 cM haplotype with the previously linked haplotype. This kindred alone now contributes a lod score of 4.4 and reduces the *IGAN1* minimal recombinant interval to 2 cM. Combining the data from all 46 IgAN families, multipoint linkage analysis at *IGAN1* yields a lod score of 9.3 ($=0.48$). The present findings confirm linkage and refine the lod-1 interval for IgAN to a 4.4 cM segment spanning ~4.9Mb.

A genomic screen for amyotrophic lateral sclerosis identifies several novel candidate regions of linkage. *Y. Bradford*¹, *T. Siddique*², *R.H. Brown*³, *D. McKenna-Yasik*³, *N. Siddique*², *W.-Y. Hung*², *B. Hosler*³, *S. West*⁴, *M.A. Pericak-Vance*⁴, *J.L. Haines*¹. 1) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Davee Department of Neurology, Northwestern Univ, Chicago, IL; 3) Day Neuromuscular Laboratory, Massachusetts General Hospital, Boston, MA; 4) Center for Human Genetics, Duke Univ., Durham, NC.

Amyotrophic lateral sclerosis (ALS; Lou Gehrig disease) is an irreversible degenerative neuromuscular disease usually resulting in death within 5 years of (typically) mid-life onset. While some large autosomal dominant adult onset and autosomal recessive juvenile onset pedigrees have been identified, mutations in only two genes (SOD1, Alsin) have been definitively shown to cause ALS. The severe course and later onset of ALS makes finding multiplex families difficult. Despite this, we have assembled a dataset of 54 adult onset multiplex families with 145 sampled affected individuals and 122 total affected relative pairs. All families were screened and were negative for mutations in the SOD1 gene. 300 microsatellite markers (~11 cM average spacing) were genotyped through these families. Parametric two-point analyses were performed under a dominant and a recessive model and the maximal heterogeneity lod scores across both models were calculated. Multipoint non-parametric scores (lod*) were also calculated. 12 markers, representing seven chromosomal regions (1p, 7p, 8q, 9p, 17p, 18p, 19q), generated two-point lod scores >1.0 in the overall dataset. Four of these regions (7p, 8q, 18p, 19q) also generated lod* scores >1.0. Of particular interest are the results on chromosome 19q, where the peak multipoint lod score was 2.0. These data suggest that further locus heterogeneity in ALS.

Genome-wide Linkage Analysis of Recurrent, Early-Onset Major Depression and Anxiety Disorders in Extended Utah Pedigrees. *N.J. Camp*^{1,2}, *M.R. Lowry*³, *R.L. Richards*⁴, *A.M. Plenk*⁵, *D.C. Hughes*¹, *L.A. Cannon-Albright*^{1,2}. 1) Genetic Research, Intermountain Health Care, Salt Lake City, UT; 2) Genetic Epidemiology, Univ Utah, UT; 3) Department of Psychiatry, Univ Utah, UT; 4) Private Practice, UT; 5) The Children's Center, UT.

Major depressive disorder (MDD) is a common and clinically heterogeneous disorder, often found comorbid with other disorders. We studied recurrent, early-onset MDD (MDD-RE) and anxiety disorders in combination in an attempt to define powerful phenotypes for genetic study. We used 87 extended Utah pedigrees ascertained for family history of MDD to investigate linkage to 3 phenotypes: 'MDD-RE'; 'MDD-RE or anxiety' and 'MDD-RE and anxiety', where in the latter definition the disorders must appear comorbid within the same individual. Pedigrees ranged in size from 2 to 6 generations, and contained between 3 and 42 individuals affected with MDD or anxiety. We identified 5 regions on chromosomes 3centr, 4q, 7p, 15q and 18q, with all except the centromeric region on chromosome 3 representing replication findings. In our analyses, the regions on chromosomes 4q and 15q were identified by sex-specific analyses. The best linkage evidence was found for a novel locus at 3p12.3-q12.3 (LOD = 3.88 for 'MDD-RE or anxiety') and at 18q21.33-q22.2 (LOD = 3.75, 'MDD-RE and anxiety') which is well-established as a susceptibility locus for bipolar disorder. Chromosomes 4q and 7p have previously been implicated as loci involved in neuroticism (4q and 7p) and panic disorder (7p), and the region on 15q for MDD-RE. Using linked pedigrees we localized the 3centr and 18q regions to 9.8 and 12.2 cM, respectively, with potential for further localization with the addition of markers in specific linked pedigrees. Our success in replication and substantial novel finding on 3centr illustrates the utility of extended pedigrees for common disorders, such as MDD. Further, it lends weight to the hypothesis that MDD and anxiety disorders have over-lapping genetic etiologies, and suggests that not only early-onset and recurrence, but comorbid diagnoses, may be useful in defining more genetically homogeneous forms of MDD phenotypes for linkage mapping.

Linkage evidence for Cutaneous Malignant Melanoma to 1p22 in Utah Pedigrees. *L.A. Cannon-Albright¹, J.M. Farnham¹, S. Leachman², N.J. Camp¹.* 1) Genetic Epidemiology, University of Utah School of Medicine, UTAH; 2) Dermatology, Huntsman Cancer Institute, University of Utah, UTAH.

The Utah extended pedigree resource for cutaneous malignant melanoma (CMM) currently comprises 24 pedigrees, ten of which were part of the Utah resource used to localize 9p21 and isolate p16. Pedigrees range in size from 3-8 generations and contained between 2-19 CMM cases (total 150). These 24 pedigrees were used to investigate the proposed CMM locus at chromosome 1p22. Our phenotype was CMM, confirmed by the Utah Cancer Registry data in the Utah Population Database (UPDB) or by medical records. Our genotyping consisted of 4 microsatellites spanning 9cM of the previously reported multipoint peak. We chose two genetic models; an affecteds-only age model, with age-dependent penetrances as determined from the original Utah resource, and a general affecteds-only dominant model. We performed multipoint linkage analysis using MCLINK, a Markov chain Monte Carlo method incorporating block Gibbs updating, which allows analysis of extended pedigrees. To combat the problem of intra-familial heterogeneity inherent in the analysis of extended pedigrees, we also performed the analysis on pedigree-splits. We used an unbiased splitting algorithm, prior to genotyping data, which iteratively removes founders from the pedigrees thus reducing the number of generations analyzed. The global HLODs were not supportive of linkage to 1p22, with the max HLOD found being 0.118 at D1S2671, using the age model and pedigree-splits with a maximum of 3 generations. We were able to locate 4 pedigree-splits that obtained pedigree LODs of between 0.528-0.867, with 3 or 4 CMM cases sharing a segregating haplotype. The average age at diagnosis of CMM was 46.5 yrs in haplotype carriers, but this was not significantly different from 52.0 yrs (all pedigrees) or 51.9 yrs (all CMM in the UPDB). No p16 mutations have been found in these 4 1p22-linked pedigrees. In conclusion, there is little evidence to support the 1p22 linkage in the 24 Utah pedigrees analyzed here. At best, the 4 pedigrees with nominal individual linkage evidence may be of use for screening for putative variants in the region, if any are discovered.

Progressive myoclonus epilepsy with polyglucosans (Lafora disease): evidence for a third locus. *E.M. Chan¹, S. Omer², M. Ahmed³, L.R. Bridges⁴, C. Bennett³, S.W. Scherer¹, B.A. Minassian^{1,5}*. 1) Program in Genetics & Genomic Biology, The Hospital for Sick Children, Toronto, Canada; 2) Department of Neurology, St. George's Hospital, London, UK; 3) Department of Clinical Genetics, St. Jame's University Hospital, Leeds, UK; 4) Department of Pathology, University of Leeds, Leeds, UK; 5) Division of Neurology, The Hospital for Sick Children, Toronto, Canada.

Lafora disease (LD) is an autosomal recessive disorder and the most severe form of teenage-onset progressive myoclonus epilepsy. LD is a unique type of glycogenosis with accumulation of a ER-associated starch-like polyglucosans forming Lafora bodies. A homogeneous clinical presentation exists despite the presence of genetic heterogeneity. Recessive mutations in either of two genes cause the syndrome, *EPM2A*, encoding a dual-specificity phosphatase with a carbohydrate-binding domain (named laforin), and *EPM2B*, encoding a putative E3 ubiquitin ligase (named malin). In total, 88% of our collection of LD families can now be accounted for by mutations in *EPM2A* (48%) and *EPM2B* (40%). We describe a family with three members affected with classic LD. Affected members of this family have no mutations in the coding regions and flanking intronic sequences of either *EPM2A* or *EPM2B*. Linkage and haplotype analyses exclude both loci from causative involvement in the disease in this family. These results indicate that a third LD gene exists. Its identification will be crucial in understanding the cellular pathway underlying polyglucosan formation. In addition, the description of additional genetic heterogeneity in LD will improve patient diagnosis, prenatal diagnosis and genetic counseling for this severe form of epilepsy.

Program Nr: 1902 from the 2004 ASHG Annual Meeting

A genome-wide linkage analysis in a large pedigree with Ehlers-Danlos syndrome, hypermobility type. *A. de Paepe, F. Malfait, P. Coucke.* Center for Medical Genetics, Ghent University Hospital, De Pintelaan 185, B-9000 Ghent, Belgium.

The Ehlers-Danlos syndrome (EDS) is a clinically and genetically heterogeneous group of heritable connective tissue disorders that is characterized by skin hyperextensibility, joint hypermobility and generalized connective tissue fragility. The most recent classification (Villefranche Nosology, 1997) recognizes six subtypes, of which the hypermobility type (former type III) is the most frequent one. This is an autosomal dominant disorder that is characterized by generalized joint hypermobility, repetitive dislocations of large and small joints, chronic musculoskeletal pain, and mild involvement of the skin with soft skin and mildly dilated scars. Except for a mutation in COL3A1, encoding collagen type III, and some mutations in TNXB, encoding tenascin-X, no causal mutations have been identified yet. We have performed linkage analysis in a three-generation pedigree of Belgian origin with EDS, hypermobility type. This family counts at least 13 affected and 8 non-affected members. Although there was some variability in the severity of the phenotype, all affected members clearly fulfilled the criteria for EDS, hypermobility type. In this family we excluded linkage to the COL1A1, COL1A2, COL3A1, COL5A1 and COL5A2 gene, the genes that are involved in other autosomal dominant types of EDS. We performed a genome-wide segregation analysis and established linkage to a 5.5cM region with a maximum LOD-score of 3.32. Ongoing studies are planned to confirm the region in other families, and mutational analysis of the strongest candidate genes within the minimal region will be performed.

Homozygosity mapping in mediterranean families identifies a novel Charcot-Marie-Tooth neuropathy (CMT4H) on chromosome 12p11.21-q13.11. A. DeSandre-Giovannoli^{1,2}, V. Delague¹, T. Hamadouche^{1,3}, E. Chouery⁴, I.

Boccaccio¹, D. Grid⁵, M. Chaouch⁶, A. Megarbane⁴, N. Levy^{1,2}. 1) Faculte de Medicine, INSERM U491, Marseille, France; 2) Departement de Genetique Medicale, Hopital enfants de la Timone, Marseille, France; 3) Institut Pasteur d'Algerie, Alger, Algerie; 4) Unite de Genetique Medicale, Universite Saint-Joseph, Faculte de Medecine, Beyrouth, Liban; 5) Genethon III, Evry, France; 6) Service de Neurologie CHU Ben-Aknoun Alger, Algerie.

Charcot-Marie-Tooth (CMT) neuropathies are a group of clinically and genetically heterogeneous hereditary motor and sensory neuropathies (HMSN); mainly characterized by muscle weakness and wasting, foot deformities and electrophysiological as well as histological changes. CMT1 is defined by a reduction of nerve conduction velocities with demyelinated fibers and CMT2 by a slight or absent reduction of nerve conduction velocities (NCVs) together with loss of large myelinated fibers and axonal degeneration. Homozygosity mapping in two consanguineous Mediterranean families from Lebanon and Algeria affected with severe autosomal recessive demyelinating CMT, evidenced linkage to chromosome 12p11.21-q13.11 in a 11.5 cM region between microsatellite markers D12S1648 and D12S1661. A maximum pairwise LOD score value (Z_{max}) of 6.97 at $p = 0.001$ was obtained for marker D12S345. Among the 90 genes identified in the candidate region, the entire coding region of two potential candidate genes, Contactin 1 (*CNTN1*) and Peripherin (*PRPH*), has been tested for the presence of mutations. Although their functions were suggestive of an implication in CMT, no disease causing mutations were identified in either gene, and *PRPH* has definitely been excluded as the causative gene for CMT4H, since it has been mapped outside the candidate interval by further genotyping. We propose to add this phenotype and locus to the expanding CMT classification, as being the CMT4H. Besides, we will present our clinical and molecular explorations regarding this severe neuropathy.

Concordance and call rate assessment of the Affymetrix 10K SNP array. *K.R. Ewen-White¹, S.C. Herbert¹, M. Papoulis¹, K. Siemering¹, G.W. Montgomery², N.G. Martin², S.M. Forrest¹.* 1) Australian Genome Research Facility, 1G Royal Parade Parkville Victoria 3050, Australia; 2) Queensland Institute of Medical Research Post Office, Royal Brisbane Hospital 300 Herston Road Brisbane 4029, Australia.

The Australian Genome Research Facility has recently installed the latest Affymetrix system incorporating the GS3000 high density scanner allowing processing of 10K and 100K SNP chips as well as all Affymetrix gene expression chips. The 10K SNP chip contains 11,555 SNPs giving an average genetic gap distance of 0.32cM and average estimated heterozygosity of 0.35. Studies suggest that around 3 SNP markers are equivalent to 1 microsatellite marker implying the 10K chip will provide significantly greater information than a 10cM microsatellite scan and at a much cheaper price of < \$0.10/GT. Published results of complex trait mapping have demonstrated that the 10K chip enables increased resolution of LOD peaks as well as highlighting additional minor peaks. These genotyping improvements have assisted in defining new regions as well as decreasing fine mapping requirements. The 10K chip is also being used to detect chromosomal deletions & amplifications up to 10 times smaller than have been found with spotted microarrays and comparative genomic hybridisation (CGH).

The AGRF have assessed the 10K chip for reproducibility measuring concordance between replicate samples and between monozygotic twins. The effect of altering call zone boundaries on call rate and accuracy has been determined. The consistency of SNP failures between individual arrays has been assessed and the effect of DNA quality and preparation methods on final call rates has been measured.

Search for endometriosis susceptibility genes in Puerto Rico. *I. Flores*¹, *D.M. Mandal*², *J.E. Bailey-Wilson*³. 1) Department of Microbiology, Ponce School of Medicine, Ponce, PR; 2) Dept. of Genetics, LSU Health Sciences Center, New Orleans, LA; 3) Inherited Disease Research Branch, NHGRI/NIH, Baltimore, MD.

The causes of endometriosis are unknown although the evidence of genetic susceptibility is extensive. The main goal of the present study is to provide the genetic basis of endometriosis in the population in Puerto Rico. Thirty-two families with two or more affected members were recruited from the island of Puerto Rico. Genotyping data were obtained on 18 markers in chromosome 10 candidate regions. The data have been checked for Mendelian inconsistencies using the program GCONVERT/SIB-PAIR. Significant allelic association was observed at the empiric p-value of 0.0038 at one of the candidate regions. The mode of inheritance of endometriosis is not known. Therefore, the LOD score was calculated assuming two simple models, dominant and recessive, each with an arbitrary 50% penetrance in gene-carriers and 5% penetrance in non-gene carriers. We used Genehunter-Plus to compute multipoint parametric LOD scores using these two models, as well as multipoint non-parametric NPL statistics and the Kong and Cox allele-sharing LOD score. Affected only analysis was performed by coding the unaffected women as unknown in the analysis. Assuming an autosomal dominant mode of inheritance, the highest LOD score obtained was 1.75 and under the autosomal recessive model, the highest LOD score obtained was 1.26. We will be extending these analyses by using models that incorporate age through multiple liability classes.

Continuing analysis of a prostate cancer susceptibility locus on 7q11-21 in Jewish families. *D.M. Friedrichsen¹, J.L. Stanford², M. Janer³, K. Deutsch³, S. Kolb², M.D. Badzioch⁴, G.P. Jarvik⁴, L. Hood³, E.A. Ostrander¹.* 1) Dept Human Biol; 2) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Institute for Systems Biology, Seattle, WA; 4) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA.

An estimated 220,900 men will be diagnosed with prostate cancer (PC), and 28,900 deaths will be attributed to the disease in the United States this year. Both epidemiological studies and segregation analyses confirm the existence of a genetic component to PC etiology, with an estimated 5-10% of all PC and 43% of early onset (55 years) disease being attributed to an inherited susceptibility. Recently, ten genome-wide scans have been published, analyzing 1,730 hereditary PC (HCP) families. The results of these studies confirm that a substantial amount of genetic heterogeneity exists in HPC.

One approach to reduce locus heterogeneity is to analyze Jewish families, which represent a more well-defined and genetically homogenous population. In our previously reported combined genome-wide scan of 36 Jewish HPC families from the Seattle-based PROGRESS study and Johns Hopkins University, we identified a region of significant linkage on chromosome 7q11-21, with an empirical P value of 0.006. Further resolution of the 7q11-21 locus in 18 Jewish PROGRESS families indicates that the minimal recombination region is 5.7 cM and contains approximately 20 RefSeq genes. This region expands to 29.2 cM and would contain over 100 RefSeq genes if three recombination events are used to define either boundary. Both SNPs and microsatellites are being evaluated in order to identify a potential founder haplotype. We have screened over 200 amplicons thus far and no obvious mutations have been found. This study highlights the utility of analyzing defined sets of families with a common origin for reducing locus heterogeneity problems associated with studying complex traits.

Program Nr: 1907 from the 2004 ASHG Annual Meeting

Linkage analysis allowing for heterogeneity and marker informativity. *T.A. Greenwood, N.J. Schork.* Dept Psychiatry, Univ California, San Diego, La Jolla, CA.

Locus heterogeneity is known to plague the identification of disease susceptibility loci in linkage mapping contexts of complex traits and diseases. Even within a field center to be used for sampling individuals for a study the family sets are likely to contain individuals with varying genetic backgrounds and genetic susceptibility profiles. We have developed novel mixture models that accommodate both locus heterogeneity and marker informativity and have applied it to large data sets. Our results provide information on not only regions of the genome likely to harbor susceptibility loci but also information on the degree to which heterogeneity influences the linkage signal at that locus. Ultimately, we find that linkage analyses that allow for heterogeneity can complement traditional techniques that do not. Our methods and analyses complement approaches taking advantage of context-specific linkage analysis, since the proposed heterogeneity models do not necessarily make assumptions about the nature of the factors contributing to and differentiating families showing linkage from those that do not (but can, if particular covariates are specified). Thus, our proposed models can be used to address questions about the ultimate comparability and combinability of data collected in different racial groups and field centers.

A comprehensive search for genetic susceptibility to MS on the X chromosome. *B.M. Herrera³, H. Armstrong², D. Dyment³, Z. Cader³, G.C. De luca³, M.R. Lincoln³, S. Orton³, C. Willer³, K. Morrison³, G.C. Ebers¹.* 1) Department of Clinical Neurology, Radcliffe Infirmary, Oxford University, Oxford, UK; 2) Dept. of Clinical Neurosciences, London Health Sciences Center, London Ontario, Canada; 3) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, UK.

Genetic and epidemiological studies have shown the importance of genes in MS susceptibility. Only one association has been consistently replicated in genetic studies: the HLA-DRB15 on chromosome 6p21. Linkage and association studies have identified candidate regions on the X chromosome. An unexplained female to male ratio of 2:1, is present in all studies. Observations from affected sib-pairs and half-sibs demonstrate a maternal parent of origin effect. We performed a genome scan of the X chromosome, in two datasets; the first consists of 552 affected sib-pairs, where we genotyped 22 X chromosome microsatellite markers. A lod score of 1.72 was found for marker DXS1683 in 219 of these sib-pairs, when stratified by the presence of DRB15 (Dyment et al 2004). In a second sample of 158 families with affected pairs of aunt-uncle/niece-nephews (AUNN), we genotyped 18 X-chromosome markers. The structure of the AUNN dataset allowed us to divide families by the sex of the carrier parent, so we were able to investigate a potential parent of origin effect in maternal and paternal families. We found no evidence for linkage within these datasets and were able to exclude linkage at $\lambda=1.33$. This study represents an exhaustive scrutiny of the X chromosome as a region involved in susceptibility to MS. Despite many suggestions from previous studies, we were not able to confirm previous observations of linkage to this region. This study shows that the X chromosome is not responsible for the observed maternal effect in MS susceptibility which is double than for paternal risk.

Genome Wide Search for Sarcoidosis Susceptibility Genes in African Americans. *S. Iyengar*¹, *C. Gray-McGuire*¹, *R.C. Elston*¹, *B. Rybicki*², *M. Iannuzzi*³, *for the SAGA consortium*³. 1) Dept Epid/Biostat, Case Western Reserve Univ, Cleveland, OH; 2) Department of Biostatistics and Research Epidemiology, Henry Ford Health System, Detroit, MI; 3) Division of Pulmonary, Critical Care, and Sleep Medicine, Mt. Sinai School of Medicine, New York, NY.

Sarcoidosis is a systemic granulomatous inflammatory disease of unknown origin that can involve any organ. The current thinking is that the granulomatous reaction characteristic of sarcoidosis occurs as a result of an immune dysregulation following an initial immune response to an inciting environmental agent in a genetically susceptible host. In the United States, African Americans are more commonly affected with sarcoidosis and suffer greater morbidity than Caucasians. We searched for sarcoidosis susceptibility loci by conducting a genome-wide, sibpair multi-point linkage analysis in 229 African-American families ascertained through two or more sibs with a history of sarcoidosis. Using the Haseman-Elston regression technique, linkage peaks with asymptotic p values less than 0.05 were identified on chromosomes 1p22, 2p25, 5p15-13, 5q11, 5q35, 9q34, 11p15 and 20q13 with the most prominent peak at D5S2500 on chromosome 5q11 (p=0.0005). We found agreement for linkage with the previously reported genome scan of a German population at chromosomes 1p, 3p and 9q. Although we found no evidence for linkage to the MHC region of chromosome 6p in our initial genome scan, an additional marker added to this region, D6S1701, showed marginally significant linkage to sarcoidosis (p=0.04). This region on chromosome 6 has previously shown association in case control studies. Our results validate the case control studies. Based on the multiple suggestive regions for linkage found in our study population, it is likely that more than one gene influences sarcoidosis susceptibility in African Americans. Fine mapping of the linked regions, particularly on chromosome 5q, should help refine linkage signals and guide further sarcoidosis candidate gene investigation.

Genomewide analyses demonstrate that novel loci predispose to drusen formation. *G. Jun¹, B.E.K. Klein², R. Klein², K. Fox¹, C. Millard¹, J. Humphrey¹, K. Russo¹, K.E. Lee², R.C. Elston¹, S.K. Iyengar¹.* 1) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison, WI.

The accumulation of lipoproteinaceous deposits (drusen) is the earliest clinical hallmark of age-related maculopathy (ARM), a multifactorial degenerative eye disease. We hypothesized that examination of size and type of drusen would give better insights into early ARM pathogenesis. We performed genomewide model-free linkage analysis using two semi-quantitative drusen traits, size and type using two sets of data: (1) 325 individuals (225 sib pairs) in 102 families from the Beaver Dam Eye Study (BDES), and (2) 297 individuals (346 sib pairs) from 34 extended families in the Family-based Age-Related Maculopathy Study (FARMS). We found evidence of linkage on chromosome 19q13.31 with size in both BDES ($p=0.029$) and FARMS ($p=0.0013$). In BDES, type ($p=0.019$) and size ($p=0.026$) showed evidence at 3p24.3, and type only at 3q25.1 ($p=0.014$). In FARMS, size showed evidence at 5q33.3 ($p=0.0021$) and 16p13.13 ($p=0.0015$), and type at 21q21.2 ($p=0.0070$). The FARMS dataset which was ascertained for severe disease gave more distinctive linkage signals. We utilized APOE genotypes as a covariate in a multipoint sibpair linkage analysis, since the chromosome 19 locus provided good support of linkage. We observed a small decrease in the linkage signal using the 2/4 genotype (reference 3/3) with size (p -values decreased from 0.0357 to 0.0719 in BDES and from 0.0087 to 0.0168 in FARMS). This result demonstrated that APOE gene did not fully account for the 19q13.31 signal. This suggests that a novel locus, close to APOE, is responsible for drusen formation. APOE has previously been associated with age related macular degeneration (AMD) in case control studies, but genome scans for AMD have been unable to detect any linkage on 19q13. Our results show that APOE effects may be mediated early in the ARM to AMD process, and thus may not be detected by standard genome scans for more severe disease.

A 10K SNP Genomic Screen in Extended Late Onset Alzheimer Disease Families. *S.J. Kang¹, C.S. Haynes¹, J.L. Haines², E.R. Martin¹, D.A. Stephan³, M.A. Pericak-Vance¹.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) The Translational Genomics Research Institute, Phoenix, AZ.

Alzheimer disease (AD) is a common, genetically complex disease whose etiology is not yet fully described. Although four genes have been identified and several other loci have been proposed, loci for a number of large families have not yet been identified. We have genotyped over 10,000 SNPs across the genome in 11 families using the Affymetrix 10K SNP chip. These multi-generational Caucasian families contain between 5 to 8 sampled individuals with AD, for a total of 69 cases. The mean number of sampled individuals per family was 10.538 (means.d.) with a minimum of 6 and maximum of 18. These families showed no evidence of linkage to previously reported linkage regions on chromosomes 2, 9, 10, and 12 and had no known evidence of mutations in APP, PS1, or PS2. Two-point parametric linkage analysis using a dominant model was performed using FASTLINK and HOMOG. Information extraction was substantially increased over our previous 8 cM microsatellite screen, demonstrating the power of the dense SNP mapping approach. The maximum LOD score across all SNPs was 4.36 for RS275838 (78.03cM) on chromosome 19, confirming the effect of APOE (71.55cM), an established risk factor for AD. LOD scores over 2.0 were obtained on chromosomes 1, 2, 3, 4, 5, 7, 8, 18, 19, 20 and 21. Aside from APOE, LOD scores greater than 2.5 were obtained on chromosome 2 (129.35cM), chromosome 4 (152.88cM), chromosome 5 (112.61cM) and chromosome 8 (74.93cM), suggesting several novel locations for further analysis (The previously reported linkage region on chromosome 2 was at 210.26cM). Multi-point analyses are ongoing as are conditional analyses controlling for APOE genotype.

Confirmation, Localization and Genetic Association of SLEH1 on 11q14 in African-American Multiplex SLE Pedigrees with Hemolytic Anemia. *J.A. Kelly¹, S. Shadfar¹, K.M. Kaufman^{1,3}, T.J. Aberle¹, G.R. Bruner¹, J.B. Harley^{1,2,3}.* 1) Dept Arthritis/Immunology, Oklahoma Medical Res Fndn, Oklahoma City, OK; 2) University of Oklahoma, Oklahoma City, OK; 3) US Dept of Veterans Affairs Medical Center, Oklahoma City, OK.

The SLE susceptibility locus, SLEH1, was first identified on 11q14 (D11S2002; LOD=4.7) in 16 African-American (AA) multiplex pedigrees that contained at least one individual affected with both SLE and hemolytic anemia (PNAS 99(18):11766-11771, 2002). In an effort to confirm this finding, we identified an additional 13 African-American pedigrees multiplex for SLE with hemolytic anemia in one or more SLE affected. The additional 13 pedigrees confirmed linkage to SLEH1 (LOD=2.0 at D11S2002). To evaluate the region for possible genetic association, we typed 112 SNPs spanning 74.3-85 Mb on chromosome 11q14-21 (average intermarker distance=109 kb; range: 248 bp-1.3 Mb) in 40 AA pedigrees linked to D11S2002. One SNP showed a weak association using TDT ($p=0.004$), PDT ($p=0.04$) and FBAT ($p=0.003$). Fine mapping of an additional 19 SNPs around this SNP produced 6 SNPs that showed family based association (at the $p=0.05$ level). In addition, two SNPs showed significantly different allele frequencies between 40 cases and 46 controls ($2=4.66$, $p=0.03$). For one of the two SNPs, a more significant difference was observed in the allele frequencies between cases and controls when the cases selected had hemolytic anemia ($2=9.31$, $p=0.002$). More SNPs are currently being typed in the neighborhood to define the LD and to help determine whether the possible association signal detected is robust. These results provide further evidence demonstrating that SLEH1 is a strong and reproducible SLE susceptibility locus. The chromosomal locus originally spanning 10 cM is now confirmed and has been further localized to a 2-3 Mb region on chromosome 11q14-21.

Clinical features of a consanguineous Pakistani family with autosomal recessive cone rod dystrophy (CORD8) and refinement of the disease locus (1q23-q24). *S. Khaliq, K. Anwar, A. Abid, M. Ismail, A. Hameed, S.Q. Mehdi.* Biomedical and Genetic Engineering Laboratories, Islamabad, Pakistan.

Cone-rod dystrophies (CRD) are a form of inherited retinal dystrophies which characteristically lead to early impairment of vision due to the simultaneous involvement of both cone and rod photoreceptor cells. Several loci/genes have so far been identified for CRD on various chromosomes including the CORD8 locus identified for a Pakistani family. This locus was mapped on chromosome 1q12-q24, consisting of a very large critical disease region of 21cM, which has been further refined in this study. All affected members of this family underwent clinical examination to determine the nature of the cone-rod dystrophy phenotype associated with this locus (CORD8). Mutation screening of important candidate genes GNAT2, HPRP3, SM4A, CRABP2 and KCNJ10 was carried out and many more microsatellite markers, recently available on database, were analysed to narrow down the disease region. All affected individuals in this family suffered from bilateral cone rod dystrophy with autosomal recessive mode of inheritance. Characteristically all patients have photophobia, marked macular degeneration, attenuated arterioles and pigment epithelium disturbance. No disease-associated mutation was found in any of the candidate genes within the CORD8 locus. Analysis of recently identified microsatellite markers within the previously reported region showed heterozygosity with some of the new markers leading to a refinement of the disease region. This combination of ocular defects suggests a typical cone rod dystrophy phenotype that could be due to a mutation in a novel gene located within the CORD8 locus. Further we have narrowed down the previously reported disease region from 21cM to 11.53cM by analyzing newly available markers and candidate genes in this region.

Mapping the GLC1G locus for Primary Open-Angle Glaucoma (POAG) in an Oregon family of Dutch origin.

P.L. Kramer^{1,2}, J.R. Samples³, K. Schilling¹, R.L. Sykes³, J. Man³, K. Rust³, M.K. Wirtz^{2,3}. 1) Neurology, Oregon Health and Sciences Uni, Portland, OR; 2) Molecular and Medical Genetics, Oregon Health and Sciences Uni, Portland, OR; 3) Ophthalmology, Oregon Health and Sciences Uni, Portland, OR.

Glaucoma is the second leading cause of blindness worldwide. Six loci and two genes have been mapped for the most common form, primary open-angle glaucoma (POAG), and are designated GLC1A, GLC1B, GLC1C, GLC1D, GLC1E and GLC1F. Myocillin mutations are associated with GLC1A and optineurin mutations are associated with GLC1E. We conducted a genome wide search for a seventh POAG locus, GLC1G, in a large Oregon family of Dutch origin with 92 members and 14 affected individuals, using microsatellite marker genotyping.

We narrowed the search to chromosome 5 and current fine-mapping strategies involve combining data from seven microsatellite markers and sequencing data from 24 single nucleotide polymorphisms (SNPs) located between 104.4 Mb and 111.2 Mb. We use the UCSC Genome Bioinformatics database, assembly July 2003, to determine the chromosomal positions of microsatellite markers and SNPs. We have identified a disease haplotype that spans 3.8 Mb between D5S2084 and D5S492. Mutational analysis of candidate genes is now in progress.

A major gene for keratoconus in Ecuador does not map to any of the known keratoconus loci. *R.A. Lewis¹, M. Gajecka², D. Winters², A. Molinari³, J.A. Pitarque³, M.H. Chahrour¹, S.M. Leal¹, B.A. Bejjani^{2,4}.* 1) Baylor College of Medicine, Houston, TX; 2) Washington State University, Spokane; 3) Hospital Metropolitano, Quito, Ecuador; 4) Sacred Heart Medical Center, Spokane, WA.

Keratoconus (KC) is a non-inflammatory thinning and anterior protrusion of the cornea that results in steepening and distortion of the cornea, altered refractive powers, and altered visual acuity. Although both genetic and non-genetic factors have been associated with KC, its molecular basis is still elusive. We identified an Ecuadorian cohort in which KC without other ocular or systemic features is transmitted as an autosomal dominant trait with incomplete penetrance. To date, we have examined, collected blood, and purified DNA from 148 individuals from 22 multiplex families with KC. Subjects were diagnosed clinically with KC by slit lamp examination and corneal topography. We excluded previously assigned KC loci on chromosomes 3, 15, 16, and 20 by linkage analysis and initiated a genome-wide screen for a KC locus. We genotyped 120 individuals with fluorescent markers with an average spacing of 10 cM spanning chromosomes 3, 4, 15, 16, 19, 20, 21, and 22 and sequenced *VSX1* coding exons in 18 KC individuals from 18 families and two control Ecuadorian individuals. KC in our families is not linked to any of the previously defined KC loci. *VSX1* was excluded as a candidate for KC in this population by sequencing of the coding exons and the exon-intron junctions. We found no evidence for linkage between KC and the markers tested.

Comprehensive genetic linkage analysis of a late-onset Alzheimer disease locus on chromosome 12. X. Liang¹, N. Schnetz-Boutaud¹, S.J. Kenealy¹, K.C. Stanton¹, T.N. Rugless¹, L. Jiang¹, J. Bartlett¹, W.K. Scott², J.R. Gilbert², M.A. Pericak-Vance², J.L. Haines¹. 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Ctr for Human Genetics, Duke University, Durham, NC.

Alzheimer disease (AD) is a progressive neurodegenerative disorder of later life with a complex etiology with a strong genetic component. ApoE is the only gene universally accepted as an important risk factor for late-onset AD (LOAD). However, more than 50% of AD cases do not carry ApoE 4 allele, suggesting that other genetic risk factors must exist. Several genomic screens have suggested that a region between chromosome 12p13 and 12q22 is a potential position for an additional locus underlying the susceptibility of AD. However, localization of this locus has been difficult. We hypothesized that some of this difficulty arises from the genetic heterogeneity underlying AD.

To test this hypothesis, we performed a 74 cM microsatellite marker screen on chromosome 12 with 15 markers in 585 multiplex families consisting of 994 affected sibpairs and 213 other affected relative pairs. Analyses across the entire dataset did not reveal significant evidence of linkage. However, suggestive linkage was observed in several more homogeneous subgroups.

In the 91 families where no affected individuals have an ApoE-4 allele, the HLOD is 1.55 at D12S1042, suggesting that ApoE and the chromosome 12 locus might have independent effects. We further examined the linkage data considering the proposed linkages to chromosome 9 (D9S741) and 10 (VR22 gene). Microsatellite marker D12S1701 generated an HLOD score of 4.19 when we ordered the autopsy confirmed families (n=228) by the covariate of VR22 LOD score, again suggesting independent effects of these two loci.

Taken together, these results indicate that the chromosome 12 locus acts independently of ApoE and VR22 to increase the risk of late-onset familial AD in a subset of families. These data suggest that the region between D12S1042 and D12S368 (~16 cM) should be the subject of further detailed genomic efforts for the disease.

A LOCUS ON CHROMOSOME 9p PREDISPOSES TO ACUTE ANTERIOR UVEITIS, A SPECIFIC DISEASE MANIFESTATION IN ANKYLOSING SPONDYLITIS. *J. Luo¹, T.M. Martin², J. Luo¹, T.M. Doyle², J.E. Coffman², F.I. Mackensen³, J.D. Reveille⁴, J.T. Rosenbaum².* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Casey Eye Institute, Oregon Health & Science University, Portland, OR; 3) Ophthalmology, University of Heidelberg, Heidelberg, Germany; 4) Rheumatology, University of Texas-Houston Health Science Center, Houston, TX.

A genome-wide scan was conducted to search for loci associated with acute anterior uveitis. Families with 2 or more members who have acute anterior uveitis and/or ankylosing spondylitis (AS) were recruited. Evidence for linkage was determined by nonparametric multipoint linkage analysis using Gene Hunter Plus. The transmission disequilibrium test was also performed. The genome-wide scan for acute anterior uveitis was compared to one for AS performed by the North American Spondylitis Consortium (NASC). Out of 978 individuals genotyped, 244 were affected with acute anterior uveitis. The data presented represent 76 affected sibling pairs for acute anterior uveitis. Of these, 6 sib pairs denied any symptoms of AS, 12 uveitis sib pairs were discordant for AS and the remaining 58 uveitis sib pairs were concordant for AS, either by self-report or by radiographic disease determination. A region at chromosome 9p showed a striking association with uveitis but not AS. The maximum LOD score at this region was 3.69 for uveitis, while the LOD score for the NASC AS cohort was not significant (<1.0). A distinct AS cohort described by Laval, et al. showed suggestive linkage at this 9p locus. Additional regions with significant linkage include the MHC locus on chromosome 6, and a region at chromosome 1q. However, these regions also showed significant linkage with AS. Transmission disequilibrium analyses supported the genome-wide scan linkage findings, including the chromosome 9p uveitis linkage. A genetic region for acute anterior uveitis has been identified by genome-wide scan. These data reveal a region on chromosome 9p as a predisposing factor in uveitis. Comparison to a companion AS scan indicates that this region may be unique to the uveitis phenotype.

Polymorphism and linkage disequilibrium patterns at the serotonin transporter gene locus (SLC6A4). H. Mansour, M.E. Talkowski, J. Wood, K.V. Chowdari, M. Bamne, A. Fagiolini, E. Frank, M.E. Thase, D.J. Kupfer, V.L. Nimgaonkar. Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA.

Polymorphisms of the serotonin transporter, SLC6A4 (17q11.1-q12), have been associated with mood disorders, as well as therapeutic response to some antidepressants. Yet, association studies have been inconsistent. Most studies have only investigated an insertion/deletion polymorphism (5HTTLPR) in the promoter region. We reasoned that other polymorphisms may contribute to the associations and the inconsistencies may be due to variations in linkage disequilibrium (LD) patterns. Therefore, we conducted LD analyses at SLC6A4.

We analyzed 5HTTLPR, as well as 11 additional polymorphisms across the SLC6A4 locus. Variation in 5HTTLPR was analyzed by resequencing, as well as a PCR based assay (Heils et al, 1996). Genotype assays for the SNPs were based on multiplex PCR followed by single base extension analysis (SnaPshot assays, ABI Inc). Our sample consists of 135 US Caucasian nuclear families having a proband with Bipolar I Disorder (BD1), available parents, and 73 patients with Major Depressive Disorder (MDD, DSM IV criteria). Cord blood samples from local Caucasian live births serve as unrelated, unselected controls (n = 182). We have evaluated pair-wise (LD) patterns separately between the SNPs among BD1 patients, their parents and the controls using r^2 and D value. Using D value, significant LD was observed among 6 SNPs, (rs140701, rs2020942, rs6354, rs2020939, rs2020937, rs2066713). Significant LD was also noted separately between 3 additional SNPs, (rs2020935, rs2020934 and rs2020933). Our analysis indicates 5HTTLPR is in significant LD with only one SNP (rs2020934). Further, another SNP flanking 5HTTLPR that is localized to the repeat motif (rs25532) is not in LD with the other SNPs. Our analyses in over 200 individuals (cases, parents and controls) suggest that rs25532 is monomorphic among all individuals homozygous for the 5HTTLPR insertion. Further association analyses with BD1 and MDD are currently ongoing. These analyses may help resolve some of the persistent controversies involving the etiological role of SLC6A4 in mood disorders.

Association of ACE polymorphisms and Alzheimer disease. *E.R. Martin¹, P. Bronson¹, R.H. Chung², P-T. Xu¹, J.L. Haines³, J. Gilbert¹, M.A. Pericak-Vance¹.* 1) Duke University Medical Center, Durham, NC; 2) North Carolina State University, Raleigh, NC; 3) Vanderbilt University Medical Center, Nashville, TN.

Several studies have evaluated the gene for angiotensin converting enzyme (ACE) on chromosome 17 for association with Alzheimer disease (AD). Though association studies have been conflicting, a recent meta-analysis concluded that the ACE gene is likely to play a role in AD risk (Elkins et al 2004). Despite this conclusion, the specific mechanism underlying this association has yet to be identified and most studies have looked at a single insertion/deletion polymorphism in intron 16 of the ACE gene. To further examine the effect of ACE variants in AD, we examined seven polymorphisms in the gene. Markers were genotyped in a large AD family dataset (324 families with 1,073 phenotypically discordant sibling pairs) and an independent case-control data set (281 cases and 677 controls). Many of these families, singleton cases and controls have not been tested for association with ACE polymorphisms previously. We found significant association with four ACE SNPs (p-values between 0.007 and 0.04) in the family dataset using the pedigree disequilibrium test. Two SNPs also showed association in the independent case-control sample (p-values=0.028 and 0.030), and this association remained when we adjusted for age, sex and APOE-4 status. The replication of significant association in independent family and case-control samples provides strong support for the role of ACE in Alzheimer disease. Despite our findings of association with several markers, the strong linkage disequilibrium between markers makes it difficult to distinguish which polymorphisms may be contributing to risk. Further study is warranted to understand the role of specific polymorphisms and the biological mechanism affecting AD risk.

Type I punctate palmoplantar keratoderma: refinement of the locus on chromosome 15 and evidence for genetic heterogeneity. A. Martinez-Mir¹, A. Zlotogorski⁶, D. Londono⁴, D. Gordon⁴, A. Grunn³, E. Uribe⁵, L. Horev⁶, I.M. Ruiz⁵, N.O. Davalos⁵, O. Alayan⁶, J. Liu³, T.C. Gilliam³, J. Miljkovic⁸, A. Stanimirovic⁹, J.C. Salas-Alanis⁷, A.M. Christiano^{1, 2}. 1) Dept Dermatology, Columbia University, New York; 2) Dept Genetics & Development, Columbia University, New York; 3) Columbia Genome Center, Columbia University, New York; 4) Lab of Statistical Genetics, Rockefeller University, New York; 5) Hosp Gral Occidente Zapopan, Mexico; 6) Dept Dermatology, Hadassah-Hebrew University Medical Center, Jerusalem; 7) Serv Medico Univ Autonoma Nuevo Leon, Mexico; 8) Maribor Teaching Hospital, Slovenia; 9) Medical School Zagreb University, Croatia.

Palmoplantar keratodermas (PPK) are a heterogeneous group of disorders of keratinization for which only a few molecular defects have been described. We report the identification and fine-mapping of a locus for type I punctate PPK. A genomewide scan was performed on an autosomal dominant pedigree and linkage to chromosome 15 was established. With the addition of two new PPK families of diverse geographical origin, we confirmed the mapping of the locus to a 9.98-cM interval, flanked by D15S534 and D15S818 (LOD score of 4.93, at D15S988). In order to refine the location of the PPK locus, we genotyped all available markers within the region and narrowed the locus to an interval of 8.89 cM, corresponding to a region of 3.7 Mb. We have recently identified 6 new PPK families from Slovenia. To evaluate the role of the PPK locus in this group of families, markers covering the interval on chromosome 15 were genotyped in those pedigrees with two or more affected individuals. The PPK locus on chromosome 15 cosegregated with the disease phenotype in all pedigrees tested. Very recently, Zhang et al have reported the identification of a second locus for punctate PPK on chromosome 8 in a Chinese pedigree. Genotyping of markers in this region failed to show cosegregation with the disease in our pedigrees, suggesting genetic heterogeneity. The results reported here will help in the identification of a new gene involved in skin integrity that could also contribute to the understanding of the multiple organ involvement in syndromic forms of PPK.

Identification of a locus for exudative age-related macular degeneration on chromosome 16p. *V.P.M. McConnell¹, G. Silvestri², A.E. Hughes¹*. 1) Department of Medical Genetics, Queen's University, Belfast, United Kingdom; 2) Ophthalmology and Vision Science, Queen's University, Belfast, United Kingdom.

Age-related macular degeneration (AMD) is the leading cause of blindness in elderly Caucasians. The exudative form, which is characterized clinically by choroidal neovascularization and fibrous scarring of the macula, is responsible for 80% of AMD-related blindness. Genetic predisposition in AMD is now well established, but remains largely undetermined. The aim of our study was to identify a locus for exudative AMD in a large family with several affected members, and to assess the importance of this locus in the Northern Irish population. Thirty members of the family were examined over a ten-year period and phenotyped using the Rotterdam AMD grading system for stereo-digital fundus photographs. A genome-wide screen was undertaken using 400 highly polymorphic microsatellite markers with linkage analysis restricted to affected individuals. The disease segregated as an autosomal dominant trait and mapped to 16p12-p13. Further refinement using additional microsatellite markers and haplotype analysis suggested that the disease gene was located between 3 and 19Mb. The maximum multipoint Lod score of 3.2 was obtained near D16S3103 (17.6Mb). Two disease haplotypes segregated in different branches of the family. An association study was performed using 200 unrelated exudative AMD cases and a similar number of controls, using clustered markers close to candidate genes. The most significant association found to date was near EMP2 ($p=0.01$), however, no mutation was detected in this gene within the large family. This is the first disease locus to be identified for exudative AMD. The combination of familial linkage and positive association data implies that the causative gene on chromosome 16p may play an important role in AMD.

Autosomal dominant Nocturnal enuresis: A study of an Indian Family. *R. Meda*¹, *J.V. Solanki*², *U. Ratnamala*¹, *U. Radhakrishna*¹. 1) Molecular Genetics Laboratory, Green Cross Blood Bank & Gen, Ahmedabad, India; 2) Department of Animal Genetics & Breeding, Veterinary College, Gujarat Agriculture University, Anand, India.

Nocturnal enuresis, or nightly bedwetting, is most common in children and affects approximately 15-20% of school age children between the ages of 4 and 16 and it continues to present in 2-3% adults. It is more common among boys than girls and about 5 to 7 million children wet the bed. Several factors cause bed-wetting; some of these include hormonal factors, Urinary tract infections, abnormalities in the spinal cord, and bladder size. In addition, Genetic factors also contribute to the pathogenesis. Several families with autosomal dominant and autosomal recessive modes of inheritance have been reported. The genes responsible for autosomal dominant (ENUR1 (OMIM 600631) and ENUR2 (OMIM 600808)) have been mapped to chromosome 13q13-q14.3 (Nature Genet. 10: 354-356, 1995) and 12q13-q21 (J. Med. Genet. 34: 360-365, 1997) respectively, but no mutation-causing gene has yet been identified. We have studied a large five-generation Indian pedigree for bedwetting in which the anomaly segregates as an autosomal dominant trait. The pedigree consists of 27 individuals with 11 affected (eight males and three females) and the age distribution of these affected is from 5-48 years. There are no other associated anomalies present in this family. We have genotyped this family for all polymorphic microsatellite markers flank the disease loci at chromosome 13q13-q14.3 and 12q13-q21. These markers were selected since they were used for the original linkage analysis for autosomal dominant ENUR1 and ENUR2. Analyzing 15 individuals, all markers yielded significant negative (-2.0) at = 0. Thus ENUR1 and ENUR2 can be excluded as the candidate region responsible for nocturnal enuresis in this family. We are planning to perform genome-wide linkage analysis in this family to identify the responsible locus. Email: u_c_rao@hotmail.com.

A novel locus for pure recessive Hereditary Spastic Paraplegia maps to chromosome 10q22.1-10q24.1. I.A.

Meijer^{1, 2}, *P. Cossette*¹, *J. Roussel*¹, *M. Benard*¹, *S. Toupin*¹, *G.A. Rouleau*¹. 1) Centre for Research in Neuroscience, McGill University Health Centre Research Institute, Montreal, PQ, Canada; 2) Department of Biology, McGill University.

The Hereditary Spastic Paraplegias (HSP) are a group of clinically and genetically heterogeneous disorders characterized by progressive lower limb spasticity. In this study we present a single generation French Canadian family with autosomal recessive pure HSP. We analyzed the family for linkage to the known recessive loci at the start of the study (*SPG5*, 7, 11) and no evidence for linkage was found. We then proceeded to study the dominant HSP loci (*SPG3*, 4, 6, 8, 9, 10) in the family. A significant LOD score of 3.04 was obtained for marker D10S1755 (*SPG9*) with two point parametric linkage analysis. A maximum LOD score of 4.49 at theta 0 was found for more telomeric markers: D10S1786 and D10S1765. Haplotype analysis identified a compound heterozygote haplotype and two recombinants, which defined a critical interval of approximately 26Mb flanked by D10S606 and D10S1758. This novel recessive locus *SPG27* partially overlaps (6.1Mb) with the existing *SPG9* locus. We have either mapped a novel locus for pure recessive HSP to chromosome 10q22.1-10q24.1 or we have identified the first case of allelic disorders with different mode of inheritance in HSP. If the disorders are indeed allelic, our results have reduced the *SPG9* interval by 3Mb.

Linkage Analysis at the IFNGR1 Locus in Visceral Leishmaniasis. *L.M. Olson¹, N. Schnetz-Boutaud¹, R.R. Rodriques², R. Dietze², C.E. Carter³, C. Li¹, J.L. Haines¹.* 1) Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, Tennessee; 2) Nucleo de Doencas Infecciosas, Universidade Federal do Espirito Santo-UFES, Brazil; 3) Department of Biological Sciences, Vanderbilt University, Nashville, Tennessee.

Leishmaniasis is a parasitic infection transmitted by the bite of a sand fly. The two major forms of the disease are cutaneous and visceral leishmaniasis (VL). Cutaneous leishmaniasis is an infection of the skin that produces multiple ulcers or sores. Visceral leishmaniasis or Kala-azar is an infection of the internal organs and may produce fever, weight loss, anemia, and enlarged liver or spleen. VL is usually fatal if left untreated. We hypothesized that genetic variation underlies part of the variation in response to infection. Initial analysis focused on sixteen SNPs in and near six genes related to immune response. The six genes included IL10 on chromosome 1, IL4 on chromosome 5, IFNGR1 and TNF on chromosome 6, IFNG on chromosome 12, and IL12RB1 on chromosome 19. In preliminary linkage analysis, the data set consisted of seven multiplex VL families which showed a non-parametric multipoint LOD score, HLOD, of 1.66 at the hCV7578627 SNP in the IFNGR1 gene. After such encouraging linkage results, eleven additional trio families were included in the association analysis. The pedigree disequilibrium test (PDT), Geno-PDT and Tsp were used to assess association and linkage. The most significant result, though marginal with a p-value = 0.08, was the association of maternal transmissions for the Tsp or associated transmission/disequilibrium test (TDT) for SNP hCV7578627. Severity in leishmaniasis may be accounted for by analyzing additional SNPs to further explore the linkage and association in IFNGR1.

Linkage and association analysis of chromosomal 12q13 region in Italian atopic asthmatic families. *C. Patuzzo*¹, *C. Migliaccio*², *G. Malerba*¹, *R. Galavotti*¹, *S. Venanzi*³, *E. Trabetti*¹, *P.F. Pignatti*¹. 1) Sect Biol & Genetics, Mother-Child, Biol & Genetics, Verona, Italy; 2) International Institute of Genetics and Biophysics, CNR, Naples, Italy; 3) Department of Cellular Biology and Neurosciences, ISS, Rome, Italy.

Several reports have identified the chromosomal region 12q as related to asthma and atopic phenotypes in different populations. Our previous linkage analysis of chromosome 12 markers with allergic asthma phenotypes in 116 families from North East Italy (Malerba et al. *AJRCCM* 2000; 162:1587) indicated suggestive linkage with marker D12S390 (51.1 Mb from pter, Ensembl map v22). The highest multipoint lod score estimation was for the clinical asthma phenotype (mlod = 2.81, p=0.003). No linkage was thereafter observed for any phenotype and a CA repeat in the first intron of the Interferon γ (IFNG) gene (66.8 Mb from pter) or three intragenic microsatellites in the neuronal Nitric Oxide Synthase 1 (NOS1) gene (116.1 Mb from pter). The present study is aimed to improve the definition of the region near the D12S390 marker. For this purpose the sample of 45 families with at least one asthmatic sib pair was used for linkage disequilibrium mapping and a nested association-based study. A set of five microsatellite markers between D12S368 and D12S1644, covering a distance of 5 Mb, was used as well as SNPs in three different genes: keratin 4-type II cytoskeletal 4 or cytokeratin 4 (KRT4), eukaryotic translation initiation factor 4B (EIF4B) and signal transducer and activator of transcription 6 (STAT6). TDT analysis was performed on estimated haplotypes. The TRANSMIT programme was used to evaluate TDT and the significance was assessed with Bootstrap procedure. We obtained a TDT X2 value of 4.07 with P=0.0053 for the KRT4 gene and the clinical asthma phenotype. Multipoint linkage analysis (GENEHUNTER 2.1 computer programme) showed positive but non significant results. Further studies to verify the association data on the KRT4 gene will be necessary.

Linkage of the Metabolic Syndrome to a Genetic Location on Chromosome 7q in Mexican Americans. S.

Puppala¹, J. Schneider¹, R. Arya², T. Dyer¹, S. Fowler², L. Almasy¹, J. Blango¹, M.P. Stern², R. Duggirala¹. 1) Genetics, Southwest Fndn Biomedical Res, San Antonio, TX; 2) Medicine/Clinical Epidemiology, University of Texas Health Science Center, San Antonio, TX.

The metabolic syndrome (MS) consists of a cluster of related disorders including central obesity, dyslipidemia, insulin resistance and hyperinsulinemia, hyperglycemia and hypertension. Several epidemiological studies have shown that MS is a predictor of both type 2 diabetes (T2D) and coronary heart disease (CHD). Recently, the National Cholesterol Education Program / Adult Treatment Panel III (NCEP/ATPIII) proposed that MS requires the presence of at least 3 of the following 5 risk factors: increased waist circumference (102 cm in men or 88 cm in women), hypertriglyceridemia (150 mg/dl), low HDL cholesterol (40 mg/dl in men or 50 mg/dl in women), hypertension (130/85 mm Hg), and high fasting glucose (110 mg/dl). Given the epidemic of MS, the NCEP/ATPIII definition for MS has been used widely in both clinical practice and epidemiology. However, knowledge of its genetic basis is extremely limited. We therefore performed a genome scan of the MS phenotype defined in accordance with the NCEP/ATPIII criteria, using variance components linkage analysis, to identify major susceptibility loci for the MS with the program SOLAR. We analyzed phenotypic data from 741 participants distributed across 39 low-income Mexican American families in the San Antonio Gallbladder Study (SAFGS), for whom a 10-15 cM map is available. The prevalence of MS in these families was 44%. Perhaps for the first time, after accounting for the covariate effects of age, we found strong evidence (lod score = 3.6, P = 0.00002) for a major locus on chromosome 7q between the markers D7S2212 and D7S821, which influences MS. Suggestive evidence for linkage was found on regions of chromosomes 8q near the marker D8S1136 (lod score = 2.6) and 11p near the marker D11S1999 (lod score = 2.3). A positional candidate gene in our chromosomal region of interest is *CD36* (fatty acid translocase). In conclusion, we found strong evidence for linkage of MS in the Mexican American population to a region on chromosome 7q.

First genomic screen of Neural Tube Defects reveals regions of interest on chromosomes 7 and 10. E.

Rampersaud¹, T.M. George², E.C. Melvin¹, D.S. Enterline², D. Siegel¹, G. Worley², J. Mackey², J. Allen¹, L.E. Floyd¹, S. West¹, P. Hammock¹, F. Swift¹, J.R. Gilbert¹, M.C. Speer¹. 1) Ctr Human Genetics, Duke Univ, Durham, NC; 2) Duke Univ, Durham, NC.

Birth defects are the leading cause of death in babies under 1 year of age. Neural tube defects (NTD) with a frequency of 1/1000 in American Caucasians are the second most common birth defect. Periconceptional maternal folate supplementation has been shown to reduce NTD risk by 50-70%; however, studies in humans of folate-related genes and other developmental genes have failed to identify a major gene. The etiology of NTDs remains unknown. A traditional linkage approach to identify regions of interest is complicated in NTDs due to a paucity of families with two or more affected individuals available for sampling. We present findings from a genome scan of 44 multiplex pedigrees. Multipoint parametric and nonparametric analyses were performed using Allegro. To account for clinical heterogeneity we used a broad phenotype definition to include all NTDs and then allowed only families with two or more persons with lumbosacral myelomeningocele. Initial results revealed several regions of interest, including chromosomes 7 and 10 both with max parametric lod scores > 2.0 . Chromosome 7 produced the highest lod score (MLOD=2.45 at D7S3056) and showed consistent linkage evidence across all analyses. Further analyses demonstrated that results on chromosome 7 were being primarily driven by a single large pedigree, family 8776 that by itself generated a lod score of 2.40. When this family was removed from analysis, chromosome 10 was the most interesting region with a peak lod score of 2.12 at D10S1731. The availability of newly emerging technology via the Affymetrix Genechip Mapping 10K SNP Array allowed us to perform an independent screen of family 8776 by itself using a dense map. A comparison of linkage results from both screens is presented. Since multiplex NTD families are difficult to find, this screen is likely to be the only one performed with little chance for replication. Thus the synthesis of these results represents a valuable and novel resource for the identification of susceptibility genes for NTD.

Combined analysis of genome scans from five twin cohorts to locate quantitative trait loci for body mass index and stature in the GenomEUtwin project. *S. Sammalisto¹, T. Hiekkalinna¹, N. Martin², J. Harris³, D. Boomsma⁴, K. Christensen⁵, K. Ohm Kyvik⁵, N. Pedersen⁶, T. Andrew⁷, T. Spector⁷, E. Widen⁸, A. Palotie⁸, L. Peltonen¹, M. Perola¹, GenomEUtwin.* 1) Dept Molecular Medicine, Natl Public Health Inst, Helsinki, Finland; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) Norwegian Institute of Public Health, Oslo, Norway; 4) Free University, Amsterdam, Netherlands; 5) University of Southern Denmark, Odense, Denmark; 6) Karolinska Institutet, Stockholm, Sweden; 7) St Thomas Hospital, London, United Kingdom; 8) University of Helsinki, Finnish Genome Center, Finland.

European twin cohorts provide a unique competitive advantage for investigations of the role of genetics and environment or life style in the aetiology of common traits. The EU-funded GenomEUtwin (www.genomeutwin.org) consortium consists of eight twin cohorts (Australian, Danish, Dutch, Finnish, Italian, Norwegian, UK and Swedish). As a proof-of-principle study for joint analyses of these large cohorts, we performed QTL analysis of body-mass index (BMI) and stature (body height) using genotypic data from six genome-wide scans performed on the GenomEUtwin participating countries. The study material consisted of 5723 individuals: Australia (n=1323), Finland (n=879), Netherlands (n=876), Sweden (n=102) and United Kingdom (n=2228). The genetic marker maps were integrated using physical location information and interpolation the genetic distances from the DeCode genetic map, using its markers as an anchoring set (www.bioinfo.helsinki.fi/cartographer). The raw marker data was pooled by a program developed by us, MERGESCAN, which uses the information from Cartographer to facilitate joint analysis for different datasets for combined genome-wide analyses. We used the program Merlin for variance components analysis with age, sex and cohort as covariates. The covariate adjusted heritability of BMI was found to be 64% and of stature 89% in the pooled data set. We found evidence for a QTL on chromosomes 6q, 8q and 10q determining human stature. We plan to integrate more data in these analyses from GenomEUtwin participants in near future.

A MHC-chromosome 2 interaction in JRA affected sibpairs. *M.L. Sudman¹, L. Guyer², M. Ryan², M.A. Keddache¹, W.M. Brown³, C.D. Langefeld³, S.S. Rich³, C. Valis³, W.C. Nichols¹, M.B. Moroldo², S.D. Thompson², D.N. Glass².* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Division of Rheumatology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Wake Forest University School of Medicine, Winston-Salem, NC.

