Malaria is a global health problem affecting approximately 40% of the world's population, with a prevalence of 300-500 million clinical cases per year. Around 90% of these cases are in sub-Saharan Africa and result in over 1 million deaths per year, predominantly of children. Host genetic factors have been shown to play a central role in resistance mechanisms against malaria infection and clinical malaria, e.g. sickle-cell trait. In order to identify more genes associated with malaria susceptibility, a high-throughput SNP genotyping technique was adopted. Forty-one genes were identified as possible candidates, e.g. genes from the toll-like receptor signalling pathway, suppressors of cytokine signalling and interferon-regulatory factors. Single nucleotide polymorphism (SNP) information was obtained from online databases. However, most SNPs did not have information on allele frequencies in Africans. A total of 202 possible SNPs were used in a two-stage screening strategy to genotype a Gambian case-control study group using the Sequenom MassARRAY assay. The SNP assay PCRs were typically 7-plex, giving a total of 30 sets. Each set was used in an initial screen of 188 severe cases and 188 mild controls and if there was a significant association with a malaria phenotype ( $p < 0.05$ ) this was followed by screening of the remaining 1056 samples, giving a total of 538 severe malaria cases, 338 mild malaria cases and 562 controls. From the first 140 SNP assays, 35% of assays were successful, 23% significantly deviated from Hardy-Weinberg equilibrium, 29% of the SNPs were non-polymorphic in this dataset and 12% of assays failed outright. From this initial data, analysis of 48 SNPs using a 3x2 Pearson's chi-squared test, an association between one of the SNPs and malaria disease status was significant for both genotype ( $\chi^2=14.15$ ,  $p=0.0008$ ) and allele ( $\chi^2=5.74$ , Odds Ratio=1.49 (95% C.I. 1.06-2.09,  $p=0.017$ )). The genotype association remained significant after Bonferroni correction for multiple testing ( $p=0.038$ ).

**Expression profiling in muscle from untreated children with juvenile dermatomyositis (JDM) with pathological calcifications.** *Y.-W. Chen*<sup>1</sup>, *L.M. Pachman*<sup>2</sup>. 1) Center for Genetic Medicine Research, Childrens National Medical Center and George Washington University, Washington, DC; 2) Dept of Pediatrics, The Childrens Mem. Institute for Education and Research, Northwestern University, Chicago, IL.

JDM is the most common pediatric inflammatory myopathy. Children with JDM may develop pathological calcifications (PCa<sup>++</sup>), which contribute to both the morbidity and mortality of this often chronic disease. We established that PCa<sup>++</sup> are associated with: 1) prolonged duration of untreated disease, 2) TNF-308A polymorphism, 3) disease activity. The goal of the study is to identify differentially expressed genes in muscle from JDM patients with and without PCa<sup>++</sup> to understand the molecular mechanisms involved in the process. Muscle biopsies from 10 untreated JDM (5 with PCa<sup>++</sup>, 5 without PCa<sup>++</sup>) and four control children were expression profiled using Affymetrix human U133 chips containing ~42,000 full-length genes and ESTs. Comparisons between JDM +/- PCa<sup>++</sup> and gene changes with p-values less than 0.001 were selected for further analyses. Expression levels from the control samples (changes from baseline) were determined. The results showed that JDM with PCa<sup>++</sup> patients had upregulation of ICAM2, MARKS (myristoylated alanine-rich protein kinase C substrate), ICAM3, and MASP1 (mannan-binding serine protease-1) compared to untreated children with JDM without PCa<sup>++</sup>. Twenty-six genes down-regulated the most prominent (greater than two fold) in the JDM with PCa<sup>++</sup> group were IL-12 receptor B2, and 8 other genes. Comparison with control samples showed that ICAM2 and MARKS were upregulated in JDM with PCa<sup>++</sup>, while ICAM3 and MASP1 were down regulated in JDM without PCa<sup>++</sup>. We concluded that upregulation of adhesion molecules, ICAM-1,-2, -3 may play a role in localizing the site of PCa<sup>++</sup>. Persisting inflammation is associated with PCa<sup>++</sup> in JDM muscle. Contributing factors are: duration of untreated disease; increased TNF- associated with the TNF-308A allele, and decreased expression of the IL-12 receptor. We expect that further dissection of differential expression profiles in JDM may lead to a better understanding of the pathophysiology of PCa<sup>++</sup>.

**Molecular basis of complete C4A and C4B deficiencies in human SLE and kidney diseases.** *Y. Yang<sup>1</sup>, K. Lhotta<sup>2</sup>, E.K. Chung<sup>1</sup>, C.Y. Yu<sup>1</sup>.* 1) Molecular and Human Genetics, Columbus Childrens Research Institute, and Department of MVIMG, OSU; 2) Department of Clinical Nephrology, Innsbruck, Austria.

Complete deficiencies of human complement C4A and C4B are strongly associated with infectious disease, systemic lupus erythematosus (SLE) or kidney diseases. So far, 29 individuals with complete C4A and C4B deficiencies have been identified. The molecular basis of complete C4 deficiency has been determined only in five subjects with three different deleterious mutations, including a 2-bp insertion in exon 29, a 1-bp deletion in exon 20, and a 1-bp deletion in exon 13. In these complete C4 deficient patients, two common HLA haplotypes that affect multiple individuals in different families have been revealed. To investigate the molecular basis of complete C4 deficiency in these two HLA haplotypes, four families with 7 patients from the Alpine region were recruited. They are either homozygous in HLA A24 Cw7 B38 DR13 or HLA A30 B18 DR7. They have SLE, recurrent hematuria with membranous nephropathy, or Henoch-Schoenlein purpura. Definitive genomic Southern blot analysis and pulsed field gel electrophoresis experiments revealed a single, long mutant C4A gene in three patients with the HLA B38-DR13 haplotype, and an unusual bimodular RCCX module with two short mutant C4B genes and with two steroid CYP21B genes in four patients with the HLA B18-DR7 haplotype. Long-range PCR strategies were applied to amplify and clone the mutant C4A and C4B genes. The three mutant C4 genes were sequenced to completion except the endogenous retrovirus in the long C4A gene. A novel 2-bp deletion in exon 13 was discovered in the mutant C4A genes. The identical G to A nucleotide substitution at the splice junction of intron 28 was found in the two C4B mutant genes. Hence, there are two hot-spots with deleterious mutations in C4A<sub>Q0</sub> and C4B<sub>Q0</sub>: one is located at exon 13; the other is located within a 2.6 kb genomic region spanning exon 20 to exon 29. Definitive SSP-PCR and RFLPs have been created to facilitate screening of the C4 gene mutations. This will help determine the prevalence of C4 mutants in infectious and autoimmune diseases more accurately.

**Systemic lupus erythematosus (SLE) is associated with private mutations and public haplotypes of DNASE1 and DNASE1L1.** *D. Xu<sup>1</sup>, M.K. Lee<sup>1</sup>, K. Dalakishvili<sup>1</sup>, Y. Wang<sup>1</sup>, N. Shen<sup>2</sup>, S.L. Chen<sup>2</sup>, J.E. Salmon<sup>3</sup>, M.C. King<sup>1</sup>.* 1) Medical Genetics and Genome Sciences, U Washington, Seattle WA; 2) Institute of Rheumatology, Shanghai, China; 3) Hospital for Special Surgery, New York, NY.

DNASE1 and its homologs, all involved in clearance of DNA from autoantigenic nucleoprotein complexes, are candidate genes for inherited predisposition to SLE. DNASE1 homologs are 40% to 56% identical in protein sequence and differ in chromosome and in cellular localization: for example, DNASE1 (16p13.3) is secreted and DNASE1L1 (Xq28) membrane-bound. DNASE1-deficient mice develop features similar to human SLE and an inherited nonsense mutation in DNASE1 has been reported in two Japanese patients. We evaluated DNASE1 and DNASE1L1 genomic sequences, htSNP-defined haplotype blocks, and message expression levels in Caucasian SLE cases and matched controls and in Chinese SLE patients and their parents. In a Caucasian SLE patient, we identified a novel DNASE1 protein truncating mutation due to a tandem 56-bp duplication and a stop at codon 86. This mutation is not found in other SLE patients or in >1000 controls. DNASE protein activity of this patient, measured by the SRED method, is lower than that of controls ( $P < 0.0001$ ). Furthermore, an unrelated haplotype of DNASE1 ("CGG") is 4-fold more common among Caucasian SLE patients than controls (OR = 4.02; 95% CI [1.51,11.3]), and in Chinese families, a parent with DNASE1\*CGG is more likely to transmit this haplotype to a child with SLE ( $P = 0.03$  by TDT). DNASE1L1 haplotypes defined by htSNPs and a 3'UTR 196-bp deletion differ in frequencies between Caucasian SLE cases and controls ( $P = 0.007$ ). Transcript expression of DNASE1L1 differs very significantly by haplotype (Hotelling  $P < 0.00001$ ) and within each haplotype cluster is lower for SLE cases than controls ( $P = 0.01-0.03$ ). Similar analyses of DNASE1L2 and 1L3 are underway. Inherited variation in the DNASE1 family may play an important role in the pathogenesis of SLE. Integrating patients genotypes at these loci into future clinical trials of recombinant human DNASE1 therapy may be beneficial.

***ASCT2*, key molecule in placental morphogenesis, escapes from imprinting in placenta.** *N. Yahagi*<sup>1</sup>, *H. Asada*<sup>2</sup>, *R. Kosaki*<sup>3</sup>, *T. Takahashi*<sup>1</sup>, *K. Kosaki*<sup>1</sup>. 1) Department of Pediatrics, Keio Univ, Tokyo, Japan; 2) Department of Obst, Keio Univ, Tokyo, Japan; 3) Division of Medical Genetics, Saitama Children's Medical Center Iwatsuki, Japan.

From an evolutionary standpoint, genome imprinting is observed only in mammals (eutherians). Because only the mammals have placenta and that most imprinted genes are expressed in placenta, it is speculated that genomic imprinting co-evolved with the placental system. Furthermore, the conflicting theory states that imprinting regulates the balance between the maternal and fetal nutrients. In terms of nutrient transfer in human placenta, the syncytiotrophoblast cell layer represents the maternal-fetal barrier. Syncytiotrophoblasts are formed by the fusion of cytotrophoblasts with a help of Syncytin, an endogenous retroviral envelope glycoprotein and its receptor *ASCT2*, sodium-dependent neutral amino acid transporter type2. We attempted to determine whether human *ASCT2* is imprinted in placenta in view of its crucial role in the formation of placental barrier and its map location to the vicinity of the known imprinted gene cluster on 19q13. Allelic expression of the *ASCT2* transcript was determined using RT-PCR analysis with a primer pair designed to amplify across the *g/c* single-nucleotide polymorphism within exon 1. In all of the 6 term placental tissue samples shown to be heterozygous for the *g/c* polymorphism, the *ASCT2* gene was expressed by both the maternally and the paternally derived alleles. We conclude that the *ASCT2* escapes from imprinting in human placenta. Because imprinting patterns can vary in a developmental stage-specific and tissue-specific manner, evaluation of purified syncytiotrophoblasts at earlier phases of gestation may be required in future studies.

**Logistic regression reveals a tetragenic interaction underlying the mouse epistatic circler phenotype.** *E. Franssen*<sup>1</sup>, *K. Cryns*<sup>1</sup>, *F.L. Wuyts*<sup>2</sup>, *G. Van Camp*<sup>1</sup>. 1) Center for Medical Genetics, University of Antwerp (UIA), Antwerp, Antwerp, Belgium; 2) Department of ENT, University Hospital of Antwerp (UZA), Antwerp, Belgium.

The epistatic circler mouse is characterized by circling behavior, caused by a malformation of the horizontal semicircular canal (Cryns et al. unpublished results). This phenotype is observed in a fraction of the F2 generation from an intercross between *C57L/J* and *SWR/J* mouse strains. Genetic mapping studies have indicated that mutations in at least four different genes contribute to this condition: one gene from from the *SWR/J* strain (referred to as *Ecs*), localized at mouse chromosome 14, and three genes originating from the *C57L/J* strain (referred to as *Ecla*, *Eclb* and *Eclb*), located on chromosome 3, 4 and 13 respectively (Cryns et al. Genome Res. 12:613-617 (2002)). The recessive *Ecs* gene is necessary but not sufficient, whereas the exact nature of the contribution of the *Ecl* genes is less clear.

The F2 generation of the *C57L/J* X *SWR/J* intercross yielded 144 mice homozygous for the disease-associated *Ecs* allele carrying all possible combinations of *Ecl* alleles. Ninety-one mice were affected and 47 were not. Here we perform a logistic regression analysis to model the contribution of the three *Ecl* genes. Stepwise logistic regression indicates that the effect of these genes is non-additive. The *Eclb* locus is the main locus. *Ecla* and *Eclc* only contribute in the presence of at least one copy of *Eclb*.

This study proves that it is at least in model organisms possible to identify the genes involved in oligogenic traits. As vestibular dysfunction in man is probably a multigenic trait, identification of the genes involved in the epistatic circler mouse has considerable relevance to the study of balance disorders.

**SHFM3 is Associated with a Genomic Rearrangement in 10q24.** *X.J. de Mollerat<sup>1</sup>, D.B. Everman<sup>1</sup>, F. Gurrieri<sup>2</sup>, C.T. Morgan<sup>1</sup>, E. Sangiorgi<sup>2</sup>, P. Gaspari<sup>2</sup>, J. Amiel<sup>3</sup>, M.J. Bamshad<sup>4</sup>, R. Lyle<sup>5</sup>, J.E. Allanson<sup>6</sup>, B. Le Marec<sup>7</sup>, H. van Bokhoven<sup>8</sup>, N.E. Braverman<sup>9</sup>, U. Radhakrishna<sup>5</sup>, V. Elghouzzi<sup>3</sup>, S. Antonarakis<sup>5</sup>, R.E. Stevenson<sup>1</sup>, A. Munnich<sup>3</sup>, G. Neri<sup>2</sup>, C.E. Schwartz<sup>1</sup>.* 1) Greenwood Genetic Center, Greenwood, SC; 2) Istituto di Genetica Medica, Univ Cattolica, Roma, Italy; 3) INSERM U-393 Hopital Necker-Enfants Malades, Paris, France; 4) Dept of Genetics, Univ of Utah, Salt Lake City, UT; 5) Division of Medical Genetics, Univ of Geneva Medical School, Geneva, Switzerland; 6) Dept of Genetics, Childrens Hospital of Eastern Ontario Research Inst, Ontario, Canada; 7) Facult de Mdecine de Rennes I, Rennes, France; 8) Dept of Human Genetics, Univ Medical Centre Nijmegen, Nijmegen, The Netherlands; 9) John Hopkins Univ, School of Medicine, Baltimore, MD.

Split Hand-Split Foot Malformation (SHFM) is characterized by hypoplasia/aplasia of the central digits with fusion or deformation of the remaining digits. One locus for this condition, SHFM3, is located in 10q24. The phenotype of the Dactylaplasia (Dac) mouse, which has a SHFM-like phenotype, results from two different alleles, Dac1J and Dac2J. Both alleles arise from a disruption of the dactylin gene located in a region syntenic to 10q24. Mutation analysis of the DACTYLIN gene was conducted in 9 SHFM probands from families linked to 10q24. Screening of the coding region of DACTYLIN by SSCP and sequencing, failed to detect any point mutations. However, Southern, PFGE and dosage analyses demonstrated a complex rearrangement associated with a ~0.5 Mb tandem duplication in all the probands. Analysis of additional individuals found two individuals with non-familial SHFM with this rearrangement. The distal breakpoints are clustered in an 80 kb region and the proximal breakpoints are clustered in a 130 kb region. This duplicated region contained an extra copy of a portion of the DACTYLIN gene and the entire LBX1 and B-TRCP genes, both of which are known to be involved in limb development. Thus, it would appear that SHFM3 is a genomic disorder, a growing class of disorders associated with submicroscopic duplications, deletions or inversions.

**Polymorphisms in dysbindin (DTNBP1, 6p22.3) are associated with intermediate phenotypes measured by the Premorbid Adjustment Scale (PAS) in cases of childhood onset psychosis.** *M. Gornick<sup>1</sup>, A.M. Addington<sup>1</sup>, A. Sporn<sup>1</sup>, N. Gogtay<sup>1</sup>, D. Greenstein<sup>1</sup>, M. Lenane<sup>1</sup>, P. Gochman<sup>1</sup>, D.R. Weinberger<sup>2</sup>, J.L. Rapoport<sup>1</sup>, R.E. Straub<sup>2</sup>.* 1) Child Psychiatry Branch, NIH/NIMH, Bethesda, MD; 2) Clinical Brain Disorders Branch, NIMH, NIH, Bethesda, MD.

Straub et al (2002) recently identified 6p22.3 gene dysbindin as a schizophrenia susceptibility gene through a positional cloning effort. We studied a rare cohort consisting of 98 probands who have onset of psychotic symptoms before the age of 13. Seventy-one of these probands received a diagnosis of schizophrenia, and the remaining 27 have psychosis NOS (not otherwise specified), 11 of whom have subsequently developed bipolar disorder. Information on these subjects included cognitive and behavioral ratings of early development, history of medication response, neuropsychological and cognitive test performance, smooth pursuit eye movements, and premorbid development. We tested SNPs in and around dysbindin and performed family-based TDT analysis using the Spielman program TDT-STDT, haplotype analyses using the program TRANSMIT, and quantitative TDT using the software QTDT. A SNP allele located upstream of exon 1 was preferentially transmitted to affecteds (TDT-STDT p value 0.01). Furthermore, the QTDT analyses showed several significant findings. In particular, transmission of the rare alleles of 2 adjacent SNPs was strongly associated (empirical p values = 0.0009-0.003) with worse premorbid functioning as measured by the Premorbid Adjustment Scale (PAS). These findings strengthen the evidence that dysbindin is an important risk factor for schizophrenia and may play a key role in premorbid development. REFERENCES: Straub et al. Genetic variation in the 6p22.3 gene DTNBP1, the human ortholog of the mouse dysbindin gene, is associated with schizophrenia *AJHG* 71, 337 (2002).

**Haplotype structure of the UDP-glucuronosyltransferase 1A1 (*UGT1A1*) gene and its relationship to serum total bilirubin concentration in a Korean male population.** C.S. Ki<sup>1</sup>, K.A. Lee<sup>2</sup>, S.Y. Lee<sup>1</sup>, H.J. Kim<sup>1</sup>, S.S. Cho<sup>3</sup>, J.H. Park<sup>3</sup>, S. Cho<sup>3</sup>, K.M. Sohn<sup>3</sup>, J.W. Kim<sup>1</sup>. 1) Department of Laboratory Medicine, Samsung Medical Center, Seoul, Korea; 2) Department of Laboratory Medicine, College of Medicine, Korea University, Seoul, Korea; 3) Clinical Research Center, Samsung Biomedical Research Institute, Seoul, Korea.