Juvenile Rheumatoid Arthritis (JRA) is a complex genetic disorder and is the most common chronic rheumatic inflammatory condition in childhood, with an estimated 50,000 children diagnosed in the US. The disease is phenotypically and genetically heterogeneous and distinct from adult onset RA. A genome scan (386 microsatellite markers) was done on 121 families containing 247 affected children (NIAMS supported JRA Affected Sibpair [ASP] Registry). In addition, individuals were typed for HLA-DR. Pedigree disequilibrium tests at the DRB1 locus revealed excess transmission of the DR8 haplotype to offspring with pauciarticular JRA (haplotype-specific $P = 2.0 \times 10^{-6}$). Other haplotypes, including HLA-DR11, 13 and 4, are well documented to be associated with susceptibility (or resistance) to one or more subtypes of JRA. To evaluate potential interactions between HLA-DR and other genomic regions, nonparametric linkage analysis was performed on 32 pedigrees with offspring concordant for the presence of at least one DR8 allele. The strongest evidence for linkage in these pedigrees was near D2S168 at 35 cM (2p25, LOD=6.00). Fine mapping with 13 additional microsatellites produces a LOD=6.09 and reduced the LOD-1 support interval to 7 cM (31.6-38.6 cM). Suggestive evidence for linkage in these 32 pedigrees was observed at D14S292 at 131.5 cM (14q32, LOD=1.84). Repeating these analyses on the pedigrees with at least one offspring having HLA-DR4 yielded a LOD=2.48 at 3p27, and on pedigrees concordant for the presence of either DR8, DR11 or DR13 yielded a LOD=2.34 at 17q25. Linkage disequilibrium analyses based on a dense SNP map of the 2p25 region are underway.

Environmental Covariates Yield Major Gains in Power in Linkage Analysis. *T.N. Turley-Stoulig¹, A.J.M. Sorant², J.E. Bailey-Wilson², D.M. Mandal¹.* 1) Dept. of Genetics, LSU Health Sciences Center, New Orleans, LA; 2) NHGRI/NIH, Baltimore, MD.

Inclusion of covariates in linkage analysis of complex traits may increase the power to detect linkage. To identify situations in qualitative trait linkage analysis with large power gain, this study evaluates the effect of inclusion of a covariate on power and type I error for qualitative trait linkage analysis under various inheritance models.

A binary trait with penetrance determined by a dominant biallelic locus and modified by a quantitative covariate was simulated with G.A.S.P., using various degrees of penetrance, disease allele frequency and covariate effect. For each model, segregation analysis was performed (REGDHUNT) on a large singly ascertained sample to provide a trait model for use in the model-based analysis. Then the trait and linked ($\alpha=0.01, 0.05$) and unlinked markers were generated for 10,000 samples of 300 nuclear families with 4 offspring. Each linkage sample was analyzed with model-based (LODLINK, S.A.G.E. 3.1) and model-free (revised Haseman-Elston regression SIBPAL, S.A.G.E. 4.5, using the mean-corrected cross-product as dependent variable) methods, with and without the covariate.

Under examined inheritance models, both LODLINK and SIBPAL provided more powerful linkage analysis and conserved type I error with covariate inclusion. Under models with moderate to strong genetic effect and moderate covariate effect, power to detect linkage with LODLINK was increased as much as 6-fold when the covariate was included in analysis.

Identification of two candidate loci for intracranial aneurysms in the French Canadian population. *D.J. Verlaan¹, M.P. Dubé¹, J. St-Onge¹, N. Satgé¹, M.C. Wallace², G.A. Rouleau¹*. 1) Centre for Research in Neurosciences, McGill University, Montreal, Canada; 2) Division of Neurosurgery Toronto Western Hospital, University of Toronto, Toronto, Canada.

Introduction: Intracranial Aneurysms (ICA) are a common and serious problem of uncertain etiology. ICA rupture is responsible for approximately 10% of all strokes. It is a serious condition because the first manifestation is almost always rupture, leading to death in 50% of cases and significant morbidity in an additional 30%.

Aim: The purpose of our study is to map a gene (or genes) that predisposes to intracranial aneurysms (ICA) in the French Canadian population.

Methods: An 8cM genome-wide scan was performed on a large French Canadian family affected with intracranial aneurysms (affected cases only). All individuals were successfully genotyped at 531 markers with a success rate of 95%. Haplotypes were reconstructed by using the Maxprob functions and multipoint linkage analysis was performed using the parametric and non-parametric functions of the Genehunter v.2.1 program. For the analysis, an autosomal dominant model with a disease allele frequency of 0.5% and a phenocopy rate of 5% was used. A high penetrance of 95% was used because an affected-only analysis was performed.

Results: Ten different loci were found to be slightly positive (LOD1). Further genotyping and analysis with another affected individual reduced the number of positive loci to 2. Multipoint analyses of the two loci show that they have a LOD score close or equal to 3. These loci are found on chromosome 12q23-24 and 5p15-14.

Conclusion: Genotyping of additional French Canadian families will permit us to determine if both or only one of these loci harbor a susceptibility gene for intracranial aneurysm in the French Canadian population.

Sex-specific genetic architecture of whole blood serotonin levels. *L.A. Weiss*¹, *M. Abney*¹, *E.H. Cook*^{2,1}, *C. Ober*¹. 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept Psychiatry, Univ Chicago, Chicago, IL.

Recently, we identified integrin 3 (*ITGB3*) on chromosome 17q as a quantitative trait locus (QTL) for whole blood serotonin in the Hutterites (Weiss et al., in press, Eur J Hum Genet). Because we found serotonin level to be sexually dimorphic in this population, in the current study we evaluated the sex-specific genetic architecture of serotonin. Whole blood serotonin was measured by HPLC in 300 females and 267 males, who were genotyped for 1,123 autosomal markers. Tests developed for QTL mapping in large pedigrees include a linkage method (homozygosity-by-descent [HBD]) and an association method (allele-specific HBD [ASHBD]) and utilize the probability of HBD at a locus or allele, respectively, as a predictor of the trait value (Abney et al., 2002, Am J Hum Genet 70:920-34). Both sexes had high broad heritability ($H^2=0.99$), but females had a higher additive component ($h^2_{\text{male}}=0.27$, $h^2_{\text{female}}=0.63$), suggesting that serotonin level shows sex-specific architecture. Both sexes contributed to a linkage signal on chromosome 12q ($\text{LOD}_{\text{male}}=2.0$, $\text{LOD}_{\text{female}}=0.99$, $\text{LOD}_{\text{all}}=2.4$) and 16p ($\text{LOD}_{\text{male}}=2.0$, $\text{LOD}_{\text{female}}=0.74$, $\text{LOD}_{\text{all}}=2.4$). In contrast, the serotonin QTL on 17q at *ITGB3* showed linkage in males only ($\text{LOD}_{\text{male}}=2.7$, $\text{LOD}_{\text{female}}<0.1$, $\text{LOD}_{\text{all}}=1.9$), as did a region on 2q ($\text{LOD}_{\text{male}}=2.1$, $\text{LOD}_{\text{female}}<0.1$, $\text{LOD}_{\text{all}}=0.61$). On the other hand, a region on 6q was specific to females ($\text{LOD}_{\text{male}}<0.1$, $\text{LOD}_{\text{female}}=2.8$, $\text{LOD}_{\text{all}}=0.99$). The association test showed overall more results of suggestive significance in males than females: 7 markers in 4 regions (including *ITGB3* and the serotonin transporter gene) vs. 1 marker, respectively. This analysis is consistent with heritable sexual dimorphism in whole blood serotonin levels resulting from a combination of sex-specific and sex-independent loci. As a result, effects contributed by a subgroup of the population (one sex) were missed in the undivided sample. If sex-specific genetics is as general a phenomenon in humans as it is in model organisms, mapping of complex traits may be enhanced by modeling for different architecture in males and females.

LD-PPL: the Posterior Probability of Linkage (PPL) with Linkage Disequilibrium (LD). *X. Yang¹, L.M.*

Brzustowicz^{2, 3}, A.S. Bassett^{4, 5}, V.J. Vieland^{6, 7, 8}. 1) Department of Biostatistics, University of Iowa, Iowa City, IA; 2) Department of Genetics, Rutgers University, Piscataway, NJ; 3) Department of Psychiatry, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, NJ; 4) Genetics Research Program, Centre for Addiction and Mental Health, University of Toronto, Toronto; 5) Department of Psychiatry, University of Toronto, Toronto; 6) Center for Statistical Genetics Research, University of Iowa, Iowa City, IA; 7) Program in Public Health Genetics, University of Iowa, Iowa City, IA; 8) Department of Psychiatry, University of Iowa, Iowa City, IA.

PPL as a Bayesian method for pedigree data has been developed for linkage analysis based on direct measurement of posterior probability of linkage in the past years. One limitation of the method has been that it assumes linkage equilibrium in the population from which the families are sampled. When a marker locus is closely linked to the disease susceptibility loci, it is highly likely that they are in linkage disequilibrium (LD). One would assume that stronger linkage signals would be detected by taking LD into consideration if there are reasons to believe that LD exists. We have developed a method for directly measuring the linkage evidence with linkage disequilibrium (LD-PPL), which involves recovering marginal posterior density by integration over nuisance parameters including LD coefficient, locus heterogeneity parameter and other trait model parameters. Simulation studies have showed increased LD-PPL compared to PPL with increased LD level in a variety of generating models with linkage. It is also observed that LD-PPL is consistently smaller than corresponding PPL when the marker and the disease are unlinked. We have applied this method to a previously published schizophrenia data set, where strong LD has been detected between the region of CAPON on 1q22 and schizophrenia. 15 SNPs within this region are investigated. Stronger linkage signals have been obtained using LD-PPL than PPL suggesting the LD-PPL method may be more powerful for gene identification even in complex disorders.

Linkage study of the candidate gene *SCN2A1* in familial mesial temporal lobe epilepsy (FMTLE). C.V. Maurer-Morelli¹, N.F. Santos¹, R.B. Marchesini¹, R. Secolin¹, E. Kobayashi², F. Cendes², I. Lopes-Cendes¹. 1) Medical Genetics, FCM/UNICAMP, Campinas, SP, Brazil; 2) Neurology, FCM/UNICAMP, Campinas, SP, Brazil.

Purpose: Mutations of voltage-gated sodium channel genes are known to be responsible for some types of human epilepsy. In a recent report, a mutant *Scn2a* mice showed focal seizures activity in the hippocampus with extensive cell loss and gliosis within the CA1, CA2, CA3 areas and hilus. Recently, we described a large group of families segregating a distinct type of temporal epilepsy named FMTLE, with evidence of a strong genetic predisposition for the development of hippocampal atrophy. Complex segregation analysis provided evidence for the presence of a major gene segregating in this disorder. The objective of this study was to carry out linkage studies in FMTLE in order to investigate whether the human *SCN2A1* may play a role in the etiology of FMTLE.

Methods: We studied 29 unrelated families segregating FMTLE. Among these families we have identified two kindreds that are significantly informative for linkage analysis: F-10 and F-26. A total of 57 individuals, including 32 patients were analyzed in this study. We genotyped five polymorphic dinucleotide repeat markers flanking the *SCN2A1* region on chromosome 2q22-q23: D2S347, D2S129, D2S151, D2S2241 and D2S141. The screening was performed by PCR amplification. Two-point lod scores (Z) were calculated for each family separately using the LINKAGE package.

Results: Simulation analysis for the two kindreds (F-10 and F-26) indicates a Z_{max} of 8.9, 4.5 and 4.4 respectively. The two Brazilian families segregating FMTLE showed negative lod score for all markers genotyped, ranging from -1,22 to -3,40 at different recombination fractions.

Conclusion: Our results suggest that, although the hippocampal lesion in the mutant *Scn2a* transgenic mouse is similar to that found in FMTLE patients, the *SCN2A1* gene is not the major locus involved in the etiology of the disease in our patients.

A novel Locus for Maternally Inherited Human Gingival Fibromatosis at Chromosome 11p15. *L. Hu¹, Y. Zhu¹, Z. Huo², W. Zhang³, Y. Zhang¹, Y. Xia¹, B. Li¹, X. Kong¹.* 1) Health Science Center, sibs., Shanghai, shanghai, China; 2) Ningxia Medical College, Yinchuan 750004, Peoples Republic of China; 3) Qingdao Haici Hospital, Qingdao 266033, Peoples Republic of China.

A novel Locus for Maternally Inherited Human Gingival Fibromatosis at Chromosome 11p15 ABSTRACT Human isolated gingival fibromatosis is an oral disorder characterized by a slowly progressive benign enlargement of gingival tissues. The most common form of hereditary gingival fibromatosis (HGF) is usually transmitted as an autosomal dominant trait. We reported here for the first time a newly identified maternally inherited gingival fibromatosis in two unrelated Chinese families was mapped to human chromosome 11p15 with a maximum two point lod score of 8.70 at D11S4046(= 0) for family 1 and of 6.02 at D11S1318 for family 2. A critical region from D11S1984 to D11S1338 was defined by haplotype analysis. A cluster of known maternally expressed genes is mapped within this interval and is considered as candidate genes. We have screened mutations in all known maternally expressed genes within this region for individuals of these two families, no mutation at coding sequence and intron-extron boundary of these genes was found. According to Knudson's hypothesis of "two hits", mutation or epigenetic mutation of an imprinted tumor suppressor may increase tumor susceptibility. This result provide valuable clues for the identification of a candidate tumor suppressor on human chromosome 11p15.5 and also provide first direct evidence that imprinting (or imprinted gene) mutation results in tumorigenesis.

Using population structure to map complex diseases. *B. Peng*¹, *W. Amos*², *F. Balloux*³, *M. Kimmel*¹. 1) Department of Statistics, Rice University, Houston, TX; 2) Department of Zoology, Univ. of Cambridge, Cambridge, UK; 3) Department of Genetics, Univ. of Cambridge, Cambridge, UK.

In population-based case-control association studies, population structure can lead to highly significant but spurious associations. The attempts to avoid this problem lead directly to the popularity of transmission disequilibrium tests and recently, some statistical methods that use genomic markers to control for population structure in population-based studies. The two main methods are Genomic Control which estimates the degree of overdispersion generated by population substructure, and Structured Association which uses marker data to estimate structure present in the data. However, these approaches have significant drawbacks when susceptibility factors are distributed heterogeneously in the sample. We propose an alternative approach. Instead of treating the sample as comprising a number of homogeneous units, we estimate the relatedness between pairs of individuals and then assume that more related individuals / families share more susceptibility factors in common than less related individuals / families. In this way we combine the measurement of structure with the estimation of degree of association between markers, flexibly and in a way that bypasses the need to estimate discrete sub-groups. Our method consists of three steps: 1) estimate family relatedness and combine this with data on marker location to construct the weighting system, 2) estimate locus-level inbreeding and association measures and obtain summary measurements using the relatedness-aware weighting matrix and 3) test the significance of each value using exhaustive randomizations. We have focused on the leprosy dataset of Siddiqui et al. (2001) to validate our method. Siddiqui and co-workers report a genetic linkage scan of the genomes of 224 families from South India, containing 245 independent affected sib-pair. In a two-stage genome screen using 396 microsatellite markers, they found significant linkage on chromosome 10p13. We use a dataset consisting of 394 individuals in 96 nuclear families. The results we obtain are very close to those obtained in the original study.

Linkage disequilibrium analysis of recombination hotspot at the upstream region of the α -globin gene. *J. Ohashi*¹, *I. Naka*¹, *J. Patarapotikul*², *H. Hananantachai*², *G. Brittenham*³, *A. Clark*⁴, *S. Looareesuwan*², *K. Tokunaga*¹. 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Microimmunology and Clinical Tropical Medicine, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand; 3) Department of Pediatrics and Medicine, Columbia University, College of Physicians and Surgeons, New York, New York, USA; 4) Department of Molecular Biology and Genetics, Cornell University, Ithaca, New York, USA.

Recombination hotspot located upstream of the α -globin (HBB) gene has been intensively studied by pedigree analysis, sperm typing approach, and linkage disequilibrium (LD) analysis so far. Our previous study based on patterns of LD among 44 biallelic markers in Thai suggested a putative recombination hotspot spanning 2.0 kb in length at the upstream of the HBB gene (Ohashi et al., *AJHG* 74:1198-1208). The putative hotspot was found to include a binding site for the repressor protein BP1, which contains a tandem (AT)_x(T)_y repeat. In this study, to narrow the region of the recombination hotspot, we analyzed several polymorphic sites including (AT)_x(T)_y repeat in the putative recombination hotspot in Thai and Japanese populations. The following linkage disequilibrium and haplotype analyses suggested that this hotspot consisted of 683 bp and did not include the BP1 binding site. The localization of recombination hotspot would give valuable information for better understanding of the mechanism of recombination in the human genome.

Haplotype structure in the genes encoding thermosensitive receptors and experimental pain sensitivity in humans. *H. Kim, R.A. Dionne.* PNMB, NIDCR / NIH, Bethesda, MD.

Even though the individual gene effects may be small, interactions among the genes and environments may make a substantial contribution to the final manifestation of the pain sensitivity. The haplotype, a particular combination of alleles observed in populations, focuses on patterns of a few single nucleotide polymorphisms (SNPs) that define each haplotype and has contributed to the identification of genes for Mendelian disease and, recently, disorders that are common but complex in inheritance. Normal subjects (387 females and 260 males) from 4 major ethnic populations were evaluated for their heat and cold pain sensitivity and SNPs genotyped from genes encoding transient receptor potential A subtype 1 (*TRPA1*), transient receptor potential M subtype 8 (*TRPM8*), transient receptor potential V subtype1 (*TRPV1*) and -opioid receptor subtype 1 gene (*OPRD1*). The haploblocks based on solid spine LD method were generated by Haploview version 2.05 with SNPs whose minor allele frequency > 0.2, genotype success rate > 0.9. Departure from Hardy-Weinberg equilibrium was tested by a χ^2 test. Analysis of variance was performed to evaluate the association between haploblocks and heat and cold pain sensitivity. From these 4 genes region, there are 6 haploblocks in European Americans, 3 blocks in African Americans, 4 blocks in Hispanic, and 4 blocks in Asian Americans. We found differences in haplotypes among populations from screened genes except for the *TRPM8*, in which we could not find any haploblocks. We found significant associations between experimental pain sensitivity and haplotype blocks from *TRPA1* and *TRPV1* in this human cohort ($p < 0.05$). Our observations demonstrate that haplotypes of *TRPA1*, *TRPV1*, and *OPRD1* have different patterns in each ethnic population and those from *TRPA1* and *TRPV1* contribute to individual variations in experimental pain sensitivity.

Genome-wide SNP association studies for cardiovascular adverse reactions by calcineurin inhibitors in renal transplant recipients. *T. Mushiroda*¹, *Y. Ohnishi*¹, *S. Saito*¹, *T. Yamazaki*¹, *N. Kamatani*¹, *Y. Beck*², *Y. Nakamura*^{1,3}. 1) SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Tokyo, Japan; 2) Department of Surgery and Bioengineering, Advanced Clinical Research Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 3) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Cardiovascular events are relatively common and severe adverse outcomes caused by treatment with calcineurin inhibitors (CNIs). We conducted case-control association studies using gene-based 52,608 single nucleotide polymorphisms (SNPs) with 72 patients receiving cyclosporine or tacrolimus after renal transplantation to identify the susceptible genes to cardiovascular events. The overall incidence of cardiovascular events was 13.9% (ten patients) among 72 patients treated with either of the drugs. We observed associations with p-value of <0.001 at 19 SNP loci calculated by allele frequency model, at 14 SNP loci by dominant inheritance model, and at 8 SNP loci by recessive inheritance model. On the basis of information of the ten selected SNPs in order of significance of p-value, we attempted to establish a scoring system to predict the risk of cardiovascular toxicity of the treatment and found that the system well separated the patient groups according to absence or presence of ADR. Score distribution patterns in general Japanese populations are quite similar to those in the ADR-negative group, but quite different from those in the ADR-positive group, indicating that pharmacogenetic testing with the prediction scoring system may provide a good indicator for careful monitoring cardiotoxicity and for treating the adverse reaction at an early stage to avoid the fatal condition.

Autosomal Dominant Adult Detrusor Instability with Childhood Nocturnal Enuresis: Localization to a 12cM

Region on 13q14.11. *M.F. Buckley¹, T. Roscioli¹, G.L. Mullan¹, A. Morris², K. Moore², J.A. Donald³*. 1) Molecular & Cytogenetics Unit, Prince of Wales Hosp, Randwick, Australia; 2) Pelvic Floor Unit, St. George Hospital, Sydney, Australia; 3) Department of Biological Sciences, Macquarie University, Sydney, Australia.

Nocturnal Enuresis (NE) and Detrusor Instability (DI) is a common, complex genetic disorder of bladder control for which genetic loci have been reported on chromosomes 4, 8, 12, 13 and 22. No genes have been isolated for this condition. We report preliminary evidence for a novel locus in a further Caucasian family in which DI, NE and day wetting show an autosomal dominant pattern of inheritance. The twelve affected individuals in this family consist of ten adult females, one female child and one male adolescent. Two of the affected individuals were diagnosed with DI by urodynamic testing without clinical symptoms. A further five adult females had the clinical phenotype of DI, as did one female child with persistent day wetting. One individual was phenotypically normal but was an obligate carrier by pedigree and therefore likely to be non-penetrant. A partial genome scan was carried out using genetic markers at loci previously implicated in NE (D4S2960, D8S264, D12S80, D12S86, D13S263, D13S291, D22S343, D22S446). Preliminary LOD score estimates were calculated assuming an autosomal dominant pattern of inheritance, phase-known and with incomplete penetrance. The loci on chromosomes 4, 8, 12 and 22 did not segregate with the DI phenotype. A LOD score of 2.11 at D13S263 suggested linkage to 13q14.11. A higher resolution scan was therefore performed at 5cM intervals between the centromere and D13S263 on chromosome 13. Two alleles at D13S171 and D13S219 segregated with the phenotype, being present in all affected and obligate carrier individuals. The locus D13S263 that was previously implicated in NE lies telomeric to the region defined in this study. Lack of recombination between loci D13S171, D13S219 and the phenotype suggests linkage despite the modest LOD score for D13S171. Analysis of a further two informative individuals and reanalysis of the data using multipoint linkage is in progress.

A first-pass genome-wide scan for susceptibility to amyotrophic lateral sclerosis using 2,500 microsatellite markers. *A. Al-Chalabi¹, V.K. Hansen¹, C.L. Simpson¹, J. Knight², B. Neale², P.C. Sham², M.R. Turner¹, C.E. Shaw¹, P.N. Leigh¹, J.F. Powell³.* 1) Neurology, Institute of Psychiatry, London, United Kingdom; 2) Statistical Genetics, Institute of Psychiatry, London, United Kingdom; 3) Neuroscience, Institute of Psychiatry, London, United Kingdom.

ALS is a relentlessly progressive fatal neurodegenerative disorder of motor neurons. In about 2% of all cases, mutations are found in the superoxide dismutase 1 gene (SOD1). Numerous candidate gene screens have yielded inconsistent results, possibly because of phenotypic heterogeneity. We performed a genome-wide scan for association using microsatellite markers using a two-stage design in which a non-stringent first pass is followed by a stringent replication pass.

Individuals from a clinic-based population were selected on the basis of disease severity. Controls were from the same geographical region and matched for age and sex. DNA pools were made with the highest and lowest quintiles for age of onset, and the remainder split by clinical phenotype (limb or bulbar onset of symptoms). Microsatellites were selected to target gene-dense regions or candidate genes and typed on an ABI 3100 genotyper (Applied Biosystems). For the first pass, results were prioritised using metaregression of allele frequencies against phenotype weighted by the inverse of the measurement variance.

There were 300 cases and 300 controls with 60 in each of the age of onset pools, 123 in the limb onset and 57 in the bulbar onset pool. More than 3000 microsatellites were typed, for which results were obtained for 2210. The metaregression analysis was neither conservative nor anticonservative. There were 6 markers with $p < .01$. The most significant result was for marker D3s1298 with $p = .0001$.

This is the first genome-wide analysis of sporadic ALS. A replication study of the 6 positive markers in a second population is required.

A QTL on chromosome 11q determines decrease of mean arterial blood pressure over time despite weight gain in a single Mexican American family. *G. Cai¹, J.W. Kent, Jr.¹, R.A. Bastarrachea¹, S.A. Cole¹, L. Atwood², J. Blangero¹, J.W. MacCluer¹, A.G. Comuzzie¹.* 1) Genetics, SW Foundation for Biomed Res, San Antonio, TX; 2) School of Medicine, Boston Univ.

Although genome scans have been performed to search for quantitative trait loci (QTLs) influencing variations in blood pressure, none has examined rate of change in mean arterial blood pressure (MBP, mm Hg/year). We conducted a genome wide scan to localize QTLs for average changes of systolic, diastolic, and mean arterial blood pressures (rSBP, rDBP, rMBP) in 653 Mexican Americans using SOLAR. A significant linkage for rMBP was found near marker D11S4464 (LOD = 5.42). The same marker also was linked to rSBP and rDBP (LOD = 2.78 and 3.99, respectively). Interestingly, pedigree-specific LOD analysis revealed that a single family of 62 members contributed 3.92 to the total LOD score of 5.42. In contrast to the general population where blood pressures increase when people get older, this family presented a decreasing trend of SBP, DBP, and MBP, although they did get heavier and had larger waist circumferences. Also, six members of this family are diagnosed as hypertensive. Out of the 62 members in this family, 35 members use alcohol and 27 smoke. However, no genotype by drinking or by smoking interaction was detected. The trait presented as a bimodal distribution in this family after accounting for the effect of covariates of smoking, drinking, sex, age, age-squared, sex by age interaction, and yearly change in waist circumference, suggesting a single allele dominant pattern with incomplete penetrance. The QTL on chromosome 11q does not overlap regions previously identified for variations in blood pressure in the same data set. This implies that distinct genes contribute to the variation in rMBP. Given the magnitude of the signal, the fact that the linkage signal came from a few dozen people, the unique phenotype (decreasing blood pressures in spite of weight gain), and the bimodal distribution of the trait, which is classic for a single allele effect, it is highly likely that we will be able to find the causal gene(s) through future fine mapping and single nucleotide polymorphism analysis.

A genome-wide search for creatinine clearance QTLs in West Africans with Type 2 Diabetes. *G. Chen¹, A. Adeyemo^{1,2}, J. Zhou¹, T. Johnson³, A. Amoah⁴, J. Acheampong⁵, G. Okafor⁶, Y. Chen¹, G. Dunston¹, F. Collins⁷, C. Rotimi¹.* 1) Natl Human Genome Ctr, Howard Univ, Washington, DC; 2) University of Ibadan, College of Medicine, Ibadan, Nigeria; 3) University of Lagos, College of Medicine, Endocrine and metabolic Unit, Lagos, Nigeria; 4) University of Ghana Medical School Dept. of Medicine, Accra, Ghana; 5) University of Science and Technology Dept. of Medicine, Kumasi, Ghana; 6) University of Nigeria Teaching Hospital Dept. of Medicine, Enugu, Nigeria; 7) National Human Genome Research Institute, NIH, Bethesda, MD.

Chronic renal failure occurs with a frequency of 200 cases per 1 million persons and two-thirds of all cases are associated with diabetes and/or hypertension. Creatinine clearance is commonly used to estimate renal function in clinical practice and a decreased creatinine clearance is an early sign of CRF. We have investigated the genetic determinants of creatinine clearance by conducting a genome wide search for QTLs linked to creatinine clearance in 691 type 2 diabetes patients (321 sib pairs and 36 half-sib pairs) in West Africa. We defined the phenotype using two residual models for creatinine clearance: a basic model (that included fat mass, fat-free mass, pulse rate, pulse pressure and glucose as covariates) and a full model (that included all the variables in the basic model as well as C-peptide levels). Suggestive linkage evidence was found in three genomic regions: 7p13 (peak LOD score = 2.20, $p = 0.0007$ @55cM), 10q22 (peak LOD score = 2.0, $p = 0.0012$ @93cM) and 2q14 (peak LOD Score = 1.95, $p = 0.0014$ @133cM) using the full model. Linkage peaks were found in the same regions using the basic model but these did not reach suggestive linkage evidence level. Candidate genes in or around the linkage regions include: GCK, OGDH, HK1 (involved in glucose metabolism) and GPR17 (transduce cellular signals). In summary, there are QTLs showing linkage to creatinine clearance in this study and the inclusion of C-peptide in the genetic model improved the ability to detect these loci.

Program Nr: 1944 from the 2004 ASHG Annual Meeting

Linkage study of panic disorder: genome screen and fine mapping. A..J. Fyer¹, S.P. Hamilton³, G.A. Heiman¹, V. Haighighi^{1,2}, M. Durner¹, A. deLeon¹, O.V. Evgrafov¹, M. Bautista³, R. Costa¹, P.a. Tabares¹, P. Adams¹, T.C. Gilliam^{1,2}, D.F. Klein¹, S.E. Hodge^{1,4}, J.A. Knowles¹, M.M. Weissman¹. 1) Dept Psychiatry, Columbia University/NYSPI, NY, NY; 2) Dept Genetics and Development, Columbia University, NY, NY; 3) Dept of Psychiatry, UCSF, San Francisco, CA; 4) Dept of Biostatistics, Columbia University, NY, NY.

Panic disorder is a common illness characterized by recurrent, unpredictable episodes of intense anxiety. Significant evidence indicates a genetic contribution to etiology with heritability estimated at 35-49% but no specific mode of transmission. We previously reported a genome-wide screen (average spacing 9cM) in 120 multiplex panic disorder pedigrees. Here we present further work in this sample. Genome scan data have been re-analyzed using additionally available genotypings and clarification of family structure. Analyses were carried out under two modes of inheritance (dominant, recessive) using three pre-designated diagnostic thresholds for panic disorder (Broad, Intermediate, Narrow). Two-point and multipoint lod scores (under assumption of homogeneity and heterogeneity), as well as NPL scores were calculated for each phenotype-model combination. Consistent with previous results, three regions (chromosomes 2, 9, 15) received convergent support for suggestive linkage from at least two of the three analytic methods (i.e. two point, multipoint, NPL). Fine mapping (2-4cM) data from each of these regions are being analyzed and will be presented. In addition, as panic disorder is twice as common in females as males, we will also present analyses of the genome-wide data allowing for independent male and female recombination fractions.

Genetics of recurrent early-onset major depression: Genome scan linkage analysis of the full GenRED study sample. *P. Holmans*¹, *M.M. Weissman*², *G.S. Zubenko*³, *J.R. DePaulo, Jr.*⁴, *R.R. Crowe*⁵, *W.A. Scheftner*⁶, *P. Adams*², *J.A. Knowles*², *D. March*², *W.N. Zubenko*³, *M.G. McInnis*⁴, *D. MacKinnon*⁴, *K. Murphy-Eberenz*⁷, *M. Gladis*⁷, *S. Boutelle*⁵, *D.H. Marta*⁶, *J. Thomas*⁴, *E. Miller*⁴, *D.F. Levinson*⁷. 1) Dept Psychological Medicine, UWCM, Cardiff, United Kingdom; 2) Dept Psychiatry, Columbia Univ, and NY State Psychiatric Institute, NY, NY; 3) Dept Psychiatry, Univ of Pittsburgh, Pittsburgh, PA; 4) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 5) Dept Psychiatry and MHCRC, Univ of Iowa, Iowa City, IA; 6) Dept Psychiatry, Rush Univ Medical Center, Chicago, IL; 7) Dept Psychiatry, Univ of Pennsylvania, Philadelphia, PA.

The GenRED (Genetics of Recurrent Early-Onset Depression) project has collected 680 families containing 927 independent affected sibling pairs plus additional non-sibling affected relatives. DNA specimens and diagnostic data will be made available by NIMH. The primary allele-sharing analysis (ALLEGRO) of all 685 informative affected pairs in the first 297 families demonstrated genome-wide significant linkage (Z-likelihood ratio=4.14, $p=0.023$, 103.2 cM) on chromosome 15q (AJHG 74:1154-1167, 2004). In the full sample (1,508 pairs), 15q was the most positive region, but at the suggestive level (Zlr=2.98 at 105.4 cM); the second part of the sample (Zlr=0.31) did not add support for linkage. Zlr>2.0 was observed on chromosomes 1 (211.16 cM), 5 (190.77 cM) and 8 (37.84 cM). In a secondary logistic regression analysis with sex as a covariate (M-M, M-F, F-F pairs), linkage was observed on chromosome 17q (28.0 cM, lod=1.11 without and 4.37 with covariates, chromosome-wide $p=0.0012$, reaching genome-wide significance), with excess sharing in M-M (0.58) and M-F (0.56) pairs. Modest evidence for sex effects was observed on chromosomes 6 and 8. On chromosome 12, where Abkevitch et al. (AJHG 73:1271-1281, 2003) reported significant linkage in males (110 cM), excess sharing was observed at 100.4 cM in M-M pairs in both parts of the scan (0.61, 0.57) and overall (0.59), but results did not reach significance here. These results suggest that chromosomes 15q and 17q may harbor susceptibility genes for recurrent, early-onset major depression.

Genome-wide linkage analysis of lipids in Chinese and Japanese from the SAPPHIRe family study. *C.F. Hsiao¹, Y.F. Chiu¹, L.T. Ho³, Y.J. Hung⁴, K.D. Wu², H.H. Sheu⁵, D. Curb⁷, T. Quertermous⁶, C.A. Hsiung¹.* 1) Biostatistics & Bioinformatics, National Health Research Ins., Taipei, Taiwan, Taiwan; 2) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 3) Department of Medicine, Taipei veterans General Hospital, Taipei, Taiwan; 4) Department of Medicine, Tri-Service General Hospital, Taipei, Taiwan; 5) Department of Medicine, Taichung Veterans General Hospital, Taichung, Taiwan; 6) Stanford University School of Medicine, Stanford, CA; 7) Pacific Health Research Institute, Honolulu, Hawaii.

Lipid levels are recognized as major risk factors for coronary heart disease (CHD). Discovery of major loci underlying quantitative lipid traits could help to elucidate the genetics of CHD. We performed a genome-wide search for quantitative trait loci (QTL) linked to lipid phenotypes in 1538 Han Chinese subjects (509 families) and 625 Japanese subjects (204 families) not taking lipid-lowering medications from the Stanford-Asian Pacific Program in Hypertension and Insulin Resistance (SAPPHIRe) study. The multipoint variance-components method was used to test for linkage between marker loci and each trait by maximum likelihood methods adjusted for linear and nonlinear effects of age as well as effects of gender, BMI, smoking, alcohol consumption, physical activity, and field center. The highest LOD score detected was 3.22 for logarithmically transformed high-density lipoprotein cholesterol (HDL) on chromosome 12 at 113 cM in Han Chinese. This score overlaps the positive findings for HDL reported in Mexican Americans (chromosome 12 at 96 cM). Although no strong evidence for linkage was found in Japanese, some modest peaks were found in several regions that have been reported in other published genome scans. For example, the Japanese SAPPHIRe peaks for HDL (chromosome 3 at 212 cM, LOD=1.51; chromosome 1 at 167 cM, LOD=1.54) were very close to the QTLs for HDL reported in the scans of the Pima Indian subjects (Chromosome 3 at 182 cM), and in the white American HyperGEN (Chromosome 1 at 159.9 cM).

SNP mapping at 100kb-interval in chromosome 21 for localizing the risk loci of late-onset Alzheimer's disease. K.

Kamino¹, T. Kida¹, M. Yamamoto¹, A. Nuripa¹, T. Tanaka¹, T. Kudo¹, H. Yamagata², T. Miki², T. Uema³, H. Akatsu⁴, M. Takeda¹. 1) Div Psychiatry and Behavioral Proteomics, Dept Post-Genomics and Diseases, Osaka Univ Grad Sch Med, Suita, Osaka, Japan; 2) Dept Geriatric Medicine, Ehime Univ, Onsen-gun, Ehime, Japan; 3) Dept Psychiatry, Osaka General Medical Center, Sumiyoshi-ku, Osaka, Japan; 4) Chojyu Medical Institute, Fukushima Hospital, Toyohashi, Aichi, Japan.

Late-onset Alzheimer's disease (LOAD) is one of typical polygenetic disorders, and twin studies in North European countries noted that genetic factors are more important than environmental ones to develop LOAD. Given that patients with Down syndrome develop Alzheimer's pathology at their 30s, we hypothesized that some genes in chromosome 21 harbor the risk effect of LOAD. To search for the risk loci, we performed SNP scanning at 100 kb-interval in chromosome 21 against 188 LOAD cases including 69 cases with definite LOAD and 375 population-based control subjects, using the 5' nuclease assay (TaqMan assay, ABI). This study protocol was approved by Osaka University Genome Committee and the written informed consent was obtained from either subjects or their relatives. Among 417 SNPs, 14 showed allelic linkage disequilibrium with LOAD, judged by p value less than 0.05. One region identified by 3 neighboring SNPs spanning 200 kb was highlighted as a risk locus, and these SNPs also showed a significant effect to modify age-at-onset. This region was located within Down Syndrome Critical Region (DSCR) mapped at 21q22.2, and showed linkage disequilibrium with LOAD also in extended 378 LOAD cases ($p < 0.005$). Although this risk locus should be evaluated in more extended subjects, we propose here that the DSCR harbors a risk locus of LOAD. Our results also indicated that a 100kb-interval scanning against well-defined patients and controls could be effective to screen susceptibility loci of polygenetic disorders.

A Genome Scan for Genes Involved in Vesicoureteral Reflux. *H.R. Kelly^{1,2}, A. Yoneda^{1,2}, D. Shields³, C. Molony^{3,4}, A. Green¹, P. Puri², D. Barton¹.* 1) National Centre for Medical Genetics, Conway Institute for Biomolecular and Biomedical Research and Department of Medical Genetics, University College Dublin; 2) Children's Research Centre, Our Lady's Hospital for Sick Children, Crumlin, Dublin 12, Ireland; 3) Department of Pharmacology, Royal College of Surgeons, Dublin 2, Ireland; 4) Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, 19104.

Vesicoureteral reflux (VUR), the reverse flow of urine from the bladder into the ureter and kidney, is a common disorder, found in 1-2% of children. VUR can cause kidney damage and is a common cause of end-stage renal failure and severe hypertension in children. It is caused by a shortening of the segment of the ureter that runs through the submucosal layer of the bladder wall. The milder grades of reflux may resolve with time but more severe grades require medical or surgical intervention. VUR occurs frequently in families, suggesting that it is inherited but the mode of inheritance is unknown. Blood from 170 families with more than one child affected with VUR was collected. We are using this resource in an affected-sib-pair approach to search for VUR gene(s). Although no VUR genes have yet been identified, we have excluded all the loci suggested by Feather et al (*Am J Hum Genet* 66:1420-5, 2000). We have recently completed a genome scan using SNP markers across 630 samples to identify the loci involved in VUR. 630 DNA samples from 134 families with >1 child affected with VUR were selected. These families contained 183 sibpairs: 113 sibpairs, 18 sibtrios, 1 sibquad and 1 sibquin. There are 3 sets of twins in the study. Of the 644 samples (630 samples, 14 replicates) sent to Illumina, genotypes were reported on 638 across 4,753 Loci. 3,030,221 genotypes were reported out of a possible 3,032,414 giving a call rate of 99.93%. The mean heterozygosity for the genome scan across 4754 markers was 0.45. Analysis using Genehunter and Merlin indicates the presence of 10 regions with significance p-values <0.01, on 9 different chromosomes. This analysis will map VUR susceptibility gene(s), which will be the first step towards determining the molecular basis of this disorder.

Dissection of the oligogenic susceptibility of familial idiopathic generalised epilepsy. *K.P. Lenzen^{1,2}, A. Heils², G. Rudolf², J.F. Prud'homme², R. Nabbout², O. Dulac², F. Zara², A. Bianchi², R. Robinson², R.M. Gardiner², A. Covanis², B. Koeleman², D. Lindhout², S. Lorenz², P. Nurnberg¹, T. Sander^{1,2}.* 1) Max-Delbrueck-Centrum, Berlin, Berlin, Germany; 2) European Consortium on the Genetics of Idiopathic Generalised Epilepsy.

Idiopathic generalised epilepsies (IGE) affect about 0.3% of the general population and account for 30% of all epilepsies. The aetiology of common IGE syndromes, such as juvenile myoclonic epilepsy (JME) and idiopathic absence epilepsies (IAE), is genetically determined, but the complex pattern of inheritance suggests an oligogenic predisposition. The aim of the present collaborative European genome scan was to map IGE loci and to dissect its oligogenic aetiology. Our linkage study included 90 European families ascertained through a proband with either IAE or JME, and one or more siblings affected by an IGE trait (IGE or generalised spike wave EEG discharges). In total, 561 microsatellite polymorphisms with an average intermarker spacing of 7 cm were genotyped in 377 family members. Non-parametric multipoint linkage analyses, using the GENEHUNTER program, revealed suggestive evidence ($P < 0.01$) for novel IGE loci in the chromosomal regions 5q32 ($Z_{NPL} = 2.87$, $P = 0.002$), 11q13 ($Z_{NPL} = 2.87$, $P = 0.002$) and 13q32 ($Z_{NPL} = 3.51$, $P = 0.0003$). To dissect seizure type-specifying susceptibility loci, two distinct family subgroups were selected by the presence of either myoclonic seizures (JME-families; $n = 38$) or absence of seizures (IAE-families; $n = 52$). In the JME families, maximum evidence for linkage was found in the chromosomal regions 13q32 ($Z_{NPL} = 2.41$, $P = 0.009$), 16q22 ($Z_{NPL} = 2.50$, $P = 0.007$) and 19q13 ($Z_{NPL} = 2.37$, $P = 0.009$). In the IAE families, linkage hints were obtained on chromosome 11q13 ($Z_{NPL} = 3.54$, $P = 0.0002$) and 13q32 ($Z_{NPL} = 3.51$, $P = 0.0002$). Our present linkage results indicate an IGE locus in the region 13q32 that confers susceptibility to a broad IGE spectrum, whereas three additional susceptibility loci on 11q12, 16q22 and 19q13 seem to specify various seizure types in an age-related manner.

Fine mapping and SNP analysis of positional candidates at the pre-eclampsia susceptibility locus, *PREG1*, on chromosome 2.

E.K. Moses^{1,2}, *E. Fitzpatrick*¹, *H.H. Goring*², *H. Liu*¹, *A. Borg*¹, *S. Forrest*³, *D.W. Cooper*⁴, *S.P. Brennecke*^{1,5}. 1) The Royal Women's Hospital, Melbourne, Australia; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, Texas; 3) Australian Genome Research Facility, Melbourne, Australia; 4) School of Biological Sciences, Macquarie University, Sydney, Australia; 5) Department of Obstetrics & Gynaecology, University of Melbourne, Australia.

Pre-eclampsia/eclampsia (PE/E) is the most common and serious disorder of human pregnancy and is associated with substantial maternal and perinatal morbidity and mortality. A large genetic component to susceptibility to PE/E has been clearly demonstrated and genome scans in Icelandic, Australian/New Zealand and Finnish families have localised putative susceptibility loci to chromosome 2. The locus identified in the Aust/NZ study (designated *PREG1*) spanned a very broad (~ 85 cM) region, with the multipoint LOD-score curve displaying 2 peaks, one on 2p (LOD = 1.96 at 109.2 cM) and one on 2q (LOD = 2.58 at 144.7 cM). Here we describe our fine mapping of the *PREG1* locus with 25 additional STR markers and genetic analysis of two positional candidate genes. Using the robust two-point linkage analysis implemented in the ANALYZE program, all 25 markers gave positive LOD scores with significant evidence of linkage being seen at D2S2313 (151.5 cM) achieving a LOD score of 3.37 under a strict diagnostic model. Suggestive evidence of linkage was seen at D2S388 (107.46 cM) with a LOD score of 2.22 under the general diagnostic model. Two candidate genes beneath the peak on 2p were selected for further analysis using public SNPs within these genes. A maximum LOD score of 3.5 was obtained for a SNP in *TACRI* and 3.33 for a SNP in *TCF7L1*, both achieving genome-wide significance. The STR marker D2S286 for which the Icelandic group obtained their highest LOD score of 4.77 is also within *TACRI*. We therefore suggest that we have identified the same locus on 2p in our Aust/NZ population. However, our significant linkage on 2q is by distance genetically unlinked to the 2p locus and we therefore further suggest that it represents evidence of a separate locus.

Program Nr: 1951 from the 2004 ASHG Annual Meeting

A Whole-Genome Association SNP Panel for Functional Regions. *P.C. Ng, L. Zhou, R. Shen, M.S. Chee, A. Oliphant, K.L. Gunderson.* Illumina, Inc., San Diego, CA.

There are two approaches that have been proposed for whole-genome association studies: the direct approach and the indirect approach. The indirect approach relies on linkage disequilibrium between a marker and a causative variant while the direct approach uses candidate causative variants as markers. The advantage of the direct approach is that fewer SNPs need to be genotyped which results in fewer false positives and lower costs. Moreover, association provides a candidate gene.

To facilitate the direct approach, we have selected approximately 100,000 validated and double-hit SNPs from dbSNP that are located in or near functional regions across the genome. These are assayed using Illumina's whole genome genotyping (WGG) assay on the BeadChip platform. We have concentrated on SNPs in coding regions as well as SNPs in potential regulatory regions. Over 30,000 SNPs lie in transcribed sequences. Those in coding sequences are candidates for affecting protein function and those in UTRs could affect regulation. Another 30,000 SNPs lie in putative regulatory regions. Additional SNPs were chosen so that most exons have at least one marker within 10 kb so that even if the causative variant is not present in the panel, other markers in the panel could be in linkage disequilibrium with the causative SNP. Despite being exon-centric, marker density is relatively homogeneous across the genome. Therefore, the final design is a hybrid that accommodates both the direct and indirect strategies.

By focusing on SNPs in known and candidate functional regions, it is now possible to find disease loci by the direct approach. This panel could also potentially be used for quantitative analysis of allele-specific expression and genomic copy number. Illumina's WGG BeadChip SNP panel enables studies on variation in functional regions throughout the genome.

Examination of chromosomal regions identified in a genomic screen for dementia in Amish families. *S. Prasad¹, J.M. van der Walt¹, S. Slifer¹, P.C. Gaskell¹, W.K. Scott¹, E.R. Martin¹, A. Crunk², D. Fuzzell², M. Creason¹, L. Jiang², K. Spencer², N. Schnetz-Boutaud², K. Welsh-Bohmer³, S.R. Johnson³, C.E. Jackson⁴, C.C. Kroner¹, M.A. Pericak-Vance¹, J.L. Haines²*. 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC; 4) Scott and White Clinic, Temple, TX.

We have previously studied the Amish populations in the Midwest and demonstrated a familial effect in late-onset dementia that is not accounted for by APOE. We performed a microsatellite genomic screen in seven complex pedigrees with 123 total sampled individuals (42 affected), using a standard set of microsatellite markers at ~10 cM density. MtDNA analysis indicates that the Amish families originate from three distinct genetic subgroups: Adams County, IN (Group 1), Elkhardt/LaGrange, IN (Group 2) and Ohio (Group 3) (van der Walt et al. ASHG, 2004). In the overall dataset, strongest signals were observed for chromosomes 4, 8, 10 and 20 (Max LOD = 2.16, 2.65, 3.30 and 3.19 respectively). Follow-up analysis included genotyping and analysis of 30 single nucleotide polymorphisms (SNPs) for chromosome 4; 16 SNPs and 3 microsatellites for chromosome 8; 33 SNPs and 2 microsatellites for chromosome 10 and 19 SNPs for chromosome 20. The follow-up dataset included two new families (total affecteds=51). The markers were analyzed under both parametric affecteds-only and non-parametric models using Simwalk2 program. The two-point analyses revealed positive lod scores only on chromosomes 4 (MaxLOD= 1.28) and 10 (MaxLOD=1.04) in overall dataset. Analyses in the Amish subgroups revealed two interesting regions on chromosome 4. Group 1 had a multipoint maximum LOD score of 2.15 at 153Mb and Group 2 had MaxLOD=1.92 at 86Mb. Subgroup analysis did not substantially change the MaxLOD results for chromosomes 8, 10 or 20. These data suggest that multiple loci, one of which is on chromosome 4, may account for risk in the Amish dementia population and may have different effects in different family subgroups.

Genome-Wide Scan for Angiotensinogen Among Nigerian Families Revealed Evidence of QTL on

Chromosomes 1 and 17. *B.O. Tayo¹, X. Zhu², Y. Liang³, A. Luke², P. Muti¹, A.A. Adeyemo⁴, R.S. Cooper².* 1) Department of Social and Preventive Medicine, SUNY at Buffalo, Buffalo, NY; 2) Department of Preventive Medicine and Epidemiology, Loyola Medical School, Maywood, IL; 3) Department of Biostatistics, SUNY at Buffalo, Buffalo, NY; 4) Department of Pediatrics, College of Medicine, University of Ibadan, Ibadan, Nigeria.

Angiotensinogen (AGT) has been intensely studied in the pathogenesis of hypertension over the last several years. As a part of an ongoing family study on the genetics of hypertension in Blacks, we performed a genome-wide scan on 117 Nigerian families comprising of 550 adult members using the software SOLAR to investigate the evidence of possible quantitative trait loci (QTLs) modifying AGT level in this population. We therefore used 378 tandem repeat markers spanning the entire genome with an average map density of 9 cM. The overall heritability of AGT in this population was 76%. Our results of variance component linkage analysis of sex adjusted AGT revealed two positions with genome-wide statistically significant LOD scores of 3.68 on chromosome 17 at 74 cM (between markers D17S2180 and D17S1290), and 3.33 on chromosome 1 at 288 cM (on marker D1S2682) which is close to the position of AGT gene. Other weaker evidences of linkage were found on chromosome 4 (LOD = 2.52) and chromosome 13 (LOD = 2.28). These results suggest the existence of QTLs for AGT on chromosomes 1 and 17 in this black population.

Program Nr: 1954 from the 2004 ASHG Annual Meeting

Hot and cold recombination spots based on the East Finland founder population. *P. Uimari, O. Kontkanen, M. Pirskanen, R. Fuentes, J.T. Salonen.* Jurilab Ltd, Kuopio, Finland.

Linkage disequilibrium (LD) or non-random association of alleles at different loci varies across the genome. In some parts of the genome LD is strong and some regions show weak LD mainly because the area is a hot spot for recombinations. LD was studied in the East Finland founder population that was established some 15 generations ago by 400-800 individuals. The Affymetrix 100k genotyping assay was used for genotyping 118 unrelated individuals. LD was measured for SNPs that were 20-40kb apart from each other. A sliding window approach was used to calculate a mean LD for a 1Mb region with a 0.9Mb overlap between the regions. On average D' was 0.75 for SNPs 20-40kb apart. As was expected, the average D' varied across the genome. As low as $D'=0.2$ was observed for the region in chromosome 12 (113.5Mb 114.3Mb, 12q24.2) including TBX3 gene involved in the regulation of developmental processes; in chromosome 3 (116.2Mb 117.0Mb, 3q13.31) including GAP43 (growth associated protein 43) and LSAMP (limbic system-associated membrane protein); and in chromosome 5 (16.6Mb 17.2Mb, 5p15.1) including MYO10 (myosin). On the other hand, a 2Mb long region in chromosome 8 (77.12Mb 79.1Mb, 8q21.11) indicated very few historical recombinations ($D'0.95$). Totally over 20 regions were observed with an exceptionally high level of LD ($D'0.95$) in regions longer than 0.5Mb.

Program Nr: 1955 from the 2004 ASHG Annual Meeting

A Genome-Wide Scan for Low-Density Lipoprotein Peak Particle Diameter: The Mexican-American Coronary Artery Disease Study. *D. Wang¹, H. Yang¹, M. Quiñones², P. Blanche³, I. Enriquez², X. Jimenez², R. De La Rosa², J. Cadenas², S. Patel², K.D. Taylor¹, W.A. Hsueh², R. Krauss³, J.I. Rotter¹.* 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Children's Hospital Oakland Research Institute, Oakland, CA.

Increased levels of small, dense LDL particles are associated with increased risk for coronary artery disease (CAD). Significant genetic contributions to this trait have been demonstrated by family and twin studies. In order to identify loci that contribute to LDL peak particle diameter (PPD), we performed a genome-wide scan in 82 two-generation Mexican-American families ascertained via a parent diagnosed with CAD. Samples of 360 individuals, including adult offspring and their parents, were genotyped using the Marshfield screen set 12 (380 autosomal microsatellite markers at ~10cM interval). LDL PPD was measured in 235 adult offspring using nondenaturing gradient gel electrophoresis. Heritability was estimated using the variance component method implemented in SOLAR and linkage analyses were conducted using both the variance component method (SOLAR) and the sib-pair regression method implemented in SAGE. The estimated heritability for LDL PPD was 0.85 ($p < 1E-7$) after adjusting for gender, age, and BMI. The strongest evidence for linkage was found on chromosome 17q23 at D17S2193 with a LOD score of 3.1 using the multi-point variance component method and with a p-value of 0.0006 using the sib-pair regression method. This result confirmed the recent finding in the Qubec Family Study. Other suggestive linkages (LOD > 1.3) were also found on chromosomes 1p31, 3q13.1, 8p22, and 14q31. These significant heritability and linkage results suggest a major locus for LDL PPD on chromosome 17q as well as other possible loci contributing to this common CAD risk phenotype.

MSX1 Interacts with PAX9 in Human Tooth Agenesis. *A.R. Vieira¹, R. Meira², A. Modesto³, J.C. Murray¹.* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept. Pediatric Dentistry, Brazilian Lutheran University, Canoas, RS, Brazil; 3) Dept. Pediatric Dentistry and Orthodontics, Federal University of Rio de Janeiro, Rio de Janeiro, RJ, Brazil.

Individual family studies for tooth agenesis have been used to examine the role of genes but a broader genetic epidemiological approach has not been applied. In this study we sought to determine the association between tooth agenesis and DNA sequence variation in the genes MSX1 and PAX9 in an ethnically diverse human population. Since cleft lip/palate is also associated with both tooth agenesis and the gene TGFA we included TGFA in the analysis as well. Cheek swab samples were obtained for DNA analysis from 116 case/parent trios. Proband had at least one developmentally missing tooth, excluding third molars. Genotyping was performed using SSCP or kinetic PCR assays. Transmission distortion of the marker alleles and DNA sequence analysis were performed. Results showed that tooth agenesis is associated with markers of the genes MSX1 ($p=0.01$) and TGFA ($p=0.01$). No mutations were found in MSX1 or PAX9 coding regions. There was statistically significant data (Table) that suggests MSX1 interacts with PAX9 ($p=0.02$) (Table note: T/NT=transmitted/non-transmitted).

Genes	informative meioses	T/NT	p
MSX1-PAX9	28	10/2	0.02
MSX1-TGFA	23	11/6	0.39
PAX9-TGFA	15	4/1	0.23

These findings suggest that MSX1, PAX9, and TGFA play a role in isolated dental agenesis in humans.

Performance of whole genome amplified samples for microsatellite genotyping. *C. Bark, J. Pettengill, Y. Tsai, P. Boyce, J. Golembieski, J. Gearhart, L. Stewart, M. Zilka, K. Doheny.* Ctr Inherited Disease Research, Johns Hopkins Univ, Baltimore, MD.

Currently the Center for Inherited Disease Research (CIDR) performs microsatellite whole genome linkage scans as a service. For some studies the amount of genomic DNA available is limited. Recently, whole genome amplification of genomic DNA has started to emerge as a viable solution to this problem. In order to evaluate the performance of whole genome amplified DNA samples in microsatellite genotyping, high-quality (lymphoblast-derived) DNA samples were sent to the service labs of Molecular Staging(MS) and Rubicon Genomics(RU). The whole genome amplification (WGA) products were then tested at CIDR using our standard laboratory protocols. Six samples were PCR amplified in 11 independent reactions, resulting in data for 18 markers. Reactions for the control samples(non-WGA) were repeated 4 times, the MS and RU samples were repeated 6 times.

	CONTROL	Molecular Staging	Rubicon Genomics
Genotypes Attempted	414	648	648
% Missing	5.96	2.10	10.54
% Discordant	0	1.61	2.90
% Unbalanced Het	0.26	0.19	6.07

Discordant calls were observed in 2 markers. Discrepancies resulting from the Rubicon products were clearly related to poor morphology of a dinucleotide repeat marker and a single incident of allele drop out. Discrepancies resulting from the Molecular Staging products could have occurred due to unknown laboratory error. In comparing the two WGA methods, the MS derived WGA samples performed better for all three performance measures.

Meta-Analysis of Linkage Studies with BMI: Sum of Lod Scores Analysis. *H. Lyon*¹, *A. Lakhanpal*², *J. Nemes*^{1,3}, *M.J. Daly*³, *J.N. Hirschhorn*^{1,3}. 1) Division of Genetics, Children's Hospital, Boston, MA; 2) Harvard University, Cambridge, MA; 3) The Broad Institute, Cambridge, MA.

Body mass index (weight/height²) is an accurate, heritable and simple measure that correlates with and predicts complications of obesity. Linkage to BMI has been reported in many regions, some of which coincide, but it is not clear which loci, if any, show more evidence of linkage than expected by chance. A combined analysis would be well powered to detect linkage, but raw genotype data are generally unavailable. Methods to combine reported results of multiple linkage studies include parametric methods (e.g. p value pooling, Allison and Heo 1998) or nonparametric methods (Genome Scan Meta-Analysis, GSMA, Badner and Gershorn 2002). GSMA can combine methodologically diverse studies with rank-sum tests to assess significance of linkage at each locus, but this method loses information because each scan's best region is assigned the same rank regardless of LOD score.

We have developed an approach that retains a parametric flavor but allows assessment of significance by permutation. At each genomic location, the test statistic is the sum of LOD scores (SOL) across all studies including only LOD scores ≥ 2 in the calculation to minimize reporting bias. If only p values are reported, we estimate LOD scores = $\ln(p)/2 \cdot \ln 10$. We calculate the SOL at each of 135 bins across the genome. Rather than using arbitrary bins of fixed width, we define bin boundaries using a flexible sliding window to maximize the number of linkage peaks in a bin. To generate a null distribution for assessing significance, we randomly reassign the locations of the LOD scores ≥ 2 and repeat the entire process, including bin definition (10,000 times). To apply this method to BMI, we combined data from 28 linkage studies. We found non-random clustering of linkage peaks in several regions, most notably 3q27. These regions are good targets for candidate gene association studies to identify obesity genes.

Program Nr: 1959 from the 2004 ASHG Annual Meeting

Association study of SPINK5, IL18, and SELP gene polymorphisms with atopic asthma. *F. Belpinati, G. Malerba, E. Trabetti, L. Xumerle, R. Galavotti, P.F. Pignatti.* DMIBG - Biology & Genetics, Univ of Verona, Verona, Italy.

Three genes recently described as associated with atopic asthma have been studied in a sample of 71 North-East Italian family trios with one atopic-asthmatic child. The genes were SPINK5 (serine protease inhibitor - Kazal-type5, chromosome 5q31-33), IL18 (chromosome 11q21-q24) and SELP (p-selectin, chromosome 1q24). The polymorphisms analyzed were: D386N and E420K, 105A/C and V640L in the SPINK5, IL18 and SELP gene, respectively. All the individuals were characterized for clinical asthma, total serum IgE level, skin prick test positivity to common aeroallergens, rhinitis, and bronchial hyperresponsiveness to methacholine. A significant association was found between the SPINK5-E420K polymorphism and clinical asthma ($p=0.014$), atopy ($p=0.014$), IgE levels ($p=0.01$), SPT ($p=0.013$) and rhinitis ($p=0.036$). No association was found for SPINK5-D386N polymorphism, nor for SELP or IL-18 gene polymorphisms and any of the phenotypes. These results are in accord with the association of the 5q31-32 region with allergic asthma phenotypes and suggest that SPINK5 or a closely located gene may play a role in the disease.

Progress of high throughput genetic studies to identify tractable target genes associated with human disease. *S. Chissoe, S. Brewster, D. Burns, B. Caulkins, J. Cogswell, R. DeMent, T. Fleming, D. Hosford, E. Lai, L. Middleton, D. Montgomery, S. Pillai, J. Riley, S. Sehgal, N. Spurr, P. St. Jean, J. Stuart, S. Sundseth, D. Yarnall, A. Roses.* Genetics Research, GlaxoSmithKline, Res Triangle Park, NC, Harlow and Stevenage UK, Upper Merion and Providence, PA.

A significant challenge in the process of developing drugs to address unmet medical need lies in the validation of targets relevant to that disease. Attrition throughout the development process, due in part to intractability, presents further challenges to targets once validated. To address these issues, and to leverage disease understanding with the power of the genome era, a series of high throughput association studies has been initiated.

Three key study components will be described, including the initiation of disease collections, the characterization of tractable genes, and the development of a high throughput infrastructure for sample handling, genotyping and analysis. Collaborations with clinical investigators have been established in twelve disease areas, where rigorous phenotypic data and genetic samples are collected. Through their informed consent for genetic studies, these subjects directly advance focused research aimed at identifying genes associated with human disease. A catalogue of tractable target genes has been assembled, and these genes have been characterized by SNP discovery and mapping. Selected assays are then genotyped against samples of interest, and association analysis performed.

The association study paradigm includes a primary genetic screen followed by a secondary genetic screen to identify confirmed genes. In this way, an enriched pool of targets involved with human disease can be obtained for evaluation. Tractable genes associated with human disease will have a greater likelihood of surviving attrition during the drug development process. These targets also will increase our knowledge of disease pathways that will contribute to hypothesis-driven drug discovery.

Allelic association of the poliovirus receptor-related gene (PVRL2) with the disease course of multiple sclerosis (MS). *S. Gregory*¹, *S. Schmidt*¹, *S. Sawcer*², *L.F. Barcellos*³, *J. Sims*¹, *C. DeLoa*³, *J.R. Oksenberg*³, *S.L. Hauser*³, *A. Compston*², *M.A. Pericak-Vance*¹, *J.L. Haines*⁴. 1) Dept Medicine, Ctr Human Genetics, Durham, NC; 2) Dept Neurology, Cambridge University, United Kingdom; 3) Dept Neurology, UC San Francisco, CA; 4) Ctr Human Genetics Research, Vanderbilt Univ, Nashville, TN.

Multiple sclerosis (MS) is a complex disorder with evidence for genetic influences on both the risk of becoming affected and the disease course. The disease course is highly variable, with some patients not suffering from major disability for several decades post-diagnosis, while others reach wheelchair dependency within a few months or years after onset. We have previously reported association of the APOE-4 allele with severe MS and the APOE-2 allele with a mild disease course. While it is conceivable that APOE may harbor a causal variant that directly influences MS expression, the allelic association may also be due to linkage disequilibrium (LD) with one or more variants in a nearby gene. To test this hypothesis, we have genotyped 40 SNPs within a 0.5 Mb interval around APOE that includes 16 known and novel transcripts, including the poliovirus receptor (PVR), the poliovirus receptor-related gene (PVRL2), and a gene coding for an outer mitochondrial membrane protein (TOMM40). We have assembled one of the largest available data sets for examining MS modifier genes in this region by combining patient data from US and UK cohorts, for a total of almost 1,500 patients and their relatives. Statistical analysis of the 40 SNPs revealed the strongest association with a mild disease course for an SNP within intron 6 of the PVRL2 gene ($p=0.001$). No association with MS risk was found. The association of a viral receptor gene with disease course is consistent with the hypothesis that viral infections may play a role in MS etiology. Molecular work to identify the causal variant responsible for this association is underway.

Replication of the dissection of a human coagulation factor VII QTL. *D.M. Warren¹, S. Cole¹, J.M. Soria², J.C. Souto², J. Fontcuberta², J. Blangero¹, J.W. MacCluer¹, L. Almasy¹.* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Coagulation factor VII (FVII) is a vitamin K-dependent protein whose activated form plays a role in the physiological cascade leading to blood clot formation. High levels of FVII have been identified as a risk factor for cardiovascular disease. Recently, the first complete dissection of a quantitative trait locus (QTL) for FVII in humans was conducted using data from Spanish families enrolled in the Genetic Analysis of Idiopathic Thrombosis (GAIT) study. This QTL is located on chromosome 13q, and overlaps the FVII structural gene. Interpretation of the results of that dissection was complicated by the occurrence of two groups of SNPs in complete linkage disequilibrium (LD) that could not be differentiated statistically. One group included four SNPs, and the other, seven. The potential for different patterns of LD in other populations suggests statistical methods may provide an alternative to laboratory-based methods in resolving questions of the individual contributions of each of these SNPs to variation in FVII levels. In order to test this, and to examine further the genetic basis of variation in plasma levels of FVII, we are using maximum likelihood methods to evaluate the FVII QTL polymorphisms examined in GAIT in 522 individuals from 21 Mexican American families participating in the San Antonio Family Heart Study (SAFHS). Preliminary results based on one marker from each SNP group identified in GAIT show FVII levels are associated with two promoter SNPs (-401G/T and -402G/A). In the SAFHS, these two SNPs are in weak LD ($r^2 = -0.274$), whereas they are in equilibrium in GAIT. This suggests we will find a different LD structure in the SAFHS versus that observed in GAIT. We are currently typing the remaining SNPs in this QTL to complete our test of whether a different LD structure in this population will decrease the size of the SNP groups and thereby narrow the number of SNPs requiring laboratory testing.

Characterization of the linkage disequilibrium structure and identification of tagging-SNPs in XRCC4. *K. Allen-Brady, N.J. Camp.* Genetic Epidemiology, Dept. of Medical Informatics, University of Utah, Salt Lake City, UT.

The protein product of the X-ray Repair Complementing Defective Repair in Chinese Hamster Cells 4 (XRCC4) gene (chromosome 5q13-q14) plays an integral role in both the nonhomologous end-joining pathway that functions to repair DNA double-strand breaks in mammalian cells as well as V(D)J recombination, which is essential for diverse immune response. XRCC4 is therefore a popular choice as a candidate gene in association studies for multiple cancer sites. We have characterized the linkage disequilibrium (LD) structure and identified tagging single nucleotide polymorphisms (tSNPs) across this gene in a cohort of unrelated, non-BRCA1/2 breast cancer cases and controls (n=47, n=47) using a principal component analysis (PCA) method [Horne & Camp, *Genet Epidemiol* 2004; 26:11-21]. All SNPs available from Applied Biosystems (ABI) Assays-on-Demand were selected across the XRCC4 gene and genotyped for all subjects. This constituted a total of 21 SNPs at a resolution of approximately one SNP every 10 kb. Genotype completion rate was >99%. From this Caucasian population of subjects, 12 distinct haplotypes with a frequency > 0.01 were estimated using an expectation maximization algorithm. Using the PCA method we identified four LD groups, which captured 97% of the haplotype diversity. The LD groups were mostly contiguous, except for disruption of both groups I and II by two SNPs clearly not in LD with their neighbouring markers. These two SNPs constituted LD group IV by the PCA method. ABI also suggests four LD groups for this gene, but their groups are contiguous and thus they do not capture this disruption of LD structure. The PCA method established that a single tSNP from each group was sufficient to explain >90% of the variance for each group. When analyzed separately, breast cancer cases and controls both gave similar results as the combined analysis, suggesting that affected status does not impact the LD structure of the gene. In conclusion, four SNPs were found to be sufficient to cover >90% of the genetic variation of the total 21 SNPs studied in XRCC4.

Dietary Control Reveals The Association Of Hexokinase 4 (GCK) Polymorphisms With Fasting Glucose. *J. Cui¹, K.D. Taylor¹, X. Guo¹, M.F. Saad², J.I. Rotter¹, R.M. Krauss³*. 1) Medical Genetics, Cedars-Sinai Medical Center, Los Angeles, CA; 2) UCLA, Los Angeles, CA; 3) Children's Hospital Oakland Research Institute, Oakland, CA.

Glucokinase (hexokinase 4, GCK) converts glucose to glucose-6-phosphate and serves as the sensor for glucose in the pancreas. Alternative splicing of GCK results in a longer mRNA specific to pancreatic beta-cells. GCK mutations have been associated with maturity onset diabetes of the young, but the role of GCK variation in glucose metabolism for the general population is unclear. We investigated the relationships between 5 GCK SNPs (mean spacing 6.5 kb) and plasma glucose measurements in 317 healthy male siblings from 144 families given two diets differing in fat and carbohydrate composition. DNA was collected for genotyping from parents and siblings. Blood samples were obtained from siblings after 4 weeks each on isocaloric high fat (HF, 41% of energy from fat) and low fat (LF, 21% of energy from fat) diets in a randomized, crossover study design. Genotyping was performed with TaqMan MGB technology. Using HaploView, a haplotype block composed of 3 SNPs was identified; two SNPs towards the 5-end were each in different block. Associations of individual SNPs and haplotypes in this block were tested with general estimating equations (GEE) that control for familial correlations. Haplotype 4 (H4) of the block was significantly associated with a lower plasma glucose on the HF diet (83.731.13 in subjects with H4 vs 87.010.61 mg/dl without H4, meanSE, $p=0.025$) but not on the LF diet (84.841.35 with H4 vs 85.880.57 mg/dl without H4). The frequency of H4 in founders was 11%. While these SNPs are located in introns, each is located within a region conserved between human and rodents. These results suggest that variation in the GCK gene is important for plasma glucose levels under the condition of a high fat diet. Since GCK forms part of a possible regulatory complex located on the outer mitochondrial membrane, these results are consistent with the recent evidence implicating mitochondrial function in type 2 diabetes, particularly when the beta-cell is subjected to a high level of free fatty acids.

Program Nr: 1965 from the 2004 ASHG Annual Meeting

A haplotype regression model with errors. *C.S.J. Fann, H.-C. Yang.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Integration of statistical regression model and haplotype association test not only benefits the adjustments of confounding variable, environmental exposure, risk factor and interactive effect simultaneously, but also provides more information in deciphering complex disorders compared with single locus analysis. Nevertheless, the errors in individual haplotype inferring and phenotypic classification may jeopardize the increased power of haplotype regression analysis. The former attributes to unknown phase of gametic haplotypes and the latter comes from the difficulties in clinical diagnosis or phenotypic definition. We assess the impacts induced by the two kinds of errors and propose a feasible likelihood-based haplotype regression model to formulate the linkage-disequilibrium mapping allowing for errors. We reconstruct individual haplotypes by applying a Bayesian inference using Gibbs sampling. The underlying sampling strategy is the popular case-control study. The inference procedure is also applicable to QTL analysis by considering a generalized linear model. Analyses of authentic data and simulated data are carried out to illustrate and evaluate the proposed method.

Program Nr: 1966 from the 2004 ASHG Annual Meeting

5kb-Resolution SNP map on chromosomes 8q, 9, 18q, 22, and X for the International HapMap Project. *L. Galver, S.S. Murray, A. Oliphant, M. Chee.* Illuminia, Inc, San Diego, CA.

The International HapMap Project is a collaboration among five countries to produce a single nucleotide polymorphism (SNP) haplotype map that identifies common patterns of sequence variation in the human genome (The International HapMap Project, 2003). An initial goal of the project is to generate a SNP map with >5% MAF (minor allele frequency) across the genome with an average spacing of 5 kb. The SNPs will be genotyped on 270 individuals from several populations. We are creating the map for chromosomes 9, 22, X, 8q and 18q, which comprises ~15% of the genome. Approximately 95,000 assays with >5% MAF have been developed so far, and we expect to complete our portion of the 5kb map by September of 2004. Using an average multiplex of 1536 SNP assays in a single reaction (Fan et al., 2003), the data are of high quality with reproducibility, heritability and call rates >99.9%. With the combination of other genotyping centers using the Illumina BeadArray system, >50% data will be generated using the BeadArray™ technology.

We have analyzed the haplotype structures in a CEPH Caucasian sample in three 500kb genomic regions (8q24, 9q34, 18q12) using the methods described in Gabriel et al. (2002). These regions had an average SNP density of 2.9kb +/-0.2kb. All three regions demonstrated similar haplotype block sizes and diversity with an average haplotype block size of 23.2kb +/-3.9kb and an average 4.4 +/-0.3 haplotypes per block. Approximately 67% of the genome was represented in a haplotype block in these three regions. We plan to conduct similar analyses on all of our genotyping data.

We have also analyzed the X chromosome and found distinct boundaries for the pseudoautosomal and homology regions. Both regions have unique population signatures which have enabled us to determine which SNPs lie in these evolutionarily distinctive regions.

Significant association of VLDLR and VEGF in age related macular degeneration. *J.L. Haines¹, L.M. Olson¹, N.C. Schnetz-Boutaud¹, S. Schmidt², W.K. Scott², A. Agarwal³, E. Postel⁴, J.R. Gilbert², M.A. Pericak-Vance².* 1) Ctr for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Ctr for Human Genetics, Duke Univ, Durham, NC; 3) Dep't Ophthalmology & Visual Sciences, Vanderbilt Univ, Nashville, TN; 4) Duke Eye Center, Duke Univ, Durham, NC.

Age-Related Macular Degeneration (AMD) is a significant causes of vision loss in the elderly and has a significant genetic component. To dissect the genetics of AMD, we have assembled a dataset of 165 multiplex and simplex families and a second dataset of 401 cases and 159 examined normal controls. 8 candidate genes were tested based on their potential functional role in AMD. IL1A and CKB were chosen because cDNA microarray experiments demonstrated significantly altered expression in AMD retinal tissue. VLDLR, A2M, LRP6 were chosen because of their known relationship to APOE, which has been consistently demonstrated to modify the risk for AMD. MGST1 was chosen because of its role in oxidative stress, and DCP1 had a previously published association. VEGF was examined because of its role in vascular growth and because it is a target for inhibition therapy in AMD. We used family-based and case-control analyses on multiple SNPs within each gene. Analyses were done using two diagnostic criteria, one including both mild and severe AMD, and the other including only severe AMD. A total of 35 SNPs were tested. A2M and CKB did not demonstrate any association under any analysis. DCP1 generated a single nominally significant SNP ($p=0.03$) only in the family-based analysis. IL1A had two nominally significant SNPs ($p=0.02$; 0.02), LRP6 had three nominally significant SNPs ($p=0.02$; 0.05 ; 0.05), and MGST1 had two nominally significant SNPs ($p=0.02$; 0.03); these results were only found in the case-control analyses. Two genes, VLDLR and VEGF, had nominally significant results in the family-based analyses (VLDLR, $p=0.05$; VEGF, $p=0.001$). These results were replicated in the case-control analyses (VLDLR, $p=0.01$; VEGF, $p=0.02$). While we cannot definitively exclude any of these genes from playing a role in AMD, the replicated positive associations for VLDLR and VEGF suggest that they may play a significant role in AMD.

Protein tyrosine phosphatase *PTPN22* and rheumatoid arthritis. X. Hu¹, S. Schrodi¹, V. Carlton¹, V. Garcia¹, Q. Huang², R. Brandon³, H. Alexander¹, M. Chang¹, K. Ardlie⁴, J. Catanese¹, D. Leong¹, M. Seldin⁶, L. Criswell⁷, D. Kastner⁸, P. Gregersen⁵, E. Beasley³, C. Amos², J. Sninsky¹, A. Begovich¹. 1) Celera Diagnostics, Alameda, CA; 2) University of Texas, Houston; 3) Celera Genomics, Rockville, MD; 4) Genomics Collaborative, Inc, Cambridge, MA; 5) North Shore-LIJ Research Institute, Manhasset, NY; 6) University of California, Davis; 7) University of California, San Francisco; 8) NIH, Bethesda, MD.

We have previously shown that the minor allele of a missense single nucleotide polymorphism (SNP; R620W, rs2476601) in the hematopoietic-specific protein tyrosine phosphatase *PTPN22* is strongly associated with rheumatoid arthritis (Discovery study: allelic $p=6.6E-04$; Replication study: allelic $p=5.6E-08$; Begovich et al. 2004). Bottini et al (2004) have independently shown that the same allele (W620) is associated with type 1 diabetes, suggesting that *PTPN22* may be a key regulator of the immune system. To determine whether *PTPN22* harbors additional causal SNPs/haplotypes, we sequenced the gene in 48 RA patients; to date all but two small exons have been resequenced. We found only one other missense SNP (Q262R, freq = 2%); this SNP was not associated with RA. We then investigated haplotypes in *PTPN22* by genotyping 32 additional SNPs in the discovery sample (475 cases and 475 individually matched controls). Haplo.score (Schaid et al 2002) predicted 10 common (frequency > 1%) haplotypes, only one of which carries the W620 risk allele. A subset of 13 tagging SNPs, identified using the software Redigo (Hu et al. 2004 in press) in combination with biological and statistical information, were used to genotype the replication sample (840 cases in 463 families and 926 individually matched controls). Although there was some heterogeneity between the samples sets, the strongest replicated association was seen for the haplotype containing the W620 risk allele. When we applied a method similar to that proposed by Thomson et al. (1988) and Valdes et al. (1997), we found a second haplotype showed mild evidence for association independent of the R620W SNP. However, our data suggest that the haplotype containing the W620 missense variant is the major risk haplotype of *PTPN22*.

Program Nr: 1969 from the 2004 ASHG Annual Meeting

Accounting for unobserved polymorphisms when evaluating haplotype tagging SNPs. *M.M. Iles.* Medical Epidemiology and Biost, Karolinska Institutet, Stockholm, Sweden.

Haplotype tagging SNPs (htSNPs) are widely used as a means of capturing the majority of the genetic diversity in a region while minimising the amount of genotyping to be performed. Ideally, selection of htSNPs should be carried out using data on all polymorphisms in a region. However, it is usually possible to genotype only a subset of all the SNPs in a region and use these data both to select the htSNPs and judge their efficacy. We demonstrate using publicly available real data that such a strategy leads to an overestimation of htSNP performance and that this bias increases as the observed SNPs become more sparse. At an observed SNP density of 2kb, htSNP analysis suggests that the htSNPs capture on average 95% of the observed variation, when in fact they capture 88% of the unobserved variation. At a density of 10kb htSNP analysis suggests that 93% of the observed variation was captured, when in fact they capture on average only 78%. We propose a method utilising cross-validation to correct for this problem and show that such an approach is both unbiased and more accurate than existing methods. The strategy is applicable both to small-scale studies of a few regions and to large-scale studies of whole chromosomes or genomes such as HapMap.

Program Nr: 1970 from the 2004 ASHG Annual Meeting

Haplotype Association Mapping of Quantitative Trait Loci, A Population Based Approach. *J. Jung, R. Fan, L. Jin.*
Department of Statistics, Texas A&M University, College Station, TX.

In this report, population based regression models are proposed for high resolution haplotype linkage disequilibrium mapping of quantitative trait loci. Suppose that a quantitative trait locus is located in a chromosome region. In the region, a haplotype block is typed which may consist of several markers such as SNPs. Suppose that a population sample is available. For each individual in the population sample, both trait value and genotype at the haplotype block are observed. Two regression models, genotype effect model and additive effect model, are proposed to model the association between the haplotype block and the trait locus. By analytical formulae, we show that the genotype effect model can be used to model the additive and dominant effects simultaneously; the additive effect model only incorporates and takes care of additive effect. The non-centrality parameters of F-test statistics are derived to make power calculation and comparison.

Program Nr: 1971 from the 2004 ASHG Annual Meeting

Evidence for linkage and association to chromosome 19p in autism. *J.L. McCauley, R. Delahanty, T.L. Edwards, L.M. Olson, J.L. Haines, J.S. Sutcliffe.* Center for Human Genetics Research, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

Autism is a complex genetic neuropsychiatric disorder in which affected individuals have life-long disabilities in three core phenotypic domains: language, social relationships, and patterns of compulsive and stereotyped behaviors. Several genomic screens in multiplex autism families have identified numerous loci across the genome, and a few of these (e.g. 7q, 2q) have been replicated across multiple studies. We recently completed a genomic screen in 144 multiplex autism families and identified suggestive evidence for linkage on chromosome 19p13 exhibiting a multipoint heterogeneity LOD (HLOD) of 2.55 at 40cM using a recessive model. To refine linkage information and narrow the linked interval, we genotyped and analyzed single nucleotide polymorphism (SNP) markers at ~1 cM intervals flanking the peak marker D19S930. In addition to narrowing the linkage peak, follow-up association analysis revealed that a marker 5 kb 5' to the CRSP7 gene showed significant association ($P=0.001$) using the PDT test. CRSP7 is subunit 7 of a cofactor required for Sp1 transcriptional activation. To date we have examined 18 SNPs across a 163-kb region inclusive of CRSP7. Several nominally-significant single marker associations have been identified across this large (80kb) linkage disequilibrium block as measured by D' , however no association has been detected in regions immediately flanking the block boundaries. The block spans the CRSP7, SLC35E1, and CHERP genes, in agreement with recent HapMap Project data. Although potential biological relevance of these genes to autism is uncertain, they are positional candidates that may play a role in autism susceptibility.

Identification of significant autism associations on chromosome 7q. D.A. Skaar¹, J.M. Jaworski¹, E.R. Martin¹, A.E. Ashley-Koch¹, J.L. Benton¹, J.L. McCauley², J.L. Haines², J.S. Sutcliffe², G.R. DeLong¹, H.H. Wright³, R.K. Abramson³, M.L. Cuccaro¹, J.R. Gilbert¹, M.A. Pericak-Vance¹. 1) Duke Univ Medical Ctr, Durham, NC; 2) Vanderbilt University, Nashville, TN; 3) University of South Carolina, Columbia, SC.

Multiple studies have indicated that an area of chromosome 7q contributes to autism susceptibility. Microsatellite markers on 7q, d7s1813 (102.82cM), d7s821 (109.1cM), d7s477 (111.79cM), and d7s496 (119cM), have significant linkage. In addition, haplotype and recombination analysis has identified that the region 119.8-122.5cM is predominantly shared among families with autistic individuals. These indications, as well as the location of candidate gene *RELN* in this area, led us to fine-map this region. SNPs approximately 100kb apart and centered on *RELN* (111.3-121.4cM/98.8Mb-108.5Mb) were analyzed in 407 autism families. Both family history positive (fam hx+) and fam hx- families were included. A GGC repeat in the 5 untranslated region (5 UTR) of *RELN* (103.2 Mb), which has been reported as associated with autism, and several other SNPs within *RELN* were also analyzed. The *RELN* markers were also typed on 68 fam hx + families from Vanderbilt University. Significant association was seen for the *RELN* 5 UTR (P=0.002) and the *RELN* Exon 44 SNP (P= 0.03) in the overall dataset. Analysis of the *RELN* 5 UTR and four SNPs found that the most common haplotype for these families was also significantly associated with autism (P=0.002). SNP rs925720, at 98.3Mb, showed significant association (P=0.004) both in the overall data set as well as in sets stratified by family type (fam hx+ or -). There is no significant linkage disequilibrium (LD) seen between this SNP and the *RELN* markers, but rs925720 is in the region spanning the proximal breakpoint of a previously reported paracentric inversion in an autism family ((inv (7) (q22-q31.2)). Significant LD is seen between SNPs within each breakpoint region of the inversion (but not between the two regions). These results continue to support one or more regions on chromosome 7q as contributing to autism susceptibility, and *RELN* is again indicated as a strong candidate gene.

Relation between cumulative relative frequencies of haplotypes and Disequilibrium parameters on the determination of a haplotype block. *M. Tomita*^{1,2}, *R. Takemura*¹. 1) Genome Diversity Team, Integrated Database Group, Japan Biological Information Research Center, Tokyo, Japan; 2) Japan Biological Informatics Consortium, Tokyo, Japan.

On DNA sequences, domain "Hotspot" to which recombination was performed briskly exists, on the other hand, the big domain which there is no recombination not much conversely and is maintaining linkage disequilibrium also exists. It is called "haplotype block". Although the value of D' which is one of the disequilibrium parameters as an important step when determining a haplotype block, 0.9 is used as a thing more nearly experiential than theoretical backing about the threshold value. This report mentions the result which considered the determination of this D' and a haplotype block. The determination method of an old haplotype block is as follows. Since we consider that loci whose the minor allele relative frequency less than 0.1 are the mutation discovered in the comparatively new generation, then does not think it into consideration for the determination of a haplotype block. It decides as the minimum block between loci used as $D' > 0.9$. Although the above is an old determination system, initial conditions are given by considering the domain which is $D' > 0.9$ experientially as the minimum haplotype block, and it is quite determinism-like. Therefore, we investigated the relation between D' and the cumulative haplotype relative frequency. Accumulation of the relative frequency of minor alleles' haplotype of major alleles' haplotype and the value of D' have a very close relation. When a allele relative frequency was 0.5, respectively, that it is 0.95 has proved this cumulative haplotype relative frequency analytically. Moreover, whenever allele relative frequency shifted from 0.5, it also turns out that this relation collapses. Moreover, we also studied the relation between the cumulative relative frequency of three haplotypes and D' . As mentioned above, "unit of haplotype block" and "deviation of haplotype" is defined and the new determination system of haplotype block is proposed. Moreover, this has also been the standard of a new haplotype tagging SNP selection system, and it introduces also.

Significant association and linkage for Alzheimer disease and SNPs in the VR22 and LRRTM3 genes on chromosome 10q. *P.G. Bronson¹, H. Quan¹, R.H. Chung², J. Bartlett³, J.L. Haines³, D. Schmechel¹, G. Small⁴, P.T. Xu¹, J. Gilbert¹, M.A. Pericak-Vance¹, E.R. Martin¹.* 1) Duke Univ. Medical Center, Durham, NC; 2) NC State Univ., Raleigh, NC; 3) Vanderbilt Univ., Nashville, TN; 4) UCLA, Los Angeles, CA.

Linkage studies indicate chromosome 10q contains a gene contributing to Alzheimer disease (AD) susceptibility. The VR22 gene encodes -T catenin, thought to be involved in cell adhesion and interaction with presenilin1. VR22 polymorphisms have been shown to be associated with plasma amyloid protein (A42) levels (Ertekin-Taner et al., 2003), suggesting a possible role in AD. Our previous analysis of 5 VR22 single nucleotide polymorphisms (SNPs) revealed association with late-onset AD (Martin et al., 2003), but these intronic SNPs have no functional significance and a true functional variant remains unidentified. VR22 includes an intron-encoded leucine-rich repeat, which tend to form the amyloid fibrils that compose AD amyloid plaques. Leucine-rich repeat transmembrane neuronal 3 (LRRTM3) is a brain-specific protein expressed in the hippocampus. We genotyped 3 more VR22 SNPs and 3 LRRTM3 SNPs in a large family data set ascertained by Duke Univ., Indiana Univ. and NIMH, and 651 independent cases with 272 unrelated controls.

We conducted association analysis on 319 families with 1,086 discordant sibships. The pedigree disequilibrium test (PDT) yielded significant *p*-values for VR22 SNPs 6 (0.008) and 2 (0.013). The genotype PDT yielded significant *p*-values for LRRTM3 SNP 3 (0.003) and VR22 SNPs 3 (0.039) and 2 (0.049). We also found evidence of linkage, with our strongest results for LRRTM3 SNP 3 (LOD=1.77) and VR22 SNP 5 (LOD=2.29) in the NIMH families (N=349). Our independent case-control data set had significant unadjusted odds ratios that disappeared when adjusting for age at exam and gender. VR22 SNPs 2,3,5 and 6 are in linkage disequilibrium (LD), but LRRTM3 SNP 3 is independent of the VR22 and other LRRTM3 SNPs. Given the biological function of the LRRTM3 gene, our results indicate it is an excellent candidate for further study.

Testing candidate genes on 7q and 16 for autism association. *J.A. Duvall¹, M. Alarcón², J. Simon³, M.G. Arreaza³, K. Wilkes², J.L. Stone¹, S.F. Nelson¹, C. Lese Martin⁴, R.M. Cantor¹, D.H. Geschwind².* 1) Department of Human Genetics, UCLA, LA, CA 90095; 2) Department of Neurology, UCLA, LA, CA 90095; 3) Schering-Plough Research Institute, Kenilworth, NJ 07033; 4) Dept. of Human Genetics, Emory Univ., Atlanta, GA 30322.

Autism is a neurodevelopmental disorder that is characterized by language difficulties, social deficits, and repetitive, stereotyped behaviors. Numerous family and twin studies, reports of autistic individuals with chromosomal abnormalities, and genome-wide linkage scans provide compelling evidence that autism has a significant genetic component. The focus of our present report is on two promising candidate genes, A2BP1 and CNTNAP2 that are currently being investigated in the Autism Genetic Resource Exchange families. A2BP1 was identified via a case report of an affected individual with a chromosomal translocation that disrupts the gene (Martin et al., 2003). Twenty-seven single nucleotide polymorphisms (SNPs), at an average density of 63kb within A2BP1, were genotyped in 212 trios. Two blocks of 3 and 4 SNPs, each, showed nominally significant multipoint transmission disequilibrium (TD), and linkage disequilibrium (LD) within the blocks. The report of the translocation plus this nominal TD and LD, make A2BP1 a promising candidate autism gene. The second gene, CNTNAP2, is a positional candidate identified through a quantitative linkage scan (Alarcón et al., 2002) of autism endophenotypes. Preliminary association analyses of SNPs in 11 genes on 7q including 26 SNPs in this gene suggest that CNTNAP2 is nominally associated with the diagnosis of autism and with language-related quantitative endophenotypes. Interestingly, CNTNAP2 is interrupted in a family with Tourette syndrome and Obsessive Compulsive disorder, both of which share some characteristics with autism (Verkerk et al., 2003). This and the modest evidence for association reported above, make the CNTNAP2 gene a plausible candidate. We are working to confirm the disease-associated polymorphisms in A2BP1 and CNTNAP2 in independent samples, to help elucidate the genetic mechanisms underlying autism susceptibility.

Revealing the role of Glutathione S-Transferase Omega 1 in age-at-onset of Alzheimer Disease. *Y.J. Li¹, W.K. Scott¹, L. Zhang¹, S.A. Oliveira¹, D.E. Schmechel², E.R. Martin¹, J.L. Haines³, J.M. Vance¹, M.A. Pericak-Vance¹.* 1) Ctr for Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Dept of Medicine and Joseph and Kathleen Bryan Alzheimers Disease Research Ctr, Duke Univ Medical Ctr, Durham, NC; 3) Ctr for Human Genetics Research Program, Vanderbilt Univ Medical Ctr, Nashville, TN.

We previously reported Glutathione S-transferase, Omega-1 (GSTO1) associated with age-at-onset of Alzheimer (AD) and Parkinson (PD) diseases. We applied a genomic convergence approach combining genetic linkage, gene expression, and association to demonstrate a role of GSTO1 in AD and PD. SNP7 located in exon 4 of GSTO1 was found to associate with age-at-onset in these two disorders. SNP7 is a non-synonymous change, in which the SNP7-1 allele, the "A" nucleotide coding for Asp, is associated with later age-at-onset. Here, we used an expanded AD dataset to further investigate the role of GSTO1. We confirmed that the evidence of GSTO1 association with age-at-onset is consistent across three different family-based association methods. Same conclusions for GSTO1 remain after adjusting the effect of different ascertainment centers. These results imply that the association of GSTO1 on age-at-onset is not an artifact of a specific statistical method or ascertainment center. Furthermore, we performed the same association analyses on two stratified datasets, the positive and negative linkage subsets, which was based on the family specific LOD score at the peak linkage marker D10S1237. We found that the effects of GSTO1 on age-at-onset come mainly from families with positive linkage indicating that GSTO1 explains the linkage and association signals for age-at-onset. The average age-at-onset difference between GSTO1 SNP7-1 and SNP7-22 carriers in the linkage and association dataset is 6.79 (4.38), much higher than the original 1.57 (7.17) observed in the overall dataset. Thus this variant, which occurs in 33% of the population, significantly delays the age-at-onset of AD within families that share more SNP7-1 alleles.

Identification and Characterization of the Hydrolethalus Syndrome Gene. *L. Mee*¹, *H. Honkala*², *M. Kestila*², *S. Finnila*¹, *I. Visapaa*^{1,2}, *K. Hovanes*¹, *J. Lee*¹, *R. Salonen*³, *G. Jackson*⁴, *L. Peltonen*^{1,2}. 1) Dept Human Genetics, UCLA, Los Angeles, CA; 2) Dept Molecular Medicine, National Public Health Institute and Dept Medical Genetics, Univ of Helsinki, Finland; 3) Dept of Obstetrics and Gynecology, Helsinki Univ Central Hospital; 4) Dept Neurogenetics, UCLA, Los Angeles, CA.

Hydrolethalus Syndrome(HLS) is a recessive lethal malformation syndrome characterized predominantly by hydrocephaly with absent midline structures of the brain. HLS is enriched in the Finnish population with an incidence of 1:20000. Using LD and shared ancestral haplotype analysis of 18 coding SNP markers on 10 candidate genes in the HLS region 11q23-25, we restricted the interval to 525 Kb between PKNOX2 and D11S975. A conserved nucleotide variant was identified in a predicted transcript(Celera:hCG1644899) showing complete association and cosegregation with the disease alleles. Mutation analysis in HLS families revealed that all affected individuals are homozygous for this variant. The carrier frequency of the mutation in 500 control samples was 2.5% in E. Finland, 1.1% in W. Finland, and no carriers were found in the mixed European control panel. Located in the coding region of a novel transcript (HYLS), this A to G mutation results in a D211G change. HYLS has 6 alternative transcripts and is ubiquitously expressed with CNS specificity. Wild- type (WT) HYLS protein in vitro resulted in diffuse cytoplasmic staining whereas immunostaining of the mutant protein revealed distinct nuclear vesicles implying defective cellular targeting of mutant protein also in vivo. WT and mutant transgenic *Drosophila* strains expressing human HYLS were created to identify known gene interacting with HYLS. A WT line was crossed to pan-retinal, pan-neural, ubiquitous, and posterior wing drivers. A wrinkled, crumpled wing phenotype with incomplete penetrance was observed with each driver except the pan-retinal driver. WT HYLS crossed to ubiquitous and posterior wing drivers also produced abnormal bristle polarity and supernumerary bristles in the wing. These results suggest that HYLS could be involved in cell death and/or patterning of sensory organ precursors.

Program Nr: 1978 from the 2004 ASHG Annual Meeting

Association of upstream transcription factor 1 (USF1) with metabolic syndrome and related quantitative traits in Hong Kong Chinese. *M.C.Y. Ng¹, K. Miyaki¹, N.J. Cox², W.Y. So³, V.K.L. Lam³, E.W.M. Poon³, J.K.Y. Li⁴, J.C.N. Chan³.* 1) Departments of Biochemistry & Molecular Biology, and; 2) Human Genetics, University of Chicago, Chicago, IL; 3) Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong; 4) Department of Medicine, Yan Chai Hospital, Hong Kong.

Upstream transcription factor 1 (USF1) regulates the expression of genes involved in glucose and lipid metabolism. *USF1* located at chromosome 1q22-23 is associated with familial combined hyperlipidemia. We and others have previously reported linkage of this region with various metabolic syndrome (MES) traits. This study aims to assess the association of *USF1* with type 2 diabetes (T2D), MES and related quantitative traits in 179 type 2 diabetic families from Hong Kong Family Diabetes Study.

Five haplotype-tagging SNPs (rs790056, rs 3737787, rs2516839, rs2516838, rs1556259) at or near *USF1* were genotyped in 897 family members including 364 males and 533 females. The markers rs790056, rs3737787 and the 5-SNP haplotype were significantly associated with T2D (family-based association tests, $p < 0.01$). The marker rs3737787 and the haplotype showed trends of association with MES ($p = 0.057$). Quantitative trait analyzes revealed that *USF1* was significantly associated with diastolic blood pressure, LDL and fasting insulin in all subjects ($p < 0.05$). Stratification by gender revealed significant association ($p < 0.05$) of these SNPs with total cholesterol and LDL in men, and with diastolic blood pressure in women. Our results suggest that *USF1* may contribute to the development of multiple metabolic abnormalities.

Chromosome 19 and autism: fine mapping, association analysis and phenotypic subsetting. *R. Rabionet¹, D.Q. Ma¹, I. Konidari¹, E.R. Martin¹, A.E. Ashley-Koch¹, G.R. DeLong¹, R.K. Abramson², H.H. Wright², M.L. Cuccaro¹, J.R. Gilbert¹, M.A. Pericak-Vance¹.* 1) Duke Univ Medical Ctr, Durham, NC; 2) University of South Carolina, Columbia, SC.

Evidence from genome-wide screens suggests the involvement of Chromosome 19 in autism. We previously presented the results of our linkage study on 210 multiplex families ascertained through Duke and AGRE (AGRE1)(maximum heterogeneity linkage score (HLOD) of 2.38 at marker D19S593 (17.17Mb)), with the majority of the linkage signal coming from the AGRE1 subset of families. Subsequently, we examined 14 SNPs flanking D19S593 (13.23-21.38Mb) in these data as well as in 200 new families from AGRE (AGRE2). The peak HLOD in the overall dataset was for D19S593 (0.98 (DOM model); 0.78 (REC model)). Again the majority of the linkage information came from AGRE1 (HLOD=3.6 (REC model)). Using the M-test we found significant evidence for heterogeneity showing AGRE1 was significantly different from both Duke and AGRE2 with respect to these data ($p=0.001$). Fine mapping of the region with SNPs located ~ every 100Kb flanking D19S593 using association studies (Pedigree Disequilibrium Test (PDT) and Geno-PDT (genotypic associations)) showed evidence for significant association (AGRE1 dataset) for rs901792 ($p<0.005$; 16.65Mb). Markers rs1870071 (16.37Mb), rs2305777 (13.90Mb) and rs7125 (18.15Mb) also showed significant association ($p<0.05$). Rs901792 also presented significant genotypic association (geno-PDT $p<0.0005$). We also performed phenotypic stratification of our sample by Ordered Subset Analysis (OSA), using as a covariate the presence of obsessive-compulsive traits. OSA analysis of the AGRE1 families increased the multipoint LOD score to 3.294 at 43.15 cM, about 2cM proximal to d19S593. Several possible functional candidate genes are located around these markers: CRSP7, a transcription factor located between rs901792 and rs1870071; EPS15L1, a receptor for the epidermal growth factor near rs1870071; and various predicted genes, like FLJ20241, a putative NFkB activating factor, located near rs2305777. Their involvement if any in AUT susceptibility is currently unknown.

Joint risk due to chromosome 6p variation and exposure to CMV in schizophrenia susceptibility? *B.H. Shirts*^{1,2}, *J.J. Kim*^{1,3}, *M. Dayal*¹, *S. Bacanu*^{1,2}, *J. Wood*¹, *W. Xie*¹, *K.V. Chowdari*¹, *R. Yolken*⁴, *B. Devlin*^{1,2}, *V.L. Nimgaonkar*^{1,2}.
1) Department of Psychiatry and; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh; 3) Department of Psychiatry, The Catholic University of Korea, Seoul, Korea; 4) Department of Pediatrics, Johns Hopkins School of Medicine, Baltimore, MD.

We previously reported linkage/association with an anonymous marker, M6S125, on chromosome 6p21 among patients showing cytomegalovirus (CMV) exposure. We present data supporting CMV as an infectious risk factor, and report associations with several SNPs on chromosome 6p in CMV positive patients. We used a novel combination of familial aggregation and association studies to investigate the connection of CMV with liability to schizophrenia. We first evaluated exposure to CMV, using serum antibodies, among simplex and multiplex families. Exposure to CMV was significantly increased amongst multiplex families, supporting a connection between CMV exposure and schizophrenia. We also evaluated the role of genetic variation in enhancing risk in CMV seropositive patients by investigating 50 SNPs in 11 genes selected because they localize to chromosome 6p21 and encode proteins mediating CMV infectivity. Comparisons of allele and genotype frequencies in CMV+ and CMV- individuals showed highly significant associations at two SNPs at MICB and one at TNF ($p < 0.005$) indicating that associations at these loci are driven by CMV+ cases. Notably, M6S125 is localized only 6kb from MICB and 71kb from TNF. In preliminary analysis from a replicate of these findings in a separate sample we found significant differences in allele frequencies between schizophrenia patients and controls in six markers at MICB, LTA, and TNF ($p < 0.05$) regardless of CMV status. Interaction of CMV exposure in schizophrenic patients and genetic variation at MICB and TNF is biologically plausible. Our analyses suggest an intriguing interaction between exposure to CMV and variation at MICB and TNF or linked loci in the etiology of schizophrenia. If replicated, these findings would open new vistas of research into gene-environment interactions and schizophrenia pathogenesis.

Quantitative trait loci (QTL) mapping for behavioral traits in recombinant congenic lines of mice. A.

*Torkamanzahi*¹, *P. Boksa*^{1,2}, *R. Joober*^{1,2}. 1) Clinical Research, Douglas Hospital Res Centre, Verdun, Quebec, Canada; 2) Department of Psychiatry, McGill University, Montreal, Quebec, Canada.

We used recombinant congenic lines (RCLs) of mice derived from A/J (A background) and C57BL/6J (B background) to map genetic markers associated with the behavioral traits amphetamine (AMPH) induced hyper-locomotion and prepulse inhibition of tactile response (PPI). Both traits are relevant to schizophrenia, a complex psychiatric disorder in human.

We tested 10 animals (on average) for each trait, from 38 congenic and parental lines, informative for 620 microsatellite markers covering the whole genome. Total distance traveled (TDIST) and %PPI were used as indicators of AMPH-induced locomotion and tactile startle response, respectively.

Parental difference for TDIST was significant. We identified lines AcB52 and AcB63 which showed significantly elevated TDIST compared to their parental A/J strain. Markers on chromosomes 1, 9, 10 and 20 were significantly associated with TDIST in these lines. Within the B background, 3 lines significantly deviated from the parental strain. Markers associated with TDIST in these lines mapped to chromosomes 5 and 20.

With respect to tactile PPI there was no significant difference between the parental strains. However, congenic lines A51, A60, B77, B68 and B73 departed significantly from their parentals, and all showed higher %PPI. Markers on chromosomes 1, 2, 4, 6, 8, 10, 11, 17, 18, 19 and 20 were implicated with %PPI in these lines.

The informative lines harboring genes from either A/J or C57BL/6J, which are associated with variation for AMPH-induced hyper-locomotion and %PPI, provide the basis for identifying QTLs involved in these traits. Information from mouse and human genomes along with functional evidences may help to identify suitable candidate genes for behavioral traits relevant to psychiatric disorders such as schizophrenia.

LD and gene expression study of ppp3cc gene in schizophrenia samples. *B. Xu*¹, *E.W.C. Chow*², *A.S. Bassett*², *L.M. Brzustowicz*^{1,3}. 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Dept of Psychiatry, University of Toronto, and Schizophrenia Research Program, Queen Street Division, Center for Addiction and Mental Health, Toronto, Ontario; 3) Dept of Psychiatry, UMDNJ, New Jersey Medical School, Newark, NJ.

Calmodulin-dependent protein phosphatase 3 (ppp3cc) has recently been reported as a potential candidate gene for schizophrenia that may be responsible for the linkage signal on chromosome 8p21. Because the location of ppp3cc is near to the linkage signal (HLOD = 2.8, alpha=0.9) previously identified in our extended Canadian schizophrenia family, an association study was conducted on the 5 SNPs(cc1a, cc20, cc21, cc33, ccs3) that were reported associated with schizophrenia in the schizophrenia samples. Evidence for LD was assessed using PSEUDOMARKER, which, in contrast to popular TDT-based programs, explicitly separates the evidence for linkage and LD in families with multiple affected individuals. We failed to detect significant association of these SNP markers with schizophrenia in our Canadian samples. Gene expression was also examined with real time RT-PCR to assess the gene expression difference between individuals with schizophrenia and normal controls. Because it is infeasible to directly test gene expression levels in the brain cells of our Canadian samples, two alternative RNA resources were used: lymphocyte cell lines derived from our Canadian samples and brain RNA samples from post-mortem tissue obtained from several brain banks. Reverse transcript PCR indicated that ppp3cc is highly expressed in both brain and lymphocyte cell lines. For the cell lines, there was a trend (t-test p-value =0.12) towards higher expression in the subjects with schizophrenia (group mean = 1.05+/-0.34, n = 9) versus controls (group mean = 0.78+/-0.34, n = 8). Preliminary results with anonymous post-mortem brain samples did not suggest any expression differences, although the family history and 8p21 linkage status of these subjects is entirely unknown. While these initial results do not demonstrate a statistically significant difference in ppp3cc expression in schizophrenia, additional testing with more samples is clearly needed.

Simulational evaluation of effects of multiple testings on chi square statistics in regions with linkage

disequilibrium. *R. Yamada*¹, *H. Kawakami*², *T. Kawaguchi*², *T. Tsunoda*², *K. Yamamoto*¹. 1) Lab for Rheumatic Diseases, SNP Research Center, RIKEN, Yokohama, Kanagawa, Japan; 2) Lab for Medical Informatics, SNP Research Center, RIKEN, Yokohama, Kanagawa, Japan.

Linkage disequilibrium (LD) mapping with high throughput SNP genotyping has been producing promising data to identify disease-susceptible genes for multiple common diseases. Association statistics of LD mapping in those reports were unexceptionally multiple and were always subject to correction for multiple testings. Although in some cases the statistics were perfunctorily corrected by Bonferroni correction, it was apparently too conservative, because polymorphisms in a segment with LD are not independent each other. In other cases permutation test was applied for the purpose and its result was reliable. However permutation test completely depends on observed data sets and application of the test might not be advisable when a large number of data sets are processed. Therefore we simulated regions with LD and assumed to test multiple marker SNPs for association in the regions and evaluated probability distributions of maximal value of chi square statistics that were calculated for case-control association tests on multiple SNPs in a segment with LD. Number of haplotypes was set between two to ten with number of SNPs to be observed up to a couple of dozens. With the increase in number of observed SNPs, the probability distribution of maximal value of chi square statistics from each of the SNPs shifted toward the direction of statistics larger. Although degree of the shift depended mainly on the number of polymorphisms to be tested, the degree was far less than Bonferroni assumption, which was expected. Number of haplotypes affected on the statistics but its effect was smaller. Allele frequency of haplotypes and SNPs, and strength of LD also affected on the test statistics inflation. Simulation-based assessment of effects of polymorphism composition in LD-positive regions on test-statistics inflation will assist precise interpretation of LD mapping data.

A Population-Based Study of CYP11A Haplotypic Diversity and Breast Cancer Risk. *B.L. Yaspan², J.B. Elmore¹, J.P. Breyer¹, K.M. Bradley¹, Q. Cai³, Y-T. Gao⁴, W. Zheng³, J.R. Smith³.* 1) Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Cancer Biology, Vanderbilt University, Nashville, TN; 3) Department of Medicine and Vanderbilt-Ingram Cancer Center, Vanderbilt University Medical Center, Nashville, TN; 4) Department of Epidemiology, Shanghai Cancer Institute, Shanghai, PRC.

Cyp11A, the P450 side chain cleavage enzyme (P450_{scc}), is the rate-limiting enzyme of steroid hormone biosynthesis catalyzing the conversion pregnenolone to cholesterol. It is highly expressed in steroidogenic tissues: adrenal, ovary, and placenta. We hypothesized that the CYP11A gene serves as a modifier of breast cancer risk given its central role in estrogen metabolism. We tested the hypothesis in a study population of 1193 breast cancer cases and 1310 age frequency-matched controls from Shanghai, China. To comprehensively evaluate evidence for association with breast cancer we identified all common polymorphism (SNP and STR) within a 46 kb interval harboring the 30 kb gene, and genotyped the study population with those markers efficiently discriminating haplotypic diversity for analysis in a logistic regression framework. Our results demonstrate that the gene resides within a single block of strong linkage disequilibrium represented by 3 common haplotypes, each further divided into several clades. Supporting the hypothesis, a haplotype with a frequency of 10% is significantly associated with breast cancer risk (heterozygote OR=1.45 (95% CI 1.17-1.78), homozygote OR=2.20 (95% CI 1.11-4.34), Chi² P=0.0002). Among the 44 common polymorphisms discovered at CYP11A in Han Chinese, those with alleles uniquely tagging the risk haplotype include two of 3 STRs and a single SNP. Candidate functional polymorphisms are in linkage disequilibrium on the risk haplotype; in vitro tests are underway to provide functional correlates of the breast cancer association.

Pleiotropic effects of the 8.1 HLA haplotype in patients with autoimmune myasthenia gravis and thymus hyperplasia. *C. Vandiedonck¹, G. Beaurain^{1, 2}, M. Giraud¹, B. Eymard³, C. Tranchant⁴, P. Gajdos⁵, J. Dausset⁶, H-J. Garchon¹.* 1) INSERM U580, Paris, CDX 15, France; 2) Association Claude Bernard, Paris, France; 3) Hôpital de la Pitié-Salpêtrière, Paris, France; 4) Service de Neurologie, CHRU de Strasbourg, France; 5) Service de réanimation, Hôpital Raymond Poincaré, Garches, France; 6) Fondation Jean Dausset, Paris, France.

The 8.1 haplotype of the HLA complex has been reproducibly associated to several autoimmune diseases and traits and notably to thymus hyperplasia in patients with acquired generalized myasthenia gravis (MG), an autoantibody-mediated disease of the neuromuscular junction directed at the muscle acetylcholine receptor (AChR). However, the strong linkage disequilibrium across this haplotype has precluded an identification of the causative locus, also termed MYAS1. In the present study, by reconstructing haplotypes and by assessing their transmission in 73 simplex families, we could circumscribe MYAS1 to a segment of 1.2 Mbases maximum size encompassing the class III and the proximal class I region, between the BAT3 and C3-2-11 markers, therefore unambiguously excluding the class II loci. In addition, a case-control comparison disclosed a very strong association of a core haplotype in this same region following an additive model ($p=7 \times 10^{-11}$, odds ratio 6.5 for one copy and 42 for two copies of the core haplotype). Finally, this region was associated with a marked increase in serum titers of anti-AChR autoantibodies ($p=8 \times 10^{-6}$). Remarkably, this effect was suppressed by a second locus in cis on the 8.1 haplotype and located towards the class II region. Altogether the data demonstrate very significant but complex effects of the 8.1 haplotype on the phenotype of MG patients and might shed new light on its role in other autoimmune diseases.

Program Nr: 1986 from the 2004 ASHG Annual Meeting

Parent of origin effect in atopic asthmatic families. *A. Bisognin, G. Malerba, L. Xumerle, E. Trabetti, P.F. Pignatti.*
DMIBG - Biology & Genetics, Univ of Verona, Verona, Italy.

A genome wide scan for atopic asthma and related phenotypes was conducted in 123 families of North East Italian descent with two or more asthmatic children. A total of 604 individuals were genotyped for 396 microsatellite markers. The chromosomal regions that showed suggestive linkage were further analysed to explore the hypothesis of a parent-of-origin-effect (genehunter imprinting) in the development of atopy, previously reported in literature especially for dust mite sensitization. Multipoint LOD scores were maximized over disease model parameters using a stepwise gradient strategy both for imprinting and non-imprinting models. A region of chromosome 9 between D9S286 and D9S157, in linkage with dust mite and pet allergen reactivity, showed a highly suggestive evidence of imprinting obtaining a MOD (maximized lod) score of 5.04 under the imprinting model with the following parameters: $f=0.055$ (disease allele frequency), $P(+/+)=0.027$ (penetrance of genotype wild type allele /wild type allele), $P(m/+)=0$ (paternally inherited mutant allele/wild type allele), $P(+/m)=0.3$ (wild type allele/maternally inherited mutant allele) $P(m/m)=0.8$ (mutant/mutant). Under the non imprinting model a MOD score of 2.85 was obtained with parameters $f=0.105$, $P(+/+)=0.01$, $P(m/+)=0.1$, $P(m/m)=0.5$. The difference between the two MOD score values is 2.19. A previous simulation study pointed out that when the difference between the MOD score values of the two models is greater than 1.5, then the higher of the MOD scores indicates the correct mode of inheritance with high reliability. Subject to further confirmation, these data suggest the presence of a new paternally imprinted locus in chromosome 9 between D9S286 and D9S157 possibly involved in the pathogenesis of atopy.

The extent of linkage disequilibrium in the genome of the isolated population of Campora (National Park of Cilento and Vallo di Diano, Italy). *V. Colonna¹, M. Ciullo¹, T. Nutile¹, P. Zavattari², F. Cucca², M.G. Persico¹*. 1) Institute of Genetics and Biophysics A. Buzzati Traverso, CNR, Naples, Italy; 2) Dipartimento di Scienze Biomediche e Biotecnologie, Università di Cagliari, Ospedale Microcitemico, Cagliari, Italy.

This study aims to identify and characterize regions of remarkable linkage disequilibrium (LD) and to assess the relationship between LD and genetic distance in the genome of the isolated inbred population of Campora. This population was selected for the identification of allelic variants responsible of complex traits by means of genomic regions identical by descent. To establish the feasibility of such a study, we have evaluated the extent and position of genomic regions that have not undergone recombination. We have built a pedigree to include Campora inhabitants since 1500 (11,000 members 15-17 generations deep). Current members of Campora population derive from a small number of founders who survived the 1656 plague. We considered a sample of 228 autosomal chromosomes from individuals unrelated up to three generations and belonging to a 2284-member sub-pedigree. Average inbreeding coefficient in this sample is 0.004. We first scanned the Xq13-Xq21 region using 6 STRs markers that have already been used in several populations with different demographic histories and we found, as expected, significant disequilibrium. We then scanned for LD throughout the whole genome, using 1023 STRs markers with an average spacing of 3.4cM. Departure from equilibrium tested by contingency table analysis and evaluation of normalized linkage disequilibrium coefficient (D') was calculated using an improved version of the Haploxt software. Our preliminary results show that 30 regions distributed over 14 autosomes could be in significant disequilibrium within the Campora population. These genomic regions are currently under investigation in order to confirm and to verify the consistence with previously identified regions with similar characteristics in other populations. Finally, a plot of significant p-values against genetic distance suggests extended genomic regions in LD greater than that observed in large outbred populations.

Linkage Disequilibrium Mapping via Cladistic Analysis: Loss of Information due to Unknown Phase. C.V. Durrant, L.R. Cardon, A.P. Morris. Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Oxford, United Kingdom.

We recently described a method for linkage disequilibrium (LD) mapping, using cladistic analysis of SNP haplotypes in a logistic regression framework (1). However haplotypes are often not known. One possible two-stage approach is to infer the phase of multilocus genotype data and analyse the resulting haplotypes, but inferring haplotypes from phase-unknown data is prone to error. An alternative approach is to analyse the phase-unknown multilocus genotypes themselves, so here we also present an analogous method to that described in Durrant et al. (1) but for multilocus SNP genotypes instead of haplotypes. A simulation study was performed to compare the performance of the genotype and inferred haplotype analyses relative to the analysis of known haplotypes across a wide range of disease models using high-density SNP data based on empirical patterns of linkage disequilibrium. Haplotypes were inferred from the multilocus genotype data using the expectation-maximisation (EM) algorithm and haplotype analysis was performed using the best-guess phase assignment for each individual.(1) C.V. Durrant, K.T. Zondervan, L.R. Cardon, S. Hunt, P. Deloukas, A.P. Morris (2004) Linkage disequilibrium mapping via cladistic analysis of SNP haplotypes. *Am J Hum Genet* 75: 35-43.

High Resolution T^2 Association Tests of Complex Diseases Using Normal Sibs as Controls. *R. Fan*^{1,2}, *M. Knapp*².
1) Dept of Statistics, Texas A&M Univ, College Station, TX; 2) Institute of Medical Biometry, Informatics and Epidemiology, University of Bonn, Sigmund Freud Strasse 25, D-53105 Bonn, Germany.

For late onset complex diseases, parental data are usually not available. One way to study late-onset disorders is to perform sib-pair or sibship analyses. This paper proposes sibship based Hotelling's T^2 tests for high resolution linkage disequilibrium mapping or association study of complex diseases. For a sample of sibships, suppose that each sibship consists of at least one affected offspring and at least one normal sib. Assume that genotype data of multiple markers or haplotype blocks are available for each individual of the sample. Paired Hotelling's T^2 test statistics are proposed for high resolution association study using normal sibs as controls for affected sibs, based on two coding methods: haplotype/allele coding and genotype coding. The paired Hotelling's T^2 tests take not only the correlation between the haplotype blocks or markers into account, but also take the correlation within each sib-pair into account. The validity of the proposed method is justified by rigorous mathematical and statistical proof under the large sample theory. The non-centrality parameter approximations of the test statistics are calculated for power and sample size calculations.

Program Nr: 1990 from the 2004 ASHG Annual Meeting

Cosmopolitan linkage disequilibrium maps. *J. Gibson, W. Tapper, W. Zhang, N.E. Morton, A. Collins.* Genetic Epidemiology Group, Human Genetics Division, University of Southampton, Southampton, United Kingdom.

Linkage maps have been invaluable in the positional cloning of many genes involved in severe human diseases. Standard genetic linkage maps have been constructed for this purpose from the CEPH and other panels, and have been widely used. Now that much attention has shifted towards exploiting linkage disequilibrium and maps of single nucleotide polymorphisms it is of interest to examine the prospects for developing a standard LD map which is somewhat analogous to the linkage map. We have constructed and evaluated a cosmopolitan linkage disequilibrium map by combining data from a small number of populations using data for a 10 MB region on chromosome 20. We find that a cosmopolitan map, which can serve all populations if appropriately scaled, recovers 91-95% of the information contained in the population specific maps. This supports a published pilot study, which examined a number of small genomic regions with a lower density of markers. Recombination hot spots appear to have a dominant role in shaping patterns of LD. The success of the cosmopolitan map may be attributed to the co-localisation of these hot spots in all populations. Although there must be finer scale differences between populations due to other processes (mutation, drift and selection) the results suggest that a whole genome standard LD map would indeed be a useful resource for disease gene mapping.

Program Nr: 1991 from the 2004 ASHG Annual Meeting

Methods to determine the structure of linkage disequilibrium blocks: a comparative study. *A. Guilbot, C. Stalens, I. Elias-Billon, C. Aucan, D. Cohen, F. Macciardi.* Serono Genetics Institute, Biostatistics and Genetic Epidemiology, RN 7, Evry, France.

LD (Linkage Disequilibrium) occurs when two alleles at adjacent polymorphisms are found together in a chromosomal segment more often than expected if they were segregating independently in the population. The extent of LD is influenced by many evolutionary and other confounding factors, but recombination appears to dominate the pattern of LD. Efforts to map oligogenes are concerned with exploiting linkage disequilibrium between markers and putative disease-predisposing loci. So, it is vital to understand the pattern of LD across the genome or candidate region to ensure efficient screening. This task presents some difficulties since block definitions are arbitrary and, by most definition, only a proportion of the genome is composed of blocks. We based our study on a 5 Mb region that we previously characterized by genotyping around 200 SNPs in one case-control study (450 individuals). The LD structure was studied in this sample with four different haplotype-block and haplotype-diversity identification methods. In a second step, we described the underlying structure of LD in the form of a metric map. This alternative approach, assigning locations to markers in linkage disequilibrium units, avoids arbitrary block definition. By comparing the different approaches, we identified some discrepancies in terms of LD block structure clearly related to the differences in block definition. Moreover, we tested the robustness of all methods to Hardy-Weinberg disequilibrium (HWD). The first results showed that, when based on haplotype diversity, the definition of blocks can be influenced by the presence of markers in HWD. On the contrary, the metric LD map remained unchanged and identified the same LD units.

Refinement of the Locus for Myoclonus-Dystonia on Chromosome 18p11 (DYT15). *F. Han¹, D.A. Grimes^{1, 2}, A.E. Lang³, L. Racacho¹, D.E. Bulman^{1,2}.* 1) Dept Molecular Medicine, Ottawa Health Research Inst, Ottawa, ON, Canada; 2) Dept Neurology, Ottawa Hospital, Ottawa, ON, Canada; 3) Dept Neurology, University Health Network, Toronto Western Hospital, ON, Canada.