Several polymorphisms in the UDP-glucuronosyltransferase 1A1 (*UGT1A1*) gene have been reported to be associated with the serum total bilirubin (T-Bil) concentration. Since these polymorphisms lie in a relatively short region, a certain extent of linkage disequilibrium (LD) is expected between them. We tried to investigate the haplotype structure of the *UGT1A1* gene and investigated its relationship to the serum T-Bil in a Korean male population. Three common polymorphisms in the *UGT1A1* gene were genotyped in 324 healthy Korean male subjects by direct sequencing; -3279T>G, (TA)<sub>6/7</sub> (*UGT1A1*\*28), and 211G>A (G71R; *UGT1A1*\*6). We assessed the extent of LD between these polymorphisms to construct multisite haplotypes and investigated the relationship between the *UGT1A1* haplotypes and the serum T-Bil concentration. There was significant pairwise LD ( $p < 0.0001$ ) with  $D'$  values of 1.0 between all pairs of the three polymorphisms. Haplotype analysis revealed that four out of eight possible haplotypes existed in the subjects; 3279T-(TA)<sub>6</sub>-211G, 3279T-(TA)<sub>6</sub>-211A, 3279G-(TA)<sub>6</sub>-211G, and 3279G-(TA)<sub>7</sub>-211G. When the subjects were stratified into 10 subgroups according to their *UGT1A1* haplotypes, significant differences in the mean serum T-Bil concentration were observed among the subgroups ( $p=0.0001$ ). In conclusion, we demonstrated that there is complete LD between three common polymorphisms in the *UGT1A1* gene. Furthermore, we unequivocally constructed the haplotypes of the *UGT1A1* gene, and revealed that they were significantly associated with the serum T-Bil concentration in a Korean male population. To the best of our knowledge, this is one of the first studies to assess the haplotype-phenotype correlation between the *UGT1A1* gene and the serum T-Bil concentration.

**Glucocerebrosidase Mutations in Subjects with Parkinson Disease.** A.A. Lwin<sup>1,2</sup>, E. Orvisky<sup>1,2</sup>, M. Eblan<sup>1,2</sup>, E. Sidransky<sup>1,2</sup>. 1) Section on Molecular Neurogenetics, NIMH, NIH, Bethesda, MD; 2) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Recent studies suggest an association between Gaucher disease, the inherited deficiency of glucocerebrosidase, and parkinsonism. A small subset of patients with Gaucher disease who develop an early-onset, treatment refractory form of parkinsonism have been reported. Upon recent inspection, it has been noted that some Gaucher probands also have close relatives with Parkinson disease. In order to determine whether glucocerebrosidase may contribute to the etiology of parkinsonism in other cases, we determined the glucocerebrosidase gene (GBA) sequence and enzyme activity in 57 samples of brain tissue from subjects with a primary diagnosis of Parkinson disease and in tissue from 47 controls obtained from four different brain banks. Alterations in the glucocerebrosidase gene were identified in 12 samples (21%), including eight with functional mutations in GBA (N370S, L444P, K198T, and R329C) and four with probable polymorphisms (T369M and E326K). Two subjects belonged to a subset of 29 individuals who died before age 76. Thus, among these younger subjects with Parkinson disease, 27% were Gaucher carriers or homozygotes. The only GBA alterations identified among the 47 control samples were two alleles with E326K. These results suggest that mutations in glucocerebrosidase may be associated with the development of parkinsonism and altered glucocerebrosidase, even in heterozygotes, may be a risk factor for parkinsonism in some individuals.

**Chromosomal loci of alleles that protect the mouse retina from light-induced damage.** *M. Danciger*<sup>1</sup>, *J.E. Lyon*<sup>1</sup>, *D.M. Worrill*<sup>1</sup>, *J. Lem*<sup>2</sup>, *C. Grimm*<sup>3</sup>, *A. Wenzel*<sup>3</sup>, *C.E. Remé*<sup>3</sup>. 1) Dept Biol, Loyola Marymount Univ, Los Angeles, CA; 2) Ophthalmology & Cardiology, Tufts-New England Med Ctr, Boston, MA; 3) 3Laboratory of Retinal Cell Biology, University Hospital Zurich, Zurich, Switzerland.

Retinas of BALB/cByJ mice are more susceptible to light insult than those of 129S1/SvImJ. In this work, we used quantitative genetics to determine the loci that influence intense light-induced retinal damage as a step toward identifying the genes/alleles that the loci represent. Thus, 289 4-6 week old F2 progeny of an intercross between 129 and BALB/c mice were exposed to 15,000 LUX for 1 hour after pupil dilation, kept in the dark for 16 hours and then placed in dim cyclic light for 10-12 days. At the end of this time, the amount of rhodopsin remaining in the retinas was measured spectrophotometrically and was used as the quantitative trait measuring retinal damage. Neither gender nor pigmentation had a significant influence on rhodopsin loss. DNAs from F2 progeny were genotyped with 72 dinucleotide repeat markers spanning the genome. For screening purposes, the markers were first tested in 27-36 of the F2 progeny with the most rhodopsin remaining and 27-36 with the least rhodopsin. Any marker with a >95% probability of being associated with phenotype was tested in all F2s. Additional markers were typed in significant regions. Data were analyzed with the Map Manager QTX program. QTL on mouse Chrs 1 and 4 were identified with LOD scores of 6.8 and 7.0 and with percent genetic effects of 28% and 28%, respectively. In addition, two suggestive QTL were found on Chrs 6 and 2 with LOD scores of 3.6 and 3.1 each accounting for 14% of the genetic effect. For each of the QTL the 129 alleles protect the retina from light damage, and the four QTL add up to 84% of the total genetic effect. The Chr 1 QTL is in the same region as a QTL influencing constant light-induced retinal damage between two other mouse strains, and the Chr 6 QTL is in the same region as a QTL influencing age-related retinal degeneration between the BALB/cByJ and C57BL/6J-c2J strains. Identification of the gene modifiers represented by these QTL may be important for human retinal disorders that are accelerated by light exposure.

**Refined mapping of the DYX3 dyslexia susceptibility region.** *H. Anthoni<sup>1</sup>, M. Peyrard-Janvid<sup>1</sup>, P. Onkamo<sup>1</sup>, N. Kaminen<sup>2</sup>, K. Hannula<sup>2</sup>, J. Nopola-Hemmi<sup>3</sup>, H. Lyytinen<sup>4</sup>, J. Kere<sup>1, 2</sup>.* 1) Dept. of Biosciences at NOVUM, Karolinska Institute, Huddinge, Sweden; 2) Dept. of Medical Genetics, Biomedicum, University of Helsinki, Finland; 3) Dept. of Pediatric Neurology, Hospital for Children and Adolescents, University of Helsinki, Finland; 4) Dept. of Psychology and Child Research Center, University of Jyväskylä, Finland.

Developmental dyslexia is a complex disease characterized by unexpected difficulty in learning to read despite adequate intelligence, education, and normal senses. It has a prevalence of 5-15% and a wide spectrum of phenotypes probably due to the effects of multiple genes, incomplete penetrance and environmental factors. Several genetic loci have been mapped to at least five chromosomes, but to date no gene has been reported to be involved in the development of dyslexia. Our genome-wide scan results from a set of eleven Finnish families pointed out a 40 cM region located 30 cM centromeric to the previously reported dyslexia locus DYX3 on 2p16-p15. Non-parametric linkage (NPL) analysis showed the highest score of 2.55 ( $p=0.004$ ) for marker D2S2216 at 2p11.2. We performed two rounds of fine mapping using 29 additional microsatellite markers in the same set of families, as well as in 64 Finnish case-controls. These gave the highest NPL score of 3.014 ( $p=0.001$ ) for marker D2S2216. Association analysis using Haplotype Pattern Mining (HPM) gave the highest score for marker D2S286 ( $p<0.001$ ) in the six pedigrees showing linkage to the region. Together, these data narrow down the candidate region to 8 cM on 2p12-p11.2 and makes it distinct from the DYX3 locus. We have tested two genes, TACR1 and CTNNA2, for mutations in affected individuals from our set of families. These genes made good candidates as they were located within the linked region and are involved in some functions of the nervous system. No mutations could be detected in the coding regions of these two genes. To further narrow down our candidate region, we are presently adding single nucleotide polymorphism (SNP) markers to this region, and proceeding with the positional cloning of the gene.

**Evidence for gene-gene interaction in susceptibility to bipolar disorder.** *A.M. Addington<sup>1,3</sup>, C.D. Langefeld<sup>2</sup>, P.P. Zandi<sup>3</sup>, J.R. DePaulo<sup>3</sup>, J. Nurnberger<sup>4</sup>, T. Reich<sup>5</sup>, E. Gershon<sup>6</sup>, M.G. McInnis<sup>3</sup>.* 1) Child Psychiatry Branch, NIH/NIMH, Bethesda, MD; 2) Dept of Public Health Sciences, Wake Forest Univ Sch Med, Winston-Salem, NC; 3) Dept Psychiatry, Johns Hopkins Univ Sch Med, Baltimore, MD; 4) Indiana University, Indianapolis, IN; 5) Washington University, St. Louis, MO; 6) University of Chicago, Chicago, IL.