Inherited myoclonus-dystonia (MD) is an autosomal dominant disorder characterized by alcohol responsive myoclonic jerks typically affecting the arms and axial muscles. Mutations in the epsilon-sarcoglycan (SGCE) gene on 7q21 have been shown to cause MD in about 50% of cases. Previously we excluded SGCE as the cause of MD in a five-generation large Canadian MD family (A). We originally mapped a novel locus for this disorder to a 4 Mb region between the markers D18S1132 and D18S843 on 18p11 (Max LOD score of 3.96). This locus is now designated DYT15 (OMIM number: 607488). Subsequently, a second MD family (B) was shown not to have mutations in SGCE gene and was genotyped with the linked markers on 18p11. Affected individuals in Family B were found to share the same haplotype as that of family A initially for 6 markers in the linked region. Based on the shared haplotype in families A and B we identified the distal recombinant marker as D18S1363. The critical region would have been reduced to 3.27 Mb while the proximal recombinant marker was still D18S843 in these two families. We identified a recombinant SNP in the proximal region of family A and an unshared SNP allele in the distal region. Based on our 20 informative markers, we would expect a shared haplotype to occur at a frequency of less than 8.5×10^{-5} per individual. We have identified a common haplotype on chromosome 18p11 in these two families, refining the position of DYT15 gene to a 2.13 Mb critical region. We have also excluded five candidate genes as the causing genes for MD within or very close to this new critical region.

Program Nr: 1993 from the 2004 ASHG Annual Meeting

New Advances in Association Mapping of Disease Genes Using Linkage Disequilibrium Maps. *N. Maniatis, A. Collins, N.E. Morton.* Human Genetics Division, Southampton General Hospital, University of Southampton, Southampton, United Kingdom.

We have developed a simple yet powerful approach for disease gene association mapping by linkage disequilibrium (LD). This method is unique since it applies a model with evolutionary theory that incorporates a parameter for the location of the causal polymorphism. The method exploits LD maps, which assign a location in LD units (LDU) for each marker. This approach is based on single marker tests within a composite likelihood framework, which avoids the heavy Bonferroni correction through multiple testing. As a proof of principle, we tested an 890 kb region flanking the CYP2D6 gene associated with poor drug metabolising activity in order to refine the localization of a causal mutation. Previous LD mapping studies using single markers and haplotypes have identified a 390 kb significant region associated with the poor drug-metabolizing phenotype on chromosome 22. None of the 27 SNPs were within the CYP2D6 gene. Using a metric LDU map, the commonest functional polymorphism within the gene was located 14.9 kb from its true location, surrounded within a 95% confidence interval of 172 kb. The kb map had a relative efficiency of 33% compared to the LDU map. Despite the low resolution and the strong LD in the region, our results provide evidence of the profound utility of LDU maps for disease gene association mapping. Our findings also indicate that the support interval and location error are smaller than any published results. These tests are robust to large numbers of markers and are applicable to haplotypes, diplotypes, whole-genome association or candidate region studies.

Fine Mapping of Chromosome 11p Reveals Dialectic Interplay Between Genes Controlling Attention and Activity. *L.G. Palacio^{1,2}, F.X. Castellanos^{3,4}, D. Pineda², J.D. Palacio², F. Lopera², R. Long^{1,3}, J.L. Rapoport³, K. Berg¹, J. Bailey-Wilson¹, M. Arcos-Burgos^{1,2}, M. Muenke¹.* 1) NHGRI,NIH,Bethesda,MD,USA; 2) University of Antioquia, Medellin, Colombia; 3) NIMH,NIH,Bethesda MD,USA; 4) NYU Child Study Center, New York, NY, USA.

Genetic polymorphisms at human chromosome 11p have been widely reported to be associated with attention-deficit/hyperactivity disorder (ADHD) and other behavioral disorders. The most extensively replicated reports are for linkage disequilibrium (LD) between ADHD and DRD4. However, the absence of DRD4 mutations, the small effect size ($=1.9$), and the extension of this LD to the DRD4 neighborhood suggest that another locus segregating either in LD, interacting with DRD4, or a common behavioral phenotype might be the real cause of the increased risk for ADHD. We followed up a result of LD between haplotypes at DRD4 and both ADHD and normal population with a ~ 1.5 cM microsatellite screen in extended families from a genetic isolate segregating ADHD. By splitting the phenotype using latent class cluster analysis (LCCA) we found that the strongest LD as obtained by the Pedigree Disequilibrium Test (PDT) occurs between latent classes containing unaffected or normal individuals who significantly exhibit absence of one allele at the marker D11S4046 ($p=0.005$). Using genoPDT, we determined that homozygotes for this allele exhibit increased risk for ADHD. Additionally, we found LD to another allele at this locus conferring protection to develop ADHD ($p=0.04$). We hypothesize that this interplay between antagonistic alleles at the same locus defines the phenotypic class. Because LD at this marker is stronger than for DRD4 and closest to the gene for tyrosine hydroxylase (TH) (~ 200 Mb) compared to DRD4 (~ 2 Mb), TH could be the gene underlying the LD with phenotypes related to activity, attention and comorbidities associated to ADHD. We also found evidence of a population-based block of LD at the telomeric 4 Mb of 11p as additional evidence for hitchhiking of DRD4 by TH. This approach can be tested in other psychiatric conditions, as the LD was detected when using the normal phenotype classes instead of the affected ones.

Follow-up of linkage peaks on chromosomes 1q and 16p for age-related macular degeneration (AMD). M.

Pericak-Vance¹, S. Schmidt¹, Y.-T. Fan¹, S.Y. Kwan¹, N. Schnetz-Boutaud², L.M. Olson², E.A. Postel³, A. Agarwal⁴, J.R. Gilbert¹, W.K. Scott¹, M.A. Hauser¹, J.L. Haines². 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Ctr Human Genetics Research, Vanderbilt Univ Med Ctr, Nashville, TN; 3) Duke Eye Ctr, Duke Univ Med Ctr, Durham, NC; 4) Dept Ophthalmology, Vanderbilt Univ Med Ctr, Nashville, TN.

Age-related macular degeneration (AMD) is one of the most significant causes of vision loss in older adults. There is substantial evidence that genes play a critical role in its etiology. To identify susceptibility genes for AMD, several genome-wide linkage screens have recently been completed. Two of the consistent regions of interest across studies are chromosomes (chr) 1q and 16p, which we have explored in more detail. We genotyped 44 SNPs in the 153-177 Mb interval on 1q (density 0.5-1 Mb) and 94 SNPs in the 12-32 Mb interval on 16p (density 100 kb-1 Mb). All SNPs were chosen to have minor allele frequency of at least 10%. Both family-based analysis, using the pedigree disequilibrium test (PDT), and case-control analysis, using logistic regression with adjustment for age at exam and sex, were used to test for single-marker allelic association between these SNPs and AMD. The PDT was applied to a data set of 62 AMD families with 119 discordant sibling pairs, and the case-control analysis was performed on an independent data set of 556 cases and 153 rigorously examined controls. On chr 1q, we detected highly significant evidence for association ($p=0.008$ to 0.0001) in both family and case-control data sets for two SNPs at 170 Mb. On chr 16p, the PDT gave strong evidence for association ($p=0.005$) for two SNPs at 29 and 30 Mb. For both regions, most of the evidence for association came from patients with neovascular AMD. In addition, we continue to see linkage signals in both regions, particularly in families where at least two relatives are affected with neovascular AMD. Additional genotyping in both regions of interest for further localization of putative AMD susceptibility genes is underway.

MTHFR linkage disequilibrium from segregating haplotypes in a Mestizo population from Guadalajara, Mexico.

K. Rodarte^{1,2}, *N. Olivares*³, *R. Chakraborty*⁴, *F. Rivas*¹. 1) Western Biomedical Research Center, Instituto Mexicano del Seguro Social; 2) Graduate Studies Program in Human Genetics, Universidad de Guadalajara; 3) Hospital General de Occidente, Secretaria de Salud Jalisco, Guadalajara, Jalisco; 4) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Ohio.

5,10-methylenetetrahydrofolate reductase (MTHFR) polymorphisms C677T and A1298C are related to homocysteinemia, folate availability, DNA and protein methylation, and diseases. For these and other polymorphisms at this region, issues regarding selection have been discussed. (Munoz-Moran et al. *Lancet* 352:1120,1998; Rosenberg et al. *AJHG* 70:758, 2002; Zetterberg et al. *Eur J Hum Genet* 10:113, 2002). Linkage disequilibrium (LD) can shed light on some of these aspects. It is usually estimated by maximum-likelihood models. In this study, four MTHFR SNPs (A533G, A1298C, C31T, C677T) were typed by PCR-RFLP (*PaeI*, *MboII*, *AflIII*, *HinfI*) in 200 healthy volunteers from 50 families living in Guadalajara, Mexico. Data from 81 random individuals (162 independent haplotypes) were used to estimate D' (Lewontin *Genetics* 49:49, 1964). Allele frequencies were 83.0% 533G, 20.5% 1298C, 47.0% 31T, 47.0% 677T. Four-site haplotype ² value was 497 (p<0.001). Two-site D' ranges between 0.59-0.91 (minimum distance between sites = 300 bp). D' for (deleterious) haplotype 677T-1298C was -0.85. It has been suggested that over a few generations, folic acid supplementation can modify MTHFR population genetics. This and other selective implications are discussed.

Identification of genes influencing blood pressure variation on chromosome 2p in the Amish. *S. Rutherford, J.R. O'Connell, N.I. Steinle, B.D. Mitchell, A.R. Shuldiner.* Dept Medicine, Univ Maryland, Baltimore, Baltimore, MD.

Unraveling the genetic basis of common complex disorders such as essential hypertension has been complicated by the interaction of environmental influences, genetic heterogeneity and incomplete penetrance. Since the etiology of hypertension begins several years before its clinical manifestation and is a major risk factor for stroke, heart and renal failure, it is important to identify the factors that are likely to have an early influence on blood pressure (BP) determination. Previously, we conducted a genome wide search for BP variation in 691 members of the Old Order Amish population of Lancaster County, Pennsylvania, a genetically homogeneous founder population. A linkage peak for both systolic (LOD = 1.09; $p = 0.01$) and diastolic BP (LOD = 0.46; $p = 0.07$) was obtained in the Amish between 34.8 cM and 86.0 cM on the p arm of chromosome 2. This region shows consistent and convincing evidence for hypertension and BP in other studies. We now report the results of fine-mapping this region with linkage disequilibrium mapping using 26 single nucleotide polymorphism (SNP) markers located in 14 candidate genes spanning 47 Mb. We identified a cluster of 3 SNPs which show significant association with systolic BP ($P = 0.01$ to 0.04) within the genes coding for the brain and reproductive organ-expressed TNFRSF1A modulator (BRE), anaplastic lymphoma kinase (ALK) and latent transforming growth factor beta binding protein 1 (LTBP1). We also observed significant association with diastolic BP ($P = 0.004$ to 0.04) for 2 SNPs within the genes coding for UDP-N-acetyl-alpha-D-galactosamine:polypeptide N-acetylgalactosaminyltransferase 14 (GALNT14) and LTBP1. The associated SNPs constitute a region of less than 5 Mb between chromosome 2p23.2 - 2p22.3. We conclude that the 5 Mb region between 2p23.2 - 2p22.3 is likely to harbor a gene influencing BP variation in the Amish.

Significant Linkage of ADHD and Comorbidities to Loci at 4q13.2, 5q33.3, 11q22, and 17p11: Heterogeneity, Epistasis and Minimal Critical Regions; Lessons From a Genetic Isolate. *M. Arcos-Burgos*^{1,2}, *F.X. Castellanos*^{3,4}, *D. Pineda*⁵, *J.D. Palacio*⁵, *F. Lopera*⁵, *L.G. Palacio*^{1,2}, *J.L. Rapoport*³, *K. Berg*¹, *J.E. Bailey-Wilson*¹, *M. Muenke*¹. 1) NHGRI/NIH/DHHS, Bethesda, MD, USA; 2) Population Genetics, Mutacarcinogenesis and Genetic Epidemiology Group, University of Antioquia, Medelln, Colombia; 3) NIMH/NIH Bethesda MD, USA; 4) NYU Child Study Center, New York, NY, USA; 5) Neurosciences Group, University of Antioquia, Medelln, Colombia.

Attention deficit/hyperactivity disorder (ADHD) is the most common behavioral disorder of childhood. We applied model-based and model-free linkage analyses and the pedigree disequilibrium test (PDT) to the results of a genome-wide scan of extended and multigenerational families with ADHD from a genetic isolate. In these families ADHD is highly comorbid with conduct and oppositional defiant disorders and alcohol and tobacco dependence. We found evidence of linkage to markers at chromosomes 4q13.2, 5q33.3, 8q11.23, 11q22, and 17p11. Minimal critical regions were defined based on recombination events. Fine mapping applied to these regions results in combined significant linkage at chromosomes 4q13.2 (two point allele sharing LOD score from LODPAL = 4.44 at D4S3248), 5q33.3 (two point allele sharing LOD score from LODPAL = 8.22 at D5S490), 11q22 (two point allele sharing LOD score from LODPAL = 5.77 at D11S1998) and 17p11 (two point allele sharing LOD score from LODPAL = 3.73 at D17S1159). Additionally, a suggestive linkage at chromosome 8q11.23 was found (combined two point NPL log (p value) > 3.0) at D8S2332). Several of these regions are novel (4q13.2, 5q33.3, and 8q11.23) while others strongly replicate already published loci (11q22 and 17p11). The significant linkage to different genomic regions in individual families is compatible with the presence of epistasis. Analysis to dissect epistasis using the general model of Olson, and a ~200 Kb resolution fine map using SNP on a second sample of 100 nuclear families from the same genetic isolate is currently underway.

Residual Linkage at NOD2/CARD15 implicates other causal variants at the IBD1 locus. *M.M. Barmada*¹, *J.A. Cavanaugh*², *N. Risch*³, *H. Yang*⁴, *IBD International Genetics Consortium*. 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Med Genet Res Unit, ANU Medical School, The Canberra Hospital, Canberra, Australia; 3) Dept Genetics, Stanford University School of Medicine, Stanford, CA; 4) Div Medical Genetics and IBD Center, Cedars-Sinai Medical Center, Los Angeles, CA.

Linkage studies of inflammatory bowel disease (IBD) have unequivocally supported the association between Crohns disease (CD) and the IBD1 locus on chromosome 16 since its identification by Hugot et al. in 1996, and subsequent detection of three common risk alleles (RAs) in the NOD2/CARD 15 locus. These RAs are associated with disease in many Caucasian populations in Europe, the United States and Australia. Nevertheless, the three common alleles (SNPs 8, 12 and 13) do not contribute to susceptibility to disease in either African American or Japanese CD populations studied and questions remain concerning the contribution of known NOD2 RAs to the observed linkage at the IBD1 locus. We have investigated that contribution in the 733 well characterized IBD International Genetics Consortium nuclear families. As expected from previous linkage results, in those CD families in which NOD2 risk alleles are transmitted to affected offspring (N=422), there is strong evidence for linkage, with a maximum nonparametric LOD score ca.19. However, linkage is also observed in the CD families without SNPs 8,12 or 13 RAs (N=213), with a score greater than 3.0. The majority of SNPs 8,12 and 13 RAs occur in association with SNP5 allele 2. While private mutations appear to act as risk alleles in some populations, those detected to date are not usually associated with the haplotype defined by SNP5 allele 2. Functional analysis of SNP5 shows that it does not modify the NF-kB response to MDP in an *in vitro* model, but these data do not rule out altered activity for other functions of the NOD2 protein. We detect evidence of residual linkage at SNP5 (TDT p-value = 0.031, after permutation testing) in families without SNP8, 12, or 13 RAs, suggesting that SNP5 is either in linkage disequilibrium with at least one other causal variant or that SNP5 is itself causal.

Genomewide screen for intraocular pressure in the Beaver Dam Eye Study identifies two novel regions. P.

Duggal¹, A.P. Klein¹, K.E. Lee², S.K. Iyengar³, R. Klein², J.E. Bailey-Wilson¹, B.E. Klein². 1) NHGRI/NIH, Baltimore, MD; 2) Univ of Wisconsin-Madison Med School; 3) Case Western Reserve Univ, Cleveland, OH.

Intraocular pressure (IOP) is a principal risk factor for primary open-angle glaucoma (POAG), a leading cause of blindness in the world. In the US, it is estimated that 3 to 6 million people have elevated intraocular pressure (IOP). We performed a non-parametric genome-wide linkage analysis of 218 sibling pairs ascertained through a population-based cohort, the Beaver Dam Eye Study. Detailed medical histories and eye examinations were performed on all participants. IOP was measured with a Goldmann applanation tonometer in each eye. The higher IOP measurement between the eyes was used as a continuous trait, and treatment with drops, systolic blood pressure, sex and age were covariates. Using GENIBD, we estimated the single point and multipoint identity by descent sharing for the sib pairs. Linkage analysis used the modified Haseman-Elston regression models and the option that allows for the non-independence of sib pairs and uses a weighted combination of the squared trait difference and squared mean corrected trait sum in SIBPAL (S.A.G.E. version 4.5). For each marker, p-values were obtained using the asymptotic distribution of the likelihood-ratio test statistics. The two-point whole-genome scan yielded two novel loci on chromosome 6 (D6S1027, $p = 0.008$) and 13 (D13S317, $p = 0.0007$), as potential linkage regions. Neither locus has been identified previously in genome-wide screens for POAG. Multi-point linkage analysis weakened evidence for linkage in both regions. Neither region reached genome-wide significance. The chromosomes 6 and 13 regions warrant further attention; especially since neither of these loci has been previously identified in genome wide scans of POAG. It is plausible that IOP, like blood pressure, is heterogeneous and there may be loci that control the pressure in both the eye and blood. A whole genome linkage analysis is currently underway using the complete family structure from the Beaver Dam Eye Study (2231 individuals).

A genome-wide scan of episodic vertigo and migraine: Suggestive linkage to 2p11-14 and 17q23-25. *H. Lee¹, H. Wang², J.C. Jen³, C. Sabatti^{1,2}, R.W. Baloh^{3,4}, S.F. Nelson^{1,5}*. 1) Dept. Human Genetics, UCLA, Los Angeles, CA; 2) Dept. Statistics, UCLA, Los Angeles, CA; 3) Dept. Neurology, UCLA, Los Angeles, CA; 4) Dept. Surgery, UCLA, Los Angeles, CA; 5) Dept. Psychiatry and Biobehavioral Sciences, UCLA School of Medicine, Los Angeles, CA.

Vertigo is a perception of movement, either of oneself or of objects around one. It is caused by lesions of the vestibular system (from inner ear to brain pathways). Vertigo is commonly reported in patients with migraine (with or without visual aura) but there is little understanding of the molecular basis of migraine associated vertigo. It is generally accepted that there is a strong genetic component for migraine although preliminary linkage studies suggest genetic heterogeneity. There have been no prior linkage studies in families with migraine and episodic vertigo. We performed a genome-wide linkage scan in 22 families in which multiple members had episodic vertigo and migraine headache, with or without visual aura. With the Affymetrix 10K SNP Mapping Assay, we could perform rapid, accurate and efficient genotyping across the whole genome at a median intermarker distance of 105kb. We performed parametric (heterogeneity LOD [HLOD]) linkage analysis under an autosomal dominant model and nonparametric (S(all) statistics) linkage analysis as well. We report suggestive linkage on 2p11-14 (HLOD=2.9, NPL=2), and 17q23-25 (HLOD=2.5, NPL=2.4). Additional regions with evidence of suggestive linkage were observed on 5p14 (HLOD=2.3, NPL=1.5), 10q25-26 (HLOD=2.2, NPL=1.2), 16q12-21 (HLOD=2, NPL=2). We plan to test additional families to verify these suggestive regions but it appears that migraine associated vertigo is heterogenetic like other migraine syndromes.

Bivariate genome scan analysis reveals a new locus for obesity traits in Mexican American Coronary Artery

Disease (MACAD) families. X. Li¹, M.J. Quinones², D. Wang¹, I. Enriquez², X. Jimenez², R. De La Rosa², J.G. Cadenas², D.J. Bustos², W. Hsueh², J.I. Rotter¹, H. Yang¹. 1) Medical Genetics Institute, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) UCLA, Los Angeles, CA.

Obesity is one of the most important components of the metabolic syndrome. Genetic factors are involved but the mechanism and magnitude of common genetic effects are less clear. Using univariate genome scan linkage analysis, we previously reported evidence for linkage at chromosome 2q36-37 for body mass index (BMI), body surface area (BSA), and trunk fat mass as percent of body weight (FM-T%) (LOD= 2.35, 3.16, 2.62, respectively) and at chromosome 5q36 (LOD=2.18, 2.06, 1.00, respectively) in MACAD families. To identify potential loci with a pleiotropic effect on obesity traits, we evaluated the genetic correlations between traits and performed a genome-wide linkage analysis using bivariate models in 443 subjects from 101 Mexican American nuclear families ascertained through a proband with documented coronary artery disease, the MACAD study. Heritability estimates and multipoint linkage analysis were performed using a variance components procedure implemented in SOLAR. After taking into account age and gender effects, we observed significant genetic correlations between BMI and other obesity related traits (all $p < 0.01$). These significant correlations indicated that the pleiotropic effects of common genes account for 0.36 to 0.50 of genetic variance in these trait pairs, with the highest for BMI-BSA ($G^2 = 0.5$) and lowest for BMI-WHR (waist hip ratio) ($G^2 = 0.36$). Bivariate linkage analysis identified a new peak (LOD=3.25) at 25cM on chromosome 7 for the pair of BMI and BSA. These results indicate that 1) the pleiotropic effects of both genetic and environmental factors contribute to the strong correlation between BMI and other obesity traits, especially BSA, 2) the prior evidence for univariate linkage on chromosomes 2q36-37 and 5q36 was supported by bivariate analysis, and 3) an additional linkage peak at 7p15 was identified by the bivariate model. This suggests that the use of bivariate models provides additional power to identify linkage of genes responsible for obesity related traits.

Novel evidence of RP1 mutations causing autosomal recessive retinitis pigmentosa in consanguineous Pakistani families. *S.Q. Mehdi¹, K. Anwar¹, A. Abid¹, M. Ismail¹, A. Hameed¹, P. Lall², Amtul-Aziz³, S. Khaliq¹.* 1) Biomedical and Genetic Engineering Laboratories, Islamabad, Pakistan; 2) Christian Hospital, Faisal Shaheed Road, Taxila, Pakistan; 3) Al-Shifa Trust Eye Hospital, Rawalpindi, Pakistan.

The second most common cause for adRP, after rhodopsin dysfunction, is mutations in the gene for RP1, and are responsible for approximately 6-10% of all adRP in ethnically different populations. More than 35 mutations in the RP1 gene that cause adRP, are mostly clustered in exon 4 and result in premature termination of the protein. However, RP1 has not been reported to cause any other form of retinal degeneration. In this study we analyzed three consanguineous arRP Pakistani families. Exclusion studies of known RP loci showed homozygosity with markers D8S285 and D8S1815 flanking the RP1 gene locus. Heteroduplex analysis for RP1 gene using DHPLC revealed heteroduplex peaks in exon 4 of all the unaffected parents. All family members were then sequenced to identify the mutation in exon 4. In family 442RP and 452RP, a homozygous C to T missense substitution in codon 373 (ACA to ATA; T373I) was found in all the patients, while parents of the affected individuals and some of the normal siblings were heterozygous. None of the 100 normal controls carried the T373I change in the homozygous state, although some heterozygous individuals were observed. In family 336RP, a 4-bp insertion at nucleotide 1461 adds a termination codon after codon 487. This results in the production of a severely truncated protein of 487 instead of 2156 amino acids. This was homozygous in all patients, heterozygous in the parents and some normal family members, but not in normal controls. A random panel of 150 Pakistani RP patients was screened. A second missense G to A substitution (GCC to ACC; A669T) was found in a heterozygous state in one patient but not in the normal controls. These results suggest that the frequency of RP1 gene mutations is relatively low in Pakistan. To our knowledge this study provides the first report of the involvement of mutations in the RP1 gene in the autosomal recessive RP phenotype.

Fine mapping of the PDB4 locus at 5q31. *J. Morissette¹, S. Auger¹, A. Duchesne¹, N. Laurin², J.P. Brown³.* 1) Dept Molec Endocrinology, CHUL Research Ctr, Quebec, PQ, Canada; 2) Cell and Molecular Division, Toronto Western Hospital, Toronto, ON, Canada; 3) Rheumatology-Immunology, CHUL Res Centre, Quebec, PQ, Canada.

Paget disease of bone (PDB) is characterized by focal increases of the bone remodeling process. It is the second most common metabolic bone disease after osteoporosis. Genetic factors play a major role in PDB and seven loci have been reported so far. Only the PDB3 locus, localised at 5q35, has been confirmed and the gene identified. A recurrent mutation (P392L) in the exon eight of the sequestosome 1 (SQSTM1/p62) gene was detected in affected members of 11 of 24 (46%) French Canadian pedigrees and in 27 of 182 (15%) unrelated French Canadian affected individuals. A second locus, PDB4, was also localized within the same population. A localization interval of 12 cM at 5q31 was defined between markers AFM286xg9 and AFMa190xb1 using two large multigenerational families. A different disease haplotype was observed in those two families.

To further refine the PDB4 locus, we exploited the founder effect of the French Canadian population. We genotyped a total of 28 informative microsatellite markers in 12 families, 130 unrelated affected individuals and 143 individuals sampled from the general population. Ten of those markers were developed locally using the human genome sequence. Haplotypes from family members were phased using the SIMWALK V2.8 program whereas the haplotypes of unrelated individuals were phased with the PHASE V2.0 program.

Portions of the two PDB4 linked family haplotypes were found in unrelated individuals. This allowed us to narrow the PDB4 interval within a 4 cM region. This PDB4 region is now defined by the two markers AFMa103za9 and GATA2H09.

Program Nr: 2005 from the 2004 ASHG Annual Meeting

A highly informative SNP linkage panel for human genetic studies. *S.S. Murray, B.G. Kermani, R.J. Steeke, S.G. Shannon, A. Oliphant, M.S.T. Hansen.* Illumina, Inc, San Diego, CA.

We have developed a highly informative set of SNP assays designed for linkage mapping of the human genome. These assays were developed on a robust multiplexed system to provide an unprecedented combination of very high accuracy, data completeness, and high throughput for linkage studies. The performance of the system together with objective, quantitative metrics of data quality effectively eliminates the need for labor-intensive post-processing of datasets prior to linkage analysis. The linkage panel is comprised of approximately 5600 SNP loci with an average ~570 kb spacing. The average minor allele frequency for these SNPs is approximately 0.40 in a Caucasian population. Allele frequencies are also being determined in Asian and African populations. Data quality has been shown to be exceptional, with data quality metrics (call rate, reproducibility, and genotypes consistent with Mendelian inheritance) routinely >99.9%. We have also determined the relative genetic map position of each SNP locus by interpolation to a high resolution genetic map (Kong et al., 2002), where the mean genetic map interval is 0.6 cM. In addition, the relative information content of this panel is higher than the 5- and 10-cM commonly used STR marker panels tested, and is >0.95 for all chromosomes using 188 meioses derived from 8 CEPH reference pedigrees. Information content is also currently being estimated from simulated genotype data using the allele frequencies from the Asian and African populations to determine the usefulness of this panel in these populations. The potent combination of this SNP linkage panel with the multiplexed assay system provides a previously unattainable level of performance for linkage studies.

STRATIFICATION REVEALS SIGNIFICANT SEX-SPECIFIC LINKAGE TO ATTENTION-

DEFICIT/HYPERACTIVITY DISORDER (ADHD). *M.N. Ogdie¹, S.E. Fisher², M. Yang³, C. Francks², J.T.*

McCracken⁴, J.J. McGough⁴, S.L. Smalley^{3,4}, S.F. Nelson^{1,3}. 1) Dept Human Genetics, Univ California at Los Angeles, Los Angeles, CA; 2) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, UK; 3) Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 4) Departments of Psychiatry Biobehavioral Sciences, UCLA, Los Angeles, CA.

Genome-wide linkage analysis of a sex stratified sample of 308 ADHD affected sibling pairs (ASPs) indicates the presence of sex-specific susceptibility loci. A region on 5p13 (MLS 5.13, empiric $p=0.02$) yielded significant linkage to ADHD only in male sibling pairs. Simulations were performed to assess the statistical significance of observing the increase in linkage signal across the genome. Analysis of the overall genome-wide increase in evidence of linkage in the stratified samples strongly argues the presence of multiple sex-specific effect loci (empiric $p10^{-6}$). The identification of multiple distinct linkage regions in both male and female ADHD ASPs suggests that linkage analysis of sex stratified samples should be routinely conducted in ADHD linkage studies.

Evidence for Glucose Homeostasis Genes in African Americans on Chromosome 11q: The IRAS Family Study.

N.D. Palmer¹, C.D. Langefeld², S. Beck², J. Campbell², M.F. Saad³, L.E. Wagenknecht², R.N. Bergman⁴, S.S. Rich², D.W. Bowden¹. 1) The Center for Human Genomics, Wake Forest University, Winston-Salem, NC; 2) Public Health Sciences, Wake Forest University, Winston-Salem, NC; 3) Department of Medicine, University of California at Los Angeles, Los Angeles, CA; 4) Department of Physiology and Biophysics, University of Southern California, Los Angeles, CA.

Disposition Index (DI) is a quantitative measure which combines the effects of insulin sensitivity (S_I) and β -cell function (AIR) in an assessment of glucose homeostasis. We previously reported linkage of DI on chromosome 11q with a LOD of 2.61 at 67cM (LOD-1: 63-99cM) in 284 African Americans (21 pedigrees) from the IRAS Family Study. This finding was confirmed in an additional 214 African Americans (22 pedigrees) from IRASFS with a LOD of 1.83 at 60cM (LOD-1: 38-92cM). Fifteen additional SSTR markers were added to this region, resulting in an increase in the combined LOD score (LOD=3.95; 80cM) and refinement of the peak (LOD-1: 74-84cM). AIR also showed evidence of linkage to two separate regions (LOD=3.08; 64cM and LOD=2.73; 85cM) distinct from the DI peak. In contrast, S_I was not linked to this region. Information content for these markers suggests little additional linkage information could be obtained by adding markers. As S_I , AIR, and DI are mathematically and metabolically related, bivariate linkage analyses were performed. These analyses did not improve or refine the linkage signals. Thus, these data do not strongly support a hypothesis of locus-specific pleiotropy between S_I , AIR, and DI. Nine potential candidate genes in this region were evaluated for association to DI and AIR. Among these candidates, muscle glycogen phosphorylase showed the most significant associations with DI ($P<0.001-0.011$) and pyruvate carboxylase showed the most significant associations with AIR ($P<0.001-0.002$). To summarize, our African American pedigrees confirmed linkage evidence for the 11q DI locus and identified an independent AIR loci on 11q. Separate positional candidate genes provide evidence of association with DI and AIR.

Identification of a novel locus on chromosome 2q for autosomal dominant high myopia. *P.C. Paluru¹, S. Nallasamy^{1,2}, M. Devoto³, S. Brown⁴, T.L. Young^{1,2}*. 1) Department of Ophthalmology and Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Department of Biomedical Research, Nemours Children's Clinic, Wilmington, DE; 4) Department of Ophthalmology, Texas Technical University Health Sciences Center, Lubbock, TX.

Myopia, or nearsightedness, is a visual disorder of high and growing prevalence in the U.S. and in other countries. "Pathologic" high myopia, or myopia of -6.00 diopters (D), predisposes individuals to retinal detachment, macular degeneration, cataracts, and glaucoma. Autosomal dominant (AD) non-syndromic high-grade myopia has been mapped to loci on chromosomes 18p11.31, 12q21-23, 17q21-23, and 7q36. We now report significant linkage to a novel locus on chromosome 2q in a large, multigeneration family with AD high myopia. The family contains 30 participating members (14 affected). The average spherical refractive error for affected individuals was -14.15 D (range, -7.25 to -27.00). Linkage to intragenic or flanking markers for the myopic genetic syndromes of Stickler syndrome types 1, 2, and 2B; Marfan syndrome; Ehler-Danlos syndrome type 4; and juvenile glaucoma was ruled out before proceeding with a genome screen. In addition, no linkage was found to the known AD loci listed above. A full genome screen of the family was performed with 382 microsatellite markers with an average inter-marker distance of 10 cM. SimWalk2 software was used for multipoint linkage analysis based on an AD model with a penetrance of 0.9 and a disease allele frequency of 0.001. Additional fine-point mapping yielded a maximum multi-point LOD score of 5.606 at marker D2S2348. Haplotype analysis defined a critical interval of 10.37 cM on chromosome 2q37. A novel locus for AD high-grade myopia has been determined, providing further evidence of genetic heterogeneity for this disorder.

Program Nr: 2009 from the 2004 ASHG Annual Meeting

A new locus for autosomal dominant posterior polar cataract on chromosome 14q. *E. Pras, J.F. Hejtmancik.*
OGVFB, National Eye Inst, Bethesda, MD.

Background: Posterior polar cataract is a clinically distinctive opacity located at the back of the lens. It is commonly acquired in age related cataract, and may infrequently occur in pedigrees with congenital cataract. To date, four loci for autosomal dominant congenital posterior polar cataract have been identified. These include one gene CRYAB on chromosome 11, and three loci with as yet unknown genes on chromosomes 1p, 16q and 20p.

Purpose: To find the chromosomal location of a gene causing autosomal dominant congenital posterior polar cataract in three Morocco-Jewish families.

Methods: A whole genome scan was performed using microsatellite markers spaced at approximately 10cM intervals. For fine mapping 4 additional microsatellite markers were genotyped. Two-point lod scores were calculated using MLINK of the LINKAGE program package.

Results: The new cataract locus was mapped to an 11.2 cM interval between D14S980 and D14S1069 on chromosome 14q. A maximum two-point lod score of 3.67 at $\theta=0$, was obtained with the markers D14S274.

Conclusion: A gene associated with posterior polar cataract maps to the long arm of chromosome 14.

A QTL on chromosome 8q influences the skeletal maturation of healthy children during early and middle childhood. *B. Towne¹, D.L. Duren¹, J. Blangero², J.S. Parks³, M.R. Brown³, T. Dyer², S.A. Cole², A.F. Roche¹, R.M. Siervogel¹.* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Emory University School of Medicine, Atlanta, GA.

Current understanding of genetic influences on skeletal development comes mainly from studies of monogenic disorders. Few studies have examined genetic influences on normal variation in skeletal development. The tempo of skeletal maturation in healthy children is variable, with the skeletal age (SA) of a child differing up to three years from that child's chronological age. Here, we present results from an initial series of linkage analyses of the SA of children assessed at chronological ages 1 to 17 years. SA data were obtained from 9,865 hand-wrist radiographs taken between 1931 and 2002 of 1,069 children from 220 families in the Fels Longitudinal Study (Roche, 1991). SA was estimated by the FELS method (Roche et al., 1988), a maximum likelihood approach that uses measured and graded indicators of skeletal development appropriate for a given chronological age. An initial set of 478 subjects has been genotyped for some 400 autosomal markers spaced approximately every 10 cM. A variance components-based linkage analysis method (SOLAR; Almasy and Blangero, 1998) was used to analyze these data and obtain multipoint LOD scores. SA was highly heritable throughout childhood, and we found consistent evidence of linkage of SA at chronological ages 2 to 10 years to chromosome 8q between markers D8S270 (8q21.3) and D8S1784 (8q23.1). The LOD scores across these nine ages were: 1.08, 0.96, 1.55, 2.01, 2.76, 1.43, 3.16, 2.06, and 0.99, respectively. Disorders with skeletal abnormalities as part of their etiology mapped to 8q22-q24 include Klippel-Feil syndrome and Langer-Giedion syndrome. Also, the bone morphogenetic protein 1 (BMP1) gene at 8q21 is within the support interval of this study. Our future work will seek to identify specific genes and polymorphisms in this region that influence different aspects of normal skeletal development during early and middle childhood. Supported by NIH grants HD36342, HD12252, and MH59490.

Fine mapping of the keratoconus locus on 16q. *S. Tuupanen*¹, *P. Sistonen*², *T. Tervo*³, *T. Alitalo*¹. 1) Biomedicum Helsinki, Department of Obstetrics and Gynecology, Helsinki University Central Hospital, Finland; 2) Finnish Red Cross, Blood Transfusion Center, Helsinki, Finland; 3) Department of Ophthalmology, Helsinki University Central Hospital, Finland.

Keratoconus (KC; MIM 148300) is a noninflammatory corneal disorder with an incidence of approximately 1:2000. KC is characterized by progressive thinning, protrusion and scarring of the central cornea, leading to variable degree of visual impairment. It is the most common cause of corneal transplantation in Western world. We have previously performed a genome-wide linkage analysis and localized KC to 16q22.3-23.1 in 20 Finnish families. Based on haplotype analysis, we mapped the gene between markers D16S2624 and D16S3090, an interval of 6,9 cM. Each family had their own disease haplotype in this region.

The aim of this study was to fine map the 6.9 cM region with single nucleotide polymorphisms (SNPs) to narrow down the candidate gene region. We collected SNPs from public databases, concentrating first on known genes and later expanding the SNP map to span over the whole genomic region. The most promising candidate genes were covered with a tighter marker map. We have presently genotyped 78 SNPs, with an average density of 66 kb, in our family material using a SNP micro-array method. Association in the presence of linkage was tested by FBAT and Pseudomarker but none of the SNPs has so far showed significant association. This could be due to small family material and incomplete penetrance of the disease gene. On the other hand, haplotype analysis has revealed a 462 kb haplotype block where four different haplotypes, shared by 14 families, can be observed.

Based on these preliminary results we can conclude that there must be more than one mutation responsible for KC in Finnish families. To ascertain the association of the 462 kb block to KC, we have now genotyped 100 control samples with 66 of the 78 SNPs. Analysis is in progress to determine the haplotype block structure in our candidate gene region in the Finnish population.

Linkage analysis using GeneChip Microarray maps new locus for microcephaly to chromosome 12q24. V.

Drasinover¹, S. Shalev², D. Marom¹, G. Rechavi^{3,4}, N. Amariglio^{3,4}, T. Shohat¹, M. Shohat^{1,4}, N. Magal¹. 1) Dept Medical Genetics, Rabin Medical Center and Felsenstein Medical Research Center, Petah Tikva, Israel; 2) Genetics Unit, Ha'emek Medical Center, Afula, Israel; 3) Department of Pediatric Hematology-Oncology, Safra Children's Hospital and Institute of Hematology, The Chaim Sheba Medical Center, Tel Hashomer, Israel; 4) Sackler Faculty of Medicine, Tel Aviv University, Israel.

We report a large Israeli Arab family with multiple consanguineous marriages in which 9 children have congenital microcephaly associated with severe mental retardation, spasticity and hyperreflexia. Dysmorphic features are mild and non-specific. A dense genomewide linkage search of the family was undertaken using Affimetix GeneChip Human Mapping 10K array. This microarray contains over 10,000 SNPS and therefore allows efficient genotyping. Initial analysis was performed on DNA from 4 affected family members. The results showed 5 different regions with homozygosity for the same allele in more than 10 loci in a row. These regions were further analyzed using polymorphic markers in affected and unaffected family members. Four of these loci were excluded. One locus on chromosome 12q24 was identified as a possible candidate locus for the gene. This interval contains homozygous SNPs and is 8.5Mb long. Haplotype analysis using different markers within this region narrowed the locus down to 6.2 Mb with a maximum lod score of 3.4 (= 0.00) at marker D12S837. This study identified a new locus responsible for microcephaly located on chromosome 12q24. Furthermore we demonstrated that GeneChip Microarray SNPs is an efficient technique in linkage analysis of inbred families with autosomal recessive diseases.

Identification of new dinucleotide-repeats in factor gene using fluorescent PCR. *J.W Kim¹, S.Y. Park¹, D.J. Kim¹, S.Y. Kim¹, J.Y. Han², H.M. Ryu^{1,2}.* 1) Laboratory of Medical Genetics, Samsung Cheil Hosp, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Sungkyunkwan University School of Medicine, Seoul, Korea.

Hemophilia A is an X-linked inherited bleeding disorder, and linkage diagnosis using polymorphic markers in the factor gene is used to archive the carrier detection and prenatal diagnosis. The objective of this study was to establish the allele frequency and heterozygosity rate (HR) of two new (Intron 1, and 24) and other intragenic markers (Intron 13, and 22) using fluorescent PCR. Five-hundred unrelated healthy women were screened, and a hemophilic family was studied for carrier detection and prenatal diagnosis. We observed five different alleles of Intron 1, 10 of Intron 24, 9 of Intron 13, and 6 of Intron 22. The observed HR for the Intron 1, 24, 13, and 22 were 34.0 %, 35.2 %, 53.0 %, and 42.6 %, while the expected HR were 33.6 %, 36.3 %, 50.1 %, and 44.3 % respectively. Linkage analysis with the combined use of all four intragenic markers gave the informative result of 76.6% (383/500) in the Korean females. In prenatal diagnosis of a hemophilic family, a pregnancy woman was heterozygous with 3 intragenic (Intron 1, 13, and 22) and 1 extragenic St14 VNTR markers. She was considered to be a carrier, and carried a male fetus by AMXY PCR and chromosome analysis of amniocytes. Fetus did not have the mutant haplotype as his uncle, suggesting a normal male status. Our study demonstrates utility of two new intragenic markers in factor gene for the carrier detection and prenatal diagnosis of hemophilic families.

A genomic map of the candidate susceptibility loci of multiple sclerosis in N. Ireland based on the GAMES studies of European populations. *H.H. Abdeen¹, S. Heggarty², S. Hawkins³, M. Hutchinson⁴, C. Graham¹.* 1) Molecular Genetics Laboratory, Belfast City Hospital, Belfast, UK; 2) School of Pharmacy, Queens University Belfast, Belfast, UK; 3) Department of Neurology, Royal Victoria Hospital, Belfast, UK; 4) Department of Neurology, St Vincent's Hospital, Dublin, Eire.

Whole genome screening for association represents a powerful tool for identification of the susceptibility genes involved in complex genetic diseases. Assuming that at least the major susceptibility loci have arisen from common ancestors, then they may contain markers in linkage disequilibrium (LD) with the susceptibility variants. Depending on the extent of LD, such loci are expected to show some clustering of associated markers which are shared through multiple populations. We used the recently published data of case-control studies of the 16 European populations included in the Genetic Analysis of Multiple sclerosis in Europeans (GAMES) project, to construct a genomic map of the top microsatellite markers potentially associated with multiple sclerosis (MS). These have been selected from thousands of markers typed in separately pooled DNA from patients and controls of each population. The map was screened for loci showing clustering of associated markers through two or more populations. The strongest clustering was observed in the confirmed HLA locus on chromosome 6p21. Clustering was also observed in another 29 loci including 15 of the regions previously identified in the N. Irish GAMES study and 14 of other populations. These genomic regions contain genes with crucial functions in the nervous system and immunoregulatory genes, representing typical candidates for MS. To date, the top 11 loci have been further investigated by individual typing of several microsatellite markers each, in a N. Irish cohort of 200 cases and 200 controls. Association was confirmed for five of the loci reported in the N. Irish GAMES study (chromosomes 2p13, 4p16, 11q23, 19p13 and 19q13) and two of other populations (chromosomes 7q21 and 10p12). This refined screen of the human genome should provide a clearer image of the major susceptibility loci which may help the identification of the candidate genes involved in MS.

Fine mapping of the 5p13 locus linked to schizophrenia and schizotypal personality disorder in a Puerto Rican family. *I.N. Bespalova¹, G.W. Angelo¹, C.J. Smith¹, M. Durner³, L.J. Siever¹, J. Carrion-Baralt¹, J.D. Buxbaum^{1,2}, J.M. Silverman¹.* 1) Dept Psychiatry, Mount Sinai School of Medicine, New York, NY; 2) Dept Neurobiology, Mount Sinai School of Medicine, New York, NY; 3) Dept Biostatistics, Columbia University, New York, NY.

A locus involved in schizophrenia and related disorders has previously been mapped to chromosome 5p13 in a large Puerto-Rican family (Silverman et al., 1996). The family is from an isolated and genetically homogeneous population with a high frequency of relatively rare autosomal recessive diseases (Gershoni-Baruch et al., 1994; Anikster et al., 2001). The maximum two-point LOD score of 3.72 was obtained for marker D5S111, and rose to 4.37 by multipoint analysis, assuming autosomal dominant inheritance with 90% penetrance. Additional genotyping and haplotype analysis in this family placed the locus within a 4.8 cM genetic interval between markers D5S1993 and D5S631 (Durner et al., in prep). In this study, we focused on a branch of Family 17 containing two affected key recombinants flanking the critical interval on chromosome 5p13. Haplotype analysis revealed maternal allele sharing in a nuclear family with twelve siblings, three of whom are affected with schizophrenia and two with schizotypal personality disorder. We have genotyped five additional published microsatellite markers and 37 suspected densely spaced polymorphic markers across the genetic interval. We precisely mapped recombination breakpoints in two affected individuals, refined the boundaries and narrowed the minimal critical region (MCI) to 2.8 Mb. Since G-protein coupled receptors are plausible candidate genes for schizophrenia, and one of them is in the minimal critical region, SALPR, we analyzed this gene for mutations by sequencing the coding and the putative promoter regions in three siblings affected by schizophrenia. Although several new polymorphisms were detected, our results exclude SALPR as the gene for schizophrenia and related disorders in this Puerto Rican family.

Genome scan of working memory component phenotypes of dyslexia. Z. Brkanac^{1,2}, N.H. Chapman¹, R.P. Igo¹, J.B. Thomson¹, M. Matsushita¹, T. Holzman¹, V.W. Berninger¹, E.M. Wijsman¹, W.H. Raskind^{1,2}. 1) University of Washington, Seattle, WA; 2) VISN 20 MIRECC, VA PSHCS; Seattle, WA.

Dyslexia is a common disorder with complex genetics, as phenotypes do not show Mendelian patterns of inheritance. To reduce heterogeneity and increase the chances for linkage detection, we are using extensive phenotypic evaluations coupled with univariate component-based linkage analyses. We have previously shown through family aggregation and segregation analyses that working memory phenotypes have a genetic basis in our study families. We have assessed working memory with the Digit Span (DS) subtest of the WAIS-R and WISC-III. Phonological working memory was assessed with the Non Word Memory (NWM) task of the Comprehensive Test of Phonological Awareness. Families were collected through probands who had a Verbal IQ (VIQ)>90 and both performance below the population mean and discrepancy of 1 SD between VIQ and performance on at least one of ten dyslexia measures.

A genome scan with an average 10 cM resolution was performed on 438 people from 51 families selected on the basis of power to detect linkage for NWM. Multipoint Variance Component (VC) and Markov-chain Monte Carlo (MCMC) multipoint joint linkage and segregation analysis were performed. For NWM we observed numerous regions where VC dominance lod scores exceeded 1.5 and MCMC intensity ratios (IR) exceeded 5.0, well above the background level for the genome scan. VC-lod scores >2.0 that were supported by IR scores >5 were observed on chromosomes 2q, 4p, 6q, 17q, and 22q. VC-lod scores >1.5 were observed for DS on chromosomes 4q, 13p and 22q. MCMC IR results >5 for DS were detected on chromosomes 5q and 14q. Analysis of NWM adjusted for DS reduced the number of regions with VC-lod >1.5 and revealed an additional location on chromosome 7q with VC lod >2.0 and MCMC IR>5.

This study has identified novel loci potentially linked to NWM in families with dyslexia. DS has not shown strong evidence for linkage. Analysis of additional families will be needed to further refine these findings.

Sibpair linkage analyses using SNP genotypes as covariant suggests that two candidate genes 11 cM apart on chromosome 3 may independently contribute to prostate cancer risk. *Y. Ding, G. Larson, T.G. Krontiris, The ECOG E1Y97 Study Group.* Beckman Res Institute, City of Hope, Duarte CA.

We conducted single point linkage analysis of over 80 candidate genes in 402 brothers affected with prostate cancer from 201 families. Markers representing two adjacent candidate genes on chromosome 3p, *CDC25A* and *FHIT*, demonstrated suggestive evidence for linkage with identity by descent (IBD) allele-sharing statistics. Fine-structure multipoint linkage analyses were performed using LODPAL (S.A.G.E.) and MERLIN. The strongest evidence of linkage was detected for D3S1234 (located in intron 5 of *FHIT*) at 81.23 cM (maximum LOD score = 3.15, $p = 0.00007$) using LODPAL, and for both *CDC25a2* (15 kb downstream of *CDC25A*) at 70.55 cM ($NPL_{all} = 1.90$, $p = 0.03$) and D3S1234 ($NPL_{all} = 1.84$, $P = 0.03$) using MERLIN. For a subset of 38 families in which three or more affected brothers were reported, LODPAL generated a maximum LOD of 3.83 ($p = 0.00001$) at D3S1234 and a secondary peak of 2.19 at *CDC25a2*), while MERLIN produced a maximum NPL_{all} of 2.94 ($p = 0.002$) at *CDC25a2* and a smaller peak of 2.38 ($p = 0.009$) at D3S1234. We then genotyped 16 SNPs covering a 381 kb region surrounding D3S1234 and 5 SNPs spanning 148 kb region surrounding *CDC25A* on one case from each family. Using LODPAL with one-parameter model incorporating individual SNPs as covariate, we evaluated each SNP for their genotype correlation with excessive IBD sharing in all families. We found one SNP from each region with significantly increased maximum LOD scores of 5.02 and 4.72 at D3S1234 ($\alpha = 100$) and *CDC25a2* ($\alpha = 7$), respectively. Permutation tests of random SNP genotype designation to each family assuming the same genotype frequency, missing data, and value of α demonstrated a p value of ~ 0.01 for the associated SNP at D3S1234 and $p < 0.001$ for the SNP at *CDC25a2* to generate maximum LOD exceeding observed ones. These results suggest that both candidate genes *CDC25A* and *FHIT* may independently be involved in prostate cancer risk. They also demonstrate potential advantages using SNP genotypes as covariate to reduce heterogeneity and to pinpoint disease locus in the absence of unaffected controls.

Childhood cortical bone mass linked to chromosome 3p. *D.L. Duren¹, J. Blangero², T. Dyer², S.A. Cole², A.F. Roche¹, R.M. Siervogel¹, B. Towne¹.* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX.

Genetic influences on bone mass are known almost entirely from studies of adults. Despite growing awareness regarding the importance of bone mineral accrual during childhood to later bone health, few studies have examined the genetic underpinnings of childhood bone mass. In this study, we examined radiographic cortical thickness of the second metacarpal in 600 participants from the Fels Longitudinal Study at chronological age 10 years. These individuals are from 144 nuclear and extended families. Medial and lateral cortical measurements and bone diameter, were taken perpendicular to the long axis of the bone. An initial set of 356 of these individuals have been genotyped for ~400 autosomal markers spaced approximately every 10 cM. A variance components-based linkage analysis method (SOLAR; Almasy and Blangero, 1998) was used to obtain multipoint LOD scores. Ten suggestive LOD scores (> 1.9) were found for the following traits: cortical index, total cortex, lateral cortex, medial cortex, and polar moment of inertia. More importantly, two significant LOD scores (> 3.0) were found for linkage of cortical thickness measures to markers on chromosome 3 a LOD of 3.29 for linkage of total cortex to a QTL on 3p at 24 cM, and a LOD of 4.13 for linkage of lateral cortex to a QTL on 3p at 26 cM (both located between markers D3S1304 and D3S1263). One potential positional candidate gene residing in this region is the OXTR (oxytocin receptor gene). Because the oxytocin receptor was recently found to be functional in both osteoblasts and osteoclasts, and has binding affinity to both oxytocin and estrogen, OXTR is a plausible candidate gene for childhood bone accrual. These results also suggest the existence of genes on chromosomes 2, 3, 4, 10, and 12 that influence measures of bone mass at age 10. Future work will seek to identify other specific genes that influence the accrual of bone mass at different stages of childhood development. Supported by NIH grants HD36342, HD12252, and MH59490.

Association and linkage analysis of the dyslexia susceptibility locus (DYX3) on chr 2p15-p16. *T. Fagerheim^{1,2}, E. McAuley², F-E. Tonnessen³, S.D. Smith⁴, R.K. Olson⁵, B.F. Pennington⁶, J.C. DeFries⁵, A.P. Monaco².* 1) Dept Medical Genetics, University of Tromsø, Tromsø, Norway; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 3) University College of Stavanger, Centre for reading research, Stavanger, Norway; 4) Center for Human Genetics, University of Nebraska medical Center, Omaha, Nebraska; 5) Institute for Behavioral Genetics, University of Colorado, Boulder, Colorado; 6) University of Denver, Colorado.

Approximately 3-10% of people have specific difficulties in reading, despite normal intelligence, adequate education and social environment. Developmental dyslexia is viewed as a biologically complex behavioural disorder with genetic factors playing a significant role in predisposition towards the phenotype. We have previously mapped a susceptibility gene for dyslexia to 2p15-p16 (DYX3 locus) and the location has been replicated by independent studies in other populations (Canadian, UK, and US). We initiated SNP-based association screening of genes in the DYX3 locus and extended the analysis to genes surrounding the critical region. SNPs were selected based on LD information extracted from the HapMap project. 60 SNPs targeting 18 genes covering a 16.5 Mb region were genotyped in a sample of 120 twin-based families from Colorado. The most interesting association ($P = 0.006$) was found with a SNP within the NRXN1 gene for two reading related measures. In addition to association analysis, we decided to do a reanalysis of the DYX3 region from a previous genome-wide scan of the US families (120 original families) using the latest updated genetic map, new phenotypic data and including SNP data from the region. Multipoint Haseman-Elston linkage analysis gave the highest LOD score of 2.17 for reading related scores, and multipoint Variance component linkage analysis gave a maximum LOD score of 2.20 for an orthographic test. The results provided a refined candidate region. Additional SNPs will be selected for association and linkage analysis and additional sets of UK families and twin-based US families will be analysed for replication of any positive associations.

Genomic regions linked to fat storage in infants. *D. Fradin*¹, *S. Heath*², *M. Lathrop*², *P. Bougneres*¹. 1) Dpt of Pediatric Endocrinology & U561 INSERM, Hôpital Saint Vincent de Paul Paris, France; 2) National Center of Genotyping, Evry, France.

Fat stores deposited in response to abundant caloric supply are necessary to sustain the large needs for brain development in humans when infants face fasting periods. The ability for fat storage is thus likely to be an important physiological trait of human fitness. We used a sib-pair approach to characterize the genetic factors influencing fat deposition during the first two years of life. In a sample of 220 French families, we performed a genome wide linkage scan with 400 microsatellite markers to identify genomic regions that contain quantitative trait loci (QTLs) influencing body mass index (BMI), a quantitative measurement of fatness, at 2 years of age. After adjustment for sex, we found a strong linkage of the 8p12 region (LOD=2.56, $p=3.10^{-4}$) with infants BMI. The 7q31 region was also linked to BMI (LOD=1.11, $p=0.012$), as well as six other regions on chromosomes 15 (15q13.3 : D15S994, LOD=1.1, $p=0.012$), 10 (10q22-23 : D10S185, LOD=1.01, $p=0.002$), 5 (5p14.1 : D5S419, LOD=1.07, $p=0.013$ et 5q32 : D5S436, LOD=1.49, $p=0.004$), 8 (8q12.1 : D8S285, LOD=1.65, $p=0.003$ et D8S260, LOD=1.02, $p=0.02$) and 11 (11q22.1 : D11S4175, LOD=1.05, $p=0.014$ et D11S898, LOD=1.19, $p=0.01$). It is interesting that genome scans performed in adults have also identified the linkage of the 8p12, 7q31, 15q13.3 and 10q22-23 regions to obesity. No other regions showing linkage to infant BMI have been identified in adult studies of BMI. Our results suggest that the genetic factors influencing the variability of fat deposition in humans are not likely to be similar in infancy and adulthood ; however, some of them may be common to these two periods of life.

Comprehensive analysis of common variation in sex steroid pathway genes for a contribution to risk of SLE. *R. Graham*¹, *P. de Bakker*¹, *N. Burt*¹, *W. Ortmann*², *P. Rodine*², *B. Henderson*³, *D. Altshuler*¹, *T. Behrens*². 1) Molecular Biology, Harvard Medical School, Massachusetts General Hospital, Boston, MA; 2) Rheumatology and Autoimmune Diseases, School of Medicine, University of Minnesota, Minneapolis, MN; 3) Preventative Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA.

Autoimmune diseases typically exhibit a strong gender bias. In Systemic Lupus Erythematosus (SLE), the gender bias is among the most pronounced (female:male ratio, 9:1) and female gender remains the strongest known risk factor. Several lines of evidence indicate a direct role for sex steroids in modulating SLE incidence and severity, including: i) correlation of disease incidence with sex steroid hormone levels ii) direct modulation of sex steroid levels in murine models of lupus iii) efficacious treatment of model organisms and humans with anti-estrogens and androgens. Our goal is to test the hypothesis that inherited variation in the sex steroid hormone pathway influences individual risk of SLE. As part of an ongoing collaboration by Broad Institute of Harvard and MIT and the Multiethnic Cohort Study, genetic variation in 35 genes central to the sex steroid hormone pathway has been extremely well characterized. Coding regions have been resequenced in 192 individuals, and a total of 3,000 SNPs spanning 3Mb of DNA (>1 SNP per kb) have been genotyped in >2,000 chromosomes of diverse ancestry to define patterns of linkage disequilibrium. From this unusually rich dataset an efficient and informative set of SNPs (tagSNPs) have been selected to capture the vast majority of variants. We have identified and are completing genotyping of the first 750 tagSNPs from 35 genes in 215 SLE families (>1500 chromosomes). We will present analysis of single variants and combinations of variants for association to risk of SLE.

Combinatorial mismatch scan for loci associated with dementia in the Amish. *D.W. Hahs¹, A. Crunk¹, P.C. Gaskell², W.K. Scott², K.A. Welsh-Bohmer², S.R. Johnson², C.E. Jackson³, M.A. Pericak-Vance², J.L. Haines¹.* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics, Duke University, Durham, NC; 3) Scott & White, Temple, TX.

The Amish located in Indiana and Ohio are relatively isolated populations that may have increased power to detect disease susceptibility genes. Combinatorial mismatch scanning (CMS) (Heath et al., Hum Hered 2001;52:183) was developed to assess IBD sharing in distantly related individuals from such populations where standard linkage and association analyses are difficult to implement. Individuals used in this comparison were derived from six pedigrees with a total of 131 tested and genotyped individuals. Affected individuals were ascertained using the Modified Mini-Mental State (3MS) Examination and a score <87 was considered suspicious for cognitive impairment. 13 dementia cases and 13 normal controls were identified who were not related back to the grandparental generation. Comparisons were done using two Fishers exact tests, one for excess in IBD allele frequency and the other for excess in IBD genotype frequency at 417 microsatellite markers. Using the allele frequencies, 31 markers (7%) were associated with dementia at a nominal level of statistical significance ($p < 0.05$); the most significant ($p < 0.005$) were D3S1262, D5S211, D8S1477, and D19S1156. Using the genotype frequencies, 24 markers (6%) were statistically significant ($p < 0.05$); the most significant ($p < 0.005$) markers were D5S1347, D5S1480, and D5S211, spanning 36 cM. The only marker significant at the $p < 0.005$ level using both tests was D5S211. Three of the four markers with $p < 0.005$ on the allelic test were also significantly associated using the genotype test (for D19S1156, the genotype test p-value was 0.07). For nine markers p values < 0.05 were obtained for both tests: D3S1262, D4S1625, D5S211, D6S1031, D8S1477, D8S272, D10S1221, D17S921, and D18S481. Two-point lod score analysis detected a signal (lod = 2.155) at D4S1548, 8 cM from D4S1625 and another signal (lod = 2.188) at D5S1725 located 6 cM from D5S1347. The convergence of these two methods suggests that loci on chromosomes 4 and 5 may be involved in dementia.

Combined analysis of four genome scans indicates linkage with lipid parameters on chromosomes 2, 12 and 19.

B.T. Heijmans¹, M. Beekman¹, H. Putter², H.J. Van der Wijk², J.B. Whitfield³, R.R. Frants⁴, U. DeFaire⁵, N. Lakenberg¹, D.T. OConnor⁶, N.L. Pedersen⁵, N.G. Martin⁷, D.I. Boomsma⁸, P.E. Slagboom¹. 1) Molecular Epidemiology, Leiden University Medical Centre, The Netherlands; 2) Medical Statistics, Leiden University Medical Centre, The Netherlands; 3) Clinical Biochemistry, Royal Prince Alfred Hospital, Sydney, Australia; 4) Human and Clinical Genetics, Leiden University Medical Centre, The Netherlands; 5) Karolinska Institute, Stockholm, Sweden; 6) Department of Medicine, University of California at San Diego, CA; 7) Queensland Institute for Medical Research, Brisbane, Australia; 8) Biological Psychology, Vrije Universiteit Amsterdam, The Netherlands.

Elevated lipid levels in plasma are key risk factors for cardiovascular diseases. To map quantitative trait loci for lipid levels, genome-wide scans were performed in Dutch, Swedish and Australian twins. A new statistical procedure was devised to simultaneously analyse data from multiple genome scans. The study focussed on plasma levels of LDL-cholesterol and its protein constituent apolipoprotein B and on HDL-cholesterol and its main protein constituent apolipoprotein AI. Genome-wide scans with an average marker spacing of 5-10 cM were performed in 1388 dizygotic twins (694 pairs) from The Netherlands (200 pairs), Sweden (44 pairs) and Australia (450 pairs). For the simultaneous analysis, merlin-regress was used to estimate QTL heritabilities and standard errors for each of the populations separately. These estimates were then combined into a single heritability estimate by calculating the mean of population-specific heritabilities weighted according to the inverse of the squared standard error. Importantly, the analysis allows for heterogeneity between populations. LOD-scores higher than 2 were observed for HDL-C on chromosome 12q at 93 cM (LOD=2.5) and for LDL-C on 19q at 70 cM (LOD=2.4). On 2q at 186 cM, a LOD-score of 1.9 was observed for both LDL-C and ApoB levels. The contribution to the linkage signals was investigated for 19 SNPs in positional candidate genes using combined/linkage association analysis.

Genetic Association of TAS2R16 Taste Receptor on Chromosome 7 with Alcohol Dependence. A. Hinrichs¹, J.C. Wang¹, J.M. Kwon², S. Bertelsen¹, D. Dick¹, J. Budde¹, R. Allen¹, H. Stock¹, R. Crowe³, V. Hesselbrock⁴, M. Schuckit⁵, H. Begleiter⁶, B. Porjesz⁶, H. Edenberg⁷, T. Reich¹, L.J. Bierut¹, A.M. Goate¹. 1) Dept Psychiatry, Washington Univ Sch Med, St Louis, MO; 2) Depts of Neurology and Pediatrics, University of Rochester Medical Center, Rochester, NY; 3) University of Iowa School of Medicine, Iowa City, IA; 4) University of Connecticut School of Medicine, Farmington, CT; 5) UCSD School of Medicine, La Jolla, CA; 6) SUNY Health Science Center at Brooklyn, Brooklyn, NY; 7) Indiana University School of Medicine, Indianapolis, IN.

The Collaborative Study of the Genetics of Alcoholism (COGA) is a large multicenter study whose goal is to find genes that modify susceptibility to alcohol dependence and related phenotypes. A strong finding (LOD=2.9) on chromosome 7q is located at a cluster of bitter taste receptors (TAS2R). One member of this cluster, TAS2R16, is a receptor for bitter beta-glucopyranosides (such as salicin). We identified three polymorphic SNPs from the NCBI database including two non-synonymous coding SNPs, rs860170 and rs846664. The rs846664 SNP shows association using the TDT (with Transmit) for COGA (i.e. DSM-III-R and Feighner definite) and DSM-IV diagnoses of alcohol dependence ($p=0.01$ and 0.002). An additional set of trios (two parents and one COGA alcohol dependent child) unrelated to the linkage screening set was also genotyped and also showed association with the TDT ($p=0.03$). With the original sample and the additional trios we achieve a p -value of 0.002 with the COGA alcohol dependence diagnosis. We stratified the linkage sample into those families containing the mutation and those without. The pedigrees with the mutation have a sharing of 60.9% at the linkage peak on chromosome 7 for the COGA diagnosis. The families without the mutation have a sharing of 55.8% (overall sharing is 56.5%). It appears that although only 15% of the families have the mutation, those families contribute disproportionately to the linkage signal. Together these analyses provide strong evidence that variation in the TAS2R16 gene is associated with the risk for alcohol dependence.

Genome-Wide significant Non-MHC locus in Rheumatoid Arthritis families from Iceland. *A. Karason¹, K. Steinsson², V.B. Hauksson¹, E. Halapi¹, H. Jonsson¹, G. Jonsdottir¹, J.R. Gulcher¹, K. Stefansson¹, H. Hakonarson¹.* 1) deCODE Genetics, Reykjavik, Iceland; 2) University National Hospital, Reykjavik, Iceland.

Rheumatoid arthritis (RA) is a common complex inflammatory disease affecting approximately 1% of the population and is associated with reduced life expectancy. RA has a complex etiology with women being affected more frequently than men (sex ratio 3:1). Susceptibility to RA has long been associated with the Human Leukocyte Antigen (HLA) class. Specifically, the tightest association has been with DRB1*0401 and other class II HLA alleles, though it is speculated that the genetic contribution of the HLA alleles is less than 50%. RA may be triggered or exacerbated by several environmental factors such as smoking and it shows increasing frequency with increased hemispherical latitude. We performed a genome-wide scan with 1,200 microsatellite markers in 160 extended Icelandic families including 500 RA patients and over 900 of their first degree relatives. All study subjects signed an informed consent, underwent comprehensive phenotype studies to confirm the RA phenotype with respect to ACR criteria 1-7 and DRB1 status. Additional markers were typed at loci with lod scores of 2 or higher to increase the information content. Genome-wide linkage analysis demonstrated genome-wide significant (GWS) linkage on chr 3q with allele-sharing lod scores of 4.2. By typing 55 additional markers the lod on chr 3q rose from approximately 3 to 4.2 and the interval defining drop of one in lod (D3S1577 to D3S1271) narrowed to around 5 cM. We conclude that a GWS locus is present on chr 3q in patients with RA, a locus that corresponds in location to loci found in other autoimmune/inflammatory disorders. We anticipate that the gene we have mapped will significantly improve our understanding of the pathogenesis of RA and ultimately allow for new and more effective therapies to be developed.

Genetic linkage studies of stuttering in a large West African kindred. *B. Levis¹, D. Ricci¹, J. Lukong², D. Drayna¹.*
1) NIDCD/NIH, Rockville, MD. 20850; 2) Speak Clear Association of Cameroon, Douala, Cameroon.

Stuttering is a common speech disorder characterized by interruptions in the flow of speech, including prolongations of sounds, repetition of sounds or syllables and/or silent blockages. Although the fundamental cause of stuttering is unknown, both genetic and non-genetic factors are involved. Evidence for genetic factors of stuttering come primarily from twin studies, suggesting concordance rates of ~60% and ~20% in MZ and DZ twins, respectively, and a previously published linkage study of stuttering in North American families, identifying a locus chromosome 18. We are investigating the genetic causes of stuttering in a large, English-speaking West African family in which stuttering occurs as a trait with a simple inheritance pattern. This family contains 106 individuals in 5 generations, 45 of whom stutter as adults. We obtained DNA and speech samples from 44 members of this family and performed a complete genome wide scan using the Weber Marshfield panel 9, containing 394 microsatellite markers with an average spacing of 10 cM. Parametric multipoint linkage analyses under a model of autosomal dominant with reduced penetrance gave a maximum LOD score of 4.39 with markers on chromosome 1. To facilitate more precise localization of the gene causing stuttering in this family, we propose to search for a founder effect and Identity by Descent in apparently unrelated individuals in this population. To support this effort, we have obtained DNA and speech samples from 57 unrelated individuals who stutter and 50 normal controls from this population, and we are performing SNP genotyping for association studies at loci across the region showing linkage.

Dissection of BXSB lupus phenotype using mice congenic for chromosome 1 demonstrates that separate intervals direct different aspects of disease. *B.J. Morley¹, N.J. Rogers², S.J. Rose¹, J. Boyle³, S. Izui⁴, M.E.K. Haywood¹*. 1) Rheumatology Section, Eric Bywaters Centre, Faculty of Medicine, Imperial College, Hammersmith Campus, Du Cane Road, London, W12 0NN, United Kingdom; 2) Department of Immunology, Faculty of Medicine, Imperial College, Hammersmith Campus, Du Cane Road, London, W12 0NN, United Kingdom; 3) Histopathology Department, Hammersmith Hospital, Du Cane Road, London, W12 0NN, United Kingdom; 4) Department of Pathology, Centre Medical Universitaire, Geneva, Switzerland.

The BXSB mouse strain is an excellent model of proliferative glomerulonephritis seen in human Systemic Lupus Erythematosus (SLE) patients. Extensive linkage analysis has identified six non-MHC, autosomal loci (*Bxs1-6*) that contribute to SLE susceptibility in BXSB mice. In order to dissect the effects of the four chromosome 1 loci, we generated congenic lines on a C57BL/10.Y^{BXSB} (B10.*Yaa*) background.

Nephritis, qualitatively similar to BXSB, developed in three of these congenic strains. Early-onset, severe disease was observed in B10.*Yaa*.BXSB-*Bxs2/3* congenic mice and caused 50% mortality by 12 months. The delay in disease, compared to the BXSB parental strain, illustrated the necessity for multiple genetic interactions in the production of the full BXSB phenotype. Monocytosis, seen as a characteristic of BXSB was only present in the B10.*Yaa*.BXSB-*Bxs2/3* strain, and a recently developed sub-congenic has narrowed the genetic region responsible for this phenotype. In B10.*Yaa*.BXSB-*Bxs1/4* mice, disease progressed more slowly, resulting in 13% mortality at 12 months. B10.*Yaa*.BXSB-*Bxs1* mice, despite their genetic similarity to B10.*Yaa*.BXSB-*Bxs1/4* mice, developed only a low-grade glomerulonephritis with no detectable anti-dsDNA antibodies. Conversely, the *Bxs2* interval was linked to the production of anti-dsDNA Abs without concomitant glomerulonephritis. This panel of congenic mice provides an excellent resource in which to dissect the complexities of the genetic basis of lupus.

A study of linkage of anthropometric traits related to obesity in the Old-Order Amish. *G.J. Papanicolaou¹, P. Platte², C.M. Klein³, K.F. Doheny⁴, M.H. Roy-Gagnon¹, A.J. Stunkard⁵, C.A. Francomano⁶, A.F. Wilson¹.* 1) Genometrics Section, NIH/NHGRI/IDRB, Baltimore, MD; 2) Biological & Clinical Psychology, Univ. Wuerzburg, Germany; 3) Psychobiology & Psychosomatic Research, Univ. Trier, Germany; 4) CIDR, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Dept. Psychiatry, Univ. Pennsylvania, Philadelphia, PA; 6) NIA, NIH, Baltimore, MD.

Today nearly two-thirds of the U.S. population are overweight and over thirty percent are obese. As part of an ongoing study of traits related to obesity in the Old-Order Amish, seven two- and three- generation families, totaling 157 individuals (with a mean sibship of 7.2), were assessed for 21 obesity related traits including fat mass, and height, weight, hip and waist measurements. Genotyping was performed at the Center for Inherited Disease Research (Baltimore, MD) with a modified Marshfield Genetics 8 marker set consisting of 384 short tandem repeat markers with an average distance of 9 cM. Pair-wise model-independent linkage analysis identified candidate regions ($p < 0.001$) for fat mass, height, hip circumference, lean body mass, maximum lifetime weight, waist circumference, weight, and waist to hip ratio. Markers on Chromosomes on 7q, 8q, and 11q map to a number of the traits (including: height, hip and waist circumference, study and maximum lifetime weight), suggesting possible pleiotropic effects or a common etiology for the phenotypes examined.

A QTL on 6p22 is showing significant association to dyslexia in two independent samples. *S. Paracchini*¹, *C. Francks*¹, *S.D. Smith*², *A.J. Richardson*³, *T.S. Scerri*¹, *L.R. Cardon*¹, *A.J. Marlow*¹, *I.L. MacPhie*¹, *J. Walter*³, *B.F. Pennington*⁴, *S.E. Fisher*¹, *R.K. Olson*⁵, *J.C. DeFries*⁵, *J.F. Stein*³, *A.P. Monaco*¹. 1) WTCHG, Univ Oxford, UK; 2) Dept of Pediatrics, Univ Nebraska, Omaha, NE; 3) Dept of Physiology, Univ Oxford, UK; 4) Dept of Psychology, Univ Denver, CO; 5) Institute for Behavioral Genetics, Univ Colorado, Boulder, CO.

Dyslexia is one of the most prevalent of childhood cognitive disorders, and is caused in large part by genetic factors. Linkage studies have identified several regions that may contain quantitative trait loci (QTL) for this disorder. The most consistently replicated linkage is on 6p21.3-23, which has been found in five independent samples, including our own (224 UK siblings). We have previously shown using multivariate linkage analysis that the QTL on 6p21.3-23 influences variability shared between reading-related measures, but not shared with measures of general intelligence (IQ). By controlling for IQ in linkage analysis we have now refined the mapping of the QTL to a 5.8 Mb interval. We then used association analysis in our sample of 224 UK siblings to identify an underlying QTL on 6p22. We detected significant association across a 77 kb region of strong intermarker linkage disequilibrium that spans the first four exons of *KIAA0319*, the entire *TTRAP* gene, and the first exon of *THEM2*. We replicated these associations in a second set of UK siblings, and in an independent sample of US twin-based sibships. One haplotype, with 12% frequency in both the UK and US samples, is significantly associated with poor performance on several reading-related measures ($P=0.005$ for irregular word reading, $P=0.00007$ for orthographic coding, $P=0.002$ for single word reading and $P=0.02$ for spelling in the UK sample, and $P=0.02$ for single word reading, spelling and phonemic awareness in the US sample). Mutation screening of the exons and predicted promoters of *TTRAP*, *KIAA0319* and *THEM2* in 32 probands did not reveal coding changes that have obvious disruptive effects on these genes or that tag the risk haplotype. Functional studies of these genes are now required to determine the mechanism of pathogenesis.

17q25 is a candidate susceptibility region for TS: a study of two independent family samples. *P. Paschou¹, Y. Feng², A.J. Pakstis¹, W.C. Speed¹, M.M.C. DeMille¹, J.R. Kidd¹, B. Jaghori², R. Kurlan³, D.L. Pauls⁴, P. Sandor^{2,5}, C.L. Barr^{2,6}, K.K. Kidd¹.* 1) Department of Genetics, Yale University School of Medicine, New Haven, CT, USA; 2) Toronto Western Research Institute, University Health Network, Toronto, ON, Canada; 3) Cognitive and Behavioral Neurology Unit, Department of Neurology, University of Rochester School of Medicine, Rochester, NY, USA; 4) Psychiatric and Neurodevelopmental Genetics Unit, Department of Psychiatry, Massachusetts General Hospital, Harvard Medical School, Charlestown, MA, USA; 5) Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 6) Department of Psychiatry, Brain and Behaviour Programme, The Hospital for SickChildren, Toronto, ON, Canada.

Tourette Syndrome (TS) is characterized by motor and phonic tics and high comorbidity rates with other neurobehavioural disorders. The complex genetic background of the disorder remains elusive. In this study we explored the possibility that 17q25 contributes to TS susceptibility. The initial scan of chromosome 17 performed on two large pedigrees provided a non-parametric lod score of 2.41 close to D17S928. Fine mapping with 17 additional microsatellite markers increased the peak to 2.61. The original families as well as two additional pedigrees were genotyped for 25 SNPs, focusing on three genes in the indicated region that could play a role in the development of TS. Multiple three-marker haplotypes spanning all three genes studied provided significant association results ($P < 0.001$). An independent sample of 96 small families was also studied. Three of the 25 SNPs were associated with TS. The transmission/disequilibrium test for a three-marker haplotype moving window again provided multiple positive results. The background linkage disequilibrium (LD) of the region was studied in eight European populations. The pairwise tests produced unexpectedly high LD values at the telomeric TBCD gene. In conclusion our findings warrant the further investigation of 17q25 as a candidate susceptibility region for TS. [This work has been supported by NINDS-R01-NS40024. P. Paschou is supported by a Tourette Syndrome Association Research Grant Award.].

Fine-mapping of an asthma susceptibility locus on chromosome 12q using a high-resolution ldTag SNP set. *B.A. Raby¹, R. Lazarus¹, E.K. Silverman¹, A. Montpetit², J.F. Olivier², T.J. Hudson², S.T. Weiss¹*. 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) McGill University and Genome Quebec Innovation Center, Montreal, QC.

Chr.12q is among the regions most commonly linked to asthma in both genome-wide and regional linkage studies. At least two distinct loci on 12q have been described: a 28.5cM region located between 48-76.5Mb from pter, and a more telomeric locus at 108-128Mb. We have previously demonstrated evidence for linkage with asthma to the proximal locus in 55 nuclear families ascertained through the Childhood Asthma Management Program (CAMP). To narrow this region more precisely, we are using a high-resolution SNP map across the 28.5Mb region that will be genotyped using the Illumina BeadArray platform in 400 asthmatic children and their parents. SNPs selected for genotyping represent a subset of 4025 SNP with genotype data generated by the international HapMap project on 30 Caucasian CEPH trios (Jan 2004 release). We applied an algorithm that selects an optimal subset of SNP for genotyping of minimal size to assure that all SNPs that will not be genotyped are in strong linkage disequilibrium (r^2 of at least 0.9) with those that are typed. 1611 ldTag SNPs were identified (representing 64% of all SNPs with minor allele frequencies of at least 0.05 and less than 5% missing genotype data). Median r^2 between these 1611 SNPs and the remaining unselected SNPs was 0.97. From this subset assays were designed for 1536 and typed on 400 nuclear families. The June 2004 HapMap data release included ~ 2000 more SNPs for this region. We evaluated the ability of the LD-tagging SNP set generated from the original data to tag these additional SNPs. For the 3192 polymorphic (minimum MAF 0.05) SNPs not typed, the median r^2 with the typed ldTag SNPs was 0.93, with less than 22.5% of untyped SNPs having r^2 of 0.5 or less. These preliminary analyses suggest that the combined use of HapMap data and an LD-tagging fine mapping approach will provide adequate genomic coverage to enable localization of genetic variants in complex traits. The pending results of the family-based association analysis in our asthma study will be presented.

Chromosomes 4q35 and 16q23 show evidence of linkage to autoimmunity loci in lupus pedigrees. *P.S. Ramos¹, J.A. Kelly², A.N. Leiran¹, C.M. Meyer¹, K.J. Espe¹, W.A. Ortmann¹, G.R. Bruner², J.M. Olson³, T.W. Behrens¹, J.B. Harley², K.L. Moser¹.* 1) University of Minnesota, Minneapolis, MN; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) Case Western Reserve University, Cleveland, OH.

Numerous studies have suggested the existence of autoimmunity-predisposing genes. We have used autoimmunity traits as intermediate phenotypes for mapping genes in systemic lupus erythematosus (SLE) and other autoimmune diseases. We have defined autoimmunity traits based on lupus-related autoantibody profiles in 229 families multiplex for SLE. We measured frequencies, familial aggregation and correlations of autoantibodies directed against Ro/SSA, La/SSA, nRNP, Sm, dsDNA, rheumatoid factor, and antinuclear antibodies (ANAs) and antiphospholipid antibodies (aPL IgG and aPL IgM). We identified evidence of familial aggregation for anti-La, anti-nRNP, and anti-Sm ($p < 0.05$). We then performed linkage analysis using these traits in two independent pedigree collections (OMRF and MN). Non-parametric genome wide linkage analyses were performed using both the revised Haseman-Elston algorithm (SIBPAL) and an affected relative pairs approach (LODPAL) to identify chromosomal regions of increased allele sharing. We obtained significant evidence for linkage ($p < 0.000022$) on chromosome 16q23 with anti-nRNP as the trait in the OMRF collection, and suggestive evidence ($p < 0.00074$) in the same region with ANAs in the MN collection. In previous studies, significant evidence for linkage to type I diabetes has been reported to this same region. We also obtained suggestive evidence for linkage on 4q35 when using the presence of Ro and/or La autoantibodies as the trait with the OMRF collection. This region is of interest because it overlaps with the psoriasis PSORS3 locus, and both anti-Ro and anti-La are associated with cutaneous manifestation of SLE. Additional loci were identified using other autoantibody traits. These results show that using autoantibody traits as intermediate phenotypes provides evidence of the presence and locations of genes that are involved in the development of autoimmunity.

A novel locus on chromosome 2 for speed of phonological decoding. *W.H. Raskind^{1,2}, R.P. Igo³, N.H. Chapman³, J.B. Thomson⁴, M. Matsushita¹, Z. Brkanac^{2,6}, T. Holzman⁵, M. Brown¹, V.W. Berninger⁴, E.M. Wijsman^{1,3}.* 1) Departments of Medicine; 2) Psychiatry and Behavioral Sciences; 3) Biostatistics; 4) and Educational Psychology; 5) and the Locke Computer Center, University of Washington; 6) and VAPSHCS, Seattle, WA.

Dyslexia is a common developmental disorder manifested by unexpected difficulty in learning to read. Impaired phonological decoding (translation of written words into spoken words, without meaning cues) is thought to be the core deficit. We present a 10 cM genome scan of two continuous measures of phonological decoding ability: word attack (WA), and phonemic decoding efficiency (PDE). PDE measures both accuracy and speed of phonological decoding, whereas WA measures accuracy alone. Analyses were performed for PDE, WA, and PDE adjusted for WA using multipoint variance component linkage analysis (VC) and Markov chain Monte-Carlo (MCMC) multipoint joint linkage and segregation analysis methods, on 108 families containing 874 people in total. A subset of 51 families comprised of 438 sampled people was genotyped. The remaining families were used for parameter estimation. The MCMC results are reported as intensity ratios (IRs), which are estimates of the ratio of the posterior to prior probability of linkage.

The strongest signal was observed on chromosome 2 for PDE using both VC and MCMC methods (lod=2.65, IR=32.1). This signal was not seen for WA. For PDE adjusted for WA, the VC signal decreased but the MCMC signal was enhanced (lod=1.65, IR=74.2). Additional markers were genotyped in the region, and the lod score and IR for PDE increased to 3.0 and 59.5, respectively. Parametric analyses of PDE were also performed, using a model obtained by complex segregation analysis on 235 families. Maximum single-marker and multipoint lod scores were 1.84 and 2.89, respectively. In contrast, we found no evidence for linkage to regions on chromosomes 1, 2, 6, 11, or 18 that were previously implicated in phonological decoding. The consistency of results from three analytic approaches provides strong evidence for a locus on chromosome 2 that influences speed but not accuracy of phonological decoding.

Linkage Studies of Stuttering in Inbred Pakistani Families. *N. Riaz*¹, *S. Steinberg*³, *J. Ahmad*², *S. Riazuddin*², *A. Pluzhnikov*³, *N. Cox*³, *D. Drayna*¹. 1) NIDCD/NIH, Rockville, MD; 2) CEMB, University of Punjab, Lahore, Pakistan; 3) Department of Human Genetics, University of Chicago, Chicago, IL.

Stuttering is a communication disorder that affects speech fluency, and is diagnosed by the presence of syllable repetitions, syllable prolongations, and interruptions in the smooth flow of speech known as blocks. Many types of evidence suggest genetic factors contribute to stuttering. Because the genetics of stuttering is complex, we have sought specialized populations to give added power to linkage studies. One hundred consanguineous stuttering families were identified from the city of Lahore and areas around Lahore, Pakistan, where consanguineous matings are the norm. Blood and diagnostic speech samples were collected from 56 families where there were more than 3 affected individuals. Diagnosis was performed using Stuttering Severity Instrument, and quantitative measures of affection status were obtained. The male to female ratio in Pakistani stutterers is 4:1, similar to that observed in other populations. A genome wide linkage scan was done using affected individuals and their parents in 44 selected families, genotyped with the Marshfield Weber 9 Panel. Analysis was performed on 144 affecteds, 55 unaffecteds, and 27 population matched normal controls. PREST was used to identify pedigrees that required additional specification of inbreeding. Initial non-parametric analysis using Merlin gave evidence of linkage on chromosomes 1q, 11q, 12q and 18q. Additional genotyping was performed at these four linked loci to a level of 5 cM resolution, and 16 additional individuals within the same family set were included. Analysis of the enlarged data set provided consistent significant evidence for linkage on chromosome 12: the S_{homoz} scoring function in Allegro gave a LOD score of 4.68, and a LOD score of 3.29 was obtained using the S_{all} scoring function. These results suggest that a locus on chromosome 12q may contain a gene with a large effect in this population.

Analysis of Genetic Admixture and Asthma Related Phenotypes in Mexican American and Puerto Rican

Asthmatics. *K. Salari^{1,2}, S. Choudhry^{1,2}, H. Tang³, D. Lind¹, P. Avila¹, N. Coyle^{1,2}, N. Ung^{1,2}, S. Nazario⁴, J. Casal⁴, A. Torres⁴, A. Phong¹, I. Gomez⁴, E.J. Pérez-Stable¹, M.D. Shriver⁵, P.Y. Kwok¹, D. Sheppard^{1,2}, W. Rodriguez-Cintron⁴, N.J. Risch^{6,7}, E.G. Burchard^{1,2}, E. Ziv¹.* 1) University of California, San Francisco, San Francisco, CA; 2) Lung Biology Center, San Francisco General Hospital, San Francisco, CA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) San Juan VAMC, University of Puerto Rico School of Medicine, San Juan, PR; 5) Department of Anthropology, Pennsylvania State University; 6) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 7) Division of Research, Kaiser Permanente, Oakland, CA.

Genetic association studies in admixed populations may be biased if individual ancestry varies within the population and the phenotype of interest is associated with ancestry. However, recently admixed populations also offer potential benefits in association studies since markers informative for ancestry may be in linkage disequilibrium across large distances. In particular, the enhanced LD in admixed populations may be used to identify the alleles which underlie a difference in a phenotype between two ancestral populations. Asthma is known to have different prevalence and severity among ancestrally distinct populations. We investigated several asthma-related phenotypes in two ancestrally admixed populations: Mexican Americans and Puerto Ricans. We used ancestry informative markers to estimate the individual ancestry of 181 Mexican American asthmatics and 181 Puerto Rican asthmatics and tested whether individual ancestry is associated with any of these phenotypes independently of known environmental factors. We found a strong association between higher European ancestry and more severe asthma as measured by both forced expiratory volume at 1 second ($r=-0.21$, $p=0.005$) and by a clinical assessment of severity among Mexican Americans (OR: 1.37, $p=0.001$). Among Puerto Ricans we found a modest association between African ancestry and improved drug responsiveness. These results suggest that asthma severity, particularly among Mexican Americans, may be influenced by genetic factors differentiating Europeans and Native Americans.

Loci contributing to adult height and body mass index in African American families ascertained for type 2 diabetes. *M.M. Sale*^{1,2}, *B.I. Freedman*², *P.J. Hicks*^{1,3}, *A.H. Williams*⁴, *C.D. Langefeld*⁴, *C.J. Gallagher*^{1,3}, *D.W. Bowden*^{1,2,3}, *S.S. Rich*⁴. 1) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Dept. Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Dept. Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC; 4) Dept. Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC.

Height and body mass index (BMI) have high heritability in most studies, and high BMI and reduced height are important risk factors for a number of diseases. We investigated these phenotypes in African American families originally ascertained for studies of linkage with type 2 diabetes. We conducted a genome wide scan in 218 families containing 580 individuals of African-American descent. Estimates of heritability and support for linkage were assessed by genetic variance component analyses using SOLAR software. The estimated heritabilities for height and BMI were 0.43 and 0.64 respectively. We have identified major loci contributing to variation in height on chromosomes 15 (LOD=3.19 at 35 cM), 3 (LOD=2.17 at 84 cM), 8 (LOD=2.34 at 135 cM) and 17 (LOD=2.04 at 110 cM). A broad region on chromosome 4 supported evidence of linkage to variation in BMI, with the highest LOD=2.99 at 168 cM. We report the results of genome-wide scans for height and BMI in African American families. All major regions of linkage appear to confirm the existence of quantitative trait loci previously identified by other studies, providing important replicative data to allow further resolution of linkage regions suitable for positional cloning these risk loci.

A genome-wide linkage scan for quantitative trait loci influencing the craniofacial complex. *R.J. Sherwood¹, D.L. Duren¹, J. Blangero², T. Dyer², S.A. Cole², R.M. Siervogel¹, B. Towne¹.* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX.

Recent advances in developmental biology have led to the discovery of a number of genes and gene products important in the development of the skeleton and, specifically, the skull. However, as is the case with many systems, our primary understanding of the specific genes related to morphology comes from genetic disorders associated with craniofacial anomalies. In this study, we examined nine quantitative traits taken from lateral skull radiographs of 510 healthy participants from 90 families in the Fels Longitudinal Study. An initial set of 197 of these individuals have been genotyped for ~400 autosomal markers spaced approximately every 10 cM. A variance components-based linkage analysis method (SOLAR; Almasy and Blangero, 1998) was used to obtain multipoint LOD scores. Nine suggestive LOD scores (> 1.9) were found for the following craniofacial measures: posterior-anterior, basion-sella, sella-sphenoethmoidale, basion-nasion, sella-vertex. These suggestive linkages were to markers on chromosomes 3, 6, 7, 12, 13, and 22. Of these, one region is of particular interest. The QTL interval for Chromosome 13 is broad and contains two highly suggestive linkage peaks for the trait Sella-Sphenoethmoidale, one at 67 cM (LOD = 2.33) between markers D13S170 and D13S265, and the other at 108 cM (LOD = 2.57) between markers D13S1265 and D13S285. These regions covered contain genes of potential interest, most notably the ZIC2 and ZIC5 genes. Both ZIC2 and ZIC5 encode a member of the ZIC family of C2H2-type zinc finger proteins. Mutations in either gene have been shown to cause holoprosencephaly type 5, a major congenital malformation often characterized by severe craniofacial anomalies. Additionally, SPRY2, a fibroblast growth factor antagonist, is found near the 67cM peak. Several craniofacial anomalies have been associated with fibroblast growth factor mutations. Future work will seek to identify the specific genes that influence variation in the morphology of the craniofacial complex. Supported by NIH grants HD36342, HD12252, MH59490.

A GENOME SEARCH FOR GENETIC DETERMINANTS THAT INFLUENCE PLASMA FIBRINOGEN LEVELS. *J.M. Soria¹, L. Almasy², J.C. Souto¹, A. Buil¹, M. Lathrop³, J. Fontcuberta¹, J. Blangero².* 1) Dept Hematology, Hosp de Sant Pau, Barcelona, Spain; 2) Southwest Foundation for Biomedical Research, San Antonio, TX, USA; 3) Centre National de Genotypage, Evry, France.

It is widely accepted that fibrinogen levels are strongly, consistently, and independently related to cardiovascular risk. These levels are influenced by genetic and environmental factors. Among the genetic factors, only some polymorphisms in the fibrinogen genes have been reported, and they explain only a small proportion of the genetic variability. Consequently, the extent of the genetic contribution is largely unknown. To search for these genes, we conducted a genome-wide scan using 21 Spanish families from the Genetic Analysis of Idiopathic Thrombophilia (GAIT) Project. Two loci were detected, one on chromosome 12 and another on chromosome 14. There are no cardiovascular-related candidate genes on chromosome 14 which implies that this locus represents a novel cardiovascular risk factor. Importantly, the locus on chromosome 12 contains a candidate gene (TCF1) involved in the hepatocyte-specific transcription of the fibrinogen alpha and beta chain genes. Several polymorphisms in this gene showed significant association with fibrinogen levels, supporting the implication of the TCF1 gene in the determination of this phenotype. It is interesting that the chromosome 4 region, where the structural fibrinogen genes are located, showed weak evidence of linkage, indicating these genes play a minor role in the normal variation of fibrinogen levels. Our results provide strong evidence that two loci, one on chromosome 12 (most likely the TCF1 gene) and another on chromosome 14, are important determinants of plasma fibrinogen levels in Spanish families. These data should help to define the relationship between fibrinogen levels and the risk of cardiovascular disease.

Analysis of the Tasmanian multiple sclerosis genome wide scan haplotype dataset. *J. Stankovich¹, M. Bahlo¹, J.P. Rubio¹, T.J. Kilpatrick^{1,2}, C.R. Wilkinson¹, T.P. Speed¹, S.J. Foote¹.* 1) Walter and Eliza Hall Institute of Medical Research, Parkville, Victoria, Australia; 2) Howard Florey Institute, University of Melbourne, Victoria, Australia.

Multiple sclerosis (MS) is a debilitating complex genetic disease with no cure and limited treatment options. Identification of genes involved in MS is a difficult task and has so far only shown replicated association with the HLA region. We have conducted a genome wide case control haplotype sharing study in Tasmanian MS sufferers. The Tasmanian MS haplotype sharing study consists of 340 case haplotypes and 210 control haplotypes. The haplotypes were generated through probabilistic haplotype reconstruction using a number of close relatives. The study design features two sets of independent controls: a family based control (non transmitted haplotypes) and a population based control. The study design allows the testing of negative control datasets where the family based controls are compared to the population based controls as a valuable background LD check and population stratification check.

The genome wide scan analysis and ongoing fine mapping has so far identified two, low risk, common haplotypes outside of the HLA region. We show how the study design, the ongoing fine mapping and peripheral analysis are giving us added confidence in our findings.

A Genomewide Screen of 165 Families for Adolescent Onset Idiopathic Generalized Epilepsy (IGE) Susceptibility

Loci. *R. Suresh*^{1,2}, *S. Marathe*³, *I. Klotz*³, *A. Grunn*², *T.C. Gilliam*^{1,2,4}, *D.A. Greenberg*^{2,3,4,5}. 1) Genetics and Development, Columbia University, New York, NY; 2) Columbia Genome Center, Columbia University, New York, NY; 3) Division of Statistical Genetics, Dept. of Biostatistics, Mailman School of Public Health, New York, NY; 4) Department of Psychiatry, Columbia University, New York, NY; 5) Clinical and Genetic Epidemiology Unit, New York State Psychiatric Institute, New York, NY.

Genetic factors play the major role in the etiology of idiopathic generalized epilepsy (IGE). But identifying the susceptibility loci for IGE is confounded by ambiguous phenotype definition and heterogeneity. Recent findings (Durner M 2001, Winawer MR 2003) have suggested that the clinical definition of an IGE syndrome may not reflect the underlying genotype(s) as the components of the syndrome definitions overlap. Linkage analysis on the basis of seizure phenotype rather than IGE syndrome may therefore represent a more accurate phenotype definition for gene identification. Our previous genome scan for IGE susceptibility loci included 91 families and showed 1) strong evidence for linkage of IGE on chr. 18 (LOD=5.2 at D18S474) (Durner et al., 2001); 2) linkage of absence seizures to two markers on chr. 5; 3) linkage of tonic-clonic seizures to a marker on chr. 8 (Durner M, 1999); 4) replicated evidence of linkage of myoclonic seizures to chr. 6 (Greenberg et al, 2000). In this follow up study, we have completed whole-genome genotyping, data cleaning, and error checking for 74 multiplex IGE families. Analysis of this large, independent data set will provide a critical test of replication for the initial findings since the sample has been ascertained, diagnosed, and analyzed under conditions that closely match those of the previous study. We will present a complete analysis of the 74 families, and the combined 165 IGE families, exploring clinical phenotype, and more specifically examining seizure type as the critical phenotype for gene identification.

Linkage disequilibrium mapping for body mass index on chromosome 7q31-7q34 implicates multiple genes and sex-specific effects: The NHLBI Family Heart Study. *J.B. Wilk^{1,2}, Y. Jiang¹, S. Williamson¹, R. Prakash¹, A.L. DeStefano^{1,3}, R.C. Ellison², I.B. Borecki⁴, M.A. Province⁴, R.H. Myers^{1,2}.* 1) Department of Neurology, Boston University School of Medicine, Boston, MA; 2) The Section of Preventive Medicine and Epidemiology, Department of Medicine, Boston University School of Medicine, Boston, MA; 3) Biostatistics Department, Boston University School of Public Health, Boston, MA; 4) Division of Biostatistics, Washington University School of Medicine, Saint Louis, MO.

The NHLBI Family Heart Study (FHS) genome-wide scan identified a region of chromosome 7q with a LOD score of 4.9 for body mass index (BMI). We report the results of linkage and association to BMI in 90 FHS pedigrees using 418 SNPs and 7 microsatellites genotyped on 7q31-34. BMI was adjusted for age and study center, by sex, and linkage and association analyses were performed in the full sample and sex-specific subsets. Variance component linkage analysis using microsatellite data produced a LOD score of 16.4 positioned at D7S1804 (137 cM, 127 Mb Celera map). Linkage analysis using only SNPs produced a LOD of 16 at the same position, and sex-specific analysis produced LOD scores of 6.1 in females and 2.3 in males. Single SNP and haplotype association was evaluated using family-based association tests in the FBAT program, testing for association in the presence of linkage. Haplotype association results in the full sample implicated the testis development gene (NYD-SP18) at 123.15 Mb ($p=0.002$ for recessive model) and the exocyst complex component SEC8, at 128 Mb ($p=0.0008$ for dominant model), and these haplotypes were also the best results in females. In males, a haplotype in maltase-glucoamylase (MGAM) at 136.4 Mb had the best association ($p=0.002$ for additive model). Haplotypes in CALD1 and CNOT4 also produced results warranting further investigation. These data support the hypothesis that there are multiple genes on 7q31-34 influencing BMI and these genes may have sex-specific effects.

Replication study supports evidence for linkage to 9p24 in Obsessive-Compulsive Disorder. *V.L. Willour¹, Y.Y. Shugart¹, J. Samuels¹, M. Grados^{1,2}, B. Cullen¹, O.J. Bienvenu¹, Y. Wang¹, K.-Y. Liang¹, D. Valle¹, R. Hoehn-Saric¹, M. Riddle¹, G. Nestadt¹.* 1) Johns Hopkins University, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

Obsessive-compulsive disorder (OCD) is a severe psychiatric illness that is characterized by intrusive and senseless thoughts and impulses (obsessions) and repetitive behaviors (compulsions). Family, twin, and segregation studies support the presence of both genetic and environmental susceptibility factors. The only published genome scan for OCD identified a candidate region on 9p24 at marker D9S288 that met criteria for suggestive significance (Hanna et al. 2002). In an attempt to replicate this finding, we genotyped 50 OCD pedigrees using microsatellite markers spanning the 9p24 candidate region and analyzed the data using parametric and nonparametric linkage analyses under both a narrow phenotype model (DSM IV OCD definite; 41 affected sib pairs) and a broad phenotype model (DSM IV OCD definite and probable; 50 affected sib pairs). Similar to what was described by Hanna et al. (2002), our strongest findings came with the dominant parameters and the narrow phenotype model: the parametric signal peaked at marker D9S1792 with an HLOD of 2.26 ($= 0.59$), and the nonparametric linkage signal peaked at marker D9S1813 with an NPL of 2.52 ($p=0.006$). These findings are striking in that D9S1813 and D9S1792 lie within 0.5 cM (<350 kb) of the original 9p24 linkage signal at D9S288. Furthermore, pedigree-based association analyses also implicated the 9p24 candidate region by identifying two markers (D9S288 and GATA62F03) with modest evidence ($p= 0.046$ and 0.02 , respectively) for association.

Mapping susceptibility loci for idiopathic scoliosis. *C.A. Wise¹, J.A. Herring¹, X.C. Gao¹, N.M. Cain¹, S.L. Swaney¹, S. Bashiardes², R. Veile², A.M. Bowcock², M. Lovett².* 1) Seay Research Ctr, Texas Scottish Rite Hosp, Dallas, TX; 2) Genetics Department, Washington University School of Medicine, St. Louis, MO.

Scoliosis is an isolated, lateral curvature of the spine with rotation that can require surgical correction. The most common form of scoliosis is idiopathic (IS) with onset during adolescence. It has a prevalence of 1-3% in school age children and a well-described 5:1 female:male ratio in children requiring treatment. The underlying causes of IS have remained elusive, although there is some suggestion of a neurological pathogenesis. IS inheritance is complex, and a number of linked loci have been reported. We tested replication of these linkages in set of mostly nuclear IS families. A minimum Cobb angle of 15 degrees with no other associated disorders was required to be considered affected. Sixty-one affected and seventy-two unaffected individuals representing 28 families were included in the analysis. Forty-four polymorphic microsatellites from 12 chromosomal loci were genotyped and searched for evidence of linkage using Genehunter. In the combined families small positive nonparametric scores were obtained for several loci, with strongest results produced for a region of chromosome 8 (NPL = 1.52, $p=.058$ at D8S1136). This was the only region producing a positive lod score when a dominant inheritance model was applied. These scores increased when combined with data from genome wide scans in two extended families (LOD = 3.12, NPL of 2.11 ($p=0.016$) at marker D8S1136). This region encodes the SNTG1 gene that we recently reported is disrupted in an affected family with (inv(8)(p23q11.21), providing independent evidence that the chromosome 8 locus contributes to IS susceptibility. Screens of SNTG1 coding regions revealed no obvious, co-segregating mutations in the family set. To test association between common variants in SNTG1 and IS we have initiated genotyping single nucleotide polymorphisms (SNPs) in a new collection of over 90 families. SNTG1 encodes a neuron-specific member of the syntrophin family and is a plausible candidate gene for IS susceptibility contributed by the chromosome 8 region.

Pleiotropic manifestation of lipid pathway genes affecting blood pressure, obesity, glucose and insulin resistance: evidence for metabolic syndrome genes in the MACAD Study. X. Guo^{1,2}, M.O. Goodarzi^{1,2}, M.J. Quinones², J. Cui¹, S. Cheng³, R. Hughes³, J. Wang³, K.D. Taylor^{1,2}, H. Yang^{1,2}, W. Hsueh², J.I. Rotter^{1,2}. 1) Cedars-Sinai, LA; 2) UCLA, LA; 3) Roche Molecular Systems, Inc., Alameda, CA.

The metabolic syndrome (MS), characterized by the clustering of central obesity, hypertension, higher triglyceride levels, lower HDL-cholesterol concentrations, and impaired fasting glucose, is a multiplex risk factor for cardiovascular disease and type 2 diabetes. A number of genes have been reported to be associated with lipoprotein metabolism, including Lp(a), ApoA4, ApoB, ApoC3, ADRB3, CETP, LIPH, LDLR, PON1, PON2, and PPARG. We evaluated the association of these genes with other components of the MS. 656 individuals from 102 Mexican American (MA) families recruited through a coronary artery disease proband in the MA Coronary Artery Disease (MACAD) project were genotyped for 24 polymorphisms in the above 11 genes by a PCR- and immobilized probe-based multi-locus assay. We evaluated the association between each polymorphic marker and the other MS-related traits via generalized estimating equation (GEE) methods. The T allele of T3206G in ApoC3 was found to be associated with obesity: BMI ($p=.013$), elevated fasting glucose ($p=.014$), and insulin resistance: fasting insulin ($p=.009$), HOMA ($p=.021$), GINF ($p=.017$), SI ($p=.014$) when adjusting for age and sex; but the association become non-significant after further adjusting for BMI. The C allele of C(-480)T in the LIPH gene was associated with obesity: trunk fat ($p=.006$), %bodyfat ($p=.007$), and insulin resistance: fasting insulin ($p=.021$), HOMA ($p=.006$) after adjusting for age, sex, and BMI. E360H in ApoA4, T71I in ApoB, C(-641)A and C1100T in ApoC3, W64R in ADRB3, S311C in PON2, and P12A in PPARG showed associations with insulin resistance ($p: .0008-.0375$), while C93T in the Lp(a) gene showed association with diastolic blood pressure ($p=.016$). In conclusion, lipid metabolism genes, especially ApoC3 and LIPH, may be genetic markers for the metabolic syndrome. While obesity may affect the expression of ApoC3, the LIPH effect is apparently independent of obesity.

Transmission Disequilibrium Tests For Quantitative Traits Via Semi-Parametric Regression. *S. Ghosh¹, C. Mukherjee¹, H. Begleiter², L. Bierut³*. 1) Applied Statistics Unit, Indian Statistical Inst, Kolkata, India; 2) Neurodynamics Laboratory, State University of New York at Brooklyn, NY; 3) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO.

The classical transmission disequilibrium test (TDT) proposed by Spielman et al. (1993) has proved to be a powerful method for simultaneous detection of both linkage and association for binary traits. The paradigm of association in the context of quantitative traits is not very obvious and methods (Allison 1997, George et al. 1999, Abecassis et al. 2000, Monks and Kaplan 2000, Lange et al. 2002) have generally considered the intuitive concept of differences in allelic transmissions between offspring having high quantitative trait values and those having low values as evidence of linkage disequilibrium for quantitative traits. However, many of these tests use selected sampling resulting in loss of information and power or are not robust to violations in distributional assumptions of the quantitative trait. We propose a logistic link function between a marker allele transmitted by a heterozygous parent and the quantitative trait value of an offspring. This method can be shown to be statistically equivalent to the classical TDT. For multiple sibs, we develop a non-parametric regression based on kernel smoothing of the proportion of one marker allele transmitted by heterozygous parents to all sibs in a family on the mean of the quantitative trait values of the sibs. Monte-Carlo simulations are included to assess the powers of our methods. We also illustrate an application of our method using data on a quantitative phenotype defined as the number of externalizing symptoms and the ADH3 marker in the alcohol-dehydrogenase gene cluster on Chromosome 4 in the ongoing Collaborative Study On The Genetics Of Alcoholism project.

Program Nr: 2046 from the 2004 ASHG Annual Meeting

Genetic dissection of Stress Vulnerability and Antidepressant Response in a Mouse Model. *H.K. Gershenfeld, X. Liu, T. Amstein, D. Stancliffe.* Dept Psychiatry, UT Southwestern, Dallas, TX.

The tail suspension test (TST) is a simple validated screening test for the behavioral effects of antidepressants in mice. Two parental inbred strains, NMRI and 129S6, markedly differ in their responses to stressful situations measured by duration of immobility in the TST and the effects of imipramine (a tricyclic antidepressant) in reducing immobility during a 6-min test. An F2 intercross was derived from NMRI and 129S6 inbred strains (N=747 males). Both parental strains and F2 mice underwent a standardized 6-min protocol of automated TST with 2 sessions: (1) baseline and (2) imipramine (30 mg/kg, i.p.) TST. A whole genome scan of the F2 intercross with 125 markers mapped two significant basal TST quantitative trait loci (QTL) on Mus chromosomes 5 (peak 47.6 cM, Lod 8.6, 5% variance) and 12 (peak 43.5 cM, Lod 10.4, 6% variance). For imipramine response in the TST as measured by residuals, regressing out the confounding contributions of body weight and basal TST, a significant QTL was mapped on chr 5 (peak 45 cM, Lod 7.9, 5% variance). Hence, the chr 5 locus affected both basal TST and antidepressant response, suggesting the existence of a pleiotropic locus influencing both stress vulnerability and antidepressant response. The human syntenic regions of this 20 cM Mus chr 5 region, namely 9p21-23 and 1p31-35, have been mapped as possible loci for bipolar disorder. Hence, these QTL provide promising loci for testing in stress-diathesis models of human psychiatric illness and antidepressant responsiveness.

A single locus from the SLE-prone strain BXSB is sufficient to drive autoantibody production and glomerulonephritis on a non-autoimmune background. *J.M. Rankin¹, J. Boyle², A.M. Calcagno Pizarelli¹, S. Izui³, B.J. Morley¹.* 1) Rheumatology Section, Eric Bywaters Centre, Faculty of Medicine, Imperial College, Hammersmith Campus, Du Cane Road, London W12 0NN, United Kingdom; 2) Histopathology Department, Hammersmith Hospital, Du Cane Road, London W12 0NN, United Kingdom; 3) Department of Pathology, Centre Medical Universitaire, Geneva, Switzerland.

Spontaneous murine models of Systemic Lupus Erythematosus (SLE) develop a high serum level of the retroviral envelope protein gp70. This is expressed at a low level in the serum of all murine strains, however only SLE-prone strains produce anti-gp70 autoantibodies. These form immune complexes with gp70 (gp70IC) and contribute to nephritis. In the BXSB model, the over-expression of gp70 and the production of gp70IC have been previously mapped to a single locus on chromosome 13 (*Bxs6*). To narrow down the *Bxs6* interval, we have carried out rare recombinant mapping using BXSB backcross mice. Recombinant events within the *Bxs6* interval were correlated with gp70 and gp70IC levels, allowing areas to be excluded. This approach successfully localised the *Bxs6* gene/s to a 16Mb interval, from the 35Mb region defined by the linkage study. We have bred a congenic line to determine whether *Bxs6* is sufficient on a non-autoimmune background for gp70 over-expression, gp70IC production and nephritis. These mice contain BXSB chromosome 13 (20Mb-117Mb) on a B10 background, in the presence of the BXSB Y chromosome autoimmune accelerator gene, *Yaa*. Congenic mice have a high serum level of gp70 and gp70IC, and develop a mild nephritis. These effects are not dependant on the presence of *Yaa*. The phenotype of these mice therefore replicates the linkage data, although levels lie midway between B10 and BXSB, implying that there must be other contributing factors in the BXSB genome. Interestingly, congenic mice also develop anti-ssDNA antibodies to which no linkage was found, although unlike the expression of gp70, this is dependant on the presence of *Yaa*. This is therefore a relatively simple system for the study of a single locus that, alone, directs autoantigen driven autoantibody production in a complex disease, but also demonstrates epistasis.

Examination of ELN as a candidate gene in the Utah Intracranial Aneurysm Pedigree Resource. *N.J. Berthelemy-Okazaki^{1,3}, N.J. Camp¹, J. Farnham¹, A. Thomas¹, K. Zhang², L.A. Cannon-Albright¹.* 1) Medical Informatics, University of Utah, Salt Lake City, UT; 2) Department of Ophthalmology and Visual Science, University of Utah, Salt Lake City, UT; 3) Zoology Department, Weber State University, Ogden, UT.

A linkage study of Intracranial Aneurysm in Japanese subjects implicated several candidate regions/genes, with the strongest evidence in the region of the elastin gene (ELN) (Onda et al., 2001). Analysis of ELN in the Japanese dataset suggested association of an ELN haplotype with IA risk. A subsequent linkage analysis of the ELN region in 14 high risk IA pedigrees from Utah significantly confirmed the linkage between IA and the ELN region (Farnham et al., 2003). We have investigated the ELN gene as a potential candidate gene responsible for the observed IA clustering and linkage in the Utah IA pedigree resource. One IA case from each pedigree who appeared to carry a segregating ELN -region haplotype was chosen for mutation screening. Two promoter regions, 34 exons and 3 3'UTR of the ELN gene were screened for variants by DHPLC. The variants were then sequenced. Each variant identified in an IA case was also screened for in one additional affected haplotype carrier relative and in one unaffected relative to test for segregation of the ELN variant with IA in the pedigree. Evidence for variants, indicated by differences in peak heights by WAVE analysis between controls and subjects, occurred in the promoter regions PM1, PM2, exons 4 and 6, and 3 3'UTR regions. These regions were sequenced and the variants identified. A rare variant in the promoter region PM3, present in the Japanese population, was not found in the Utah families. Variants in exon 6 and in one 3'UTR region were unique to Utah. The remaining variants were identical to the ones found in the Japanese population. None of these variants were present in the controls. No variation was found in the remaining 32 exons. There was no evidence for segregation of the ELN variants found in IA cases with the hypothesized segregating chromosome 7 haplotype examined. We saw no evidence supporting ELN as the gene responsible for familial IA in the Utah resource.

DNA Polymorphisms in two Paraoxonase Genes (PON1 and PON2) are independently associated with increased risk of Ischemic Stroke in Pakistani patients. *M.A. Bangash¹, D.A. Tregouet³, M. Saeed², H. Zuberi², E. Khan², S. Khanum², J. Sajid², A.H. Khan², A. Hasan², F. Abubakar², A.A. Khan², F. Fecto², W. Ahmed², T.U. Rehman², F. Cambien³, P.M. Frossard².* 1) School of Philosophy, University of Leeds,UK; 2) Biological and Biomedical Sciences, The Aga Khan University, Karachi, Pakistan; 3) INSERM U525, University Paris VI,France.

Stroke is the most common cause of disability and the third leading cause of death worldwide. As a highly heterogeneous disorder, it has several subtypes and multiple risk factors. To identify genes involved in Ischemic Stroke (IS) susceptibility, we investigated the association of functional Single-Nucleotide Polymorphisms (SNPs) in the Paraoxonase Genes (PON1 & PON2) and IS. PON1 enzyme prevents atherosclerosis by inhibiting oxidation of LDL, a role confirmed in functional studies and animal models. We analyzed 210 IS patients and 393 age, gender and ethnicity matched controls recruited from two tertiary care hospitals in Karachi. We genotyped 7 PON SNPs using PCR and restriction digestion assays. These included five PON1 (-909 G/C, -162 A/G, -108 C/T, Q192R, L55M) and two PON2 (148 A/G, 311 C/S) SNPs. We also determined serum PON activity by measuring rates of hydrolysis of paraoxon and phenylacetate. Among the seven SNPs, three were strongly associated with IS. Frequencies of 162A (0.47 vs. 0.40, $p < 10^{-2}$), 108T (0.57 vs. 0.46, $p < 10^{-3}$) and 148A (0.49 vs. 0.42, $p < 10^{-2}$) alleles were significantly higher in patients vs. controls. After adjustment for confounders, the 108TT genotype remained independently associated with a 2-fold increase risk of IS (OR= 2.4; 95% CI, 1.5-3.7; $p < 10^{-4}$). Subjects with the 108TT ($p < 10^{-2}$) and the 909CC ($p < 10^{-3}$) genotypes also had significantly higher phenylacetate activity. Haplotype analysis did not yield more information. Here we have reported novel association of two PON1 promoter region variants (-162 A/G and -108 C/T) and one PON2 (148 A/G) variant with increased risk of IS in our Pakistani patients. Our findings suggest an etiological role of PON1 and PON2 in the complex model of IS and further functional studies are needed to establish the causative mechanism.

Linkage disequilibrium mapping of the Endothelial Nitric Oxide Synthase (*NOS3*) gene and identification of *NOS3* SNPs associated with measures of endothelial function. S. Kathiresan^{1,4}, M.G. Larson¹, C.Y. Guo¹, J.A. Vita², G.F. Mitchell³, M.J. Keyes¹, C. Newton-Cheh^{1,4}, S. Musone⁴, A. Lochner⁴, J.A. Drake⁴, R.S. Vasan^{1,2}, D. Levy¹, C.J. O'Donnell^{1,4}, J.N. Hirschhorn⁴, E.J. Benjamin^{1,2}. 1) NHLBI's Framingham Heart Study, Framingham, MA; 2) Boston University School of Medicine, Boston, MA; 3) Cardiovascular Engineering, Holliston, MA; 4) Broad Institute, Cambridge, MA.

Targeted deletion of the *NOS3* gene in mice leads to endothelial dysfunction and hypertension. We sought to comprehensively characterize common single nucleotide polymorphisms (SNPs) and haplotypes at the *NOS3* locus and to test the hypothesis that common genetic variants at the *NOS3* locus influence brachial artery endothelial function in humans. We defined the linkage disequilibrium (LD) structure for common SNPs (minor allele frequency >5%) at the *NOS3* locus (genomic span 39 kb) using 33 SNPs in 93 individuals from 12 pedigrees of European ancestry. 17 SNPs that capture most of the common variation at *NOS3* were genotyped in 1446 unrelated Framingham Heart Study participants (50% women, mean age 62 years) in whom we measured brachial artery flow-mediated dilation (FMD) after 5 minutes of forearm ischemia. Sex-specific age- and multivariable-adjusted regression models were used to examine associations of SNPs and inferred haplotypes with FMD. An intronic SNP, rs1800781, was associated with FMD, in men only (nominal p-values 0.008, and 0.02 in age-adjusted and multivariable-adjusted analyses, respectively). Two additional intronic SNPs (rs3918169 and rs3918174) in tight LD with SNP rs1800781 ($D=1.0$ for both) were also associated with FMD in men (nominal p-value 0.02 for each SNP in fully adjusted model). A common multimarker haplotype in the 3' end of *NOS3* (45% frequency) was associated with impaired FMD (nominal p-value 0.002 in sex-pooled, multivariable-adjusted analyses). We defined a parsimonious set of SNPs that captures common genetic variation at the *NOS3* locus. Our results from a large community-based sample are consistent with the hypothesis that common *NOS3* sequence variants influence interindividual variability in endothelial function in men.

Determinants of the SNP marker density required for delineating major haplotypes. C. Ouyang¹, L. Geller¹, J.-E. Gustavson¹, P.D. Rodley¹, V.R.T. Gagalang¹, G.E. Rivas¹, C.G. Lundberg¹, A. Franck¹, H.-H. Lu¹, B. Shannon², C. Deckman¹, Y. Ding¹, M. Beaulieu³, S.D. Flanagan⁴, G.P. Larson¹, T.G. Krontiris¹. 1) Division of Molecular Medicine, Beckman Research Institute of the City of Hope, Duarte, CA; 2) Westridge School, Pasadena, CA; 3) Sequenom, Inc., San Diego, CA; 4) Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA.

The extent of linkage disequilibrium (LD) has been widely discussed as the major factor determining marker density for genome-wide disease mapping studies using single nucleotide polymorphisms (SNPs). We studied the molecular haplotype structure encompassing *PLA2G6* on chromosome 22 and *CDKN1A* on chromosome 6 in a European American sample. Both regions showed limited number of major haplotypes that could be tagged by haplotype-specific SNPs (SNPs having one allele specific to a major haplotype). We then performed computer simulations using a number of randomly chosen SNPs and determined the required marker density to delineate the major haplotypes faithfully, as if the haplotype structure were unknown to us. Interestingly, the required marker density at the two loci differed significantly, from 1 SNP per 10 kb at *PLA2G6* to over 10 SNPs per 10 kb at *CDKN1A*. The latter value was directly related to an uneven distribution across major haplotypes of haplotype-specific SNPs. Our findings suggest that, besides the extent of LD, additional factors that include the distribution of haplotype-specific SNPs and the number of major haplotypes together determine the useful SNP density for a genome-wide haplotype map. A significant portion of the human genome may require a much higher density than that recommended for the initial HapMap build.

Genome-wide linkage analysis of allergic rhinoconjunctivitis in a Swedish population. *M. Bradley*^{1,2}, *B. Liming*², *C. Söderhäll*², *C-F. Wahlgren*¹, *I. Kockum*², *M. Nordenskjöld*². 1) Dept Dermatology, Karolinska Inst, Stockholm, Sweden; 2) Dept Molecular Medicin, Karolinska Inst, Stockholm, Sweden.

Allergic rhinoconjunctivitis is a common complex disorder characterized by itching and irritation in the nose, bouts of sneezing, watery rhinorrhoea, nasal congestion and itchy eyes with tears and swelling. Like other atopic disorders such as allergic asthma and atopic dermatitis, the development involves complex interactions of genes and environmental factors. To identify susceptibility loci for allergic rhinoconjunctivitis, we conducted a genome-wide linkage analysis using a non-parametric, affected-relative-pair method. The 250 families used were collected originally for an atopic dermatitis linkage study. Two regions showed favour in evidence of linkage to allergic rhinoconjunctivitis: 3q13 (D3S1278: LOD=1.67, p0.003), 4q34-35 (D4S1652: LOD=1.49, 0.005). In addition, five regions showed weaker evidence in favour of linkage: 6p22-24 (D6S1959: LOD=1.39, p0.006), 9p12-q11 (D9S1118: LOD=1.15, p0.02), 9q33.2-34.3 (D9S915: LOD=1.29, p0.01), 17q11.2 (D17S1294: LOD=1.13, p0.02) and 18q12 (D18S535: LOD=1.01, p0.02). In single-point analysis, one locus on chromosome 3 close to marker D3S1278 reaches the suggestive level (LOD=2.28, $p6 \times 10^{-4}$ while one on chromosome 17 close to marker D17S921 almost reaches this level (LOD=2.17, 8×10^{-4}). Our results support the linkage to allergic rhinoconjunctivitis on 3q12, 6p24-p23 and 9q34.3 shown in previous investigations.

Fine mapping of the critical multiple sclerosis region on 5p12-p14. *D.O. Bronnikov^{1,2}, S. Kallio², J.S. Saarela², H.M.F. Riise Stensland³, P. Pajukanta¹, A. Palotie^{1,2}, L. Peltonen^{1,2}.* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, University of California, Los Angeles, California, USA; 2) National Institute of Public Health, Department of Molecular Medicine, Helsinki, Finland; 3) Medical Biochemistry, University of Troms, Troms, Norway.