We performed a nonparametric linkage analysis of genome scan data from 148 multiplex bipolar pedigrees from the Hopkins/DANA family study and Wave 1 of the NIMH Genetics Initiative. Using a narrow phenotype model, including BPI, BPII and SA/BP as affected (assessed by SADS-L/RDC or DIGS), both single-locus and multi-locus nonparametric linkage analyses were completed. The NPL regression approach (Langefeld, 1999) utilizes the multipoint pedigree-specific NPL scores derived from the program GENEHUNTER as covariates in a conditional logistic regression model that tests for increased allele sharing. The regression model allows for joint and conditional tests of multiple loci, including evidence for heterogeneity and epistasis. The subset approach (Cox et al., 1999) weights families on evidence for linkage at one trait locus in order to test for linkage at other unlinked regions of the genome. Single-locus analyses of this combined dataset revealed suggestive evidence for linkage on chromosome 2q near D2S160 (LOD = 2.3) and 8q near D8S256 (LOD = 2.3). A multi-locus model using the NPL regression method increased evidence for linkage to 8q to a LOD of 3.8, adjusting for linkage evidence at five other regions. Both approaches identified a putative trait locus on chromosome 5q near D5S400 that did not show evidence for linkage in single-locus analysis, suggesting a significant epistatic interaction with the locus on chromosomes 2q ( $p = 0.000017$ ). Statistical approaches that are able to test for linkage at multiple regions simultaneously may provide more power as they more accurately reflect the underlying biology of complex traits and genetic heterogeneity present in collected samples.

**The metabolic clearance rate of insulin: a novel heritable risk factor for atherosclerosis.** *M.O. Goodarzi<sup>1,2</sup>, M.J. Quiñones<sup>2</sup>, H. Yang<sup>1</sup>, X. Li<sup>1</sup>, D. Wang<sup>1</sup>, I. Enriquez<sup>2</sup>, X. Jimenez<sup>2</sup>, G. Hernandez<sup>2</sup>, R. De La Rosa<sup>2</sup>, Y. Li<sup>3</sup>, M.F. Saad<sup>2</sup>, H.N. Hodis<sup>3</sup>, W.A. Hsueh<sup>2</sup>, J.I. Rotter<sup>1,2</sup>.* 1) Cedars-Sinai Medical Center, Los Angeles, CA; 2) UCLA, Los Angeles, CA; 3) USC, Los Angeles, CA.

The goal of the Mexican-American Coronary Artery Disease (MA-CAD) project is to identify genes linking insulin resistance and atherosclerosis. 101 MA families were recruited via a parent with CAD; all adults (age 18, n=568) were genotyped for 408 microsatellite markers along the genome at ~10cM density. Adult offspring and offspring spouses (n=438) underwent the euglycemic clamp and ultrasound assessment of carotid intima-media thickness (IMT), a measure of subclinical atherosclerosis. In addition to directly quantifying insulin sensitivity (whole body glucose disposal, M), the clamp yields a measurement of the metabolic clearance rate of insulin (MCRI). MCRI was correlated with IMT ( $r=0.15$ ,  $P=0.003$ ), as was M ( $r=-0.013$ ,  $P=0.009$ ). After adjusting for age, gender, and BMI, MCRI was still significantly associated with IMT ( $p=0.028$ ) while M was not ( $p=0.71$ ). Heritability estimates and multipoint linkage analyses were carried out with variance component methods in SOLAR. MCRI was found to have a heritability ( $h^2$ ) of 0.83 ( $P0.001$ ); of note, this was higher than the heritability of M ( $h^2=0.40$ ,  $P0.001$ ). A genome-wide linkage scan revealed several peaks for MCRI on chromosomes 1 (124 cM, LOD 1.85), 4 (105 cM, LOD 1.56), 6 (57 cM, LOD 1.98), 8 (37 cM, LOD 1.40), and 9 (139 cM, LOD 2.55). Insulin binding to its receptor triggers internalization of the insulin-receptor complex, which leads to clearance of insulin. Thus, MCRI may be a marker of insulin binding and action. The positive association between MCRI and IMT suggests that increased insulin action may lead to subclinical atherosclerosis, most likely via the mitogenic/growth promoting effects of insulin. We also show that MCRI is highly heritable and report several loci exhibiting linkage with MCRI. MCRI appears to be a previously unrecognized risk factor for atherosclerosis. Identification of gene(s) that influence MCRI will provide further insight into the connection between insulin action and atherosclerosis underlying the metabolic syndrome.

**Polymorphisms in the CTLA4 gene region confer susceptibility to Addisons disease.** A. Blomhoff<sup>1</sup>, B.A. Lie<sup>2</sup>, E.H. Kemp<sup>3</sup>, A.P. Weetman<sup>3</sup>, H.E. Akselsen<sup>1</sup>, A.G. Myhre<sup>4</sup>, E.S. Husebye<sup>5</sup>, D.E. Undlien<sup>1</sup>. 1) Institute of Medical Genetics, Ullevål University Hospital, University of Oslo, Norway; 2) Institute of Immunology, Rikshospitalet University Hospital, Oslo, Norway; 3) Division of Clinical Science (North), University of Sheffield, United Kingdom; 4) Department of Pediatrics and Department of Clinical Molecular Biology, Akershus University Hospital, Norway; 5) Medical Department B, Haukeland University Hospital, University of Bergen, Norway.

Addison's disease (primary adrenal insufficiency), is a rare disease with a prevalence of 4-14/100 000 in Caucasians, and is mainly caused by an autoimmune adrenalitis. The disease may occur isolated or as a part of an autoimmune polyendocrine syndrome (APSI or APSII). While APSI is a monogenic disease, both APSII and isolated autoimmune Addisons disease are genetically complex disorders. The CTLA4 (cytotoxic T lymphocyte antigen4) gene on chromosome 2q33 is associated with several autoimmune disorders. Studies on autoimmune Addisons disease and polymorphisms in the CTLA4 gene have been inconclusive. The gene encodes the CTLA4 surface molecule on activated T- lymphocytes, involved in down regulation of the immune response. New candidate polymorphisms located within a 6.1 kb region downstream of the gene have recently been revealed to be strongly associated with disease susceptibility for Graves' disease, type 1 diabetes and Hashimotos thyroiditis. These SNPs (single nucleotide polymorphisms) are probably also influencing gene splicing, and thereby the relative abundance of soluble CTLA4 versus full length isoforms. We have genotyped a total of 134 Addison's disease patients from Norway and UK with either isolated autoimmune Addison's disease or APSII, and 414 healthy controls for 5 of these newly identified SNPs. We find that alleles at these SNPs differ significantly in Addison's disease patients compared to controls. Our results demonstrate that the same polymorphisms that confer susceptibility to the above mentioned autoimmune diseases also confer susceptibility to Addison's disease. This supports that CTLA4 polymorphisms may confer susceptibility to autoimmunity in general.

Program Nr: 2121 from 2003 ASHG Annual Meeting

**A SNP in NCAM1 shows association with human neural tube defects.** *K.L. Bastress, E.C. Melvin, D. Siegel, J.R. Gilbert, D.S. Enterline, T.M. George, M.C. Speer, NTD Collaborative Group.* Duke University Medical Center, Durham, NC.

Neural tube defects (NTDs) are common birth defects with an incidence of approximately 1/1000 births with both genetic and environmental factors implicated. To date, no major genetic factors related to risk have been identified. Throughout development, cell adhesion molecules are strongly implicated in cell-cell interactions, and may play a role in the formation and closure of the neural tube. There has been evidence that expression of cell adhesion molecules are disturbed in spontaneous NTDs in avian embryos. In order to test whether neural cell adhesion molecule 1 (NCAM1) influences risk of human NTDs, we evaluated single nucleotide polymorphisms (SNPs) within the gene. Four SNPs within the NCAM1 were genotyped using TaqMan: rs2298526, rs2011505, ims\_jst013324, and rs1006826. We utilized both family-based and case-control approaches to evaluate evidence for association and/or linkage disequilibrium in this data series. We analyzed our sample set (N = 172 families) of American Caucasian simplex lumbosacral myelomeningocele families and 252 unrelated controls for evidence of linkage and association using TRANSMIT and the pedigree disequilibrium test (PDT). Transmit analysis revealed a significant association between risk for NTDs and intronic SNP rs2298526 ( $p = 0.0028$ ). Using both the PDT and geno-PDT, evidence for significant association was again found in SNP rs2298526 ( $p = 0.042$ ). These results suggest variations in NCAM1 may influence risk for human NTDs.

**Analysis of candidate genes for nuclear-encoded modifiers in families with the mitochondrial A1555G mutation and non-syndromic deafness.** *Y. Bykhovskaya<sup>1</sup>, E. Mengesha<sup>1</sup>, D. Wang<sup>1</sup>, H. Yang<sup>1</sup>, M. Shohat<sup>2</sup>, X. Estivill<sup>3</sup>, N. Fischel-Ghodsian<sup>1</sup>.*

1) Ahmanson Department of Pediatrics, Steven Spielberg Pediatric Research Center, Medical Genetics Birth Defects Center, Cedars-Sinai Medical Center and UCLA School of Medicine, Los Angeles, CA; 2) Department of Pediatrics and Medical Genetics, Basil and Gerald Felsenstein Medical Research Center, Tel Aviv University Medical School, Petah Tikva, Israel; 3) Deafness Genetics Research Group, Medical and Molecular Genetics Center, Hospital Duran I Reynals, Barcelona, Spain.

Phenotypic expression of the deafness-associated mitochondrial A1555G mutation in the 12S rRNA gene is influenced by aminoglycosides and complex inheritance of nuclear-encoded modifier genes. The position of a major modifier gene has been localized to 8p23.1, but the locations of other modifiers remain unknown. Genes for prothocadherin 15 (PCDH15), cadherin 23 (CDH23), homolog of yeast mto1 gene (MTO1), homolog of yeast mss1 gene (GTPBG3), mitochondrial transcription factors B1 (TFB1M) and B2 (TFB2M) have been proposed as candidates for being modifiers. We tested a total of 214 DNA samples from 27 pedigrees of Spanish and Italian background, and from a large Arab-Israeli kindred with maternally inherited deafness for linkage and association using SNPs and microsatellites in these genes. The non-parametric linkage analysis and TDT testing were done using all families combined as well as in the dataset divided based on linkage to the chr 8 locus and ethnicity. MTO1 and TFB1M showed strongly suggestive linkage and LD results in all families combined thus suggesting their function as nuclear-encoded modifier genes for the A1555G mutation. Sequencing analysis of the coding sequence and exon-intron junctions of the TFB1M and MTO1 genes in a subset of affected and unaffected Arab-Israeli, Spanish, and Italian family members did not reveal any relevant sequence variants. Understanding the regulation of transcription and splicing of TFB1M and MTO1, and sequencing of the regulatory regions will help clarify their involvement in the pathogenesis of maternally inherited deafness, and possibly in other mitochondrial DNA disorders. We gratefully acknowledge support by NIH/NIDCD grant RO1DC01402.

**Significant evidence for a *CARD15*-independent Crohns Disease susceptibility locus on chromosome 16.** *K.E. Adams, N.J. O'Callaghan, J.A. Cavanaugh.* Medical Genetics Research Unit, JCSMR - The Canberra Hospital, Woden, Australia.

Inflammatory bowel disease (IBD) is a complex genetic disease comprising the disease subsets of Crohns disease (CD) and ulcerative colitis (UC). Susceptibility loci for IBD have been implicated on a number of chromosomes, with the most replicated and validated being *IBD1* on chromosome 16q and *IBD3* on chromosome 6p. Three SNPs in *CARD15* have been implicated at *IBD1*, while a SNP in the promoter of *TNF*- (-857<sub>CT</sub>) has been implicated at *IBD3*. Hampe et al (2003) have recently suggested that there is a second IBD susceptibility locus on the p arm of chromosome 16, designated *IBD8*.

To investigate the possibility of a second locus we analysed a dense microsatellite marker map of the p arm of chromosome 16 in 75 Australian CD families. Maximal two point linkage (NPL=3.0) is observed at D16S685 which is located at 16p11, more than 19cM from *CARD15*. Multipoint analysis also shows significant evidence for linkage in the region of D16S685 and D16S753. TDT provides further support (p=0.002) for this locus, particularly at D16S3145, the marker previously implicated by Hampe et al (2003). Conditional analyses shows that linkage in this region is strongest in those families in which the *TNF*- -857T allele is segregating (NPL=4.0).

We have previously reported strong evidence for linkage between *IBD1* and CD in the Australian population, as well as association between two of the three risk alleles reported in *CARD15* and CD. We have also reported strong evidence for an association between the *TNF*- -857C allele and *CARD15*. Our data supports the presence of an independent locus at *IBD8*, through linkage and TDT. In addition, the association with the *TNF*- -857T allele, rather than the C allele, suggests that this novel locus is independent of *CARD15*.

**Differential allelic expression of BMP5 and COL9A1 may constitute the osteoarthritis susceptibility that has been mapped to chromosome 6.** *A. Ferreira, L. Southam, B. Dowling, L. Marcelline, Z. Mustafa, K. Chapman, G. Bentham, J. Loughlin.* Botnar Research Centre, University of Oxford, Oxford.

Primary osteoarthritis (OA) is a common disease characterised by the degeneration of the cartilage of articulating joints. We have previously linkage mapped a hip OA susceptibility locus to a 12cM interval on chromosome 6, with a maximum multipoint LOD score of 4.0. This linkage was restricted to the 146 families from our cohort that contained female affected sibling pairs concordant for hip OA. As the first stage in the association mapping of this locus, we have genotyped 36 microsatellite markers from within the 12 cM interval in the 146 female-hip families. The highest two-point LOD score was 4.8, with 11 markers having LOD scores  $> 2.0$ . We tested each marker for association to OA by the TDT. We also genotyped 220 age-matched female controls and performed a case-control analysis, using the 146 probands from our families as the cases. These tests provided moderate evidence ( $P < 0.05$ ) for association to microsatellites located close to two candidate genes: the bone morphogenetic protein 5 gene (BMP5) and COL9A1, which encodes for the 1 polypeptide chain of type IX collagen. BMP5 is a regulator of chondrocyte differentiation whilst type IX collagen is a structural component of the cartilage extracellular matrix. We had previously failed to detect association to these candidates using gene-based SNPs. Our latest data prompted us to speculate that the chromosome 6 OA susceptibility could be coded for by cis-acting variation in the regulatory elements of one or both of these two genes rather than by an alteration in protein sequence. To test this we extracted RNA from the articular cartilage of OA patients heterozygous for coding SNPs within BMP5 or COL9A1 and compared allelic output by rtPCR and single base extension. 30% of our patients demonstrated differential allelic expression at BMP5, 50% at COL9A1. This analysis implies that variation in the level of expression of these two candidates may constitute the OA susceptibility that we have linkage mapped to chromosome 6. We need to identify the cis-acting sequences responsible for this variation to be certain of this.

**High-Density Lipoprotein Cholesterol Locus on Chromosome 16 Restricted to 3.5 Mb.** *A.G. Day<sup>1</sup>, E. Sobel<sup>1</sup>, K. Lange<sup>1</sup>, A.J. Lusis<sup>1</sup>, T.W.A. de Bruin<sup>2</sup>, M.R. Taskinen<sup>3</sup>, P. Pajukanta<sup>1</sup>.* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Maastricht University, The Netherlands; 3) Helesinki University Central Hospital, Finland.

Coronary heart disease (CHD) is a multifactorial disease constituting a major health problem in Western societies. We aim to assess the largely unknown genetic background of CHD by investigating the two most common dyslipidemias predisposing to CHD, familial combined hyperlipidemia (FCHL) and low serum high-density lipoprotein cholesterol (HDL-C). These two disorders taken together affect 20-40% of families with premature CHD. We recently identified a 25-cM susceptibility locus for HDL-C on chromosome 16 in a combined analysis of Finnish and Dutch genome scans. The current aim is to restrict this 25-cM region via an analysis strategy incorporating genotyping error and locus heterogeneity considerations. Linkage analysis is sensitive to genotyping errors and locus heterogeneity in the study sample, of which both introduce noise and increase the difficulty of finding the true signal. We employed a refinement strategy to the 25-cM region on 16q that minimizes these effects. The strategy included: (1) Zeroing out all genotypes that have a posterior probability of mistyping at either allele greater or equal to an heuristically determined value of 0.5; (2) Estimating the alpha value of the cleaned data by linkage analysis; (3) Utilizing the estimated alpha value (0.5) to calculate posterior probability of linkage for each family; and finally (4) Perform linkage analysis only on those families with posterior probability greater or equal to an heuristically determined value of 0.6. This strategy refined the originally 25-cM region to a 9-cM region (i.e. the Lod minus 1 region) on chromosome 16q. Importantly, this 9-cM region equals to only 3.5-Mb with completely finished sequence and involves 40 genes, thus providing a considerably restricted region to target for fine mapping with the goal of identifying the associated gene.

**CTLA4 is a susceptibility gene for Systemic Lupus Erythematosus.** *M. Barreto*<sup>1</sup>, *E. Santos*<sup>3</sup>, *R. Ferreira*<sup>1</sup>, *C. Fesel*<sup>1</sup>, *F. Fontes*<sup>1</sup>, *C. Pereira*<sup>2</sup>, *B. Martins*<sup>2</sup>, *R. Andreia*<sup>3</sup>, *J. Viana*<sup>3</sup>, *F. Crespo*<sup>3</sup>, *C. Vasconcelos*<sup>3</sup>, *C. Ferreira*<sup>3</sup>, *A.M. Vicente*<sup>1</sup>. 1) Instituto Gulbenkian Ciência, Oeiras, Portugal; 2) Instituto de Ciências Biomedicas Abel Salazar, Porto, Portugal; 3) Associação dos Doentes com Lupus, Portugal.

Systemic Lupus Erythematosus (SLE) is a genetically complex autoimmune disorder of unknown etiology. Dysregulation of the co-stimulatory system likely contributes to the initiation and maintenance of autoimmunity due to activation of self-reactive T cells. The CTLA4 molecule, which has a role in down-regulating the activation of T cells, has been implicated in a number of autoimmune diseases such as IDDM and Multiple Sclerosis. To investigate the role of CTLA4 in the pathogenesis of SLE, we genotyped two polymorphic markers within the CTLA4 gene (an A to G transition in exon 1 and a microsatellite in the 3' UTR), in a Portuguese population sample of 115 patients and 176 controls. We found a significant association with the CTLA4 microsatellite marker ( $\chi^2=24.190$ ,  $p=0.001$ ) with a particular allele showing a protective effect ( $\chi^2=17.310$ ,  $p=0.001$ ) and another conferring susceptibility to SLE ( $\chi^2=4.636$ ,  $p=0.031$ ). Genotypes containing either the protective or the susceptibility allele were associated with SLE ( $\chi^2=16.857$ ,  $p<0.001$  and  $\chi^2=6.430$ ,  $p=0.011$ , respectively). Although the male:female ratio is not equal in the case and control samples, matching for sex did not change the overall association ( $\chi^2=21.247$ ,  $p=0.003$ ). Because case-control studies are prone to errors due to population admixture, we ran FBAT on a sample of 55 multiplex families (comprising 73 patients). We found a transmission disequilibrium of the susceptibility allele (more often transmitted to affected offspring,  $p=0.01$ ), thus corroborating the association result obtained in the case-control study. No association was found with the SNP on CTLA4 exon 1. Because the 3' UTR polymorphism may be involved in the regulation of CTLA4 mRNA stability and, consequently, of its expression, we propose that the genotype-dependent defective expression of this molecule may be responsible for a deficient down-regulation of the immune response, leading to autoimmunity in SLE.