Multiple Sclerosis (MS) is a chronic inflammatory disorder of Central Nervous System; it is a multifactorial trait with a complex mode of inheritance. Highly prevalent in Caucasians of Northern European origin (50-100/10⁵), MS is a common cause of acquired neurological disability in 20-40 year olds. Apart from the finding of strong MS linkage on Major Histocompatibility Complex, only three linked loci, located on chromosomes 5, 17 and 19, overlapped between previous genomewide scans, all replicated in Finnish study sample. The linked region on chromosome 5p is syntenic to an EAE locus on mouse chromosome 15. We restricted the initial 40cM region in a follow-up study to 9cM on 5p12-p14 using extended Finnish MS families. A set of 65 SNPs, located in coding regions and regulatory elements of known regional genes and putative transcripts, confirmed by RT-PCR from total RNA, and also regions of high synteny to mouse, were genotyped in 22 multiplex Finnish pedigrees and 42 MS trios originating from high MS-risk sub-isolate on Western coastline of Finland. Two regions, located within CTNND2 and LOC90268 genes, had a number of markers showing suggestive evidence for association. Pairwise LD between the markers located within 500kb to each other was monitored using GenePOP and several haplotype blocks, the longest one stretching over 200kb, were observed. The most informative markers belonging to these genomic regions were genotyped in additional 439 Finnish MS trios in order to replicate our initial findings. Stratification based on the origin of the studied families resulted in p-value 0.000993 with the recessive model of LD given linkage test using the Pseudomarker program. To gain some functional evidence for the associated genes, we monitored for expression differences of the genes located in the MS critical region in peripheral blood circulating T-cell fractions collected from MS patients and their healthy relatives.

A SNP in an interferon-stimulated response element in the promoter of the CHRNA1 gene, encoding the alpha-subunit of the muscle acetylcholine receptor, is associated with autoimmune myasthenia gravis. *M. Giraud¹, B. Eymard², C. Tranchant³, D. Beeson⁴, N. Willcox⁴, P. Gajdos⁵, HJ. Garchon¹.* 1) INSERM U580, Hôpital Necker, Paris, France; 2) Hôpital de la Salpêtrière, Paris, France; 3) Hôpital Civil, Strasbourg, France; 4) The Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, United Kingdom; 5) Hôpital Raymond Poincaré, Garches, France.

Myasthenia gravis (MG) is an autoimmune disease affecting neuromuscular transmission, where the prime self-antigen, the muscle acetylcholine receptor (AChR), has been unambiguously identified. The AChR alpha-chain (encoded by the CHRNA1 gene) is the target of most pathogenic autoantibodies. We had previously shown an association of CHRNA1 with MG susceptibility. Here, we have exhaustively characterized its polymorphism by re-sequencing 19.9 kb of genomic sequence encompassing the locus in 16 individuals. We have uncovered 37 new polymorphisms and confirmed another 33. Apart from one, a synonymous substitution in exon 7, all are located in non-exonic sequences. The genotyping of 35 additional single nucleotide polymorphisms (SNPs), located up to 50 kb on each side of CHRNA1, allowed us to identify an island of linkage disequilibrium (LD) spanning 40 kb, including CHRNA1 only and excluding neighbor genes. The pattern of allelic associations of common polymorphisms was characterized and their effects on the phenotype of MG patients were investigated. We disclosed a highly significant association of a group of 12 in-phase polymorphisms with an early onset of the disease (<20 years) in 186 French MG patients compared to 154 population-matched controls (OR = 3.5; P<0.00006). Remarkably, one SNP within this group, located in the promoter region, modifies a typical IFN-stimulated response element (ISRE) and potentially affects the transcriptional efficiency of CHRNA1 in immune cells. Association of this SNP was replicated in the British population, in a sample of 151 unrelated patients and 109 controls (P<0.025). This SNP is therefore a good candidate to explain the association of its group with MG and to undertake functional studies.

Linkage and Candidate Gene Analysis for Developmental Dyslexia on Chromosome 18. *T.S. Scerri¹, I.L. MacPhie¹, S. Paracchini¹, J. Walter², A.J. Richardson², C. Francks¹, J.F. Stein², A.P. Monaco¹.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom; 2) Department of Physiology, University of Oxford, United Kingdom.

Developmental dyslexia (DD) is a specific and significant impairment in reading ability despite adequate educational opportunity and intelligence, and is diagnosed in approximately 5% of school-aged children. There is strong evidence from twin and family-based studies that both environmental and genetic components play a role in the aetiology of DD, thus making it a multifactorial disorder. Several genome-wide linkage studies have identified genomic regions that may harbour quantitative trait loci (QTLs) for DD on chromosomes 2, 6, 11, 15 and 18. We first reported linkage of a DD QTL at 18p11.2 in three large independent family samples, including two from the United Kingdom (UK) and one from the United States. We have now collected a third independent UK sample of 91 families. Our combined UK sample now consists of 264 nuclear families, each with at least one dyslexic proband, that have all been genotyped for 54 polymorphic microsatellite markers across the entire length of chromosome 18, with an average inter-marker spacing of ~2.3 cM. The evidence for linkage of DD to chromosome 18 has been reassessed with this denser set of markers in our combined sample of UK families. Using four different methods of linkage analysis (Haseman-Elston, variance components, DeFries-Fulker and multivariate), and an up-to-date deCODE genetic map, we confirm the existence of the 18p11.2 QTL, and present evidence for a possible second QTL at 18q12.2. Mutation screening of the exons and predicted promoters of candidate genes within the vicinity of the 18p11.2 and 18q12.2 QTLs is currently being conducted by temperature modulated heteroduplex analysis. Thus far, we have not identified a mutation with an obvious disruptive affect within any of the candidate genes. Nevertheless, a number of single nucleotide polymorphisms (SNPs) have been identified. A selection of these, along with other SNPs reported in the online databases, are being genotyped and will be used to test for association to DD in our set of UK families.

RGS4 is associated with systemic lupus erythematosus (SLE) at 1q23.3. *H. Wu*^{1,2}, *R.M. Cantor*³, *J.M. Grossman*¹, *E. Park*¹, *A.A. Rumbin*¹, *D.J. Wallace*⁴, *B.H. Hahn*¹, *B.P. Tsao*¹. 1) Dept. of Medicine, Div. of Rheumatology, UCLA, Los Angeles, CA; 2) Dept. of Rheumatology, Ren Ji hospital, Shanghai Second Medical University, Shanghai, China 200001; 3) Dept. of Human Genetics and Pediatrics, UCLA, Los Angeles, CA; 4) Cedar-Sinai Research Institute, Los Angeles, CA.

SLE is a genetically complex, multifactorial autoimmune disease, and cumulative studies implicate multiple factors in its pathogenesis. In a Caucasian SLE cohort with 67 affected sibpairs and 224 simplex families, all patients fulfilled the American College of Rheumatology criteria for SLE. We previously found linkage of SLE to 1q23.3 in Caucasians (peak at D1S1677, 175 cM, NPL = 2.44) and association of SLE in the linked region with alleles of D1S2844 (160.1 Mb, allele-wise $p = 0.0009$). To further localize the putative SLE susceptibility gene(s), we genotyped 26 informative SNPs (frequency >10%) spanning a 1Mb region flanking D1S2844 (159.8-160.8 Mb) using the Sequenom, Pyrosequencing and TaqMan assays. All genotype distributions were consistent with Hardy-Weinberg equilibrium. We tested the 26 SNPs for LD with the SLE associated multiallelic marker D1S2844, and found that one SNP within the regulator of G-protein signaling 4 gene (RGS4) (rs2940251, $p = 0.0071$) could explain the original association with SLE. Preferential transmission of SNPs to SLE patients for 6 individual SNPs within RGS4 was tested using the Transmission Disequilibrium Test (TDT), and the TRANSMIT program which uses an EM algorithm was used to test for preferential transmission of SNP haplotypes. Preferential transmission of the major alleles of 2 individual RGS4 SNPs (rs10759, rs2940251) was observed (T: UT = 78: 50, $p = 0.013$ and 85: 61, $p = 0.047$ respectively). These 2 SNPs are in strong LD ($D = 0.85$, $p < 0.00001$) with each other. Haplotypes spanning 13 kb formed by 5 RGS4 SNPs (rs951436, rs951439, rs2661319, rs2842030 and rs10759) were associated with SLE (global $p = 0.049$, $p = 0.0001$ for the haplotype formed by all the major alleles). RGS4, expressed in multiple tissues and cell types, may modulate signal transduction by increasing the GTPase activity of G protein alpha subunits to contribute to the development of SLE.

Program Nr: 2057 from the 2004 ASHG Annual Meeting

A third locus for isolated autosomal dominant optic atrophy. *F. Barbet, S. Gerber, A. Munnich, JM. Rozet, J. Kaplan.* Genetics, INSERM U393, Paris, Cedex 15, France.

The aim of this study was to localise the gene responsible for autosomal dominant optic atrophy in two large multiplex families in which OPA1, on chromosome 3q28, and OPA4, on chromosome 18q12, were excluded. A 10 cM genome-wide search for linkage was performed in both families using fluorescent microsatellites. In each family, an haploidentity was found for all affected patients in the same chromosomal region. The maximal lod-score at this locus was equal to 3.33 with a penetrance estimated to 0.80. The minimal genetic interval containing the disease gene was equal to 3 cM when both families were considered. It has been reported that OPA1 mutations are responsible for the majority of autosomal dominant optic atrophies characterized by a large variability of severity and an incomplete penetrance (0.70). In addition, the gene responsible for the disease in one family has been reported on chromosome 18q12 but this gene may account for only a few pedigrees. This work demonstrates that a third locus exists which may account for some families affected with an isolated autosomal dominant optic atrophy, clinically different from the OPA1 phenotype. Several candidate genes involved in mitochondrial function have been identified in this novel genetic interval and are currently under investigation.

Genetic evaluation of a large family with optic atrophy. *H.K. Peters*¹, *M.V. Zaragoza*¹, *P.L. Flodman*¹, *A.B. Fulton*³, *G. Cox*⁴, *T. Huang*^{1,2}. 1) Dept. of Pediatrics, Division of Human Genetics, Univ California, Irvine, Orange, CA; 2) Dept. of Developmental and Cell Biology, Univ California, Irvine, Irvine, CA; 3) Dept. of Ophthalmology, The Children's Hospital, Boston, MA; 4) Dept. of Genetics, The Children's Hospital, Boston, MA.

Optic Atrophy (OPA) is the progressive degeneration of the retinal ganglion cells resulting in central vision loss, central visual field deficits and color blindness. The condition may be isolated or a feature of a genetic syndrome. Familial OPA shows several inheritance patterns including autosomal dominant, autosomal recessive and X-linked. The most common type of inherited OPA is autosomal dominant optic atrophy (ADOA) with an estimated incidence of 1:12,000 to 1:50,000. Typically, ADOA presents in the first decade of life and exhibits both intrafamilial and interfamilial variability. Two loci, the major locus *OPA1* on 3q28-29 and a second locus *OPA4* on 18q12.2-q12.3, have been shown to contribute to ADOA. To date, a vast number of mutations have been described in patients with ADOA in the *OPA1* gene that encodes a dynamin-related GTP protein that localizes to the mitochondria. The X-linked OPA locus, *OPA2*, has been linked to Xp11.4-p11.2 in a large Dutch pedigree. In addition to OPA, affected males displayed other neurological findings including mental retardation. Female carriers were phenotypically normal.

This report describes the clinical evaluation and genetic studies of a large, five-generation family with isolated optic atrophy in multiple affected members. Interestingly, affected males appear to present at an earlier age compared to affected females. This finding is similar to three families previously described with sex-influenced severity. To identify genetic factors in OPA, we examine the family for genetic linkage to 3q28-q29 and Xp11.4-p11.2. Elucidation of the genetic factors in this family will contribute to the understanding of hereditary optic neuropathies and modifying factors of sex-influenced traits.

A Genomewide Scan for Quantitative Trait Loci Linked to Waist Circumference in Mexican Americans. *R. Arya*¹, *J. Schneider*², *S. Puppala*², *T. Dyer*², *S. Fowler*¹, *L. Almasy*², *J. Blangero*², *M.P. Stern*¹, *R. Duggirala*². 1) Department of Medicine/Clinical Epidemiology, University of Texas Health Science Center, San Antonio, TX; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

Epidemiological studies show a rapid increase in obesity, especially abdominal obesity worldwide. Waist circumference (WC) is an important surrogate measure of abdominal fat deposition and more strongly associated with risk factors of cardiovascular disease than body mass index (BMI). Although, several quantitative trait loci (QTLs) influencing obesity-related traits have been reported, specific QTLs that independently and/or pleiotropically influence WC have not been identified in Mexican Americans, a population characterized by increased adiposity and a more centralized distribution of body fat. In this study, we performed a genome scan of WC, adjusted for BMI using a variance component linkage approach to identify loci influencing WC. We analyzed phenotypic data from 715 participants in the San Antonio Family Diabetes/Gallbladder Study (SAFDGS) (27% diabetics, 60% females, mean age [SD] 45.16 years, mean WC [SD] = 997.4/166.8 mm, mean BMI (kg/m²) [SD] = 30.9/6.9) distributed across 39 low-income Mexican American pedigrees, for whom a 10 cM map is available. We conducted a multipoint variance component linkage analysis using SOLAR. WC values were log transformed to minimize the problem of non-normality. After accounting for the covariate effects of age, sex, type 2 diabetes, and BMI, WC was heritable (N=713, h² SE = 0.34/0.08; p < 0.0001). In linkage analysis, five genetic regions on chromosomes 1, 9, 10, 11, and 17 were found to show some evidence for linkage (LOD 1.5) to WC, with the highest LOD of 2.8 (p = 0.0004) occurring between markers D1S547-D1S1609 on chromosome 1q43-44. This marker region is located within 35 cM telomeric to regions previously reported to be linked to glucose and BMI-related phenotypes. These findings suggest that both unique and common susceptibility loci may be influencing WC in Mexican Americans. This study is supported in part by NIH grants DK53889, DK42273, and DK47482.

Experimental pain sensitivity is not influenced by common haplotypes of DREAM, transcriptional repressor of the prodynorphin gene. *B. Buzas*^{1,2}, *I. Lorincz*^{1,2}, *I. Belfer*^{1,2}, *L. Diatchenko*³, *W. Maixner*³, *D. Goldman*², *M.B. Max*¹.
1) PNMB, NIDCR, NIH, Bethesda, MD; 2) LNG, NIAAA, NIH, Rockville, MD; 3) U.of North Carolina, Chapel Hill, NC.

DREAM (downstream regulatory element antagonistic modulator) is a repressor of prodynorphin transcription. Calcium inhibits DREAM binding to DRE leading to increased transcription. DREAM knockout mice display reduced pain responses to acute painful stimuli and show diminished pain behavior in chronic neuropathic and inflammatory conditions. This reduced nociception is attributed to the removal of the constitutive repression by DREAM of prodynorphin expression in the spinal cord. Thus genetic polymorphisms of DREAM may influence prodynorphin expression and nociceptive sensitivity. Informative haplotypes can capture the effects on phenotype of moderately abundant, effective alleles, even if these are unknown. By genotyping 24 SNPs, we determined the haplotype block structure of the genomic region of DREAM (90 kb, 2q21.1) in five populations (U.S. Caucasian, Finn, African American, Plains and Southwest Native Americans). In all populations there was very high pairwise LD between SNP markers 1-20 which placed 80% of the gene in one strong LD block, and evidence for extended superblock structure was also found. As expected common haplotypes and their frequencies showed similarity between the U.S. Caucasian and Finnish populations, and also between the two Native American populations, however less similarity was evident between the Native American and two Caucasian populations. We identified 4 haplotype tag SNPs that were sufficient to capture haplotype diversity in the Caucasians. These SNPs were genotyped in 231 Caucasians, and the haplotypes were analyzed for association with pain perception. 16 different measures of thermal, pressure, and ischemic pain measures were taken in each individual, and were standardized to unit normal deviates (z-scores). No statistically significant correlation between individual haplotypes and diplotypes and pain perception has been found indicating that genetic polymorphisms in DREAM do not significantly contribute to interindividual differences in pain perception.

Identification of Susceptibility Genes in Systemic Lupus Erythematosus. *A. Hellquist¹, C.M. Lindgren¹, P. Onkamo⁴, L. Berglind¹, S. Koskenmies², M. Zucchelli¹, E. Widen³, H. Julkunen⁵, J. Kere^{1, 2, 3}.* 1) Department of Bioscience, Karolinska Institutet, Stockholm, Sweden; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) Finnish Genome Center, Helsinki, Finland; 4) Helsinki Institute for Information Technology, Basic Research Unit Department of Computer Science, University of Helsinki, Finland; 5) Department of Internal Medicine, Peijas Hospital, Helsinki University Hospital, Finland.

Systemic Lupus Erythematosus (SLE) is a chronic autoimmune inflammatory disease with unclear etiology, however strong heritability has been shown. Several candidate susceptibility loci have been identified, but most of the genetic background remains unexplained as yet. In a previous genome-wide scan with 35 Finnish families affected with SLE, we detected suggestive linkage on chromosomes 5p, 6q25-q27, 14q21-q23 as well as HLA on 6p (Koskenmies et al 2004a). Further, an excess sharing of a haplotype on 14q and excess transmission of a haplotype on 6q were shown after additional markers were added at 1 cM density across the suggestive regions of linkage on chromosomes 6q23- q27 and 14q21-q23 (Koskenmies et al 2004b). We have now used a dense microsatellite and single nucleotide polymorphism (SNP) mapping approach to further limit the areas of interest on chromosomes 6q25- q27 and 14q21-q23 (altogether, 31 new microsatellites and 26 new SNPs at 44 400 kb density) by linkage disequilibrium (LD) mapping. Our association mapping results using the HPM algorithm (Toivonen et al 2000) suggest that both chromosomal regions are of interest for gene identification, and associated segments of 1.5 Mb have been identified with present resolution of markers. The project continues in an attempt to identify the respective susceptibility genes. Koskenmies S et al. *J Med Genet.* 2004a:Jan; 41(1):e2-5 Koskenmies S et al. *Eur J Hum Genet.* 2004b:Mar 31 Toivonen H T et al. *Am J Hum Genet* 2000:67(1):133-45.

Large scale Family Based Association Study in Left Ventricular Outflow Tract Malformations: A Candidate Developmental Pathway Approach. *K. McBride¹, S. Fernbach¹, L. Molinari¹, A. Menesses¹, T. Ho¹, R. Pignatelli¹, N. Kaplan³, R.A. Gibbs¹, T. Willis², M. Faham², P. Hardenbol², M. Moorhead², J.A. Towbin¹, J.W. Belmont¹.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) ParAllele Bioscience, South San Francisco, CA; 3) NIEHS.

Congenital left ventricular outflow tract (LVOT) malformations are common complex heart malformations that are a leading cause of infant mortality. Evidence from multiple sources suggests a strong genetic contribution to the etiology of LVOTO defects ($\lambda_S \approx 32$), but the gene(s) involved have not been elucidated. The pattern of inheritance is most likely oligogenic. We designed a large scale candidate gene association study using family-based controls (case-parent trios). We selected 26 groups of genes based on data from animal and in vitro models that indicate the requirement for those pathways in cardiac development. Single nucleotide polymorphisms within genes in these pathways were selected from dbSNP with an average spacing of 1.5 kb. A total of 1977 SNPs in 200 genes produced working assays using a highly multiplexed, microarray based system (Molecular Inversion Probe, ParAllele Biosciences). We genotyped 215 affected case-parent trios producing a total of 1.3 million genotypes. Transmission disequilibrium tests and Hardy Weinberg equilibrium tests were performed on all SNPs. Dependence between markers was assessed by the linkage disequilibrium metric D in HAPLOVIEW and association of haplotypes was assessed using TRANSMIT. Control for multiple testing was performed utilizing a False Detection Rate, or q value, of 0.20, for each pathway group of SNPs. In all 15 genes in 8 pathways showed FDR $q < 0.2$. We observed significant association of markers in four genes - ERBB4, ERBB3, ERBB1, and Neuregulin - within the same ligand-receptor pathway. These results demonstrate the strength of the pathway approach, and support the probable role of ERBB class receptors in LVOTO defects.

Genome Wide Linkage Analysis of a Novel Hereditary Progressive Hyperpigmentation Provides Evidence for Linkage to Chromosome 11. *T. Vogt*¹, *M. Amyere*², *M. Vikkula*². 1) Department of Dermatology, University of Regensburg, Regensburg, Germany; 2) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology & Université catholique de Louvain, Brussels, Belgium.

Familial progressive hypermelanosis is a new variant of a hereditary pigmentation disorders without associated symptoms. This phenotype has so far been observed only in three families, all living in close proximity in a small town in south-east of Germany. The phenotype, with an autosomal dominant inheritance, consists of progressive diffuse, partly blotchy hyperpigmentation, multiple caf-au-lait spots, intermingled with scattered hypopigmented appearing maculae, and lentigenes. The restricted area of occurrence of the disease and the extreme rarity of the phenotype suggest a common origin and thus a founder effect for this genetic defect. Based on this hypothesis, we performed a genome-wide linkage analysis in the three families using SNP genotyping assay, the GeneChip Human Mapping 10K Array. The results demonstrate the presence of significant linkage peak with maximal LOD of 2.156 assuming the smallest genetic distance between the three families, on the long arm of chromosome 11. All affected individuals shared the same haplotype in this area. This finding suggests that a gene involved in melanin distribution is located on chromosome 11. (<http://www.icp.ucl.ac.be/vikkula>) (vikkula@bchm.ucl.ac.be).

Identification of two novel mitochondrial DNA changes (T1243C and T1291C) in the 12S rRNA associated with nonsyndromic hearing loss. *E. Ballana*¹, *E. Morales*², *P. Gasparini*³, *E. Gean*⁴, *B. Montserrat*¹, *X. Estivill*¹. 1) Center for Genomic Regulation, Barcelona; 2) Centro Nacional de Genética Médica, La Habana; 3) Tigem, Naples; 4) Hospital St Joan de Deu, Barcelona.

Mutations in the mtDNA have been identified as a cause of syndromic and nonsyndromic forms of hearing loss. Among the nonsyndromic deafness-causing mtDNA mutations are the delT961Cn and the A1555G in the 12S rRNA gene and four mutations in the tRNA^{Ser}(UCN) gene (A7445G, 7472insC, T7510C, T7511C). The A1555G mutation in the 12S rRNA gene has been associated with aminoglycoside-induced and nonsyndromic deafness in many families. The resulting phenotype varies among family members, ranging from severe deafness, to moderate progressive hearing loss and normal hearing and it is thought to be due to the interaction between other genetic and environmental factors. A total of 455 families or deaf individuals have been collected to test them for the presence of mutations in known deafness-causing genes. In those cases where the familial history was consistent with maternal inheritance, the samples were analyzed for mutations in the 12S rRNA gene. Mutation A1555G was found in 68 cases, confirming the high frequency of this mutation in Spain. A novel mutation T1291C was identified in a three-generation Cuban family with sensorineural progressive hearing loss and without previous history of aminoglycoside exposure. Audiometric evaluation showed a more severe hearing loss at high frequencies and a wide range in the age at onset of varying from 7 to 40 years. Another non-reported mutation, T1243C, was detected in one Spanish and one Italian sample, affected of sensorineural deafness, without aminoglycoside exposure, but with differences in ages at onset. Thus, the screening of the 12S rRNA gene for various mutations, should be considered in those patients with a family history consistent with maternal inheritance. As hypothesized for the A1555G mutation, the wide variability of the underlying phenotype also found in the new identified mutations, suggest the implication of other environmental or genetic factors, which could contribute to the severity and age of onset of hearing loss.

Human Trmu related to mitochondrial tRNA modification is a modifier factor for the phenotypic expression of the deafness-associated mitochondrial 12S rRNA mutation. *M. Guan*^{1,7}, *Q. Yan*¹, *X. Li*¹, *Y. Bykhovskaya*², *E. Mengesha*², *N. Umeda*³, *P. Hajek*⁴, *R. Li*¹, *J. Peters*¹, *M. Shohat*⁵, *X. Estivill*⁶, *T. Suzuki*³, *K. Watanabe*³, *N. Fischel-Ghodsian*². 1) Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) 2Medical Genetics Institute, Ahmanson Department of Pediatrics, Steven Spielberg Pediatric Research Center, Cedars-Sinai Medical Center and David Geffen School of Medicine at UCLA, Los Angeles, California, 90049, USA; 3) Department of Integrated Biosciences, Graduate School of Frontier Sciences, University of Tokyo, Kashiwa, Chiba, 277-8562, Japan; 4) Division of Biology, California Institute of Technology, Pasadena, California 91125, USA; 5) Department of Pediatrics and Medical Genetics, Basil and Gerald Felsenstein Medical Research Center, Tel Aviv University Medical School, Petah Tikva, Israel; 6) Genes and Disease Program, Center for Genomics Regulation, Barcelona Biomedical Research Park, Barcelona, Spain; 7) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, Ohio 45229-3039, USA.

Nuclear modifier genes have been proposed to modulate the phenotypic expression of deafness-associated 12S rRNA A1555G mutation. We report here the identification of TRMU encoding a highly conserved mitochondrial protein related to tRNA modification. TRMU is ubiquitously expressed and more abundantly in tissues of high metabolic rates. We show that in families with A1555G mutation there is highly suggestive linkage and linkage disequilibrium between microsatellite markers adjacent to TRMU and the presence of hearing loss. Sequencing of TRMU in deaf members of these families revealed a missense mutation (G28T) altering an invariant amino-acid residue (A10S) in the mitochondrial targeting sequence of the gene. Strikingly, the homozygous mutation causes marked defect in mitochondrial tRNA metabolism but does not affect importing and processing of Trmu precursors. The resultant biochemical defects aggravate the mitochondrial dysfunction associated with A1555G mutation. These findings indicate that truncated TRMU, acting as a mitochondrial tRNA modifier factor, modulates the phenotypic manifestation of deafness-associated A1555G mutation.

Molecular and clinical characterization of a Japanese family with maternally inherited nonsyndromic hearing loss. *R. Li¹, K. Ishikawa², L. Yang¹, Y. Tamagawa², K. Ichimura², M.X. Guan^{1,3}.* 1) Dept Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Department of Otolaryngology, Jichi Medical School, Minamikawachi, Tochigi, Japan; 3) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, Ohio 45229, USA.

The T7511C mutation in the mitochondrial tRNA^{Ser}(UCN) gene has been identified to be associated with nonsyndromic deafness in several families from different ethnic groups including Japanese and African-American families. We report here the characterization of a Japanese family with maternally transmitted non-syndromic deafness. 14 of 21 matrilineal relatives in this family exhibited early or late-onset/progressive but non-congenital hearing impairment with a wide range of severity, ranging from severe to normal hearing. The age of onset varies from 3 years to 30 years. Sequence analysis of the complete mitochondrial genome in this pedigree revealed the presence of T7511C mutation and other variants. However, none of these mtDNA variants are evolutionarily conserved and implicated to have significantly functional consequence. Incomplete penetrance in this family indicates the involvement of modulatory factors including other mtDNA mutations/polymorphisms and/or nuclear backgrounds in the phenotypic expression of hearing impairment associated with the T7511C mutation. In particular, the absence of the ND1 T3308C and tRNA^{Ala} T5655C mutations in the Japanese family with the T7511C mutation but the presence of these mtDNA mutations in the African-American family seems to account for different penetrance between two pedigrees. However, our molecular and genetic data showed that variants of GJB2 gene may not act as a modifier factor for the phenotypic expression of the T7511C mutation in this Japanese family.

Molecular analysis of the mitochondrial 12S rRNA in Chinese subjects with hearing loss. *W.Y. Young¹, Q. Wang¹, L. Zhao¹, R. Li², M.X. Guan^{1,2}.* 1) Institute of Otolaryngology, Chinese PLA General Hospital, Beijing, China; 2) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OHIO.

Mutations in mitochondrial DNA (mtDNA) have been found to be one of the most important causes of sensorineural hearing loss. We report here a systematically mutational screening of the mitochondrial 12S rRNA and gene in 276 sporadic Chinese subjects with hearing impairments recruited from the Otology Clinic of Chinese PLA General Hospital. We showed that the frequency of the A1555G mutation is 1.8 % in this Chinese population with hearing impairment. The deafness-associated homoplasmic C1095T mutation in the 12S rRNA gene has been identified in two subjects with aminoglycoside induced deafness and one subject with auditory neuropathy. One subject carries the 961insC mutation. Furthermore, two variants A827G and T1005C in the 12S rRNA gene, which are localized at highly conserved sites, have been found in the affected individuals but absent in 118 controls, indicating that they may play a role in the pathogenesis of deafness. In addition, ten other variants have been found in this Chinese deaf population. These data strongly suggest that the mitochondrial 12S rRNA gene is the hot spot for deafness-associated mutations in the Chinese population.

Biochemical characterization of the mitochondrial 12S rRNA C1494T mutation associated with maternally inherited aminoglycoside-induced and non-syndromic deafness in a large Chinese family. *H. Zhao*^{1,2}, *R. Li*¹, *Q. Yan*¹, *X. Li*¹, *Q. Wang*², *D. Han*², *W.Y. Young*², *M.X. Guan*¹. 1) Human Genetics, Cincinnati Children's Hospital, Cincinnati, OH; 2) Department of Otolaryngology, Chinese PLA General Hospital, Beijing, China.

Biochemical characterization of mitochondrial 12S rRNA C1494T mutation associated with maternally inherited aminoglycoside-induced and non-syndromic deafness has been carried out by using cybrids constructed by transferring mitochondria from lymphoblastoid cell lines derived from the Chinese family into human mtDNA-less (o) cells. 15 cybrids derived from five matrilineal relative of the Chinese family carrying the C1494T mutation, exhibited a significant decrease in the rate of mitochondrial protein synthesis, respiration and growth, compared with 9 control cybrids derived from three controls lacking the mutation. Furthermore, exposure to high concentration of paromomycin or neomycin caused a uniformed and significant average increase in doubling time in 15 cybrid cell lines derived from three symptomatic and two asymptomatic individuals in this family carrying the C1494T mutation, when compared to nine cybrids derived from three control cell lines. These results provide a direct biochemical evidence that the C1494T mutation is the novel mitochondrial DNA mutation associated with aminoglycoside-induced and nonsyndromic deafness. This data also suggest that the nuclear background plays a determining role in the aminoglycoside toxicity.

A NRG1 signaling pathway through Fyn kinase modulates NMDA-R tyrosine phosphorylation: Genetic interaction and relevance to the pathophysiology of schizophrenia. *T. Andresson, S. Haverfield-Gross, M. Bjarnadottir, H. Stefansson, S. Bruun, V. Helgason, A. Sigmundsson, D. Firth, B. Nielsen, A. Kong, J. Gulcher, K. Stefansson, M. Gurney.* deCODE genetics, Reykjavik, Iceland.

Schizophrenia is a complex disease of unknown etiology affecting 0.5-1% of the population. The disease typically is treated with dopamine receptor type-2 antagonists such as haloperidol or with so-called atypical antipsychotic drugs such as clozapine. We previously identified Neuregulin1 (NRG1) as a gene contributing to risk of schizophrenia. Furthermore, we showed that NRG-/+ mutant mice display behavioral abnormalities that are reversed by clozapine. The hypothesis that schizophrenia may result from NMDA-R hypofunction has gained increasing support in recent years. p59Fyn, a src-family kinase, has previously been shown to phosphorylate the NMDA-R subunit NR2B on tyrosine 1472 (Y1472), thereby increasing NMDA-R channel open time and channel open probability. We have identified p59Fyn as an ErbB4 binding protein (ErbB4 is the predominant receptor for NRG1 on CNS neurons) and have demonstrated that p59Fyn kinase is activated in response to NRG1 signaling through ErbB4. Stimulation of ErbB4 by NRG1 in neuroblastoma cells leads to increased phosphorylation of NR2B Y1472. Furthermore, we find that NR2B Y1472 is hypo-phosphorylated in NRG-/+ and ErbB4-/+ mutant mice. The defect in NR2B Y1472 phosphorylation in NRG-/+ mutant mice can be reversed by clozapine at a dose that reverses the behavioral abnormality. Thus, a biochemical defect in NMDA-R subunit tyrosine phosphorylation is linked genetically and biochemically to the NRG1 signaling pathway in schizophrenia and this defect can be reversed by an atypical antipsychotic drug. In Iceland, individuals have a greater risk of developing schizophrenia if longer alleles of the microsatellite marker D16S407 in the GRIN2A promoter and the NRG1 SNP at-risk haplotype coincide. Therefore our combined genetic and biochemical data are in keeping with the glutamate hypothesis of schizophrenia. Subtle misregulation of NRG1 signaling may alter NMDA receptor modulation increasing susceptibility to schizophrenia.

A Role For Estrogen Signaling in Schizophrenia. *S.E. Dobrin, K. Ramsey, J. Parod, D. Hu-Lince, W. Liang, D.A. Stephan.* Neurogenomics Division, TGen, The Translational Genomics Research Institute Phoenix, AZ.

Schizophrenia is a frequent, disabling disease of variable expression and unknown etiology. Symptoms include hallucinations, delusions, paranoia, lack of motivation and anhedonia. The prevalence of schizophrenia is estimated to be about 1% worldwide. Ordinarily, the onset of this illness occurs in adolescence or early adulthood but has been observed in later stages of life as well. In all likelihood, schizophrenia is etiologically heterogeneous. Classical segregation analysis has been unable to identify a single mode of inheritance to explain the familiarity of schizophrenia. However, analyses suggest a complex and multigenic susceptibility to schizophrenia involving both genes and experiences in a majority of the cases. To date, no gene of major significance has been identified for schizophrenia using traditional genetic approaches. Here we present data from expression profiling RNA extracted from the prefrontal cortex of 70 unrelated individuals, 35 affected and 35 unaffected. The data was analyzed in its entirety and by examining the data by gender. We were able to identify a novel pathway for schizophrenia pathobiology. One of the pathways common among the three gene lists derived from this experiment is the estrogen signaling pathway. The estrogen receptor 1 (ESR1) and estrogen receptor 2 (ESR2) genes are up regulated 3 fold in schizophrenic males compared to unaffected males. We found no difference in either of these genes between the schizophrenic females and the unaffected females. However, we did find other genes in the estrogen signaling pathway and genes responsible for estrogen synthesis significantly up regulated in both male and female schizophrenics compared to the unaffected groups. The relative level of components of this pathway were examined at the protein level through immuno-histochemistry. The model developed from this research is able to account for a majority of the current literature surrounding schizophrenia including the many apparently divergent theories of schizophrenia etiology, genes known or thought to be associated with schizophrenia and the mode of action of antipsychotic medications prescribed for schizophrenia.

Disrupted-in-Schizophrenia-1 (DISC1) in Microtubular Dynamics and Cerebral Cortical Development. A. Kamiya^{1, 4}, T. Tomoda², K. Kubo³, R. Youn¹, Y. Ozeki^{1, 4}, P. Una⁵, M. Okawa⁴, C.A. Ross^{1, 5, 6}, M.E. Hatten², K. Nakajima^{3, 7}, A. Sawa^{1, 5}. 1) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Laboratory of Developmental Neurobiology, The Rockefeller University, New York, NY; 3) Department of Anatomy, Keio University School of Medicine, Tokyo; 4) Department of Psychiatry, Shiga University of Medical Science, Otsu; 5) Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD; 7) Department of Molecular Neurobiology, Institute of DNA Medicine, Jikei Univ. School of Medicine, Tokyo.

Although schizophrenia is one of the severest psychiatric illnesses, its pathophysiology remains unclear. Disrupted-in-Schizophrenia-1 (DISC1), identified at the breakpoint of a chromosome (1;11)(q42.1; q14.3) translocation tightly linked to schizophrenia in a Scottish pedigree, is also associated with schizophrenia in other populations, suggesting that it is a model for the pathogenesis of schizophrenia. The translocation causes C-terminal-truncation of DISC1 protein (mutDISC1). We show here that normal DISC1 is a component of the dynein/microtubule complex, regulating microtubular dynamics and neuronal migration. MutDISC1 acts as a dominant-negative, by binding to wild-type DISC1 and disturbing its normal intracellular distribution. Loss of DISC1 function impairs neurite outgrowth in vitro as well as neuronal migration in developing cerebral cortex in vivo. The defects induced by mutDISC1 support the idea that schizophrenia is a disorder of neurodevelopmental origin.

***ABCA4* mutations in recessive retinitis pigmentosa.** C.M. Zaremba¹, A.N. Yatsenko¹, W. Wiszniewski¹, M. Leppert⁵, R.A. Lewis^{1,2,3,4}, J.R. Lupski^{1,4}. 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Medicine, Baylor College of Medicine, Houston, TX; 3) Dept. of Ophthalmology, Baylor College of Medicine, Houston, TX; 4) Dept. of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Dept. of Human Genetics, University of Utah, Salt Lake City, UT.

Retinitis Pigmentosa (RP) is a clinically and genetically heterogeneous group of inherited retinal disorders, which lead to a complete loss of vision. Among the known causative autosomal recessive (ar) RP genes, mutations in *ABCA4* (*ABCR*) hold interest for their high prevalence in the population. Genetic analyses of disorders associated with *ABCA4* alterations are complicated by the large size of the gene and the heterogeneity of its variants (> 400 known). To clarify the prevalence of *ABCA4* alterations in a cohort of 29 arRP families and to explore their role in the phenotype of the disorder, we used a commercial microarray, ABCR-400, in addition to direct sequencing and segregation analyses. In 7 out of 29 (~24%) arRP families we identified 9/58 (~16%) *ABCA4* alterations. Interestingly, in two arRP families, each of the *ABCA4* disease alleles cosegregated with RP (4/58, ~7%), whereas the other 5/58 (~9%) *ABCA4* mutations were heterozygotes. In one family we found a homozygous complex allele [L541P; A1038V], which segregated with the disease in two subjects with arRP. In vitro biochemical studies indicate that the mutant complex allele has a more severe effect on ATP hydrolytic activity (~30% of wild type) than each of the mutations alone by itself. In the second RP family we identified a severe truncating allele, R408X, with a missense alteration, R602W, which presumably has an effect on ABCR trafficking as determined by recombinant ABCR constructs expressed in *Xenopus laevis*. Segregation analyses in 5 arRP heterozygous families demonstrated no direct correlation between *ABCA4* alterations and the disease phenotype. We conclude that homozygous or compound homozygous *ABCA4* mutations account for ~7% of arRP and heterozygous *ABCA4* mutations, despite having functional consequences, do not specifically influence the RP phenotype.

Identification of pathways defective in MS: computer assisted integration of linkage and expression data. D.

Chen¹, J. Saarela², R. Yuan⁴, E. Choi^{1,3}, S. Hung³, S. Benlevi^{1,3}, K. Chau Li⁴, A. Palotie^{1,3,5}, L. Peltonen^{1,2,6}. 1) Dept. Hum Genet, UCLA, CA; 2) Natl Publ Health Inst, Helsinki, Finland; 3) Dept Patholgy, UCLA, CA; 4) Dept Statistics, UCLA, CA; 5) Finnish Genome Ctr, Dept. of Clin Chem, Univ. of Helsinki; 6) Dept. of Med. Gen., Univ. of Helsinki, Finland.

A total of 4 genome scans in populations of UK, US, Canada and Finland have identified a total of 20 chromosomal regions linked or suggestive for linkage to MS. Over 1,000 genes are detected in these 20 genomic regions, all representing potential candidate genes for MS. Similarly, 17 expression studies on MS using tissues ranging from peripheral blood mononuclear cells, CD4+ cells, MS plaques, human glioblastoma cells, oligodendroglial cells and tissues derived from rat MS model have identified tens of candidate genes. Combining data from expression and linkage studies could potentially provide exciting new avenues for MS research. However, this strategy is hampered by technical problems e.g. nomenclature of genes or gene markers are often not standardized among different studies. In addition, functional relationship between genes on critical chromosomal regions and differentially expressed genes are not established. We have designed a relational database containing candidate genes derived from all MS linkage and expression studies. A java front-end client was developed to allow users to query data from the gene database. To determine potential functional relationship between genes, we constructed a computational system to allow users to interrogate between multiple datasets. Currently, this computational system has been tested using three datasets: (1) the NCBI's 60 cell-line gene expression data; (2) a large human data sampled from a diverse array of tissues, organs, and cell lines (GNF gene expression Atlas); and (3) a mouse gene expression data from segregation experiments. The analyses provided include both correlation studies and liquid association (LA) study. LA analysis on MS loci on 5p13 and 17q22-24 suggest a functional relationship between FALZ and SLC1A3 genes exemplifying identification of novel targets for further studies.

Computational strategies to identify candidate genes for genetically complex diseases: type 2 diabetes mellitus.

R.C McEachin¹, J.S. Huo⁴, J. Schwartz^{3,4}, D.J. States^{1,2}. 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Bioinformatics, University of Michigan, Ann Arbor, MI; 3) Physiology, University of Michigan, Ann Arbor, MI; 4) Cellular and Molecular Biology, University of Michigan, Ann Arbor, MI.

Complex diseases involve an interaction of genetic and environmental components in disease susceptibility, suggesting a search for candidate genes that show both genetic variability and environmental response in predisposing disease. Genetic linkage analysis localizes candidate genes that may have allelic variation related to disease, while differential expression analysis reveals genes that show an important cellular response to the environment. Using Type 2 Diabetes Mellitus (T2DM) as a test case, we show that combining genetic linkage and differential gene expression criteria yields better candidate genes than selection by either criterion alone. T2DM is used as a test case to validate the method because of its significant public health impact and complex disease susceptibility, as well as the availability of data from previous research, which provides input for the method. Using criteria developed during testing, we identified four candidate T2DM genes, which are linked to T2DM and also show differential expression coincident with the onset of disease. Among these candidates, two were previously implicated in T2DM (PTPN1 and SCARB1) and two are novel (CAPN6 and DHRS8). Notably, CAPN6 is a member of the calpain family, which is implicated in T2DM, and CAPN6 is structurally similar to CAPN10 (a.k.a NIDDM1). These four candidates also share a common element in retinol (Vitamin A) metabolism, which has been associated with T2DM susceptibility. Approximately 1.6 % of the genes assayed were previously implicated in T2DM, yielding a probability of 0.0015 for finding two or more T2DM genes in a random selection of four, suggesting that the two genes not previously implicated in T2DM are also valid candidates. More generally, these criteria are effective in improving the selection of candidate genes for one complex disease, and this method could be applied in identifying candidate genes for other complex diseases.

Gem GTPase and tau: morphological changes induced by Gem GTPase in CHO cells are antagonized by tau. F.

Oyama^{1,2}, *S. Kotliarova*¹, *A. Harada*^{3,4}, *M. Ito*⁵, *H. Miyazaki*¹, *Y. Ueyama*^{5,6}, *N. Hirokawa*³, *N. Nukina*¹, *Y. Ihara*². 1) Lab Structural Neuropathology, RIKEN Brain Science Inst, Saitama, Japan; 2) Department of Neuropathology, Faculty of Medicine, University of Tokyo, Tokyo, Japan; 3) Department of Cell Biology and Anatomy, Faculty of Medicine, University of Tokyo, Tokyo,; 4) Laboratory of Cellular and Molecular Morphology, Institute for Molecular and Cellular Regulation, Gunma University, Maebashi, Gunma, Japan; 5) Central Institute for Experimental Animals, Kawasaki, Kanagawa, Japan; 6) Department of Pathology, School of Medicine, Tokai University, Isehara, Kanagawa, Japan.

A series of observations have indicated that tau, one of the major microtubule-associated proteins, is involved in neuronal cell morphogenesis and axonal maintenance. Tau is also the major component of paired helical filaments found in the brain affected by Alzheimers disease. To explore an as yet unidentified role of tau in vivo, ~11,000 mRNAs were profiled from tau-deficient mouse brains, and compared with those from control brains at the same ages. The expression of Gem GTPase, a small GTP-binding protein of the ras superfamily, was significantly increased in the brain of tau-deficient mice at eight weeks of age. Because Gem GTPase is a negative regulator of the Rho-Rho kinase pathway for cytoskeletal organization, this protein was transiently overexpressed in CHO cells that do not express tau. Overexpression of Gem GTPase induced a marked elongation of CHO cells, and simultaneous expression of tau eliminated this effect, although tau did not bind directly to Gem GTPase. This anti-elongation activity of tau was attributed to its microtubule (MT)-binding domain, and homologous domains of MAP2 and MAP4 exhibited similar antagonistic activities. Taken together, the present results indicate that the level of Gem GTPase and its cell elongation activity are modulated by tau, and suggest that tau may be involved in a Gem GTPase-mediated signal transduction pathway.

Mitochondrial Complex I Nuclear Genes and Parkinsons Disease. *M.D. Ritchie¹, S.L. Lee², P. Silburn³, J. Prince⁴, A. Brookes⁴, G.D. Mellick⁵*. 1) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Dept of Neurology, Vanderbilt Univ, Nashville, TN; 3) Dept of Neurology, Princess Alexandra Hospital, Brisbane, Australia; 4) Dept of Genomics and Bioinformatics, Karolinska Institute, Stockholm, Sweden; 5) Univ of Queensland, School of Medicine.

Identifying susceptibility genes for common, complex disease is at the forefront of genetic epidemiology. Parkinsons disease (PD) is among the debilitating neurological disorders that have become a major focus of human genetics. Genes involved in oxidative stress and mitochondrial activity have been suggested candidate genes for PD. We reason that genetic variations in mitochondrial Complex I nuclear genes may contribute in a complex manner to disease risk. In an initial screen of 306 PD patients and 321 unrelated healthy controls ascertained from a Caucasian Australian population, no association was observed between 70 SNPs in 31 mitochondrial Complex I nuclear genes and disease risk. In this study, we used a novel statistical approach, Multifactor Dimensionality Reduction (MDR) to analyze this data along with pesticide exposure history obtained by self-reported questionnaire to explore the possibility of gene-gene and gene-environment interactions with respect to mitochondrial complex I polymorphisms and pesticide exposure. MDR was developed as a nonparametric, model free method to test for association in case-control studies of human disease. Using MDR, we detected a single locus effect in *NDUFS4* (SNP00005133, HGVbase ID) which is able to correctly predict disease status with 56.22% accuracy ($P < 0.162$). When stratified by gender, MDR also detected a highly significant association in women between the dihydrolipoyl succinyl transferase gene (*DLST*) (SNP00000234) and disease status, 61.36% prediction accuracy ($P < 0.014$). Interestingly no high-order interactions were detected between these polymorphisms and the pesticide exposure data. These findings support the possibility that *NDUFS4* is an important factor in PD susceptibility among Caucasian individuals, and that *DLST* may contribute to disease risk in women and demonstrate the utility of novel computational approaches for the detection of disease susceptibility genes.

Program Nr: 2077 from the 2004 ASHG Annual Meeting

Ethanol responsive metabolome: An insight in the regulatory network involving trans-acting factors and cis-acting motifs. *R.K. Uddin, J.A. Treadwell, S.M. Singh.* Molecular Genetics Unit, Department of Biology and Division of Medical Genetics, University of Western Ontario, London, Ontario, Canada N6A 5B7.

The effect of alcohol is realized by its effect on cellular physiology via gene expression. Ultimately it mediates alcohol's effect in the short as well as in the long term, resulting in drunkenness, FAS and addiction. It is now apparent from the genome wide works on the effects of alcohol on gene expression that some genes are invariably up-regulated or down-regulated while others are affected in an individual specific manner, depending on the genotype, age, dose or other factors. The genes identified fall in such functional categories as, cell signaling, gene regulation, stress response, protein modification, proliferation/survival and transport (Treadwell and Singh, 2004). Further a high proportion of these genes, map to QTL regions for various alcohol specific phenotypes. This comprehensive list of genes (~100) requires a more interactive and metabolomic approach for its interpretation, where a chain reaction regulates expression of a set of genes that involves specific cis-element(s) and trans-acting factor(s) and ultimately yielding a complex network of expression. An understanding of this network is vital to the elucidation of the alcohol responses and effects. We have undertaken an exhaustive knowledge based analysis of the 5' upstream sequence of the ethanol responsive genes identified by microarray to (predict and) compile a searchable database of Ethanol- Responsive-gene-Regulatory-Network (EthaRNet) involving cis-motifs and their interacting trans-factors. Individual genes and their regulatory elements implicated in alcoholism in the literature are also included in the analysis. We generate a number of individual regulatory motifs - protein interaction processes for all genes and map them in networking pathways that provides a global view of ethanol responsive transcriptional / post-transcriptional regulatory networks. The pathways are connected and allow us to predict a list of cis-regulatory elements active in the pathways that are specific to ethanol responses and effects. Supported by Canadian Institute of Health Research and Ontario Mental Health Foundation.

Quantitative TDT analysis of SNPs of candidate genes for bone mineral density in 1p36. *M. Devoto¹, K. Sol-Chuch¹, D. Stabley¹, H. Li¹, C. McKay¹, A. Tenenhouse², L.D. Spotila³.* 1) Nemours Children's Clinic, Wilmington, DE; 2) McGill University, Montreal, ON, Canada; 3) Drexel University, Philadelphia, PA.

Low bone mineral density (BMD) is one of the most important risk factors for osteoporosis, a common complex trait characterized by reduced skeletal strength and increased susceptibility to fracture. We performed a whole genome scan in Caucasian families of individuals with low BMD and identified a candidate region on 1p36 by variance component linkage analysis (maximum multipoint lod-score of 3.53 for linkage of femoral neck BMD near marker D1S214) and quantitative transmission disequilibrium test (QTDT) ($p = 0.0098$ for marker D1S2660, and $p = 0.0012$ for D1S489). To follow up on these findings, we have selected a few candidate genes on the basis of their location in 1p36 and information about function and pattern of expression. SNPs of these genes have been tested for linkage disequilibrium to femoral neck BMD in the same sample of families. Genotyping of SNPs obtained from publicly available databases or from Applied Biosystems Assays-on-Demand was performed by either Pyrosequencing or on the ABI 7900HT Sequence Detection System. Linkage disequilibrium of candidate gene SNPs and femoral neck BMD in the 40 families was tested by means of the QTDT software including sex, age and BMI as covariates. Results of this analysis were not significant for nine SNPs of the guanine nucleotide binding protein (G protein) beta polypeptide 1 gene (GNB1) and 10 SNPs of the calmodulin binding transcription activator 1 (CAMTA1) (all p -values > 0.1). One SNP of four tested in the isoprenylcysteine carboxyl methyltransferase gene (ICMT) yielded a p -value of 0.045. A fourth gene, WD repeat-containing protein 8 (WDR8) was selected because experiments in mouse had shown expression in bone and cartilage and in bone forming cells including osteoblasts and chondrocytes during ossification. Among six SNPs tested in this gene, one yielded a nominal p -value of $p = 0.005$ for association with femoral neck BMD. Additional tests are in progress to confirm these finding using additional SNPs of the same genes and haplotype analysis.

Association of single nucleotide polymorphisms (SNPs) in the PPARG gene and interaction with COL1A1 gene in susceptibility for osteoporosis in elderly women. *J. Li¹, S.K. Ro¹, N. Umblas¹, J. Mangacat¹, L. Lui², J.M. Zmuda³, S.R. Cummings⁴, G. Peltz⁵, R. Higuchi¹.* 1) Roche Molecular Systems, Alameda, CA; 2) University of California, San Francisco, CA; 3) University of Pittsburgh, Pittsburgh, PA; 4) California Pacific Medical Center, San Francisco, CA; 5) Roche Bioscience, Palo Alto, CA.

PPARG has been shown in a mouse model to be involved in osteogenesis. A silent mutation in exon 6 of the PPARG gene and a mutation in an Sp1 binding site in intron 1 of the COL1A1 gene have been reported to be associated with reduced bone mineral density (BMD) in humans. We conducted a nested case-control osteoporosis (OP) study (n=1042) among older women that involved genotyping of 23 SNPs in 6 genes, including 6 SNPs in PPARG and the Sp1 polymorphism in COL1A1. PPARG and COL1A1 allele and genotype frequencies in women with incident hip (n=275) and vertebral (n=262) fractures (HFX and VFX), and low BMD (n=276) were compared with those in controls without these phenotypes (n=278). Two of the PPARG SNPs (Pro12Ala and VN102), which are in linkage disequilibrium, showed an association with HFX. Individuals with HFX have 7.0 and 7.7% higher frequency of the genotype CC (Pro12Ala) (odds ratio [OR]=1.8, p=0.02 after adjusting for age, weight, and estrogen use [adjustment]) and GG (VN102) (OR=1.9, p=0.01 after adjustment) than those in controls, respectively. There was no significant association between PPARG and VFX and low BMD after adjustment. However, we observed an interactive effect between PPARG and COL1A1 genotypes on both VFX and low BMD (p=0.009 and 0.002 respectively after adjustment). For VFX and low BMD, the OR for the Pro/Pro genotype among women who had the COL1A1 risk allele was 2.9 (p=0.01) and 5.9 (p=0.0008) respectively after adjustment. In contrast, there was no significant relationship between PPARG Pro/Pro genotypes and any of above three OP phenotypes among women who had no COL1A1 risk allele. The same effect was also observed for PPARG_VN102. These data indicate a novel association between PPARG and HFX and an interlocus interaction between PPARG and COL1A1 and the genetic susceptibility to OP in older Caucasian women.

Absence of association of the matrilin-3 polymorphism T303M (rs8176069) with osteoarthritis. *J.L. Min¹, I. Meulenbelt¹, N. Riyazi², M. Kloppenburg², H.A. Pols³, C.M. van Duijn⁴, P.E. Slagboom¹.* 1) Medical Statistics, LUMC, Leiden; 2) Rheumatology, LUMC, Leiden; 3) Internal Medicine, Erasmus MC, Rotterdam; 4) Epidemiology & Biostatistics, Erasmus MC, Rotterdam, The Netherlands.

Osteoarthritis (OA) is a joint disease characterized by degeneration of articular cartilage and remodeling of the subchondral bone with sclerosis. It has been demonstrated that genetic factors play a considerable role in the onset of OA described by various definitions. *MATN3* is an interesting candidate gene for OA encoding a noncollagenous extracellular oligomeric matrix protein. In this gene, an association of a missense mutation (T303M) involving a conserved amino acid substitution among patients with hand OA (0.02) as compared to the Icelandic population (0.01) was observed. To replicate these findings, we have genotyped three polymorphisms, rs2242190, rs8176069 (T303M) and rs8176070 in the *MATN3* gene in two populations. Firstly, a random sample of 809 subjects from a Dutch population-based cohort (the Rotterdam study) was studied. In this study, radiographic OA for hip, knee, hand and spine OA was assessed. Secondly, the GARP study (Genetics, Osteoarthritis and Progression) was investigated consisting of 191 affected siblings with symptomatic and radiographic OA in more than one joint group. Both in the Rotterdam (0.014) and the GARP study (0.011), we observed a 2-3 times higher allele frequency of T303M than in the Icelandic population (0.005). In contrast to the Icelandic study, no significant association with similar phenotypes for hand OA in the Rotterdam study was observed. In addition to what was studied in the Icelandic population, we tested whether the T303M variant and/or haplotypes of the three *MATN3* polymorphisms were associated with OA of the hip, knee or spine. Among 21 T303M carriers, OA was not occurring more frequently than in the 809 subjects from the Rotterdam study. The three polymorphisms combined to major haplotypes of which the frequencies were similar to that in the Icelandic population. None of these haplotypes were consistently associated with the presence of OA at any joint group tested. Our results do not support the T303M variant to be involved in OA.

Association between a *CCR5* haplotype and juvenile rheumatoid arthritis. *S. Prahalad*¹, *J.F. Bohnsack*¹, *D. Dunn*², *S.D. Thompson*³, *D.N. Glass*³, *R. Weiss*², *M. Bamshad*^{1,2}. 1) Dept Pediatrics, Univ Utah, Salt Lake City, UT; 2) Dept Genetics, Univ Utah, Salt Lake City, UT; 3) Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Juvenile rheumatoid arthritis (JRA), the most common cause of chronic childhood arthritis, is mediated by Th1-immune responses. In children with JRA, synovial fluid T-cells express high levels of the Th1-chemokine receptor *CCR5*, which has been implicated in susceptibility to rheumatoid arthritis. We hypothesized that genetic variation in the 5'*cis*-regulatory region of *CCR5*, which are known to cause variable *CCR5* expression, will be associated with susceptibility to JRA. To test this hypothesis, we analyzed patterns of variation in the 5'*cis*-regulatory region of *CCR5* in a well-characterized cohort of 124 multiplex families containing 250 affected children from a NIH-sponsored JRA affected sibpair registry. The upstream region of human *CCR5* (-2867 to -1745), which included the *CCR5* promoter, was sequenced using standard methods. Ten single nucleotide polymorphisms (SNPs) and 8 haplotypes were identified, most of which have been described previously. SNPs and haplotypes were tested for association with JRA by transmission disequilibrium testing (TDT) using Transmit 2.5.4. Analyses were repeated after stratification by onset-type and age of onset. Two common haplotypes were observed. TDT did not demonstrate deviations of expected transmission of any of the *CCR5* SNPs or haplotypes to the JRA cohort as a whole. However, after stratification, one of the *CCR5*-haplotypes was significantly ($p < 0.04$) under-transmitted to children with JRA who had disease onset before age 6. The same haplotype also was under-transmitted to children with polyarticular JRA, but this did not reach statistical significance ($p = 0.08$). The SNP (C927T) that defined this haplotype was also under-transmitted to children with early onset JRA ($p = 0.053$). Interestingly the presence of this *CCR5*-haplotype has been previously shown to influence the progression of acquired immune deficiency syndrome. We conclude that genetic variants in the *cis*-regulatory region of *CCR5* might be associated with early onset juvenile rheumatoid arthritis.

Association of a novel serotonin transporter polymorphism with obsessive-compulsive disorder based on qualitative and quantitative traits. *P.D. Arnold¹, X. Hu², J. Trakalo¹, M.A. Richter¹, D. Goldman², J.L. Kennedy¹.* 1) Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) NIAAA/NIH, Rockville, MD, USA.

There is strong evidence that genetic determinants are involved in the etiology of Obsessive-Compulsive Disorder (OCD). Previous candidate gene investigations have indicated a possible association with the high transcribing long (L) allele of the serotonin transporter (5HTT) gene-linked polymorphic region (5HTTLPR), however findings have been inconsistent. Earlier studies have not accounted for a recently identified A/G variant within the L allele which alters transcriptional activity, with the more common LA variant associated with increased transcription and the LG allele associated with decreased transcription. In a recent case-control study, the LA allele was associated with OCD (Goldman et al., 2004). We genotyped the 5HTTLPR and the A/G variant within the 5HTTLPR in 172 nuclear families ascertained through an OCD proband, and obtained data regarding symptom severity in 139 of the probands and 36 siblings using the Yale-Brown Obsessive Compulsive Scale (YBOCS). Analysis for genetic association was conducted using the Family Based Association Test (FBAT), based on both qualitative (OCD diagnosis) and quantitative (highest known YBOCS score) traits under additive, dominant and recessive models of inheritance. For OCD diagnosis, a nominally significant association was found with the LA allele under the dominant model of inheritance ($z=2.01$, $p=0.04$). For symptom severity, the strongest finding was again for the dominant model, with a positive association with the high transcribing LA allele ($z=2.67$, $p=0.007$) that remained significant after correcting for multiple models of inheritance. These results indicate that the high transcribing LA allele may influence the OCD phenotype through its effects on expression of the serotonin transporter, and replicate the findings of an independent case-control sample. Furthermore, the stronger results based on symptom severity underscore the usefulness of analyzing quantitative traits in complex neuropsychiatric disorders.

Multi-locus effects with RELN, APOE, and SLC6A4 influence autistic disorder susceptibility. *A.E. Ashley-Koch¹, J. Jaworski¹, H. Mei¹, R. Rabionet¹, D.A. Skaar¹, M.D. Ritchie², G.R. DeLong¹, R.K. Abramson³, H.H. Wright³, M.L. Cuccaro¹, J.G. Gilbert¹, E.R. Martin¹, M.A. Pericak-Vance¹.* 1) Duke University Medical Center, Durham, NC; 2) Vanderbilt University, Nashville, TN; 3) University of South Carolina School of Medicine, Columbia, SC.