**Multigenic obesity congenic strains as novel models for cardiovascular complications of diabetes.** *D. Estrada-Smith<sup>1</sup>, X. Wang<sup>2</sup>, P. Wen<sup>2</sup>, L.W. Castellani<sup>2</sup>, A.J. Lusis<sup>1, 2</sup>, R.C. Davis<sup>2</sup>.* 1) Human Genetics, UCLA School of Medicine, Los Angeles, CA 90095; 2) Cardiology, UCLA School of Medicine, Los Angeles CA 90095.

Multigenic obesity (MOB) loci 5 and 6 influence interrelated phenotypes of obesity, insulin resistance and dyslipidemia as demonstrated by recent characterization of MOB congenic strains. Here a genomic interval from 63-165 Mb (middle MOB) from the lean CAST/Ei (CAST) strain introgressed onto an obesity susceptible C57BL/6 (BL6) background produced a congenic mouse strain displaying an atherogenic lipid profile (low HDL, high LDL and total cholesterol) that was resistant to obesity and maintained lower insulin and glucose levels compared to BL6 controls when fed an atherogenic or a high energy diet. Conversely mice with an introgressed genomic interval from 83-120Mb (distal MOB) from CAST showed multiple metabolic syndrome traits including increased plasma insulin, glucose, free fatty acids, triglycerides and adiposity when compared to controls. To further evaluate contributions of this locus to the development of atherosclerosis both congenic strains were bred onto an LDLR<sup>-/-</sup> background and fed a high fat diet. Recent NMR data indicate that middle MOB derived strains still continue to display a decrease in fat accretion when compared to distal MOB derived and LDLR<sup>-/-</sup> control strains. Similarly, this strain continues to show no impairment of glucose sensing as determined by IPGTT. And while middle MOB derived strains show little to no atherosclerotic lesion formation a subset of middle MOB mice show extensive calcification of the myocardium. In contrast, distal MOB derived strains demonstrate impaired glucose tolerance, increased adiposity and extensive atherosclerosis but no calcification. Much of the MOB locus is syntenic human loci associated with obesity, insulin resistance. Identification the susceptibility and resistance genes within the MOB loci and characterization of the pathways associated with them will reveal important interactions to elucidate the associations between the dyslipidemia, obesity and vascular disease associated with type 2 diabetes in humans.

***INSR* and *CACNA1A* are not Major Contributing Loci in Finnish Migraine Families.** M.A Kaunisto<sup>1</sup>, P.J. Tikka<sup>1,2</sup>, M. Kallela<sup>3</sup>, J.C. Papp<sup>4</sup>, A. Korhonen<sup>4</sup>, E. Hämäläinen<sup>1</sup>, T. Moilanen<sup>1</sup>, H. Harno<sup>3</sup>, H. Havanka<sup>5</sup>, M. Färkkilä<sup>4</sup>, R.A. Ophoff<sup>4</sup>, A. Palotie<sup>1,2,4,6</sup>, M. Wessman<sup>1</sup>. 1) Dept of Clinical Chemistry, Univ of Helsinki, Finland; 2) Finnish Genome Center, Univ of Helsinki, Finland; 3) Dept of Neurology, Univ of Helsinki, Finland; 4) Dept of Human Genetics, David Geffen School of Medicine, UCLA, USA; 5) Länsi-Pohja Central Hospital, Kemi, Finland; 6) Dept of Pathology, David Geffen School of Medicine at UCLA, USA.

Migraine is a common, complex neurological disorder characterized by severe unilateral pulsating headache with possible transient neurological aura symptoms. Mutations in the *CACNA1A* gene on 19p13, coding for the calcium channel alpha 1A subunit, have been demonstrated to cause familial hemiplegic migraine (FHM1), a rare autosomal dominant subtype of migraine with aura. Its contribution to the more common forms of migraine, migraine with or without aura, has been debated. The insulin receptor gene (*INSR*) on the 19p13 region has also been associated with migraine. To test the possible involvement of *INSR* and *CACNA1A* loci in migraine with aura (MA), we studied a 33 cM region covering these two loci by genotyping eight microsatellite markers: D19S247, D19S427, D19S592, D19S391, D19S394, D19S221, D19S1150, D19S226 in 72 Finnish, MA families with 757 individuals. The genotypes were analysed by the two-point parametric linkage analysis using the affecteds only model. Having MA patients as affected (n=416), the maximum combined lod scores for these markers were all 0.3 both under locus homogeneity and heterogeneity. Thus our results show no evidence for linkage to this region. When the family-based lod scores were examined, one family showed nominal linkage (lod score 1.0) to the *INSR* flanking marker D19S427 and one family to the *CACNA1A* flanking marker D19S226. Additionally, the marker D19S394 locating between the *INSR* and *CACNA1A* genes gave a lod score 1.0 in one family. Inspection of the haplotypes for each family did not support linkage. In conclusion, our findings do not support the previous studies that *INSR* and *CACNA1A* are susceptibility genes to MA. However, we can not rule out the possibility that the 19p13 region might contain a modifying locus to MA.

**Haplotype association studies in target regions on chromosomes 6q23-q27 and 14q21-q23 in systemic lupus erythematosus.** *C.M. Lindgren*<sup>1,3</sup>, *S. Koskenmies*<sup>2</sup>, *E. Widen*<sup>2</sup>, *P. Onkamo*<sup>2</sup>, *P. Sevnó*<sup>2</sup>, *V. Mkelää*<sup>1</sup>, *L. Berglind*<sup>1</sup>, *V. Ollikanen*<sup>2</sup>, *H. Julkunen*<sup>2</sup>, *J. Kere*<sup>1,3</sup>. 1) Dept. of Biosciences, Novum, Stockholm, Sweden; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) Centre for Biotechnology at Novum, Karolinska Institutet, Stockholm, Sweden.

Systemic lupus erythematosus (SLE) is a chronic, multifactorial, autoimmune disease of unknown aetiology, which displays a broad variety of clinical manifestations. Epidemiological studies as well as recent genome wide scans (GWS) and studies of candidate genes have showed a genetic background of the disease and suggested several genetic loci that might be of importance for disease susceptibility. However, most of the genetic components of SLE are still unknown. We have previously conducted a GWS in 35 Finnish multiplex families containing 169 individuals (73 affected with SLE). Using 417 microsatellites, we detected suggestive linkage on chromosome 6q23-q27 (NPL 2.5,  $p=0.01$ ) and 14q21-q23 (NPL 2.2,  $p=0.02$ ) as well as in the HLA region on chromosome 6p. Here we have performed initial finemapping adding 44 microsatellite markers at 1 cM density in the chromosome 6q23-q27 (19 markers) and 14q21-q23 (25 markers) regions in trios from 65 families, including the individuals from the initial scan. The data was analysed using two complementary approaches, haplotype pattern mining (HPM) and transmission disequilibrium test (TDT) and all results were permuted to assess the empirical significance. Our result show an excess sharing of a haplotype on 14q21-q23 ( $p=0.006$ ) and excess transmission of a haplotype on 6q23-q27 ( $p=0.03$ ), adding strength to our hypothesis that these regions may contain susceptibility genes for SLE. Further finemapping at a 200 kb density using single nucleotide polymorphisms in these regions is currently undertaken.

**Association of APOC3 and APOA5 with Triglycerides and LDL Particle Size in Families with Familial Combined Hyperlipidemia.** *R. Mar<sup>1</sup>, P. Pajukanta<sup>1</sup>, H. Allayee<sup>1</sup>, R. Cantor<sup>1</sup>, J.S. Sinsheimer<sup>1</sup>, M. Groenendijk<sup>2</sup>, G. Dallingae-Thie<sup>2</sup>, T.W.A. de Bruin<sup>3</sup>, A.J. Lusis<sup>1</sup>.* 1) Human Genetics, UCLA, Los Angeles, Los Angeles, CA; 2) Vascular Medicine, University Medical Center Utrecht, Utrecht, the Netherlands; 3) Dept. of Medicine, Academic Hospital, Maastricht, the Netherlands.