Autistic disorder (AD) is a complex genetic disorder with several putative susceptibility loci. We have examined three candidate genes (RELN, APOE and SLC6A4) to test whether they jointly confer AD risk. RELN is a positional, functional candidate gene for a 7q AD locus. Although AD linkage has not been observed in the APOE region of chromosome 19, RELN binds two APOE receptors suggesting these two genes may interact. SLC6A4 is involved in regulation of serotonin, a biomarker for AD, and several studies have reported association between SLC6A4 and AD. We examined these genes in 241 multiplex (including 99 from AGRE) and 210 singleton AD families. All AD individuals met ADI-R criteria. All SNPs examined were tested for Hardy-Weinberg Equilibrium deviations and for LD with other SNPs. We used the geno-PDT, to detect joint multi-locus associations, and the multifactorial dimensionality reduction (MDR) method. Our first hypothesis was that RELN interacts with APOE. In the overall dataset, both the geno-PDT and MDR detected significant ($p < 0.05$) 2-locus effects. However, the most significant joint effects were detected in the multiplex subset where the geno-PDT gave a significant global result ($p = 0.001$) for a SNP at position 113 in APOE with a SNP in exon 59 of RELN. The MDR analysis also detected a significant 2-locus effect between these SNPs ($p = 0.02$). The next hypothesis tested was whether RELN interacts with SLC6A4. In the singleton subset, there was evidence for a multi-locus effect of several SNPs involving combinations of 2 and 3 SNPs from both genes in the MDR analysis ($p < 0.001$). This effect was supported by MDR analysis of the entire dataset ($p = 0.02$), as well as by geno-PDT analysis ($p < 0.001$). We are further exploring these multi-locus effects to disentangle main effects and interactions. In summary, these preliminary results suggest that multi-locus effect do indeed contribute to AD susceptibility.

Collecting phenotypic data for gene discovery in Parkinsonism-the NINDS cell and DNA repository. *J. Beck¹, J. Nash¹, C. Royds¹, C. Kronenthal¹, R. Malkani², J. Werner², A. Crawley², D. Murphy², B. Ravina², K. Gwinn-Hardy².*
1) Coriell Inst Medical Research, Camden, NJ; 2) NINDS, NIH, Bethesda, MD.

While biological repositories exist for genetic studies in a variety of disorders, it is rare to find those which have standard clinical data sets and are widely available as public resources. To develop a large well-characterized sample collection in neurological disorders, the National Institute of Neurological Disorders and Stroke (NINDS) Cell line and DNA repository (<http://locus.umdj.edu/ninds>) developed clinical assessment tools for use in genetic studies of Parkinsons disease (PD) and other forms of parkinsonism. Also included in the collection are affected and unaffected blood relatives, spousal controls, and normal healthy individuals. Clinical Data Elements (CDEs) were developed which allows a standard set of phenotypic information to accompany each sample based on clinical signs. The PD CDEs were designed to reflect the widely utilized London Brain Bank Criteria in a format designed for easy use in the clinic or field. Additional design was based on the results of an NINDS sponsored meeting. Most patients with parkinsonism have PD. However, parkinsonian signs may be present in neurodegenerative disorders with different neuropathological and genetic characteristics; these include Progressive Supranuclear Palsy (PSP), Multiple System Atrophy (MSA), Corticobasal Degeneration (CBD), Spinocerebellar Ataxia (SCA) and others. Submitters obtain clinical data from the subjects history and physical examination, submit these with each sample, and these are reviewed by a board certified neurologist to ensure appropriateness for inclusion in the repository. CDEs for Parkinsonism focus on PD, but include elements which address features suggestive of other diagnoses. Additionally, separate CDEs for non-PD parkinsonian subjects, and for controls, have been developed. Electronic formats have also been developed for housing and manipulating these data, allowing simple searches for a given endophenotype, and focused genotype-phenotype studies. These clinical and databasing tools permit pooling of samples and clinical information across many studies.

***SYBL1* as a candidate gene for autism, a mixed genetic-epigenetic model.** S. Ben Shachar¹, M. Shinawi¹, Y. Jiang¹, R.E. Stevenson², A.L. Beaudet¹. 1) Molecular & Human Genetics, Baylor Col of Medicine, Houston, TX; 2) Greenwood Genetic Center, Greenwood, SC.

Autism is a complex psychiatric condition with high male to female ratio. Significant genetic contribution to autism can be implied by its high concordance rate in monozygotic twins. So far genome-wide linkage studies have failed to provide strong evidence for major autism-related loci suggesting existence of many loci. Alternatively, epigenetic changes might contribute to its etiology. *SYBL1* encodes a member of the synaptobrevins family of proteins that are involved in synaptic vesicle docking and exocytosis. It is ubiquitously expressed in many tissues including many brain structures. Interestingly, *SYBL1* is located on Xq and Yq pseudoautosomal region. It is unique in being subject to Y-specific inactivation in males. The inactivation is associated with CpG methylation of the gene promoter. We hypothesized that aberrant expression of *SYBL1* might cause autism. Defects might be de novo or inherited, ubiquitous or brain-specific, and might be associated with aberrant DNA methylation. This hypothesis could explain both the failure to find a major autistic gene and the male predominance in autism. We analyzed the methylation of the promoter region of *SYBL1* in lymphoblast cell lines of 29 autistic individuals from AGRE and NIMH collections (families with affected sib pairs), 10 from S. Carolina Autism Project (families with a single affected individual), and 24 controls. Furthermore, 19 autistic brains were examined. The methylation status was tested by southern blot analysis after double digestion with *EcoRI* and the methylation sensitive enzyme *BssH II*. Furthermore, DNA was sequenced after bisulfite treatment to precisely evaluate the CpGs' methylation of this region. The expected 1:1 ratio of methylated:non methylated allele was found in all of the brain DNAs. In the autistic lymphoblast cell lines, 3 showed hypermethylation, and 2 demonstrated hypomethylation. Among controls, we found 1 cell line with hypermethylation and 1 with hypomethylation. We conclude that alteration of expression of *SYBL1* as tested by methylation doesn't have a major contribution to the autistic phenotype.

The relationship of the 5HTTLPR polymorphism to serotonin transporter mRNA transcription. *S.L. Bradley, K. Dodelzon, H.K. Sandhu, R.A. Philibert.* Psychiatry, University of Iowa, Iowa City, IA.

The serotonin transporter (5HTT; chromosomal location 17q12) is an important regulator of monoaminergic neurotransmission and is the site of action for a number of antidepressant medications including fluoxetine (Prozac) and sertraline (Zoloft). Not surprisingly, sequence variation at 5HTT has been associated with a wide variety of neurobehavioral illness. In particular, variation at a polymorphic site known as the 5HTTLPR, which is 1.4 kb upstream of the translation start of 5HTT, has been associated in some studies with increased vulnerability to depression, neuroticism, and autism. Support for these clinical observations has included laboratory findings that 5HTTLPR variation is associated with large changes in 5HTT gene translation in a small sampling of lymphocyte cell lines (n=11). We re-examined these earlier findings by directly measuring genotype and 5HTT mRNA levels in over 80 independent lymphocyte cell lines using PCR and RT-PCR methodologies. The resulting data were analyzed by ANOVA. We found a trend for a relationship between 5HTTLPR genotype and mRNA levels with the genotype accounting for less than 8% of the total variance in 5HTT mRNA production. Furthermore, in contrast to previous reports, the small effect of 5HTTLPR variation on 5HTT mRNA production appeared to be mediated through an additive, not dominant, mechanism. These results and additional data are discussed. We conclude that although there are a number of possible explanations for our results, we conclude that further examination of the relationship of the role of the 5HTTLPR in regulating 5HTT mRNA production is warranted.

Single Nucleotide Polymorphism Analysis on Chromosome 2 in Early-Onset Alzheimer Disease Families. *C.A. Browning¹, S. Prasad¹, P. Bronson¹, D.D. Vance¹, J.M. van der Walt¹, W.K. Scott¹, J.L. Haines², M.A. Pericak-Vance¹.*
1) Center for Human Genetics, Duke University, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Recent analysis of 10cM whole genomic screen microsatellite data with age at onset as a covariate identified a region of chromosome 2 linked (LOD score = 3.2) in families with average onset of Alzheimer disease (AD) in the fifth and sixth decades. Twelve single nucleotide polymorphisms (SNPs) spanning 2.5 Mb and flanking the peak marker (D2S2944) were genotyped in 31 families (with an average of three sampled affected individuals/family) with at least one family member with early-onset AD (50-60 years). SNPs were identified through ABI Assay on Demand and genotyped using the TaqMan system. Non-parametric linkage analysis was performed using Allegro. The multipoint LOD score increased to 3.5 and peaked at rs1370369 (single point LOD score = 1.48, multipoint LOD score = 3.46). The -1 lod interval spans ~ 17 Mb. These data increase support for a locus on chromosome 2 restricted to a subset of families with early-onset family members. Mutation analysis is ongoing for functional candidate genes mapping to 1-LOD unit down support interval.

No evidence of linkage disequilibrium between RGS4 and schizophrenia in Canadian linkage families. *L.M.*

Brzustowicz^{1,2}, J. Simone¹, J.E. Hayter¹, E.W.C. Chow³, A.S. Bassett³. 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Dept of Psychiatry, UMDNJ-NJMS, Newark, NJ; 3) Dept of Psychiatry, Univ of Toronto, and Clinical Genetics Research Program, Queen Street Site, Centre for Addiction and Mental Health, Toronto, Ontario.

We have previously reported linkage of schizophrenia to chromosome 1q21-22 with a heterogeneity lod (HLOD) score of 6.50 in a group of 22 medium-sized multiplex Canadian families. Most recently, we have reported significant evidence of linkage disequilibrium (LD) between schizophrenia and markers within the gene CAPON on 1q22. Other groups have reported significant association between schizophrenia and RGS4, a gene located 700 kb distal to CAPON on 1q23. We evaluated RGS4 for LD to schizophrenia in our sample, as a potential second susceptibility locus on 1q.

To identify SNPs for LD analysis, we resequenced the RGS4 gene in 16 subjects from our sample, including the entire coding region of the gene, introns 2-4, and 1 kb of 5' region, resulting in the identification of 14 SNPs. No SNPs within coding sequence or splice sites were identified. For LD analysis, we genotyped our entire current sample of 332 subjects for 4 SNPs previously reported to be associated with schizophrenia, and another SNP just 5' to the promoter and one in the 3' UTR. Evidence for LD was assessed using the program PSEUDOMARKER which, in contrast to popular TDT-based programs, explicitly separates the evidence for linkage and LD in families with multiple affecteds. Analyses were conducted using a recessive pseudomarker model, as there is significantly stronger evidence for a recessive mode of action for the 1q locus in this sample, and using a narrow definition of affection (schizophrenia or schizoaffective disorder). No marker produced significant ($p < 0.05$) evidence for LD to markers in RGS4. This same sample and same analysis method had previously produced significant evidence (empiric study-wide p -value < 0.05) of LD to 3 markers in CAPON. These results fail to provide evidence for RGS4 as a second 1q schizophrenia susceptibility gene in this sample.

A mutation in the *ATPIA2* gene in a large family with migraine without aura. *M. Castro*^{1,2}, *C. Lemos*^{1,2}, *J. Barros*³, *C. Fraga*³, *L. Guimaraes*⁴, *P. Maciel*^{2,5}, *A. Sousa*^{1,2}, *J. Sequeiros*^{1,2}, *J. Pereira-Monteiro*^{1,2,3}, *I. Silveira*^{1,2}. 1) IBMC, UnIGENE, Porto, Portugal; 2) ICBAS, Universidade do Porto; 3) Serviço de Neurologia, HGSA; 4) Faculdade Ciências Saúde, Universidade Fernando Pessoa;; 5) ICVS, Escola Ciências Saúde, Univ. Minho, Braga, Portugal.

Migraine is a common, complex and heterogeneous disorder, presenting strong familial aggregation. Recently, the gene encoding the Na⁺/K⁺ pump 2 subunit (*ATPIA2*) has been implicated in a rare and severe familial type of migraine with hemiparesis. We selected 50 families with an apparently autosomal dominant mode of inheritance of migraine without aura (MO) or with aura (MA) and performed mutation analysis to find out whether this gene was also involved in the common type of migraine. A G-to-A transition was found at nucleotide 256, in exon three, in a large family with MO. This mutation causes an arginine-to-histidine change at codon 51 of the Na⁺/K⁺ pump 2 subunit, and was not present in 346 chromosomes from a control population. This Arg51 is conserved among subunits of the pump from other species. Na⁺/K⁺-ATPase exchanges intracellular Na⁺ for extracellular K⁺, generating ion gradients important for nerve transmission and muscle contraction. This R51H change is located in the N-terminal cytoplasmic loop, in a predicted cation ATPase transporter domain. No mutations were found in the remaining families. In conclusion, we describe the first mutation in a large family with MO. These results also indicate that the common type of migraine may in fact be caused by impaired ion homeostasis in brain, at least in some families.

Microrrearrangements of human chromosome 15q11-q13 in families with autistic disorder. *C. CERRATO*¹, *M. Ogorelkova*¹, *M. Gratacòs*¹, *X. Estivill*^{1,2}. 1) GENES AND DISEASES, CENTER FOR GENOMIC REGULATION, BARCELONA, BARCELONA, Spain; 2) Experimental and Health Sciences Department, Pompeu Fabra University, Barcelona Biomedical Research Park, Barcelona, Catalonia, Spain.

Autism is a neurodevelopmental disorder exhibiting complex genetic etiology. Human chromosome 15q11-q13 is a candidate region to autism based on linkage, linkage disequilibrium, cytogenetic abnormalities, and maternal duplications at this locus in patients with autism and autism-related phenotype. Chromosome 15q11-q13 contains several imprinted genes expressed in the brain, including small nucleolar RNA (snoRNA) genes, and is rich in segmental duplications. These sequences promote fairly frequent 15q11-q13 rearrangements resulting in Prader-Willi syndrome, Angelman syndrome, mental retardation and autism spectrum disorder. Among plausible candidate genes for autism in this region is cluster of the gamma-aminobutyric acid (GABA) receptor genes. In order to detect possible duplicon-mediated submicroscopic rearrangements of 15q11-q13, we have performed the analysis of microsatellite markers in autistic families and control samples. We have found maternally and paternally inherited duplications of microsatellite located at HBII-85 snoRNA locus in two patients, and paternal deletion at microsatellites of the GABA region in one patient. Using quantitative PCR, PFGE and additional microsatellites and single nucleotide polymorphisms in the region we are currently defining the size of these rearrangements, which should help to delineate the relationship between 15q11-q13 microrrearrangements and autistic disorder.

Supportive evidence for a relationship between genetic variants at the *brain-derived neurotrophic factor (BDNF)* locus and depressive symptoms in affective disorder and schizophrenia. S. Cichon¹, J. Schumacher², R. Abou Jamra², T. Becker³, S. Ohlraun⁴, N. Klopp^{5,6}, E. Binder⁷, T.G. Schulze⁴, W. Maier⁸, A. Van Den Bogaert⁹, T. Illig^{5,6}, P. Propping², F. Holsboer⁷, M. Rietschel^{4,8}, M.M. Nöthen^{1,2}. 1) Life & Brain Center, Univ Bonn, Bonn, Germany; 2) Inst Human Genetics, Univ Bonn, Bonn; 3) Inst Medical Biometry, Informatics and Epidemiology, Univ Bonn, Bonn; 4) Central Inst Mental Health, Division of Genetic Epidemiol in Psychiatry, Mannheim, Germany; 5) Genome Analysis Center, GSF-National Research Center for Environment and Health, Neuherberg, Germany; 6) Inst Epidemiology, GSF, Neuherberg, Germany; 7) Max-Planck-Inst of Psychiatry (MPI), München, Germany; 8) Dept Psychiatry, Univ Bonn, Bonn; 9) Dept Molecular Genetics, VIB8, Univ Antwerp, Antwerp, Belgium.

There is evidence that the brain derived neurotrophic factor (BDNF) is involved in the pathogenesis of neuropsychiatric disorders and in the therapeutic action of at least some effective drugs. The aim of this study was to investigate the potential influence of genetic variation at the BDNF locus on the development of major depressive disorder (MDD), bipolar affective disorder (BPAD), and schizophrenia. We genotyped three polymorphisms at BDNF (rs6265 leading to Val66Met, rs988748, and a (GT)_n repeat) in 465 MDD patients, 533 schizophrenia patients, 281 BPAD patients, and 1,097 controls of German origin (Bonn sample). A second sample (312 MDD patients, 444 controls) was recruited in Bavaria (Munich sample). Three-marker haplotype rs988748-(GT)_n-rs6265 produced significant associations with all phenotypes under investigation ($p=0.00006$ for Bonn MDD, $p=0.0092$ for Munich MDD, $p=0.0057$ for BPAD, $p=0.016$ for schizophrenia). Stratification of the schizophrenia sample according to the presence or absence of comorbid mood or depressive disorder showed much smaller p-values for schizophrenia with comorbid depression ($p=0.0011$) in comparison with the complete sample. In conclusion, we find supportive evidence for a relationship between genetic variants at the BDNF locus and depressive symptoms in affective disorder and schizophrenia.

FRAXE intermediate alleles are associated with Parkinson's disease. *I.C. Ciro' Candiano¹, P. Tarantino¹, N. Cutuli², G. Milana², F. Annesi¹, E.V. De Marco¹, F. Condino¹, D. Civitelli¹, P. Spadafora¹, G. De Cicco¹, S. Carrideo¹, G. Annesi¹.* 1) Inst of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy; 2) Laboratory of Molecular Genetics, Dept of Services, University of Catania, Italy.

The aim of the present study was to analyze the FRAXA and FRAXE triplet repeat variation and relative allele frequency in a population of male subjects with Parkinson's disease in comparison with normal controls. A total of 203 male patients with idiopathic PD from southern Italy were included in the study. Controls were 370 male healthy subjects from southern Italy enrolled during a previous study on aging. To determine trinucleotide repeat sizes, amplification of genomic DNA was performed using the polymerase chain reaction (PCR). FRAXA repeat sizes were determined using primers FXD and FXE. In a separate reaction, FRAXE repeat sizes were determined using primers 598 and 603. Overall allele distributions for FRAXA and FRAXE in normal controls were similar to those found in other studies. We did not find any cases of FRAXA full mutation or premutation in any of the 203 male subjects with PD or the 370 healthy controls. No difference was found in the allele distribution between patients and controls for FRAXA. No cases of FRAXE full mutation or premutation were found in either the patients or the controls. The distribution of allele size for FRAXE was significantly different (Chi squared=6.30; $p < 0.04$) between patients and control. Moreover, when the FRAXE intermediate alleles (31-60 repeats) were considered, there was a significant excess of these alleles among the experimental chromosomes ($p < 0.001$). Indeed, 13 out of 203 subjects with PD (6.4%) carried FRAXE intermediate alleles ranging from 31 to 54 repeats in respect to only one out of 370 normal controls who carried an allele of 37 repeats (0.27%). Thus, subjects carrying FRAXE intermediate alleles have a significantly increased risk of developing PD (OR 95% CI, 25.25; 3.3-194.4). The present study demonstrates that intermediate alleles for FRAXE are over-represented in male subjects with PD in respect to normal control.

Mutation Screening of NLGN3 and NLGN4 in Autism Spectrum Disorders. *L.N. Clark¹, S.K. Afridi¹, B. Chih², P. Scheiffele².* 1) Dept Pathology & Taub Inst, Columbia Univ, New York, NY; 2) Dept of Physiology and Cellular Biophysics, Center for Neurobiology and Behavior, Columbia University New York, NY.

Autism-spectrum disorders (ASD) are a heterogeneous group that differ in severity and age at onset but can share one or more of the clinical features that includes impairment in social interaction and communication, repetitive and/or obsessive-compulsive behaviors, and mental retardation. There is strong evidence for a genetic involvement in the etiology of ASD. Recent studies have implicated a family of neuronal cell adhesion molecules called Neuroligins (NL) in ASD. In a mutation screen of 158 multiplex families with ASD, Jamain et al (2003) identified the mutation, R451C, in the Neuroligin 3 gene (NLGN3) (Xq13) in two brothers from one family, and a nonsense mutation, D396X, in the Neuroligin 4 gene (NLGN4) (Xp22.3) in another family. A 2bp deletion in NLGN4 in a large French family with non-specific X-linked mental retardation has also been described. Previously, we demonstrated that the neuroligin mutations associated with ASD, NLGN3 R451C and NLGN4X D396X, result in loss-of-function and intracellular retention of the mutant proteins. Furthermore, over-expression of wild -type NLGN3 and NLGN4 in hippocampal neurons stimulates the formation of presynaptic terminals whereas the disease-associated mutations result in a loss of this synaptic function. Our findings suggest that mutations in neuroligin genes play an important role in neurodevelopmental defects. In this study, we searched for novel mutations in NLGN3 and NLGN4 by direct sequencing in addition to assaying for deletions in 99 ASD individuals from multiplex families obtained from the Autism genetic resource exchange (AGRE) consortium. All exons and exon-intron boundaries of NLGN3, NLGN4X and NLGN4Y were sequenced completely in 99 ASD subjects. To identify genomic rearrangements we have also analyzed microsatellite markers at Xp22, the region that contains the NLGN4X gene, and at Yq11.22, the region that contains the NLGN4Y gene. We report the frequency and functional consequences of mutations identified in NLGN3 and NLGN4 in 99 ASD subjects. This study was funded by the National Alliance for Autism Research.

Paraoxonase gene variants are associated with autism in Caucasian-American, and not in Italian families. *M. D'Amelio*¹, *I. Ricci*¹, *T.H. Wassink*², *L. Muscarella*³, *V. Guarnieri*³, *L. D'Agruma*³, *R. Militerni*⁴, *C. Bravaccio*⁴, *S. Trillo*⁵, *F. Montecchi*⁵, *M. Elia*⁶, *C. Schneider*⁷, *R. Melmed*⁷, *T. Pascucci*⁸, *S. Puglisi-Allegra*⁸, *K.L. Reichelt*⁹, *J. Piven*², *A.M. Persico*¹. 1) Mol Psychiatry & Neurogenetics, Univ Campus Bio-Medico, Rome, Italy; 2) Dept of Psychiatry, Univ. of Iowa Sch. of Med., Iowa City, IA and N.D.R.C., Univ. of North Carolina, Chapel Hill, NC; 3) Med. Genet. Serv., IRCCS Casa Sollievo dalla Sofferenza, S.Giovanni Rotondo (FG), Italy; 4) Child Neuropsychiatry, II Univ. of Naples, Italy; 5) Child Neuropsychiatry, IRCCS Osp. Bambino-Gesú, Rome, Italy;; 6) Neurology Serv., IRCCS Oasi Maria S.S., Troina (EN), Italy; 7) S.A.R.C., Phoenix, AZ; 8) Dept. of Psychology, Univ. La Sapienza, Rome, Italy; 9) Dept. of Pediatric Res., Rikshospitalet, Univ. of Oslo, Norway.

Our prior work points toward possible contributions of organophosphates (OPs) to autism pathogenesis in the U.S.A., and not in Italy. OP use in agriculture is equally intensive in both countries, whereas household use is much more intensive in the U.S.A. Within the framework of a gene-environment interactive model, genetically-vulnerable individuals prenatally exposed to OPs could undergo altered neuronal migration resulting in an autistic syndrome. Paraoxonase, the enzyme responsible for OP detoxification, is encoded by the PON1 gene located on ch 7q21.3. Functional SNPs located in the promoter and coding sequences of the PON1 (C-108T, L55M, Q192R) and PON2 (C311S) loci were genotyped in 163 Italian and 105 Caucasian-American trios. The R192 allele is associated with autism in the Caucasian-American and not in the Italian sample, using both case-control ($\chi^2 = 6.33$, 1df, $P < 0.05$) and TDT ($\chi^2 = 4.85$, 1df, $P < 0.05$) analyses. Specific haplotypes are associated with autism in Caucasian-American patients only ($T1^2 = 28.16$, $P < 0.01$). These data confirm our predictions, and support the hypothesis that the concurrence of genetic vulnerability and environmental exposure to OP compounds may yield autism in a sizable subgroup of North American patients. Supported by Telethon-Italy (GPP02019), the Fondation Jerome Lejeune, and the Cure Autism Now Foundation.

Program Nr: 2095 from the 2004 ASHG Annual Meeting

INVERSE REGULATION OF A7 AND A7-LIKE GENE EXPRESSION IN PREFRONTAL CORTEX: EVIDENCE OF ALTERATION IN SCHIZOPHRENIA. *V. V. De Luca, O. Likhodi, H. Van Tol, J.L. Kennedy, A.H.C. Wong.* CAMH, Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada.

The CHRNA7 gene is located on chromosome 15q13-14, a region linked with schizophrenia in several earlier studies. The 7-nicotinic receptor gene (CHRNA7) has a partial duplication of exons 5-10 including the intervening introns that map approximately 0.5 Mb proximal to the full-length CHRNA7 gene. On the 5' side of the duplicated exons are novel exons D-A, defining a hybrid gene (CHRFAM7A), which is transcribed, but it is not known whether it is translated. CHRFAM7A is transcribed in human brain and immortalized lymphocytes. The study was performed with postmortem brain obtained from the Stanley Foundation (Brodmann Area 46). CHRNA7 and CHRFAM7A mRNA levels were measured by quantitative real time RT-PCR to determine the expression relationship between CHRNA7 and CHRFAM7A in 35 schizophrenic, 35 bipolar and 35 healthy subjects. The mRNA levels of alpha7 and alpha7like genes seem to have an inverse relationship ($r=-0.36$; $p<0.01$). This negative correlation is weaker in schizophrenia ($r=-0.29$; $p=0.08$), suggesting an alteration in CHRNA7/CHRFAM7A equilibrium.

MUTATION SCREENING OF NRCAM AND IMMP2L, TWO CANDIDATE GENES FOR TOURETTES

SYNDROME AND OBSESSIVE COMPULSIVE DISORDER ON CHROMOSOME 7Q31. *R. Delorme¹, C.*

Durand¹, J. Melke¹, H. Quach¹, H. Goubran-Botros¹, M. Leboyer², T. Bourgeron^{1,3}. 1) Neuroscience, Institut Pasteur, Paris, IDF, France; 2) Inserm U513, Creteil, France; 3) University Paris 7, Paris, France.

Tourettes Syndrome (TS) is characterized by involuntary motor and vocal tics, whereas Obsessive-Compulsive Disorder (OCD) is characterized by recurrent, distressing unwanted thoughts and repetitive ritualistic behaviour. Both disorders have phenomenological and familial-genetic overlaps. Although no susceptibility genes for TS or OCD have been clearly identified, positive linkage and association studies have been reported. Chromosome 7q31 has been implicated in both disorders by the presence of a de novo duplication [46, XY,dup(7)(q22.1-q31.1)] in a proband with TS and the segregation of a translocation t(7; 18) (q31; q22.3) in a family with OCD and TS. Within 7q31, the inner mitochondrial membrane peptidase 2 like (IMMP2L) and the neural cell adhesion molecule (NrCAM) may represent suitable candidates for both disorders. Indeed, IMMP2L, disrupted in the duplication, has recently been shown to be associated with TS. NrCAM is an important mediator with multiple effects on the development of the neurons. Here, we report the mutation screening of the IMMP2L and NrCAM genes (promoter region and coding exons) in 24 individuals (16 diagnosed with TS and OCD and 8 with OCD and family history of TS). No variations were identified in the IMMP2L gene. In NrCAM, thirteen single nucleotide polymorphisms (SNPs) were identified: five in the intronic sequences and seven in coding regions. Of the exonic polymorphisms, only one changed the amino acid sequence (A526P). Linkage disequilibrium was calculated and the most informative SNPs were genotyped in 100 additional OCD patients and 95 controls. None of the SNPs showed association with OCD. In conclusion, this analysis strongly suggests that coding variations of IMMP2L and NrCAM do not play a major role in TS and OCD etiology. These results encourage us to screen additional candidate genes in the in the 7q31 region.

Program Nr: 2097 from the 2004 ASHG Annual Meeting

The effect of LDHA exon 5 genotype on mRNA production. *K. Dodelzon, S.L. Bradley, H.K. Sandhu, R.A. Philibert.*
Psychiatry, University of Iowa, Iowa City , IA.

Panic Disorder (PD) is an anxiety syndrome that affects approximately 3% of the population and is characterized by recurrent discrete episodes of fear accompanied by psychological and/or physiological symptoms, most particularly respiratory distress. Previously, we have demonstrated a relationship between a haplotype encompassing exon 5 of Lactic Dehydrogenase A (LDHA), a gene that codes for a protein that serves as a convergence point for two means of inducing PD in individuals susceptible to developing the disorder, and ventilatory response to inhaled 5% CO₂. Intriguingly, while the sequence changes associated with the exon 5 haplotype variant do not affect primary amino acid sequence, they do change the sequence in a canonical exonic splice enhancer found in LDHA exon 5. To examine whether this exon 5 sequence change affects mRNA production, we used standard PCR and RT-PCR techniques to examine the mRNA production as a function of LDHA genotype in 150 independent lymphoblast cell lines and analyzed the resulting data using ANOVA analysis. Preliminary results from the first 60 of these samples suggest a trend for a relationship between exon 5 haplotype and LDHA mRNA production. In this presentation, we present the findings from the entire sample and discuss the possible relationship between LDHA exon 5 genotype and 1) altered respiratory response to increased levels of CO₂ and 2) vulnerability to Panic Disorder.

Genetic analysis of CYP1B1, MYOC, OPTN and OPTC genes in glaucoma patients from South India. S.K.

Dorairaj¹, T.K. Ramesh², G.B. Manjunath¹, S.K. Gupta¹, M. Ali¹, M. Shah¹, A.R. Aruna², A. Kumar¹. 1) MRDG, Indian Institute of Science, Bangalore, Karnataka, India; 2) Minto Eye Hospital, Bangalore, India.

Glaucoma represents a group of optic neuropathies with different genetic basis. In India, ~1.5 million people are blind due to glaucoma. Mutations in the MYOC gene at the GLC1A locus on chromosome 1q21-q31, CYP1B1 gene at the GLC3A locus on chromosome 2p21 and the OPTN gene at the GLC1E locus on chromosome 10p14 have been found in patients with glaucoma. The purpose of the present study was to screen sequence variations in these genes as well as in OPTC in a total of 146 glaucoma patients ascertained mostly from the state of Karnataka and its border areas with states of Andhra Pradesh and Tamilnadu, south India. Of these, 116 were affected with adult-onset primary open-angle glaucoma (A-POAG), 18 were with juvenile-onset primary open-angle glaucoma (J-POAG) and 12 were with primary congenital glaucoma (PCG). The coding regions of CYP1B1 and MYOC were screened for mutations and variations in all of the 146 patients using a combination of PCR-SSCP and DNA sequence analyses. Our analysis revealed a total of five mutations (two novel and three known) and seven variants/polymorphisms in CYP1B1. No mutation was found in MYOC. However, we have detected one known and one novel polymorphisms in this gene. Screening of 116 A-POAG patients showed one novel and one known risk-factor associated mutations in OPTN. In addition, two novel and one known polymorphisms were also detected in OPTN. Screening of OPTC in 116 A-POAG patients showed one novel and two previously known polymorphisms. (This work was supported by a grant from the CSIR, New Delhi).

Program Nr: 2099 from the 2004 ASHG Annual Meeting

A protective role of HLA-A*02 in Multiple Sclerosis. *K. Duvefelt, B. Brynedal, E. Akesson, I. Roos, J. Hillert.*
Neurology, Neurotec, Karolinska Institute, Stockholm, SWEDEN.

Multiple sclerosis (MS) is a chronic neurological disease affecting the central nervous system. The pathology is due to activated immune cells that are able to cross the blood brain barrier and attack myelin sheaths surrounding the axons. This leads to demyelination and disturbance of neurological functions. The cause of the disease is multifactorial and includes both genetic and environmental components. The HLA class II haplotype HLA-DRB1*1501,DRB5*0101,DQA1*0102,DQB1*0602 is the only genetic factor that consistently has been associated with MS. We have previously reported an association of the HLA-A gene with MS. The present study was conducted to further corroborate these data in a new and larger material within the same population. Genomic typing corresponding to serological specificities was conducted with allele-specific primers. HLA-A and DRB1 alleles were examined in 669 Swedish MS- patients and 715 controls (healthy blood donors). In this material we confirm that HLA-A*02 carriers have a decreased risk of developing MS (Odds ratio =0.47, two tailed P-value Fishers exact test= 7.2×10^{-12}). This association is independent of the well established HLA-DRB1*15 association (OR 3.4). Carrying both HLA-A*02 and HLA-DRB1*15 results in an OR of 1.15.

The wild-type form of the Tau protein is not degraded by the 26S proteasome. *S. Feuillette, O. Blard, M. Lecourtois, T. Frebourg, D. Campion, C. Dumanchin.* Inserm U614, Faculty of Medicine, Rouen, France.

Tau-positive inclusions in neurons are consistent neuropathological features of the most common causes of dementias like Alzheimer's disease and frontotemporal dementia. Ubiquitinated Tau positive inclusions have been reported in brain of Alzheimer's disease patients but the involvement of the ubiquitin-dependent proteasomal system in Tau degradation remains controversial. Therefore, we investigated whether the proteasome pathway is involved in endogenous Tau degradation both *in vitro* and *in vivo*. First, SH-SY5Y human neuroblastoma cells were treated with different proteasome inhibitors, ALLN, MG132, lactacystin and epoxomicin. Under these conditions, neither total nor phosphorylated endogenous Tau protein levels were increased. In contrast, an unexpected decrease of Tau protein was observed after treatment of cells with the proteasome inhibitors MG132, lactacystin and epoxomicin. The decrease of Tau that we observed was potentially related to apoptosis since we observed that this decrease simultaneously occurred to pro-caspase 3 and PARP cleavages. Second, we took advantage of a temperature sensitive mutant allele of the 20S proteasome in *Drosophila*. Genetic inactivation of the proteasome also resulted, in *Drosophila*, not in an increase but in a decrease of Tau. In conclusion, these results obtained *in vitro* and *in vivo* demonstrate that endogenous Tau is not degraded by the proteasome. Thus, it is likely that Tau, like the SOD1 protein becomes a substrate of the proteasome only in pathological conditions.

Association testing in patients with major depressive disorder and psychotic features. *B. Franke^{1,2}, R.J. Verkes², A. van Raaij¹, S. Hanssen¹, J. Janzing², J.K. Buitelaar², H. Scheffer¹.* 1) Dept Human Genetics, UMC Nijmegen, Nijmegen, Netherlands; 2) Dept Psychiatry, UMC Nijmegen, Nijmegen, Netherlands.

Major depressive disorder (MDD) is the leading cause of disability among those age five and older, and the second leading source of disease burden. MDD is mainly characterized by a depressed mood or a loss of interest and pleasure in daily activities for at least a two week period. Ten to 25% of women and 5 to 12% of men are affected by MDD within an entire lifetime. At any one point in time, 5 to 9% of women and 2 to 3% of men are likely to be clinically depressed. Psychotic features are observed in 10 to 15% of MDD patients. In addition to the symptoms of MDD, psychotic depression includes some features of psychosis, like hallucinations or delusions. The causes of MDD have not yet been identified but genetic factors are known to be involved. However, MDD represents a heterogeneous group of disorders and the genetic contribution to the disorder is likely to be very complex. Subclassification of patients or phenotype characteristics is therefore required before the genetics of MDD can be studied successfully. In the work presented here, we attempted to subclassify MDD by concentrating on MDD with psychotic features only. Eighty Dutch patients with well characterized MDD and psychotic features were compared with 150 healthy controls. Association testing was performed for frequent genetic variants in genes coding for transporters of the neurotransmitters serotonin (SLC6A4), norepinephrine (SLC6A2) and dopamine (SLC6A3). Genetic variants were chosen to represent the different haplotype blocks within the selected genes. At least two variants were analyzed for each of the genes and haplotypes were constructed. Genotype and allele frequencies were found to be similar to earlier studies involving these genetic variants. None of the variants or haplotypes tested appeared to be a major risk factor for MDD with psychotic features.

Program Nr: 2102 from the 2004 ASHG Annual Meeting

Mutational screening of the ATP1A2 / FHM2 gene in ninety six individuals with sporadic or familial hemiplegic migraine (FHM), AHM, and EA phenotypes. *K. Gardner, C. Patankar, N. Pathe, W. Makhoul, M. Soso, S. Keryanov.*
Dept Neurology, Veteran's Administration Hospital and Univ Pittsburgh, Pittsburgh, PA.

Background: Familial hemiplegic migraine has been associated with missense mutations in a Chr19p / FHM1 calcium channel gene CACNA1A and a Chr1q / FHM2 sodium potassium ATPase gene ATP1A2. Episodic ataxia (EA-2) has been associated with truncating mutations in the CACNA1A gene. Some families and individuals with episodic ataxia and alternating hemiplegia have clinical overlap with hemiplegic or other forms of migraine. Methods: Sporadic hemiplegic migraine individuals and small families (<2-3 FHM, AHM, EA) were evaluated after obtaining IRB approved consent using structured validated headache interview (KG), physical exam (KG) or record review (KG). Questionnaire data included demographic and past medical history, ethnic background, headache triggers, and medication response. Headache type was classified using I.H.S. criteria. Mutational analysis was performed in 4/ 23 ATP1A2 exons among sporadic individuals and selected family members after primer optimization, radiolabeled PCR amplification, electrophoresis on SSCP gels, and autoradiogram exposure. Conformers will be analyzed by PCR based sequencing. Results: Mostly sporadic hemiplegic migraineurs individuals were identified. Only one lacked a family hx of nonhemiplegic migraine or headache. Most referred with EA had additional migraine or family hx of migraine. Individuals from small families included 5 AHM individuals from 4 families, most with additional nonhemiplegic migraineurs. Two conformers were identified, one each from exons 16 and 19 in two with HM. The remainder of the 23 exons are under investigation with sequence variants to be described. Conclusion: Only a small number of genetic variants are identified in the previously reported mutant exons of the ATP1A2 gene among this enriched collection of sporadic or small family individuals with hemiplegic migraine, episodic ataxia, or alternating hemiplegia. This is consistent with expected complex inheritance for heterogenous disorders, especially in the setting of sporadic occurrence or small family size.

Genes Regulating the Adrenergic System and Childhood-Onset Mood Disorders. *L. Gomez¹, I. Burcescu¹, K. Wigg¹, N. King², A. Vetro³, E. Kiss³, K. Kapornai³, J.L. Kennedy², M. Kovacs⁴, C.L. Barr^{1,5}, The International Consortium for Childhood-Onset Mood Disorders.* 1) Toronto Western Research Institute, Toronto, Ontario, Canada; 2) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 3) Department for Child and Adolescent Psychiatry, Szeged University, Szeged, Hungary; 4) University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 5) The Hospital for Sick Children, Toronto, Ontario, Canada.

The adrenergic system is implicated in the therapeutic mechanism of antidepressants and regulates a number of behavioural and cognitive functions that further implicate this system in the development of depression including attention, memory, response to stress, behavioral impulsivity and anxiety. Further, a recent genome scan of early-onset depression, identified the chromosomal locations of three of the adrenergic receptors; ADRA1B on 5q23-q33.3, ADRA2A, and ADRB1 on 10q24-q26, and ADRB3 on 8p12-p11.2, as linked to depression. In this study we examined the role of the adrenergic system in childhood-onset mood disorders (COMD) defined as age of onset < 14, using 195 nuclear families with 225 affected children collected in Hungary. We tested multiple polymorphisms across each of the genes for the adrenergic receptors; ADRA1A, ADRA2A, ADRA1B, ADRA1D, ADRA2B, ADRA2C, ADRB1, ADRB2, and ADRB3, for evidence of association using the transmission disequilibrium test. We found no significant evidence for association with the 23 markers genotyped in these genes thus far and therefore it is unlikely that the adrenergic receptors play a major role in the genetic susceptibility to COMD.

A polymorphism in the CYP46 gene affects the risk of Alzheimers disease in Finnish patients. *S. Helisalmi¹, S. Vepsäläinen¹, A.M. Koivisto^{1,2}, A. Mannermaa³, S. Iivonen¹, M. Hiltunen¹, H. Soininen^{1,2}.* 1) Neuroscience and Neurology, Kuopio University, Kuopio, Finland; 2) Department of Neurology, University Hospital, Kuopio, Finland; 3) Department of Pathology and Forensic Medicine, University Hospital and Kuopio University, Kuopio, Finland.

Background: CYP46 gene encodes cholesterol 24-hydroxylase, the rate-limiting enzyme catalyzing the conversion of cholesterol to 24S-hydroxycholesterol, which is the primary cholesterol elimination product in the brain. **Objectives:** To study if alleles of single polymorphic sites in the CYP46 gene have influence on the risk of the developing Alzheimers disease (AD). **Methods:** The frequencies of two single nucleotide polymorphisms (SNPs) and apolipoprotein E (APOE) were assessed in 422 AD patients and 469 cognitively healthy controls. Genotypes of the study groups were compared using binary logistic regression analysis. Linkage disequilibrium between markers was estimated and two-locus haplotype was constructed. **Results:** One SNP (rs754203) had significantly different allelic and genotypic frequencies between the AD and the control subjects. **Conclusion:** Taken together, these findings suggest that polymorphism(s) in the CYP46 gene increase risk for AD and support a potential role for CYP46 in AD.

Severe myoclonic epilepsy in infancy (SMEI) resulting from *SCN1A* and *GABRG2* mutations inherited from non SMEI parents. *S. Hirose*¹, *G. Fukuma*¹, *T. Kanaumi*¹, *S. Ueno*², *A. Ishii*¹, *Y. Haga*³, *A. Hamachi*¹, *M. Yonetani*¹, *M. Itho*⁴, *S. Takashima*⁵, *S. Kaneko*⁶, *A. Mitsudome*¹. 1) Dept Pediatr, Sch Med, Fukuoka Univ, Fukuoka; 2) Rehab Med, Inst Brain Sci, Sch Med, Hirosaki Univ, Hirosaki; 3) Dept Pediatr, Public Biyou Hosp Jimokujichyou; 4) Dept Mental Retard and Birth Defect Res, NCNP, Tokyo; 5) Yanagawa Inst for Dev Disabilities, Child Neurol, Interna Univ Health and Welfare, Yanagawa; 6) Dept Neuropsych, Sch Med, Hirosaki Univ, Hirosaki, Japan.

Mutations of genes encoding 1 subunit of a sodium channel (*SCN1A*) and 2 subunit of GABA_A receptor (*GABRG2*) have been reported to cause severe myoclonic epilepsy in infancy (SMEI). Most of such mutations were *de novo* in accordance with sporadic occurrence of SMEI, while febrile seizures and epilepsy are often seen in relatives of patients. Here we report two mutations of *SCN1A* and *GABRG2* which were found in individuals with SMEI and inherited from their parent who did not have SMEI. Both mutations were heterozygous and not found in 182 volunteers. One is a missense mutation of *SCN1A*, c.5045T>C:F1682S, which was identified in a girl with SMEI and her father with simple febrile seizures. F1682 was a highly conserved in Segment 5 in Domain IV of 1 subunit where is a hot spot for the mutations of SMEI. The other is a novel nonsense mutation of *GABRG2*, c.118C>T:Q40X, which was detected in dizygotic twin girls with SMEI and their apparently healthy father but not in their mother with seizures in childhood. The father's mutation was *de novo*. Electrophysiological studies of GABA_A receptors reconstituted with 1, 2 and 2 subunits on HEK cells revealed that mutant 2 with Q40X suppressed GABA-induced current values of the receptors. Immuno-staining brain specimens from one of the twins with anti GABA_A receptors indicated aggregations of the receptors in the somas of some neurons and neuropils. Our findings suggest that the full development of some of SMEI could also involve another putative genetic factor possibly inherited from the parents.

Linkage and association analysis of DNA variants in neuropeptide and neurotransmitter candidate genes in panic disorder. *L.M. Hodges¹, F. Haghighi², G.A. Heiman³, M. Durner³, O.V. Evgrafov³, C.T. Gilliam^{2,3}, S.E. Hodge³, J.A. Knowles^{2,3}, A.J. Fyer³, M.M. Weissman³, S.P. Hamilton¹.* 1) Dept of Psychiatry, University of California SF, San Francisco, CA; 2) Columbia Genome Center & 3) Dept of Psychiatry, Columbia University College of Physicians and Surgeons.

A clear genetic component underlies the complex etiology of panic disorder (PD) as evinced by family, segregation, and twin studies. The following neuropeptide and neurotransmitter pathway genes have all been implicated in animal studies of anxiety behavior or in targeted gene deletion experiments: gastrin-releasing peptide, gastrin-releasing peptide receptor, corticotropin-releasing hormone receptor, tachykinin receptor, and GABA receptor 5 and 3 subunits. In addition, pharmacological agents targeting a number of these gene products may be used to treat anxiety and PD. In support of these biological hypotheses we observe evidence for linkage in the genomic regions surrounding many of the candidate genes in recent unpublished genome-wide scan of PD. The high density of SNP markers derived from the Human Genome Project and characterized by the International HapMap Project allows the use of these markers for construction of informative haplotypes for linkage disequilibrium mapping studies of complex disorders. Using high throughput methods for genotyping SNPs (FP-TDI and fluorogenic 5-nuclease), we have employed a family-based design to investigate the role of these variants in the genetic susceptibility to PD. In 994 subjects, from 120 PD pedigrees, as well as 41 independent parent-proband triads, we genotyped an average of 5 SNPs per gene. Common and evenly distributed SNPs were chosen in order to cover the genomic regions of interest. Complementary statistical approaches of linkage and association analysis will be employed to test correlation between genetic variations in these genes and the susceptibility to PD. Both parametric (using recessive/dominant genetic models, three diagnostic models, and tests of heterogeneity) and nonparametric linkage analysis will be performed along with family-based association analysis. These data are currently being analyzed, and the results will be presented.

RARE VARIATIONS AND STOP MUTATIONS IN THE NEUROLIGIN GENES IN AUTISM AND

ASPERGER SYNDROME. *S. Jamain¹, H. Quach¹, C. Betancur², H. Goubran-Botros¹, C. Durand¹, J. Melke¹, R. Delorme¹, M. rastam³, C. Colineaux², IC. Gillberg³, H. Soderstrom³, B. Giros², D. Bonneau⁴, H. Firth⁵, M. Leboyer², C. Gillberg³, T. Bourgeron^{1 6}.* 1) neuroscience, Institut Pasteur, Paris, IDF, France; 2) Inserm U513, Creteil, France; 3) Goteborg University, Goteborg, France; 4) CHU Angers, Angers, France; 5) Addenbrooke's Hospital, Cambridge, UK; 6) Univeristy Paris 7, Paris, France.

Autism is characterised by qualitative impairments in social interactions and communication and associated with restrictive interests and repetitive behaviours. In a recent paper, we reported mutations in X linked neuroligins (NLGN3 and NLGN4) in subjects with autism and Asperger syndrome. The association of neuroligins with autism was recently also supported by the identification of a frame-shift mutation of the NLGN4 gene in one large family with mental retardation and autism. Neuroligins are cell adhesion molecules that contribute to the formation of synapses In humans, five neuroligins have been described and all of them are localised in chromosomal regions previously associated with autism. Here, we report the analysis of the five NLGN genes in individuals with autism. To investigate whether these genes may have a role in autistic disorder, we systematically screened all neuroligin genes for mutations in the coding sequence in 90 (NLGN1, NLGN2) to 290 (NLGN3, 4 and 4Y) individuals affected with autism or Asperger syndrome. In addition, single nucleotide polymorphisms (SNPs) identified in this study were analysed for association with autism.

Defining a locus for holoprosencephaly on human chromosome 14 and characterization of candidate genes. *D.*

Kamnasaran^{1,2,3}, *D.W. Cox*³. 1) Surgery (Pediatric Neurosurgery), Hospital For Sick Children, Toronto, Ontario, Canada; 2) Surgery (Neurosurgery), Western Hospital, University of Toronto, Toronto, Ontario, Canada; 3) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Twelve Holoprosencephaly (HPE) loci have been proposed on 11 chromosomes, with four genes mapping to these loci found mutant among patients. We have defined a locus for holoprosencephaly on human chromosome 14q13, denoted as HPE8, between the markers D14S49 and AFM205XG5 by mapping the deletion intervals of 6 affected patients. Annotation of 3.5 Mb genomic sequence within this interval identified 23 possible genes. We identified five possible candidate HPE genes, namely, NPAS3, C14ORF10, C14ORF11, C14ORF19 and SNX6 that are expressed in human fetal brain (20 to 33 wks gestation). The cDNA sequences encoding the full or partial open reading frames were isolated by combinations of RACE and cDNA library screenings on human fetal brain cDNA libraries. The NPAS3 gene was excluded for further analyses since this gene was found disrupted in a family affected with schizophrenia. The C14ORF10 and C14ORF19 genes were also tentatively excluded for further analyses since a partial human cDNA sequence was obtained and/or the function was characterized in a model organism that is inconsistent with our current criteria for a candidate gene for holoprosencephaly. The murine orthologs of the remaining two HPE candidates (C14ORF11, SNX6) were shown expressed using RT-PCR, as early as 7 dpc to 12 dpc in whole embryos, with continued expression in the head from 14 to 18 dpc. Whole mount in situ hybridization on 11 dpc murine embryos showed both *Snx6* and *C14orf11* genes were expressed in the developing central nervous system and other extra-cranial tissues. Northern analysis on human adult multi-tissue blots showed ubiquitous expression in several adult and brain tissues of a 1.7 kb transcript for C14ORF11, and 3.4 kb transcript for SNX6. Cellular localization studies with C-EGFP fused HPE proteins demonstrated the SNX6 and C14ORF11 proteins were localized in the cytoplasm of COS1 and transformed skin fibroblasts.

BDNF variants are associated with Parkinson's disease: the GenePD study. *S. Karamohamed¹, J. Latourelle¹, J.B. Wilk¹, A.L. DeStefano¹, B. Racette², J.S. Permuter², R.H. Myers¹, A. Parsian³.* 1) Dept Neurology, Boston Univ Sch Medicine, Boston, MA; 2) Department of Neurology, Washington University School of Medicine, MO; 3) Human Genomics Laboratory, University of Arkansas for Medical Sciences, AR.

Parkinson disease (PD) is the second most common progressive neurodegenerative disorder, with a prevalence of approximately 1% at the age of 65, increasing to 45% by the age of 85. The role of genetics in early-onset PD has been established, but the genetic contribution for the more common late-life form remains less clear. One prominent candidate gene is the brain-derived neurotrophic factor (BDNF) on chromosome 11p13. BDNF is a trophic factor for dopaminergic neurons and protects nigral dopamine neurons in animal models of PD. We investigated five single nucleotide polymorphisms (SNPs) in the BDNF gene in 611 familial PD cases (581 with known onset ages) from 329 families from the GenePD study and 249 controls. We typed one SNP in the promoter region (C-1331T), two intronic SNPs (rs2049045, Celera SNP C1751792), and two coding SNPs (C270T and G198A). Three SNPs (rs2049045, C1751792, and G198A) spanning 14 Kilo base region, were associated with PD onset age. The G198A SNP codes for a nonsynonymous amino acid substitution (M66V). Homozygosity for the rare allele of G198A (A) is associated with a 5.4 year later onset ($P = 0.0001$). Homozygosity for the rare allele of C1751792 (GG) was associated with 4.6 years later onset ($P = 0.007$), and homozygosity for the rare allele of rs2049045 (C) with a 5.2 year later onset ($P = 0.005$). A haplotype of these three did not show stronger association than the individual SNPs. Conversely, while no individual SNP showed association to PD affection, the haplotype of C-1331T with rs2049045; and C1751792 or G198A was associated with affection ($P < 0.05$). Studies to explore the effects of these SNPs on gene expression and sequencing for additional SNPs is in progress. The findings support the hypothesis that BDNF variants or expression plays an important role in influencing PD onset or risk.

Mutations in BBS proteins cause anosmia in humans and defects in olfactory cilia structure and function in the mouse. *N. Katsanis¹, H.M. Kulaga¹, C.C. Leitch¹, E.R. Eichers², J.L. Badano¹, A. Lesemann¹, J. Hill³, B.E. Hoskins³, J.R. Lupski², P.L. Beales³, R.R. Reed¹.* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Baylor College of Medicine; 3) University College London.

Defects in cilia have been associated with several human disorders including Kartagener syndrome, polycystic kidney disease, nephronophthisis and hydrocephalus. We proposed recently that the pleiotropic phenotype of Bardet-Biedl syndrome (BBS), which encompasses retinal degeneration, truncal obesity, renal and limb malformations and developmental delay is due to dysfunction of basal bodies and cilia. Here we show that BBS patients manifest partial or complete anosmia. To test whether this phenotype is due to ciliary defects of olfactory sensory neurons, we examined the olfactory and respiratory epithelia of mice ablated for each of *Bbs1* or *Bbs4*. Loss of function of either BBS protein results in a dramatic phenotype of the olfactory, but not the respiratory epithelium, including severe reduction of the ciliated border, trapping of olfactory ciliary proteins in dendrites and cell bodies, downregulation of expression of olfactory markers and disorganization of the dendritic microtubule network that coincides with the mislocalization of the BBS-interacting protein PCM1. Our data provide the first *in vivo* evidence of the role of BBS proteins in the microtubule organization of mammalian ciliated cells and indicate that anosmia might be a useful determinant of other pleiotropic disorders with a suspected ciliary involvement.

Genome-wide microsatellite association studies for Alzheimers disease. *H. Kawakami¹, H. Morino¹, H. Terasawa¹, M. Oda¹, H. Maruyama¹, T. Miyachi¹, K. Sasaki², Y. Izumi³, R. Kaji³, G. Tamiya⁴, H. Inoko⁴, M. Matsumoto¹.* 1) Clinical Neuroscience and Therapeutics, Hiroshima Univ Graduate Sch Biomedical Sci, Hiroshima, Japan; 2) Kinoko Espoir Hospital, Kasaoak, Okayama; 3) Clinical Neuroscience, Tokushima University, Tokushima; 4) Molecular Life Science, Sch Medicine, Tokai University, Isehara, Kanagawa.

The most common form of dementia in the elderly is Alzheimer disease (AD) that is believed to be genetically complex. It has been established that apolipoprotein E contributes to late-onset AD. However, other genetic factors contributing to AD are still unknown. Therefore, we investigated the susceptibility gene of AD. We performed the genome-wide association study using about 24,000 of microsatellite markers as a tool for identifying disease susceptibility regions. One hundred and sixty AD patients were pooled for the 1st set. Similarly, 160 healthy individuals were pooled for the 1st set as controls. We performed Fishers exact test and a significant difference was determined when a p-value was less than 5%. About 80 % of microsatellite markers obtained the data. After the analysis, 11.6 % of markers showed significant differences. We will perform the further screening of the 2nd set and the 3rd set pooled samples using these positive markers.

Opposite effects of genetic background on the acoustic startle response in the fragile X knockout mouse. R.F.

Kooy¹, P.P. De Deyn², V. Errijgers¹. 1) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Department of Neurochemistry and Behaviour, University of Antwerp, Antwerp, Belgium.

Fragile X knockout mice, a validated animal model for the human mental retardation disorder were subjected to the Acoustic Startle Response (ASR). This brainstem reflex may serve as a neuronal basis for behavior. The magnitude of this sudden response to a loud noise was measured. At different sound levels of 90, 100 and 110 dB, fragile X knockout mice in an inbred C57BL/6 knockout background showed a 48% increase, no significant difference, and a 16% decrease in ASR magnitude when compared to wild type littermates, respectively. In C57BL/6 x 129P2/OlaHsd F1 hybrids at sound levels of 100 and 110 db, a 32% and 14% decrease in ASR of the knockout mice when compared to wild type littermates was measured, respectively. In contrast, F2 intercross knockout mice showed a 13% and a 10% increase in ASR, respectively. The opposite effect caused by the difference in genetic background is remarkable as, to our knowledge, hardly any test has been described in which opposite effects of a knockout mutation are caused by differences in genetic background. This case is especially remarkable, as the F1 and the F2 generation both consist for 50% of C57BL/6 and for 50% of 129P2/OlaHsd. Only the distribution along the chromosomes differs: the F1 generation has one chromosome of each parental strain, whereas in the F2 generation the distribution of the genomic material is semi-randomly. We believe that such differences may be the consequence of modifier genes in either the C57BL/6 or the 129P2/OlaHsd background, and attempt to map these using a large population of F2 knockout hybrids using the wild type littermates as controls.

Investigation of Dopamine D1 Receptor Pathway-Associated Genes in Attention Deficit/Hyperactivity Disorder.

N. Laurin¹, J. Crosbie², A. Ickovicz², T. Pathare², W. Roberts², M. Malone², R. Tannock², R. Schachar², J.L. Kennedy³, C.L. Barr^{1,2}. 1) Cell and Molecular Division, Toronto Western Hospital, Toronto, ON, Canada; 2) The Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, ON, Canada.

Attention-deficit hyperactivity disorder (ADHD) is characterized by marked inattention, hyperactivity, and impulsivity. A dopamine system dysfunction has been proposed as an underlying factor of the disorder. Indeed, positive association and/or linkage have been found for genes in the dopamine pathways, including the dopamine receptor D1 and D5 (DRD1 and DRD5). In this study, we have tested two genes involved in the DRD1/5 signaling pathway as candidates for ADHD susceptibility: PPP1R1B, which encodes DARPP32, a major target for dopamine-activated adenylyl cyclase and the CALCYON gene which encodes a brain-specific DRD1/5-interacting protein. Three bi-allelic polymorphisms in PPP1R1B and six in the CALCYON gene were genotyped in 215 nuclear families. Association was assessed with the transmission/disequilibrium test, using ETDT for individual alleles and TRANSMIT for haplotypes. Quantitative trait analyses were performed using FBAT in relation to ADHD symptom scores. No association was found between the three DARPP32 polymorphisms and ADHD and no biased transmission was observed for any of the DARPP32 haplotypes. CALCYON analysis, however, has shown significant evidence for biased transmission of two polymorphisms, found in the 5' and intronic regions of the gene ($\chi^2=5.042$, 1df p=0.025 and $\chi^2=4.738$, 1df p=0.030). Quantitative traits analyses demonstrated that these polymorphisms are associated with both the inattentive and hyperactive/impulsive symptoms of ADHD. In addition, two CALCYON haplotypes demonstrated significant evidence for biased transmission ($\chi^2=4.79$, 1df p=0.029 and $\chi^2=4.67$, 1df p=0.030) and significant relationships were also found with both dimensions of the disorder. In summary, these findings do not support DARPP32 as a susceptibility factor in ADHD. However, our data suggest that the CALCYON gene may be involved in ADHD and needs further studies.

Variations in the brain-derived neurotrophic factor (BDNF) gene and susceptibility to bipolar I disorder. *F.W. Lohoff¹, T. Sander², J. Gallinat², W.H. Berrettini¹*. 1) Psychiatry, University of Pennsylvania, Philadelphia, PA; 2) Max Delbrück Centrum, Gene Mapping Center, Berlin, Germany.

Background: Recent studies have indicated that the brain-derived neurotrophic factor (BDNF) gene is involved in the etiology of bipolar disorder (BPD). The BDNF gene maps to the short arm of chromosome 11, a region where linkage studies have suggested a putative locus for BPD. Two family based association studies showed that the functional polymorphism Val66Met in the BDNF gene is associated with BPD, however others could not confirm results. Here we performed a replication study in an independent sample and tested the hypothesis that the Val66Met variation and four additional variations in the BDNF gene confer susceptibility to BPD.

Methods: 627 bipolar I patients and 998 healthy controls were genotyped for the Val66Met polymorphism. Four additional SNPs across the BDNF gene were genotyped in 345 patients and 266 controls, using Applied Biosystems assay-on-demand SNP genotyping assays as per manufacturers protocol. Genotypes and allele frequencies were compared between groups using Chi square contingency analysis. LD was calculated and haplotypes were estimated using the cocophase program.

Results: Allele frequencies of the Val66Met polymorphism differed significantly between BPD patients and controls ($\chi^2=4.4$; $df=1$; $p=0.036$; $OR=1.21$). All genotype counts were in Hardy-Weinberg equilibrium. We observed strong LD in the 3' end of the gene but could not demonstrate LD in the 5' end of the gene. Haplotype analysis showed that combination of rare alleles in the 5' end of the gene differed significantly between patients and controls ($p=0.01$; $OR=0.54$).

Conclusions: These results suggest that the Val66Met polymorphism in the BDNF gene might increase susceptibility to BPD in the Caucasian population. However, rare haplotypes in the 5' end of the gene which are not in LD with the Val66Met SNP, might decrease susceptibility to BPD. Further studies are necessary to elucidate the involvement and pathophysiology of BDNF in BPD.

Metallothionein genes (MT-I, -II and -III) and ethanol preference: studies involving expression in the brain and MT-I/MT-II knockout mice. *K.D. Loney, R.K. Uddin, S.M. Singh.* Molecular Genetics Unit, Department of Biology and Division of Medical Genetics, University of Western Ontario, London, Ontario, Canada N6A 5B7.

Variability in ethanol preference phenotypes of mouse strains offers a suitable model for studies on this endophenotype of alcoholism and fetal alcohol syndrome. We have hypothesized that it may be determined by gene expression profiles in the brain (Treadwell, Pagniello and Singh, 2004). Further, we have reported (Loney, Uddin, and Singh, 2003) that metallothionein-II (MT-II) is an ethanol-responsive gene in the brain, with basal mRNA levels positively correlating with the ethanol preference phenotypes of four inbred mouse strains (A/J, BALB/cJ, DBA/2J; alcohol avoiders, and C57BL/6J; alcohol preferring). In this study we report novel results on MT-I and -III gene expression in the brain and explore the involvement of MT-II in ethanol preference determination through MT-I/MT-II gene knockouts. Results of semi-quantitative RT-PCR have shown MT-I to be an ethanol-responsive gene in all four strains of mice (1.3-1.9X), with C57BL/6J showing the smallest increase in mRNA level following ethanol treatment. The brain-specific MT-III was found to be unresponsive to ethanol, but interestingly C57BL/6J, the alcohol preferring strain, appeared to have the lowest mRNA levels when compared the three alcohol avoiding strains, which were observed to have 1.3-1.5X greater levels. In addition to expression studies, results from two-bottle choice tests with 10% ethanol and water have revealed that MT-I/MT-II knockouts in the 129/Sv background have a slightly higher measure of ethanol preference compared to their wild-type controls. This finding, while interesting, is contrary to our hypothesis that decreased MT-II expression would result in a decrease in ethanol preference. Taken together, these results continue to offer the possibility that the metallothionein gene family may be involved in alcohol-related phenotypes, such as ethanol preference. However, this association is not direct and may depend on the interacting genes and background genotypes. Supported by CIHR, NSERC, and Ontario Mental Health Foundation.

Genetic characterization of human Citron in bipolar disorder. A.M. Lyons-Warren¹, J. Chang¹, M. Garant³, M.G. McInnis¹, A. Sawa^{1,2}. 1) Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Neuroscience, Johns Hopkins University, Baltimore, MD; 3) Division of Endocrinology, Diabetes & Nutrition, University of Maryland Baltimore.

DISC-1 (Disrupted in Schizophrenia-1) has recently been associated with bipolar disorder (BP) (Maeda et al, this meeting 2004). Yeast two-hybrid analysis of DISC-1 revealed several protein interactors, possibly as part of a signaling pathway. Citron was selected from among these DISC-1 interactors for further investigation because the gene coding for *Citron* is located on chromosome 12q24, a reported locus for BP in several linkage studies. Citron is a cytoskeletal synaptic protein that plays a key role in cytokinesis, neurogenesis, and glutamatergic neurotransmission. The sequence for human *Citron* was not available; therefore, we compiled it from contig sequences available from NCBI and UCSC databases. The human gene contains 6,105 base pairs divided into 47 exons, as well as 6 protein domains including a kinase domain and a DISC-1 binding domain. Human and mouse *Citron* exhibit a 96% homology. We next conducted a family-based association study of *Citron* and BP. Select regions, chosen based on functional importance, were directly sequenced in BP patients from families with evidence of linkage to 12q24. This analysis resulted in the discovery of a novel single nucleotide polymorphism (SNP) in exon 23 of human *Citron* gene and confirmed the existence of a second SNP, also in exon 23. We then extended the study to span the entire gene, including 7 additional SNPs from the NCBI database. Our initial association study of these 9 SNPs in samples from 65 BP pedigrees revealed a marginally significant association (P0.02) with BP for one haplotype. Thus, we have characterized and provided the initial study of human *Citron*.

Multifactor-Dimensionality Reduction (MDR) reveals gene-gene effects on GABA_A receptor subunit genes. *D.Q. Ma¹, H. Mei², A.E. Ashley-Koch¹, E.R. Martin¹, P.L. Whitehead¹, M.M. Menold¹, M.D. Ritchie³, G.R. DeLong⁴, R.K. Abramson⁴, H.H. Wright⁴, M.L. Cuccaro¹, J.P. Hussman⁵, J.R. Gilbert¹, M.A. Pericak-Vance¹.* 1) Duke university medical center, center for human genetics, Durham, NC; 2) North Carolina State University, Raleigh, NC; 3) Vanderbilt University, Nashville, TN; 4) University of South Carolina, School of Medicine, Columbia, SC; 5) Hussman Funds, Ellicott City, MD.

Autism is complex genetic disorder likely due to a combination of genetic and environmental factors and their associated interactions. GABA is the primary inhibitory neurotransmitter in adult brain. Eight GABA classes (α1, α2, α3, α4, α5, α6, α7, and α8) and twenty receptor subunit genes have been characterized in mammals. Multiple lines of evidence implicate GABA_A receptor (GABAR) systems in autism. The GABA Autism Project will test all known GABAR subunits and selected GABAergic related genes to identify genetic factors associated with autism risk: RG1| LOC16, GABRA2, GABRA4 and GABRB1 on 4p12, GABRB2, GABRA6, GABRA1, GABRG2 and GABRP on 5q34-q35.1, GABRR1 and GABRR2 on 6q15, as well as GABRA5, GABRB3 and GABRG3 on 15q12. Intronic and silent mutation SNPs within each gene were analyzed in 399 Caucasian autism families. MDR was employed to identify the best model among all possible locus combinations in each chromosome. Prediction error and consistency for each model were considered to identify the potential locus for further test of the interaction among genes cross chromosomes. MDR revealed statistically significant 3-locus effect on all 4 chromosomes (chromosome4:rs1497571,rs2280073,rs6289 within RG1|LOC16,GABRA2 and GABRB1,p=0.011;chromosome5:rs2962407,hcv11814555, hcv3165046 within GABRB2,GABRA1 and GABRP gene, p 0.000; chromosome6: rs423463,hcv9866022,rs2148174 within GABRR1 and GABRR2 gene,p=0.001;chromosome15: rs1426217, hcv42974,hcv2078506 within GABRB3,GABRA5 and GABRG3 gene,p=0.031). Moreover,MDR showed a significant multi-locus effect with hcv11814555 (GABRA1) on chromosome5 and hcv42974 (GABRG3) on chromosome15(p=0.001). These findings suggest that GABAergic genes are significant contributors to autism risk and may involve complex interactions.

NMDA receptor NR2B subunit gene GRIN2B in schizophrenia and bipolar disorder: polymorphisms and expression levels. *L. Martucci, A.H.C. Wong, V. De Luca, O. Likhodi, G.W.H. Wong, N. King, J.L. Kennedy.* Dept Neurogenetics, CAMH, Univ Toronto, Toronto, ON, Canada.

The NR2B protein subunit appears to be critical for a number of the basic structural and functional attributes associated with the NMDA receptor. We studied three polymorphisms located in the gene for NR2B, namely GRIN2B: G-200T, located in the 5'UTR, and the A5806C and T5988C, located in the 3'UTR. We tested the association between these markers and schizophrenia using a sample consisting of 192 case control pairs matched by age, gender, and ethnical background, and a sample of 86 trios. The same markers were studied in our sample of 318 bipolar disorder trios, of which 158 probands displayed psychotic symptoms. We also studied post-mortem cortical mRNA levels of GRIN2B in groups of 35 each of SCZ, BP and healthy controls; DNAs from these groups were also genotyped for the G-200T marker. Our schizophrenia case-control sample and the SCZ triad sample combined show association of the G allele of this marker with the disease ($p=0.0034$). The T5988C marker was associated with BP disorder ($p=0.02$), whereas the A5806C marker showed positive association with those among the bipolar patients who had psychotic symptoms ($p=0.0038$). The haplotype analyses also showed preferential transmission of haplotype G-C-T in BP disorder and of haplotype T-C-C in SCZ. The analysis of overall haplotype frequencies in the case control sample showed marked differences between cases and controls ($p=0.01$). We found no difference in GRIN2B expression levels between schizophrenia, bipolar disorder and healthy controls. No association was present between those groups and either allele of the promoter marker. The gene expression sample, however, is significantly smaller compared to our Toronto based samples and thus might have insufficient power to detect subtle changes both in expression levels and genotype. Other confounding factors such as chronic disease state and antipsychotic treatment could have altered these findings. These results overall support the hypothesis of a role of GRIN2B in the pathogenesis of schizophrenia and of bipolar disorder.

Expression profiles for 6p reading disability locus (DYX2) gene-candidates. *H. Meng¹, S.D. Smith², J. Kenyon², K. Hager³, M. Held¹, J.C. DeFries⁴, R.K. Olson⁴, B.F. Pennington⁵, J. Gelernter⁶, G.P. Page⁷, J.R. Gruen¹.* 1) Dept Pediatrics, Yale Child Health Research Center, Yale Univ, New Haven; 2) Munroe Meyer Institute, Univ of Nebraska Medical Center, Omaha; 3) WM Keck Foundation Biotechnology Resource Laboratory, Yale Univ, New Haven; 4) University of Colorado, Boulder; 5) University of Denver, Denver; 6) Department of Psychiatry, Yale Univ, New Haven; 7) Department of Biostatistics, University of Alabama at Birmingham, Birmingham.

Reading disability (RD), or dyslexia, is the most common neurobehavioral disorder affecting children, with a prevalence rate of 5 to 17.5%. An expanding large body of evidence indicates that RD is genetically based, with heritability between 0.4 and 0.6. We recently described a peak of association at marker JA04 (Kaplan et al, 2002, *AJHG*, 70: 1287) with orthographic choice ($\chi^2_{sq} = 11.49$, $p = .0007$) on 6p21.3-22, where several groups have independently found linkage. We also identified several candidate genes in the vicinity of JA04 that are strongly expressed in human brain (Londin et al, 2003, *BMC Genomics*, 4: 25). To distinguish which candidate gene could be responsible for the peak of association, and would warrant further interrogation for alleles that could render susceptibility to RD, we developed a panel of 147 single nucleotide polymorphism (SNPs) spanning a 1.2Mb region around JA04. Markers were chosen from the public domain (dbSNP) and Celera databases. We genotyped 154 RD families ascertained at the Colorado Learning Disabilities Research Center (Boulder) by TaqMan and pyrosequencing. Markers were tested for both transmission disequilibrium and total association with 11 reading performance phenotypes. These data localize the association peak to a narrow region spanning 500kb and 6 genes with poor performance in several reading tests. We also assessed expression of each gene in 18 sub-regions of human brain by real time RT-PCR. The location of the association peak and expression patterns implicates 3 genes in particular that warrant further interrogation for RD allele(s).

Increased BDNF plasma levels in patients with eating disorders are associated to the -270C/T polymorphism.

J.M. Mercader¹, M. Ribases¹, M. Gratacos¹, A. Badia², L. Jimnez², R. Solano², J. Vallejo², F. Fernandez-Aranda², X. Estivill^{1,3}. 1) Genes and Disease Program, Center for Genomic Regulation, Barcelona; 2) Department of Psychiatry, Hospital Princeps dEspanya, LHospitalet de Llobregat; 3) Experimental and Health Sciences Department, Pompeu Fabra University, Barcelona, Catalonia, Spain.

Anorexia nervosa (AN) and bulimia nervosa (BN) are complex psychiatric conditions where genetic and environmental factors are involved. Murine models and association studies in patients with eating disorders (ED) suggest a potential role of brain-derived neurotrophic factor (BDNF) in eating behavior. We have reported a consistent association of BDNF single nucleotide polymorphisms (SNPs) and ED. The 270C/T BDNF SNP is associated to BN, and the Val66Met variant to both AN and BN in six different European populations. We present here the analysis of BDNF levels in blood of patients with AN and BN that have been genotyped for BDNF SNPs. We assessed the BDNF blood concentration in a clinical sample of 118 Spanish Caucasoid ED patients (54 AN and 64 BN) and 68 sex-matched unrelated controls. BDNF levels were significantly higher in both AN (46.725.9 ng/ml) and BN (41.023.4 ng/ml) patients than in control subjects (16.45.7 ng/ml; $p < 0.0005$). We did not find a significant effect of the Met66 functional variant on BDNF levels, as both Met66 carriers and non-carriers showed increased BDNF concentrations. In contrast, mean BDNF levels were significantly higher in ED patients homozygous for the 270C variant (4924.2; $p = 0.012$) than those carrying the 270T allele (26.917.245), which showed BDNF levels similar to controls. The altered BDNF plasma levels observed in this study provide physiological evidence of a possible role of this neurotrophic factor in AN and BN, and strongly argues for its involvement in eating behavior and body weight regulation.

Large scale association analysis for identification of genes underlying late-onset Alzheimers disease. *T. Miki¹, H. Yamagata², K. Taguchi¹, W. Zhong¹, K. Kamino³, Y. Akatsu⁴, Y. Tabara², I. Kondo².* 1) Dept of Geriatric Medicine, Ehime Univ Sch of Medicine, Onsegun, Ehime, Japan; 2) Dept of Medical Genetics, Ehime Univ Sch of Medicine, Onsegun, Ehime, Japan; 3) Division of Psychiatry and Behavioral Proteomics, Osaka Univ, Suita, Japan; 4) Choju Medical Insitute, Fukushima Hospital, Toyohashi, Japan.

Alzheimers disease (AD) is a complex disease with both environmental and genetic determinants. To date, most studies of AD genetics have focused on a candidate gene approach in unrelated cases and controls, a design that is more powerful than linkage analysis in families when examining a specific gene of interest. Many vascular risk factors such as hypertension, diabetes mellitus, and hypercholesterolemia have recently been shown also to increase the risk of AD. To investigate large scale association analysis for identification of AD genes, we chose a total of 230 candidate genes (67 reported AD-related genes, 163 atherosclerosis-related genes) and carried out high throughput genotyping (TaqMan-probe method) for SNPs in 380 late-onset AD and 380 controls. A total of 3/67 (4.5%) atherosclerosis-related genes and 10/163 (6.1%) AD-related genes showed significant association (p 0.05). Most AD-related genes including IL10, GSK3B, APP, PEN2, PS1, PS2, A2M, HMMR, ACE, BACE, SNCA showed no association. Positive chromosomal loci were 1, 2, 3, 7, 8, 9, 10, 11, 12, 13, 15, 17, 19, 21. Our results indicate some of AD-risk genes may include atherosclerosis-related genes.

SCA8 BAC transgenic mice: cerebellar dysfunction and 1C2/ubiquitin positive neuronal inclusions. *M. Moseley*¹, *Y. Ikeda*¹, *W. Gao*², *M. Weatherspoon*¹, *M.T. Su*³, *H.M. Hsieh-Li*³, *G.J. Lee-Chen*³, *G. Chen*², *K.C. Reinert*², *T.J. Ebner*², *J.W. Day*¹, *L.P.W. Ranum*¹. 1) Inst Human Genetics; 2) Dept Neuroscience, Univ MN, Minneapolis, MN; 3) Dept Life Science, Natl. Taiwan Nml. Univ, Taipei, Taiwan.

Spinocerebellar ataxia type 8 (SCA8), a slowly progressive ataxia, is caused by a CTG expansion. To understand the molecular mechanism of SCA8 we developed a transgenic mouse model using a human BAC clone with the normal (11 CTGs) or expanded (118 CTGs) SCA8 repeat tract. Two high copy expansion lines have a progressive, severe phenotype of impaired locomotion, weight loss and death (14 to > 52 wks). A more slowly progressive, later onset (~12-18 mos) phenotype affecting gait is observed in all 5 remaining expansion lines with no similar phenotype in 3 control transgenic lines. No evidence of cerebellar or CNS degeneration was found in affected mice, although *in vivo* optical imaging studies demonstrate neuronal dysfunction of the parallel fiber-Purkinje cell circuit (with reduced GABA-ergic inhibition) in both high and low copy expansion but not control lines. 1C2 and ubiquitin positive nuclear inclusions were found in Purkinje and pontine neurons of the high copy number expansion but not control transgenic animals. These results parallel our observation of 1C2 inclusions in human autopsy tissue from our large SCA8 family (see Ikeda *et al.*). The 1C2 antibody has been reported to recognize both glutamine and leucine expansions. The known SCA8 transcripts have a short ORF encompassing the CTG repeat that conceptually translates a poly-leucine tract. Although we have not detected a transcript in the CAG direction, a polyQ expansion remains a formal possibility. Alternatively, CUG containing SCA8 transcripts may be noncoding and act through an RNA mechanism similar to FXTAS in which CGG containing transcripts induce the formation of 1C2 negative but ubiquitin positive inclusions, however we have not detected CUG RNA foci in SCA8 brains. Our results demonstrate that the SCA8 CTG repeat expansion causes a neurological phenotype affecting the physiology of the cerebellum in mice and this phenotype relates to that of the human disease by the presence of 1C2-positive, intranuclear inclusions.

The BDNF gene is associated with rapid cycling bipolar disorder. *D.J. Mueller¹, V. De Luca¹, T. Sicard¹, N. King¹, M. Lanktree¹, J. Strauss¹, E. Mundo², F. Macciardi¹, P. Muglia¹, J.L. Kennedy¹.* 1) Neurogenetics Section, Centre for Addiction and Mental Health (CAMH), University of Toronto, Toronto, ON, Canada; 2) Department of Psychiatry, University of Milan, Italy.

We have previously reported significant associations between the Val66Met and GT(n) repeat polymorphisms of the BDNF gene with bipolar disorder (BD). However, these findings have not consistently been replicated which may be explained by considerable methodological heterogeneities among studies. In our sample of 312 nuclear families (with at least one offspring affected with BD) we have added four novel SNP markers (rs3763965, hCV11592756, rs2049045, rs2140887) located within or in the vicinity of the BDNF gene and performed TDT and haplotype analyses. Furthermore, we investigated whether our findings may be determined by the phenomenon of rapid cycling (RC) that has been present in 58 patients (19%). RC is defined by the occurrence of four or more (depressive and/or manic) mood episodes within 12 months. Our analyses revealed that both the hCV11592756 and the rs2049045 SNPs were significantly associated with BD using TDT analyses ($p=0.02$ and $p=0.009$ respectively). These two SNPs appear to belong to a haplotype block flanking the Val66Met and GT(n) repeat polymorphisms. The haplotype including the hCV11592756 (A-allele), Val66Met (G-allele), GT(n) repeat (allele 3) and rs2049045 (G-allele) proved to be over transmitted (49:25) in patients with BD ($p=0.008$). Interestingly, and despite the reduced sample size and reduced power, TDT analyses revealed significant associations with similar or higher likelihood ratio scales with all four SNPs in the sample of patients with RC as compared to the total sample. Conversely, removing patients with RC from the total sample led to non-significant findings with all four SNPs. Our findings suggest that the BDNF gene is likely to be associated with a specific homogeneous subgroup of patients with BD, namely RC. Thus, non replications in studies focusing on the BDNF gene and BD may either be due to a non-distinction of RC and/or limited samples and power. Our observations should be taken into account in studies dealing with the BDNF gene in mood disorders.

The social deficits of the secretin receptor knockout mouse: animal models relevant to autism. *I. Nishijima¹, T. Yamagata², C. Spencer³, O. Alekseyenko³, E. Weeber⁴, J. Sweatt⁴, M. Momoi², R. Paylor³, D. Armstrong⁵, D. Nelson³, A. Bradley⁶.* 1) Department of Pediatrics, The Ohio State University, Columbus, OH; 2) Department of Pediatrics, Jichi Medical School, Tochigi, Japan; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Division of Neuroscience, Baylor College of Medicine, Houston, TX; 5) Department of Pathology, Baylor College of Medicine, Houston, TX; 6) The Wellcome Trust Sanger Institute, Cambridge, UK.

Autism is a neurodevelopmental disorder marked by behavioral features and linguistic development problems. Secretin is a peptide hormone that is secreted from the duodenum to stimulate the pancreas to secrete pancreatic juice, a mixture of products that includes protease and bicarbonate. The receptor for secretin is a G-protein coupled receptor that is expressed not only in the pancreas, but also in the brain. Recent reports indicate that secretin alleviates the symptoms of autism in some patients. However, there are conflicting reports regarding secretins effects. To analyze the mechanisms between secretin signaling and the development of autism, we generated the secretin receptor deficient mice. The mutant mice appeared normal; however, they had social behavioral abnormalities. In addition, we observed a significant reduction in hippocampal long-term potentiation (LTP) induction following high frequency stimulation and throughout the induction and maintenance phases of LTP. These results suggest that secretin signaling may be involved in normal neuronal and social behavioral development. Secretin receptor deficient mice may provide valuable new perspectives on diseases of autism.

Molecular investigation of SNPs previously associated with Parkinson disease (PD) risk. *M.A. Nouredine¹, J.M. van der Walt¹, M.A. Hauser¹, E.R. Martin¹, J. Pearson², M.A. Garcia-Blanco², J.M. Vance¹.* 1) Center for Human Genetics, Duke Univ. Medical Ctr, Durham, NC; 2) Duke University Medical Center, Durham, NC.

PD is marked by death of dopaminergic neurons (DN) within the substantia nigra. Current research supports the involvement of fibroblast growth factor 20 (FGF20) in the survival of DNs. We have recently reported a strong association between PD and FGF20 in a large family-based study. SNPs rs1989754 (C allele, $p=0.0006$) and ss20399075 (T allele, $p=0.0008$) are both positively associated with PD risk and exist in strong linkage disequilibrium (LD). Stratified and haplotype analyses suggest that rs1989754C does not have an independent effect on risk; however, its effect is observed in the presence of ss20399075T. Molecular strategies are needed to identify the causal SNP in this association. We predicted that rs1989754 lies within a site (CGTG) required for binding of the hypoxia-induced factor Hif1-. We hypothesized that FGF20 expression may be regulated under hypoxia, and that rs1989754 may affect this expression. To test this hypothesis, we first examined whether FGF20 transcription is regulated by hypoxia. We demonstrate here that FGF20 transcript level increases two fold in PC12 cells grown under hypoxic conditions. We also show that the sequence containing and flanking rs1989754 can function as a binding site for Hif1- only in the presence the G allele (protective) but not the C allele (risk). Finally, we use cell culture-based luciferase reporter system to investigate if this potential Hif1- binding site is hypoxia-responsive in vivo and if this response is affected by the allele difference at rs1989754. Our initial results suggest that this site (either G or C at rs1989754) is not hypoxia responsive, which argues against the involvement of this potential Hif1- binding site in mediating the hypoxia response observed in FGF20. In conclusion, we provide the first evidence that FGF20 is hypoxia responsive and demonstrate molecular support for our association results that suggest rs1989754 is not a causal variant and that the association of rs1989754 with PD was due to strong LD with ss20399075. We intend to investigate the role of this SNP in the regulation of FGF20.

Failure to confirm association between AKT1 haplotype and schizophrenia in a Japanese case-control

population. *T. Ohtsuki*¹, *T. Inada*², *T. Arinami*¹. 1) Department of Medical Genetics, University of Tsukuba, Tsukuba, Ibaraki, Japan; 2) Department of Psychiatry and Psychobiology, Nagoya University, Graduate School of Medicine, Nagoya, Aichi, Japan.

AKT1 is a serine/threonine kinase known as protein kinase B. Glycogen synthase kinase 3 (GSK3) is one of the substrates of AKT1 and AKT1/GSK3 signaling is known as a target of lithium. AKT/ GSK-3 signaling pathway might be relevant to dopamine-related disorders. Recently, Emamian et al identified AKT1 as a potential schizophrenia susceptibility gene in families of northern European origin. Levels of the AKT1 protein and phosphorylation of GSK3 at Ser9 in lymphocytes and frontal cortex were significantly lower in patients with schizophrenia in comparison with the controls. In multi-SNP haplotype analysis, haplotypes in the AKT1 gene were associated with schizophrenia. Significant association between schizophrenia and an AKT1 haplotype associated with lower AKT1 protein level was shown. In this study, we attempted to confirm the association between AKT1 haplotypes and schizophrenia in Japanese subjects comprising of 559 patients with schizophrenia and 567 controls. We genotyped 5 SNPs using TaqMan assay. Tests for single-marker allelic association were performed by chi-square analysis. Haplotype was estimated with an expectation-maximization (EM) algorithm. Tests for haplotypic association were performed with COCAPHASE software. Pair-wise linkage disequilibrium (LD) was calculated with GOLD software. We observed no significant allelic or haplotypic association with schizophrenia. There may be several reasons such as the different ethnical background and familial loading, why we could not confirm the association between AKT1 haplotype and schizophrenia in our Japanese samples. Furthermore, we can not exclude the existence of a weak association because the 95% confidence interval of the odds ratio was 0.76-1.38 in our population. Written informed consent was obtained from all subjects. This study was approved by Ethics Committee of each authors affiliation.

Haplotype and association studies of variations in -Synuclein gene among Parkinson's disease population. A.

*Parsian*¹, *R. Sinha*¹, *B. Racette*², *J.H. Zhao*³, *J.S. Perlmutter*². 1) Arkansas Birth Defects Research Center, University of Arkansas for Medical Sci, Little Rock, AR; 2) Department of Neurology, Washington University School of Medicine, St. Louis, MO; 3) Department of Epidemiology and Public Health, University College London, London, UK.

We detected an association between a dinucleotide repeat (SNCA) in -Synuclein gene and sporadic Parkinsons disease (PD, Parsian et al., 1998). To replicate our previous finding in a larger sample and further determine the role of -Synuclein in the development of PD, we screened a sample of 226 familial PD, 353 sporadic PD, and 130 controls with the SNCA marker and 3 SNPs (770, int3, and int4) in the gene. There was Hardy-Weinberg disequilibria only with SNP int3 that was excluded in the haplotype analysis. There was also significant difference in allele frequency between African American and American Indian groups for SNCA marker ($p=0.03$). These two samples were excluded from further analysis because of sample size. Comparison of allele frequency differences between PD and controls for single-locus was significant only for SNCA ($p= 0.014$). This result was further shown via haplotype analysis of SNCA-int4 markers. One of the interesting results of our haplotype analyses is with inclusion/exclusion of SNP int3. The global case control association was not significant when the SNP int3 was included in four loci haplotype analysis. Otherwise, two and three loci haplotpes comparisons were significant. The explanation is that inclusion of locus in Hardy-Weinberg disequilibria in haplotype analysis will reduce power as shown by Epstein and Satten (2003). Our results indicate that SNCA locus may be in linkage disequilibrium with a mutation in the gene or itself could be a risk factor for PD.

Genetic study of LRP2/Megalin gene variants in autistic disorder. *I. Ricci¹, M. D'Amelio¹, R. Militerni², C. Bravaccio², S. Trillo³, F. Montecchi³, M. Elia⁴, C. Schneider⁵, R. Melmed⁵, T. Pascucci⁶, S. Puglisi-Allegra⁶, L. D'Agruma⁷, K.L. Reichelt⁸, A.M. Persico¹.* 1) Mol Psychiatry & Neurogenetics, Univ. Subgroups of autistic patients consistently display alterations in specific biochemical and morphological parameters (i.e., endophenotypes), including enhanced urinary oligopeptide excretion rates. This biochemical trait is present in up to 60% of autistic children compared to age- and sex-matched controls. Oligopeptides, 3-10 aminoacids in length, are physiologically filtered by the renal glomeruli and undergo tubular reabsorption through an LDL receptor family member, the lipoprotein receptor-related protein 2 (LRP2) also known as megalin or gp330. Reduced LRP2 amounts and/or altered LRP2 function could thus explain the enhanced urinary excretion rates present in this subgroup of autistic patients. Interestingly, LRP2 plays also a relevant role in human brain development particularly during the first trimester of pregnancy, by exerting the placental uptake of maternal LDL cholesterol. In addition, the LRP2 gene is located on human ch 2q31-q32.2, within a region linked to autism in several genome scans. We are in the process of genotyping eight SNPs spanning the LRP2 locus in 223 simplex and 28 multiplex families with primary autistic probands and in 186 controls. Initial assessments of two SNPs located in exons 3 and 54 currently yield non-significant case-control and intra-familial association trends. Supported by Telethon-Italy (GPP02019), the Fondation Jerome Lejeune, and the Cure Autism Now Foundation.

Investigation of the DAOA/G30 locus in panic disorder. *J. Schumacher*¹, *R. Abou Jamra*¹, *T. Becker*², *N. Klopp*³, *P. Franke*⁴, *C. Jacob*⁵, *P. Sand*⁵, *J. Fritze*⁶, *S. Ohlraun*⁷, *T.G. Schulze*⁷, *M. Rietschel*⁷, *T. Illig*³, *P. Propping*¹, *S. Cichon*⁸, *J. Deckert*⁹, *M.M. Noethen*⁸. 1) Institute of Human Genetics, University of Bonn, Germany; 2) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Germany; 3) Genome Analysis Center (GAC), GSF-National Research Center for Environment and Health, Neuherberg, Germany; 4) Department of Psychiatry, University of Bonn, Germany; 5) Department of Psychiatry, University of Würzburg, Germany; 6) Department of Psychiatry, University of Frankfurt, Germany; 7) Central Institute of Mental Health, Division Genetic Epidemiology in Psychiatry, Mannheim, Germany; 8) Life & Brain Center, University of Bonn, Germany; 9) Department of Psychiatry, University of Münster, Germany.

The DAOA/G30 locus on chromosome 13q33 can be considered a strong positional and functional candidate for panic disorder (PD). In the present study, we assessed whether genetic variation at this locus contributes to the development of PD using a case-control association study. We analyzed five SNPs in a German sample of 152 patients and 208 controls. In the single-locus analyses, three of five tested SNPs were significantly associated with PD at the $p < 0.05$ level (allelic odds ratios range between 1.35 and 1.39, genotypic odds ratios range between 1.84 and 2.12). Further support was obtained at the haplotypic level, suggesting risk-conferring as well as protective haplotypes. A stringent adjustment for testing multiple loci through a robust permutation procedure yielded an empirical p -value of 0.11 for the single marker analysis, suggesting the possibility of a chance finding. However, given that we have previously observed the very same alleles and haplotypes to be associated with disease in bipolar affective disorder and schizophrenia in the German population, we believe that our findings are of importance and warrant further replication. Our results suggest that DAOA/G30 contributes to psychiatric disease beyond diagnostic boundaries. It will be a matter for future studies to fully elucidate the phenotypic expression of the DAOA/G30 locus.

Genetic analysis of glutamatergic signalling genes in alcohol dependence. *G. Schumann¹, M. Soyka², D. Rujescu², F. Matsuda³, A. Szegedi⁴, S. Wellek¹, N. Dahmen⁵, U. Preuss², M. Lathrop³, A. Heinz⁴, F. Henn¹, K. Mann¹.* 1) Central Inst. of Mental Health, Mannheim, Germany; 2) Dept. of Psychiatry, University of Munich; 3) Centre National de Gnotypage, Evry, France; 4) Dept. of Psychiatry, Humboldt University, Berlin; 5) Dept. of Psychiatry, University of Mainz.

Ethanol-induced glutamatergic signal transduction has been shown to influence pathophysiological mechanisms central to the development of alcohol dependence, including tolerance, withdrawal symptoms, craving, relapse and ethanol-related neurotoxicity. Ethanol acts specifically by inhibiting ionotropic N-methyl-D-aspartate (NMDA) receptors. Glutamatergic activation of NMDA-receptors initiates a Ca-mediated signal transduction cascade, which activates Calmodulin-dependent kinase (CamK) and the Ras pathway, leading to activation of the transcription factor CREB. Other proteins activated by NMDA receptors via PSD 95 include neuronal nitric oxide synthase (nNOS) and its effector GMP-kinaseII as well as Phosphatidyl Inositol Kinase 3 and the MAP kinase pathway. The goal of the present study is to systematically analyse genetic variations of NMDA-receptor subtypes and functionally related signal transduction genes which are known to be involved in glutamatergic neurotransmission in ethanol dependence in a large sample of German patients with alcohol dependence and unrelated controls. We attempted to include those NMDA-related genes where evidence for an alteration of alcohol drinking behaviour has been given in behavioural tests using knock-out mice. To this end we identified 10 genes involved in glutamatergic signal transduction and performed a SNP-discovery programme by sequencing analysis of the regulatory domains, exons and exon-intron boundaries of each gene. Next we performed haplotype analyses and genotyped those SNPs which account for the 95% most frequent haplotypes in a sample of 600 patients with alcohol dependence and 500 controls. Genotype-phenotype analysis with particular emphasis on oligogenic interactions was performed using a classical regression analysis. The results of this project will be presented.

***Pain1*, A MAJOR QUANTITATIVE TRAIT LOCUS FOR CHRONIC PAIN IN THE MOUSE, IS ALSO**

ASSOCIATED WITH CHRONIC PAIN LEVELS IN HUMANS AND RATS. Z. Seltzer^{1,2}, R. Dorfman³, E. Gershon², Y. Lu¹, Y. Blech-Hermoni¹, J. Livneh^{2,7}, Y. Shir^{4,5}, J-J. Vatine⁶, I. Sabsovich¹, T. Peretz⁵, M. Devor², R. Pfeiffer⁷. 1) University of Toronto, ON, Canada; 2) Hebrew University, Jerusalem, Israel; 3) Hospital for Sick Children, Toronto, ON, Canada; 4) McGill University, Montreal, QC, Canada; 5) Hadassah University Hospital, Jerusalem, Israel; 6) Reuth Medical Center, Tel Aviv, Israel; 7) Sheba Medical Center, Tel Hashomer, Israel.

Nerve injury produces chronic pain in some, but not all humans. Similar variability in chronic pain is also seen in rodents. We reported localizing a quantitative trait locus (QTL) in mouse chromosome 15 (at marker D15Mit28) that has a major effect on chronic pain following neurectomy. In the present study we examined whether this QTL, named *Pain1*, plays a role in chronic pain of rats and humans as well. Using 15 microsatellite markers we genotyped chromosome 7q13 in 45 HA and 37 LA rats, a region orthologous to mouse *Pain1*. Six markers on other chromosomes were genotyped as controls. HA rats were selectively bred from Sabra strain rats to express high levels, and LA rats to express low levels of chronic pain following nerve injury. We found that 6 of the 15 markers on 7q13 and 2 of the 6 control markers were dimorphic in the tested DNA samples. Significant linkage disequilibrium was found between the 2 rat lines and markers on 7q13, peaking at D7Got98 ($p < 0.000$), but not with the control markers. We then genotyped the orthologous regions of *Pain1* on human chromosomes 8q24 and 22q12-13 in 2 cohorts: women postmastectomy (N=650) and men and women following leg amputation (N=250), 55-80% of whom developed chronic pain. Significant association with chronic pain was found for microsatellite markers on 22q12-13 ($p < 0.01$), but not on 8q24. Then we genotyped 22q12-13 with a dense array of haplotyping SNPs and minimized the region associated with chronic pain to 50 kbp ($p < 0.002$). These results indicate that: (1) this rodent model for chronic pain is relevant for the study of pain genetics in humans, and (2) a gene at *Pain1* confers risk for chronic pain, making it an attractive target for further genetic studies in human chronic pain syndromes of various etiologies.

Glucocerebrosidase mutations in autopsy samples from subjects with parkinsonian syndromes. *E. Sidransky¹, J. Nguyen¹, J. Walker¹, O. Goker-Alpan¹, H.I. Hurtig², J.Q. Trojanowski³, B. Giasson⁴.* 1) NSB, NIMH/NHGRI, NIH, Bethesda, MD; 2) Dept. Neurology, U. Penn; 3) Dept. Path. & Lab. Med., U. Penn; 4) Dept. Pharmacology, U. Penn.; Philadelphia, PA.

An association between Gaucher disease (GD) and Parkinson disease (PD) has been demonstrated by the identification of parkinsonism in some patients with GD and among Gaucher carriers. Recently, screening of 57 brain bank samples from subjects with sporadic PD identified mutations in the glucocerebrosidase gene (GBA) in 17%. To better define the clinical and pathologic features among subjects carrying GBA mutations, we genotyped 23 brain samples from unrelated donors autopsied at the University of Pennsylvania. The samples included 9 cases with the pathologic diagnosis of Lewy Body Variant Alzheimer Disease (LBVAD), 4 with Diffuse Lewy Body Disease (DLB) and 10 with PD. Sequencing of all exons of GBA revealed that 5 subjects were heterozygous for mutations and 3 subjects carried the E326K alteration. Two of the 9 subjects with LBVAD had N370S and 1 carried I161N. The other 2 mutant alleles, A359X and T267I + E326K, were found among the 5 subjects with DLB, and E326K was found in 2 of the 10 subjects with PD. The age at death of the 23 subjects ranged from 58-97 years. The 7 subjects identified with GBA alterations were among the subjects with a younger age at death. Seven additional samples with the diagnosis of Multiple System Atrophy (MSA) were also screened, but no GBA alterations were identified.

This study confirms our previous observation that GBA mutations are observed with increased frequency in subjects with parkinsonism, but demonstrates that many do not have classic Parkinson disease. This finding supports the theory that mutant GBA protein may contribute to the formation of the insoluble aggregates seen in a gamut of neurodegenerative conformational disorders and may serve as a risk factor for the development of parkinsonian syndromes. By unraveling the relationship between altered GBA protein and parkinsonism, we may advance our understanding of the genetics, pathogenesis and treatment of different forms of parkinsonism.

Lack of linkage, association, or mutation with EKN1 and dyslexia in a colorado twin cohort. *S.D. Smith¹, H. Meng², J. Kenyon¹, M. Held², K. Hager³, J.C. DeFries⁴, B.F. Pennington⁵, R.K. Olson⁴, G.P. Page⁶, J.R. Gruen².* 1) Munroe Meyer Institute, Univ of Nebraska Medical Center, Omaha; 2) Department of Pediatrics, Yale Child Health Research Center, Yale Univ, New Haven; 3) WM Keck Foundation Biotechnology Resource Laboratory, Yale Univ, New Haven; 4) University of Colorado, Boulder; 5) University of Denver, Denver; 6) Department of Biostatistics, University of Alabama at Birmingham, Birmingham.

A candidate gene, EKN1, was recently described in a cohort of dyslexics from Finland for the dyslexia locus, DYX1 on chromosome 15q (Taipale et al, 2003, PNAS, 100(20): 11553). In this report a (2;15)(q11;21) translocation disrupting EKN1 segregated with dyslexia in a two-generation family, and one sequence polymorphism in the 5' untranslated region and a missense mutation showed significant association in 99 dyslexics compared to 195 controls ($p=0.006$ and 0.02). To confirm these results we interrogated the same polymorphisms in a cohort of 150 nuclear families with dyslexia ascertained through the Colorado Learning Disabilities Research Center (Boulder). We found a similar prevalence for the two polymorphisms, but could not confirm linkage nor transmission disequilibrium. Furthermore, we did not find any additional mutations in the 10 exons of EKN1 sequenced in at least 2 severely dyslexic subjects from 3 extended families with suggestive linkage to chromosome 15 markers ($LOD>1.0$). We conclude that while mutations of EKN1 may contribute to genetic susceptibility for dyslexia in the Finnish families reported, the effect was not seen in our cohort of predominantly European-American white families.

Molecular Studies on DYX1C1, a candidate gene for dyslexia. *I. Tapia-Paez¹, N. Kaminen², H. Anthoni¹, M. Peyrard-Janvid¹, J. Kere^{1,2}.* 1) Dept. of Biosciences at Novum, Karolinska Institute, Huddinge, Sweden; 2) Dept. of Medical Genetics, Biomedicum, University of Helsinki, Finland.

Dyslexia is a complex disorder characterized by reading disability despite normal intelligence and education; it affects 5-10% of the population. Genetic studies have repeatedly pointed several loci linked to dyslexia in chromosomes 2, 3, 6, 11, 15 and 18. Despite the efforts, only one gene has been cloned, DYX1C1 in chromosome 15 (Taipale et al, PNAS 2003 100(20): 11553-8). This gene was identified through studies in a Finnish family in which the translocation t(2;15) (q11;q21) cosegregated coincidentally with dyslexia. Two sequence changes in DYX1C1 displayed association with dyslexia in other families. One introduces a stop codon truncating the protein by four amino acids. The second change is in the 5UTR, close to the translation initiation site, this change affects the putative DNA binding site for several transcription factors and the Kozak sequence. To understand possible functional consequences of this change, we prepared constructs to study the binding of proteins in EMSA assays. Allele specific differential retardation of mobility was observed with two cell and nuclear extracts, suggesting that the dyslexia-associated polymorphism encompasses a site for nuclear factor binding. Studies are underway to identify the differentially binding protein(s). In another approach, we are studying the co-localisation of DYX1C1, p23, hsp90 and hsp72 in gene transfection models. Comparison of DYX1C1 from human and other nonhuman primates revealed differences in the sequence both in the coding and non-coding regions. Interestingly the changes are clustered in exon 5. We have prepared constructs with these changes and are currently investigating their possible differential processing in a neuroblastoma cell line.

Association of Catechol-o-methyltransferase with Schizophrenia in North American mixed and Portuguese populations. *J.M. Trakalo¹, J. Cui¹, T. Klempan¹, K. Schindler², M.H. Azevedo², C. Pato², M. Pato², F. Macciardi¹, J.L. Kennedy¹.* 1) Psychiatric Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, Canada; 2) Centre for Psychiatric and Molecular Genetics, SUNY Upstate Medical University and Behavioural Health Care Line, Syracuse, New York, USA.

Catechol-o-methyltransferase (COMT) is a catalytic enzyme responsible for the metabolism of dopamine and other catecholamines. The importance of the role of COMT in dopaminergic neurotransmission, coupled with its location on chromosome 22q11, a region associated with psychosis, has made COMT a continued target of association studies of schizophrenia, although these studies to date have failed to produce a definitive conclusion regarding the role of COMT in schizophrenia. The focus of many of these studies is a functional polymorphism, Val158Met, responsible for a 3-4 fold reduction in COMT activity. In this study, we examined the Val158Met polymorphism, along with two other polymorphisms, an A/G substitution at position -287 and a C-Insertion in the 3'UTR, for association with schizophrenia. 114 triad families from a mixed population collected in Toronto, Canada, and 156 multiplex families collected from mainland Portugal and the Azores Islands were genotyped for all three markers and analyzed using the TDT-STDT, FBAT, and Transmit programs. No significant associations were detected using the TDT approach; however, a significant association was detected for the -287A/G polymorphism in the Toronto population with FBAT ($z=2.009$, $p=0.044$). In addition, a significant association was detected in the Portuguese sample for the 3'UTR polymorphism ($z=2.246$, $p=0.025$). No significant associations were detected for the Val158Met polymorphism under either of these methods. Finally, haplotype analyses using Transmit revealed a significant association in the Portuguese population for two common haplotypes ($p=0.0058$ and $p=0.0192$). Together, these results support a role for COMT in the aetiology of schizophrenia; however, it appears at present that the alleles responsible do not include the Val158Met polymorphism. Further studies including more markers and increased sample size are warranted in order to clarify the current findings.

Association between a T/C polymorphism of the CYP46 intron 2 and the late-onset Alzheimers disease. *L. Wang¹, B. Wang¹, F. Jin¹, Z. Yang², C. Zhang¹, Z. Liu³, C. Zheng³, S. Ueda⁴.* 1) Human & Animal Genetics, Inst Gen, Chinese Academy Sci, Beijing, China; 2) Laboratory for Medical Genetics, Institute of Geriatrics, Beijing hospital, Ministry of Health, Beijing 100730, China; 3) Jiangbin Hospital, Nanning, Guangxi 530021, China; 4) Dept. of Biological Science, Graduate School of Sciences, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan.

We analyzed 99 sporadic late-onset Alzheimers disease (LOAD) Han Chinese patients and 113 healthy Han Chinese as controls, in order to investigate possible involvement of the cholesterol 24-hydroxylase (CYP46) gene (T/C in intron 2) and apolipoprotein E (APOE) gene polymorphisms in the manifestation of LOAD. We found an obvious association between CYP46 TT genotype and LOAD (OR=2.98, 95 percent, CI 1.64-5.44, P0.001). A clear increase of the risk to develop AD was also observed in subjects carrying both the CYP46 TT genotype and the APOE 4-allele (OR=12.94, 95 percent, CI 4.26-39.32, P0.001). Our data reveal that not only CYP46 TT homozygotes but also T allele carriers have an increased risk for LOAD in Chinese population. Our data reveal that CYP46 TT homozygots and T allele carriers have an increased risk for LOAD in Chinese population, and suggest a strong synergetic interaction between CYP46 TT genotype and APOE 4 carrier status.

Gene Expression Profiles in APOE Isoform-Specific Hippocampus of Alzheimer Disease (AD) Using Serial Analysis of Gene Expression (SAGE) and Long-SAGE. *P-T. Xu, Y-J. Li, C. Kroner, X-J. Qin, A. Green-Odlum, C. Hulette, D. Schmechel, J. Ervin, M. Hauser, M. Pericak-Vance, J. Gilbert.* Dept Medicine & Human Genetics, Duke Univ Medical Ctr, Durham, NC.

There is overwhelming evidence that multiple genes play an important role in Alzheimer disease (AD). Serial analysis of gene expression (SAGE) and Long-SAGE are powerful techniques for the generation of quantitative information about tissue specific gene expression. To identify new genes conferring susceptibility to Alzheimer disease, and study the influence of APOE genotype on gene expression in AD, we have generated four SAGE libraries using human brain hippocampal RNA isolated from AD patients with APOE3/3, APOE3/4 and APOE4/4 alleles, and a normal control (APOE3/3). We have also generated two Long-SAGE libraries using human brain hippocampal RNA isolated from an AD patient with APOE3/3 allele and a non-demented control (APOE3/3). Quantitation of the number of times a particular tag is observed provides the patterns of gene expression in APOE allele specific AD and non-demented control hippocampal samples. SAGE and LongSAGE library construction was performed with 10 ug total RNA according to the standard SAGE protocol. All the SAGE and Long-SAGE libraries were estimated to contain more than 480,000 tags (>14,400 clones). We have sequenced 2,500 clones of APOE3/3 control SAGE library and 2,500 clones of APOE3/3 AD SAGE library using ABI 3700 automated sequencer. Analyses of sequence files of these two libraries using the eSAGE software demonstrate 78,125 tags extracted from APOE3/3 AD library and 70,456 tags extracted from APOE3/3 control. A total of 37,899 transcripts are identified. Preliminary analysis indicates that 351 genes are more than 5 fold differentially expressed in AD patients and normal control with $p < 0.05$. In AD patients, 148 genes were significantly up-regulated and 203 genes were down-regulated compared with normal control. Through the combined use of both Affymetrix microarray and SAGE, we have obtained a detailed and quantitative APOE isoform-specific gene expression profile of known and/or novel new genes conferring susceptibility to Alzheimer disease.

PR missense variants: a possible association with puerperal psychosis. *J. Yan¹, J. Feng¹, J. Chen¹, C. Katz¹, I.R. Jones², N. Craddock², S.S. Sommer¹.* 1) Dept Molecular Genetics, City of Hope, Duarte, CA; 2) Dept Psychological Medicine, University of Wales College of Medicine, UK.

Steroid and thyroid hormone administration can alter behavior; in occasional individuals, psychosis can result. The levels of progesterone and other hormones change dramatically after birth, suggesting that mutations in the steroid receptor gene family may predispose to puerperal psychosis. To investigate this possibility, the progesterone receptor gene was scanned by DOVAM-S (Detection of Virtually All Mutations-SSCP) in 146 patients with puerperal psychosis. Seven missense variants, three silent changes and two intronic changes were identified. Three missense variants at highly conserved amino acids were found in nine patients with puerperal psychosis while none were found in 100 ethnically matched healthy controls (P=0.008). A possible association between PR and puerperal psychosis may warrant further study.

Association Study of the Myelin Oligodendrocyte Glycoprotein (MOG) Gene in Obsessive-Compulsive Disorder and Schizophrenia. *G.C.M. Zai¹, N. King¹, P. Arnold¹, E. Burroughs², G.W.H. Wong¹, W.G. Honer⁴, C.L. Barr³, M.A.*

Richter², J.L. Kennedy¹. 1) Neurogenetics Section, CAMH, University of Toronto, Toronto, Ontario, Canada; 2) Anxiety Disorders Clinic, CAMH, University of Toronto, Toronto, Ontario, Canada; 3) Department of Psychiatry, University of Toronto and The Toronto Western Hospital, Toronto, Ontario, Canada; 4) Department of Psychiatry, University of British Columbia, Vancouver, British Columbia, Canada.

Obsessive-compulsive disorder (OCD) and schizophrenia (SCZ) are serious neuropsychiatric disorders and might involve autoimmune processes. The human leukocyte antigen (HLA) system has been implicated in several genetic studies of SCZ, whereas a subgroup of children with OCD are believed to develop symptoms in response to Group A beta-hemolytic streptococcal infections. The myelin oligodendrocyte glycoprotein (MOG) gene, which is located close to the HLA region on chromosome 6p, is considered a candidate for OCD and SCZ due to its association with white matter abnormalities and its role in immune processes, particularly in mediating the complement cascade. Four polymorphisms in the MOG gene, (CA)_n, (TAAA)_n, and two intronic polymorphisms, C1334T and C10991T, were investigated for the possibility of association with OCD using 159 OCD probands and their families, with SCZ using 111 SCZ probands and their families, and 182 SCZ case-control samples (matched with age, gender, and ethnicity). We investigated the transmission of alleles/haplotypes of these four MOG polymorphisms using the transmission disequilibrium test and TRANSMIT TDT haplotype test in OCD and SCZ, family-based association test (FBAT) in OCD, Kruskal-Wallis Test and case-control analysis in SCZ. FBAT analysis of MOG-(TAAA)_n showed positive association with OCD (allele 2, P=0.02) and with quantitative symptom severity (P=0.020). The haplotype 1.2.2.13 of MOG (P=0.01) was also significantly associated with OCD. However, we did not observe biased transmission of alleles/haplotypes or significant differences between the allelic/genotype distributions of SCZ cases and healthy controls. Our results suggest that MOG is not associated with SCZ, but may play a role in OCD.

Association of PNMT promoter haplotypes with blood pressure and venodilation response to isoproterenol. X.

Bao¹, P. Mills², B. Kennedy¹, J. Freimund¹, A. Joynor¹, M. Milic¹, C. Feinman¹, M.G. Ziegler¹. 1) Dept Medicine, Medical Ctr, Univ California, San Diego, San Diego, CA; 2) Dept Psychiatry, Medical Ctr, Univ California, San Diego, San Diego, CA.

Blunted vasodilator responses to agonists have been implicated in the pathogenesis of hypertension, but the identity of the contributing genes, especially the genetic variants, remain largely unknown. Phenylethanolamine N-Methyltransferase (PNMT) is the terminal enzyme in the synthesis of epinephrine, the primary endogenous α -agonist. To investigate the role of PNMT in the development of hypertension and the mechanisms involved, we examined the associations of PNMT promoter haplotype with blood pressure and dorsal hand vein dilation response to α -agonist isoproterenol. Two single nucleotide polymorphisms (SNPs) at promoter 353 (A/G) and 148 (A/G) were genotyped in 218 white subjects. By using a maximum likelihood method, all 4 possible haplotypes were found in our population: AA (55.5%), GG (31%), AG (12.4%), and GA (1.1%). Subjects with haplotype AG had significantly higher diastolic but not systolic blood pressure (782 mmHg vs. 741 mmHg for other haplotypes, $p=0.04$), which was even more significant in subjects with diplotype AG/AG (883 mmHg vs. 762 mmHg) and in the younger group (age<45, $p=0.004$). Dorsal hand vein response to ISO, as measured by ultrasound, was nearly completely blunted in subjects with haplotype AG (0.920% vs. 322% for Haplotype AA and 424% for Haplotype GG, $p<0.001$ by ANOVA, $n=88$). In addition, Haplotype AG was associated with increased brain PNMT activity by 15% ($p=0.03$), elevated plasma epinephrine level by 80% ($P=0.03$), and decreased lymphocyte α_2 -adrenergic receptor sensitivity by 40% ($p=0.04$) when compared with other haplotypes. In conclusion, PNMT promoter haplotypes appear to correlate with PNMT enzymatic activity, epinephrine production and α_2 -adrenergic receptor function, and thus can be used to predict the venodilation response to α -agonists as well as individual variation in blood pressure.

Complexities of molecular diagnosis for ventricular arrhythmias. *L. Baumbach, T. Miller, H. Travers, L. You, M.E. Ahearn, W. Lanier, E. Estrella, S. Elliott, R. Myerburg, N. Bishopric.* Univ Miami Sch Medicine, Miami, FL.

Molecular diagnosis of Long QT syndrome (LQTS) and related arrhythmogenic disorders remains highly complex, due to numerous private mutations, variants of unknown significance, and decreased penetrance alleles. We report our initial laboratory experience performing mutation screens of five LQTS disease genes (KVLQT1, KCNH2, KCNE1, KCEN2, SCN5A) in 34 consecutive probands referred from a tertiary care hospital for clinically suspected LQTS or Jervell-Lange-Nielsen syndrome (JLNS) (n=20), unexplained sudden cardiac death (SCD; n= 10), or pharmacologically-induced LQT and *torsade* (PI-LQT; n=4). Mutation screening was conducted using exon-specific PCR, SSCP, and DNA sequencing of all SSCP variants. DNA variants were reviewed for relative frequency and possible disease association using mutation databases and published literature. Presumed disease-causing mutations were detected in seven (39%) suspected LQTS patients. Five of these were in KVLQT1; two were in KCNH2. Five were novel (71.4%). Coinheritance of these alterations with disease presence was proven in 6/7 families analyzed. It is of interest that two of the five cases with KVLQT1 mutations had a second mutation (D85N) in KCNE1, the modifying subunit of KVLQT1. A number of synonymous and non-synonymous SNPs were also detected in all genes. In SCD patients, two (20%) carried pathogenic mutations (one in KCNH2, one in SCN5A), while the remaining patients displayed numerous SNPs in all five genes, including at least one SCN5A variant in each patient. Of the four PI-LQT patients, only one had a known pathogenic mutation (KVLQT1, G189R), while two had rare and/or novel SNPs (KCNH2 1809 C>T; KVLQT1 I93I + SCN5A G3183A). These results suggest that with increased availability of genetic testing for LQTS, *bona fide* disease-causing mutations are likely to be identified in fewer than 50% of all patients referred with suspected LQTS, and that the majority of patients will harbor novel and/or common gene variants of unknown significance. Additional functional and epidemiological studies are warranted to establish better genotype-phenotype correlations in LQTS.

Identification of Three Novel Mutations in MEF2A Associated with Coronary Artery Disease and Myocardial Infarction. *MR. Krishna Bhagavatula*^{1,2,3}, *Chun. Fan*^{1,2}, *June. Cassano*², *Edward.F. Plow*^{1,2}, *Eric.J. Topol*^{1,2}, *Qing. Wang*^{1,2,3}. 1) MolecularCardiology,LRI; 2) CenterforCardiovascularGenetics,CCF; 3) Dept of BGES,CSU.

Background: Coronary artery disease (CAD) and myocardial infarction (MI) are the leading cause of deaths in the U.S. We have recently established MEF2A, encoding a transcription factor in the endothelium of coronary arteries, as the first gene responsible for autosomal dominant CAD/MI gene (Science, 2003; 302: 1578-1581), and a 21-bp deletion of MEF2A was identified in a large family with CAD/MI. However, the prevalence of MEF2A mutations in the CAD/MI population is unknown. Here we report the results from mutational analysis of MEF2A in 200 independent patients with CAD/MI (males <55 years and females <60 years of age) and 200 individuals with normal angiograms. **Methods:** Mutational analysis was carried out using SSCP and DNA sequence analyses. The functional consequence of the newly-identified MEF2A mutations were examined using a transcription activation assay with the ANF-700p-luciferase reporter gene and transient transfection of wild type or mutant MEF2A proteins in HeLa cells. **Results:** Three novel mutations were identified in exon 7 of MEF2A in four of 200 CAD/MI patients (2%), and none of the mutations were detected in 200 normal individuals. These mutations include N263S identified in two independent CAD/MI patients, P279L in one patient, and G283D in another patient. Analysis of family members revealed that the father of the patient with mutation P279L also carried the mutation and has the diagnosis of CAD. The three mutations are located within or close to the major transcription activation domain of MEF2A (amino acids 274-373), and significantly reduced the transcription activation activity of MEF2A. These results suggest that N263S, P279L, and G283D are functional mutations. **Conclusions :** These results provide the first confirmatory evidence of our previous report that MEF2A mutations cause CAD and MI and indicate that a significant percent of the CAD/MI population (2%) may carry mutations in MEF2A. Further definition of the prevalence of MEF2A mutations is clearly warranted.

Association of the STRK1 gene PDE4D with Stroke in a U.S. Population. *V.H. Brophy¹, S.K. Ro¹, A.M. Valdes¹, S. Gretarsdottir⁴, G. Thorleifsson⁴, L. Lui², J. Mangacat¹, N. Umblas¹, L.G. Bentley¹, J. Li¹, S. Cheng¹, J.R. Gulcher⁴, K. Stefansson⁴, S.R. Cummings³, W.S. Browner³, H.A. Erlich¹.* 1) Roche Molecular Systems, Alameda, CA; 2) University of California, San Francisco, CA; 3) California Pacific Medical Center, San Francisco, CA; 4) deCODE Genetics, Reykjavik, Iceland.

Phosphodiesterase 4D (PDE4D) underlies the STRK1 linkage peak on chromosome 5q12 identified in Iceland for stroke. We genotyped 13 single-nucleotide polymorphisms (SNPs) and one microsatellite in a nested case-control sample of elderly white women (>65 years) from the Study of Osteoporotic Fractures (SOF) in the U.S. The fourteen polymorphisms lie in two large regions of the 1.5-Mb gene, one at the 5 end and one in the middle. The 249 women who suffered an ischemic stroke during an average of 5.4 years of follow-up were compared to 587 controls. Two SNPs showed borderline or significant association with stroke in recessive models: SNP222 (hazards ratio [HR] 0.60, P=0.05) and SNP42 (HR 1.35 P=0.09). (In the Icelandic population, the relative risks (RR) were 0.88, P = 0.11 and 0.67, P = 0.01 respectively, for additive models.) Adjustment for age, hypertension, diabetes, smoking, and weight also yielded borderline significance for SNP219 and SNP220 for SOF stroke. Additionally, we found that four of the SNPs were associated with hypertension in all samples (P<0.05) and SNP175 was associated with hypertension in the control samples (P = 0.006, OR 1.65). Estimated haplotype frequencies suggested association of a 5-SNP haplotype at the 5 end of the gene (AACAG, OR 0.68, P=0.06) while a 6-SNP haplotype had an OR of 1.91 (ACTATG, P=0.02). These differed from the stroke-associated Icelandic haplotypes of the same SNPs at one site each: AACAA, (RR 1.8, P=0.00002) and ACCATG (RR 1.5, P=0.0004, unpub.) respectively. Differing LD patterns within these large haplotypes and with the causal variant(s) may explain the variability in associations between the two populations. These data are consistent with an association of the PDE4D gene and stroke in a non-Icelandic population.

An association study supports *COL24A1* as a modifier gene in human heart failure. *K.M. Carlson*¹, *B.R. Pedersen*², *M.P. Donahue*², *E.R. Hauser*², *W.E. Kraus*², *H.A. Rockman*², *D.A. Marchuk*¹. 1) Molecular Genetics and Microbiology, Duke University, Durham, NC; 2) Medicine, Duke University, Durham, NC.