Familial combined hyperlipidemia (FCH) is a complex lipid disorder characterized by elevated plasma triglyceride and cholesterol levels. The (APO)LIPOPROTEIN A1/C3/A4 gene cluster on chromosome 11 has long been recognized as a modifier of plasma triglycerides. APOA5 lies 27kb downstream of the cluster and has been shown to influence triglyceride levels in mice and humans. Previously, three restriction enzyme polymorphisms in the APOA1/C3/A4 gene cluster were analyzed in 18 Dutch FCH probands and their relatives. The rare alleles of Xmn and Msp sites in APOA1 and Sst site in APOC3 were more frequent in probands than in normolipidemic spouses. A specific combination of haplotypes with one chromosome carrying the X1M1S2 (1-1-2) haplotype and the other carrying the X2M2S1 (2-2-1) haplotype was associated with elevated plasma lipid levels when compared to the wild type combination of haplotypes (1-1-1/1-1-1). In this study, we extended the analysis to include APOA5 in order to study its effects on plasma triglycerides in FCH subjects. Seven SNPs across the APOA1/C3/A4/A5 region were analyzed in 80 FCH probands and their normolipidemic spouses and in 27 Dutch FCH families. In the case-control study, the strongest evidence of association was obtained with the Xmn and Msp SNPs in APOA1 ( $P = 0.0009$ ). Family based tests indicate significant association of triglycerides and LDL particle size with SNPs in APOC3 and APOA5. Two haplotypes, one containing the rare alleles of Xmn and Msp (2-2-1-1-1) and the other containing the rare alleles of Sst and a SNP within APOA5 (1-1-2-1-2) were enriched in probands when compared to normolipidemic spouses. A third haplotype containing the rare allele of a SNP within APOA4 (1-1-1-2-1) was over-represented in spouses. These data demonstrate a complex genetic contribution of this locus to FCH by conferring both susceptibility and resistance.

**Defining the linkage disequilibrium region containing the Tau gene and identifying haplotype tagging**

**polymorphisms.** *S.A. Oliveira<sup>1</sup>, E.R. Martin<sup>1</sup>, W.K. Scott<sup>1, 3</sup>, F. Zhang<sup>1</sup>, J.M. Stajich<sup>1</sup>, L.T. Middleton<sup>2, 3</sup>, A.D. Roses<sup>2, 3</sup>, B.L. Scott<sup>1, 3</sup>, K. Fujiwara<sup>1</sup>, M.A. Pericak-Vance<sup>1, 3</sup>, J.M. Vance<sup>1, 3</sup>, Duke CHG/GlaxoSmithKline Parkinson Disease Genetics Collaboration.* 1) Ctr Human Genetics, Box 2903, Duke Univ, Durham, NC; 2) GlaxoSmithKline, Research Triangle Park, NC; 3) Duke CHG/GlaxoSmithKline Parkinson Disease Genetics Collaboration.

Parkinson disease (PD) is the second most common neurodegenerative disorder and is characterized by resting tremor, rigidity, bradykinesia, and gait disturbances. Its etiology remains unknown but the most common, late-onset form of PD is believed to result from the interaction of environmental and genetic factors. We previously detected linkage of late-onset PD with a region on chromosome 17 encompassing the microtubule-associated protein Tau, and found association of the Tau H1 haplotype with risk of idiopathic PD in a family-based study, which has been replicated by other groups in subsequent case-control studies. To subdivide the H1 haplotype in sub-haplotypes potentially even more significantly associated with risk for developing PD, we analyzed 28 single nucleotide polymorphisms (SNPs) in the Tau region. These SNPs are located in or flank the corticotropin-releasing hormone receptor 1, presenilin homolog 2, Tau, Saitohin, and KIAA1267 genes. Five of these SNPs are haplotype tagging SNPs that capture 96% of all the existing haplotype diversity in this region, replacing the previous H1/H2 haplotypes. Single locus and haplotype association analyses revealed that several SNPs and haplotypes are more significantly associated with PD than the Tau H1 haplotype. To define the region of LD around Tau, we analyzed seven additional SNPs flanking the 28 SNPs mentioned above and an LD map in this region was constructed. Analysis of these seven additional flanking SNPs suggests that the significant area of LD around Tau spans approximately over two megabases. These results will also be useful for association studies in other neurodegenerative diseases reported to be associated with the Tau haplotype such as progressive supranuclear palsy, corticobasal degeneration, frontotemporal lobar degeneration syndromes, and primary progressive aphasia.

**Association of functional mutations within the secreted frizzled-related protein 3 gene (FRZB) with susceptibility to hip osteoarthritis in females.** *J. Loughlin<sup>1</sup>, B. Dowling<sup>1</sup>, L. Marcelline<sup>1</sup>, K. Chapman<sup>1</sup>, Z. Mustafa<sup>1</sup>, C. Ciesielski<sup>2</sup>, D. Carson<sup>2</sup>, M. Corr<sup>2</sup>.* 1) Botnar Research Centre, Univ Oxford, Oxford, United Kingdom; 2) Department of Medicine, University of California San Diego.

Primary osteoarthritis (OA, MIM 165720) is a late-onset arthritis that demonstrates an oligogenic and multifactorial mode of transmittance. We have previously linkage mapped a hip OA susceptibility locus to chromosome 2q with a maximum multipoint LOD score of 1.6 in 378 affected sibling pair (ASP) families. This linkage encompasses the gene encoding FRZB (2q32.1), a Wnt antagonist that regulates chondrocyte development. We have investigated FRZB as the potential 2q susceptibility gene. We identified two common single nucleotide polymorphisms (SNPs) within FRZB that each result in the substitution of conserved arginine residues, in exon 4 (Arg200Trp) and exon 6 (Arg324Gly). The exon 6 mutation had an increased frequency in the 220 female probands from our 378 families compared to 399 age-matched female controls ( $P = 0.04$ ). An increased frequency was also observed in an independent cohort of 338 female hip cases ( $P = 0.04$ ). The odds ratio for the mutant allele was 1.5. Haplotype analysis revealed a significant difference between all 558 affected females and the female controls ( $P = 0.002$ ) whilst the possession of a mutant allele of both SNPs was a particular risk factor (odds ratio = 3.6). A partitioning analysis demonstrated that the original linkage was accounted for by those female families in which at least one copy of the two FRZB mutations was segregating. Functional studies demonstrated that the Arg324Gly substitution reduced the ability of the FRZB protein to antagonise Wnt signalling. This antagonism was further reduced in the compound mutant. This data implies that functional mutations within FRZB confer susceptibility for hip OA in females.

**DRB1 gene and Graves' disease in children: case-control and family-based studies.** *Y-J. Lee<sup>1, 2, 4</sup>, C-Y. Huang<sup>1</sup>, M-R. Chen<sup>1</sup>, F-S. Lo<sup>3</sup>, C-H. Lin<sup>1</sup>, S-G. Tsan<sup>2</sup>, C-W. Dang<sup>2</sup>, H-F. Liu<sup>2</sup>, C-C. Chu<sup>2</sup>, M. Lin<sup>2</sup>.* 1) Dept Pediatrics & Medical Res, Mackay Memorial Hosp, Taipei, Taiwan; 2) Dept of Medical Res, Mackay Memorial Hosp, Taipei, Taiwan; 3) Div of Endocrinology, Dept of Medicine, Chang Gung Children's Hospital, Tao-Yuan, Taiwan; 4) Dept of Pediatrics, College of Medicine, Taipei Medical University, Taipei, Taiwan.

We evaluated the association and linkage between the DRB1 gene and Graves' disease in children in both population-based and family-based settings.

#### **Subjects and Methods**

120 unrelated children with Graves' disease (age at diagnosis 9.43.1 years), their parents (66 families), and 190 healthy adults were enrolled. The subjects were Chinese living in Taiwan. The study was carried out after the approval of the local ethnic committee and written informed consents given by the individuals or guardians. Genotyping of the DRB1 gene was by PCR-SBT and direct sequencing. **Statistical analysis** Patients and controls positive for an allele were compared by the  $\chi^2$  test. TDT was used to test the data from families. Corrected p values (pc) were calculated using the Bonferonni inequality method. Statistical significance was defined as pc 0.05.

#### **Results**

Table 1. Alleles frequencies of the DRB1 gene in children with Graves' disease and adult controls (only alleles with pc0.05 listed)

DRB1	Pt(240) %	Ct(380) %	RR	95% CI	pc
09012	79	32.9	59	15.5 2.67	1.8-3.9 5.2E-6

49 parents were heterozygous for DRB1\*09012. Among them, 40 (81.6%) were transmitted and 9 (18.4%) not transmitted with an RR of 4.44 (pc = 8.5E-5).

#### **Conclusion**

This study demonstrates that DRB1\*09012 confers a risk of Graves' disease in children.

**Fine mapping of a candidate susceptibility region on chromosome 11 in Ankylosing Spondylitis.** *J. Lee<sup>1</sup>, J.D. Reveille<sup>2</sup>, L. Luo<sup>1</sup>, J. Bruckel<sup>3</sup>, M. Weisman<sup>4</sup>, M.A. Khan<sup>5</sup>, R. Inman<sup>6</sup>, H.R. Schumacher<sup>7</sup>, W.P. Maksymowych<sup>8</sup>, T.M. Martin<sup>9</sup>, J.T. Rosenbaum<sup>9</sup>, D.T.Y. Yu<sup>4</sup>, M. Stone<sup>6</sup>, L. Jin<sup>1</sup>.* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Division of Rheumatology, University of Texas - Houston, Houston, TX; 3) University of Toronto, Toronto; 4) University of California-Los Angeles, Los Angeles, CA; 5) Case-Western Reserve University, Cincinnati, OH; 6) University of Toronto, Toronto, ON, Canada; 7) University of Pennsylvania, Philadelphia, PA; 8) University of Alberta, Edmonton, AB, Canada; 9) Oregon Health & Science University, Portland, OR.

A genomewide scan that we recently conducted in families with two or more siblings with ankylosing spondylitis (AS) has implicated a broad region on the long arm of chromosome 11 (11q) spanning 68 cM continuously from 88.89 cM to 156.86 cM with the strongest peak at 125.84 cM in susceptibility to AS. The purpose of this study is to carry out fine mapping of this broad region in order to confirm and extend our previous findings and attempt to more precisely localize the susceptibility region(s). In addition to the nine markers on chromosome 11q typed in the ABI PRISM Linkage Map MD-10, an additional nine microsatellite markers flanking three potential susceptibility regions on chromosome 11q identified in the genomewide scan were typed. Two point and multi-point non-parametric linkage analyses were conducted using the NPL-all statistic implemented in GeneHunter 2.1. Overall 269 affected sibling pairs of primarily European ancestry concordant for AS by modified New York criteria with available sacroiliac radiographs from 121 pedigrees were genotyped. The linkage in this region is supported by multi-point analysis where positive linkage is seen at two regions, one spanning 15 cM continuously from 109.3 cM to 124.7 cM with the strongest peak at 118.5 cM ( $p = 0.014$ , NPL=2.191) and a second spanning 10 cM between 135.6 and 145.4 cM with the strongest peak at 141.9 cM ( $p=0.005$ , NPL score = 2.612). These data strongly suggest the presence of at least one (and possibly two) region(s) on chromosome 11q involved in susceptibility to AS.

**Fine mapping of candidate susceptibility regions in Ankylosing Spondylitis on Chromosome 6q25.** *J. Luo<sup>1</sup>, J.D. Reveille<sup>2</sup>, J. Lee<sup>1</sup>, J. Bruckel<sup>3</sup>, M. Weisman<sup>4</sup>, M.A. Khan<sup>5</sup>, R. Inman<sup>6</sup>, H.R. Schumacher<sup>7</sup>, W.P. Maksymowych<sup>8</sup>, T.M. Martin<sup>9</sup>, D.T.Y. Yu<sup>4</sup>, M. Stone<sup>6</sup>, J.T. Rosenbaum<sup>9</sup>, L. Jin<sup>1</sup>.* 1) Center for Genome Information, Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Division of Rheumatology, University of Texas - Houston, Houston, TX; 3) Spondylitis Association of America, Sherman Oaks, CA; 4) University of California-Los Angeles, Los Angeles, CA; 5) Case-Western Reserve, Cleveland, OH; 6) University of Toronto, Toronto, ON; 7) University of Pennsylvania, Philadelphia, PA; 8) University of Alberta, Edmonton, AB, Canada; 9) Oregon Health & Science University, Portland, OR.

A genomewide scan that we have recently conducted in families with two or more siblings with ankylosing spondylitis (AS) has implicated a region on the long arm of chromosome 6 (6q) spanning 24 cM around 154.10 cM in susceptibility to AS in addition to the significant contribution of the MHC located on the short arm of chromosome 6 (6p21.3). The purpose of this study is to carry out fine mapping of this region in order to confirm and extend our previous findings and attempt to more precisely localize the susceptibility region(s). In addition to the three markers in this region on chromosome 6q typed in the ABI PRISM Linkage Map MD-10, an additional five microsatellite markers flanking this potential susceptibility region on chromosome 6q identified in the genomewide scan were typed. Two point and multi-point non-parametric linkage (NPL) analyses were conducted using the NPL-all statistic implemented in GeneHunter v.2. Overall 269 affected sibling pairs of primarily European ancestry concordant for AS by modified New York criteria with available sacroiliac radiographs from 121 pedigrees were genotyped. The linkage in this region is supported by multi-point analysis where positive linkage is seen at a region, one spanning 33.4 cM continuously from 144.5 cM to 177.9 cM with the strongest peak at 154.1 cM ( $p = 0.003$ ,  $NPL=2.617$ ). To conclude, in addition to the MHC, these data strongly suggest the present of another region on chromosome 6, located on the long arm (around 6q25) involved in susceptibility to AS.

**Family-based associations between the angiotensin-converting-enzyme gene insertion/deletion polymorphism and multiple cardiovascular risk factors in Chinese.** X. He, D. Zhu, G. Wang, H. Zhou, W. Zhang. Shanghai Inst of Hypertension, Shanghai 2nd Med. University, Shanghai, China.

**Objectives:** To investigate whether the insertion/deletion (I/D) polymorphism of the angiotensin-converting-enzyme gene (ACE) is associated with multiple cardiovascular risk factors in Chinese hypertensive nuclear families. **Methods:** Genotyping of ACE I/D polymorphism was performed in a total of 1248 Chinese individuals from 304 hypertensive nuclear families. Family-based association tests including transmission disequilibrium tests (TDT and Sib-TDT) and quantitative trait locus (QTL) analysis were applied to interrogate the effects of the ACE I/D polymorphism on both hypertension status and parameters of several other cardiovascular risk factors including obesity, hyperlipidemia and hyperglycemia. **Results:** Weak transmission disequilibrium was detected between hypertension status and ACE I/D polymorphism ( $P=0.048$  for TDT and  $P=0.038$  for Sib-TDT, respectively). Significant association between ACE D allele and body mass index (BMI) was demonstrated in women but not in men, and the analysis favored an additive ( $P=0.007$ ) or a dominant model ( $P=0.002$ ) of inheritance. No association of ACE I/D polymorphism with plasma triglycerides, total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol and fasting glucose was found. **Conclusion:** Our family-based study suggests that the ACE I/D polymorphism plays a weak role in the development of EH; and the D allele of ACE was significantly associated with a higher BMI in Chinese women but not in men.

**A polymorphism in the promoter region of catalase gene is associated with essential hypertension in Chinese and demonstrates differential transcription activity.** *Y. Li<sup>1,2</sup>, X. Zhang<sup>2</sup>, Z. Wang<sup>1,2</sup>, Y. Li<sup>1</sup>, D. Zhu<sup>3</sup>, W. Huang<sup>2</sup>, L. Jin<sup>1,4</sup>.* 1) School of Life Sciences, Fudan University, Shanghai, China; 2) Chinese National Human Genome Center at Shanghai, Shanghai, China; 3) Shanghai Institute of Hypertension, Shanghai Second Medical University, Shanghai, China; 4) Center for Genome Information, Department of Environmental Health, University of Cincinnati.

Catalase is an important antioxidant enzyme and we showed previously that a polymorphism at its promoter region, -844C/T, is associated with essential hypertension in an isolated Chinese population in Anhui Province. We extended the case-control studies to an outbred population including 1,006 individuals from Shanghai area (average age 549.66 yo, 482 affected/524 controls). The results confirmed the association between genotype frequencies and phenotype ( $P = 0.01$ ), and the association becomes more evident after age stratification ( $P=0.006$  at age between 45-55 yo). We further studied the effect of variation -844C/T on catalase expression. The expression of reporter gene luciferase is analyzed in several cell lines transfected with construct vectors containing 1.2Kb catalase upstream sequence with either C or T variant. It was observed that the expression of luciferase increased by 47.5%, 132% and 56.58% separately transfected with the T variant compared with the C variant in ECV-304, 293, and HeLa cell lines. Furthermore, the results of western blot showed an increase trend of catalase protein in the individuals carrying T/T, T/C to C/C in blood.

**High-density linkage disequilibrium mapping at the 15q12 GABA receptor subunit cluster identifies association in autism.** *J.L. McCauley<sup>1</sup>, L.M. Olson<sup>1</sup>, R. Delahanty<sup>1</sup>, T. Amin<sup>1</sup>, E.L. Organ<sup>1</sup>, E.L. Nurmi<sup>1</sup>, M.M. Jacobs<sup>1</sup>, S.E. Folstein<sup>2</sup>, J.L. Haines<sup>1</sup>, J.S. Sutcliffe<sup>1</sup>.* 1) Program in Human Genetics, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN; 2) Department of Psychiatry, Tufts University/New England Medical Center.

Autism is a complex genetic neuropsychiatric condition characterized by deficits in social interaction and language and patterns of repetitive or stereotyped behaviors and restricted interests. Chromosome 15q11-q13 is a candidate region for autism susceptibility based on observations of chromosomal duplications of this region in a small percentage of affected individuals and findings of linkage and association. We have performed linkage disequilibrium (LD) mapping across a 1-Mb interval containing a cluster of GABA<sub>A</sub> receptor subunit genes (GABRB3, GABRA5 and GABRG3) thought to be good positional and functional candidates. This region has demonstrated increased evidence for linkage in phenotypic subsets of autism (Shao et al. 2003; Nurmi et al. 2003). Intermarker LD was measured for each of 59 single nucleotide polymorphism (SNP) markers spanning this region, corresponding to an average SNP spacing of ~1 per 17.7 kb. Examination of these data allowed identification of haplotype blocks across the interval, and these blocks were characterized for common (>5%) haplotypes present in our population. Using this information, individual SNPs and multi-SNP haplotypes were examined for evidence of allelic association to autism, using a dataset of 163 combined multiplex and simplex families. Analysis revealed nominally significant (P<0.05) association at 11 of the 59 markers, corresponding to three sites in GABRB3, two in GABRA5 and one in GABRG3. Findings in GABRB3 and GABRA5 are correlated with the position of increased linkage in this region. While ultimate interpretation will require replication in independent samples, these studies suggest that multiple autism risk alleles are present in this region on chromosome 15q11-q13.

**Provisional Mapping of an Adult-Onset Primary Open Angle Glaucoma (POAG) Locus to 5q33-q35. S.**

*MONEMI*<sup>1</sup>, *A. CHILD*<sup>2</sup>, *A. DASILVA*<sup>1</sup>, *O. LEHMANN*<sup>3</sup>, *G. SPAETH*<sup>3</sup>, *R.P. CRICK*<sup>4</sup>, *M. SARFARAZI*<sup>1</sup>. 1) SURGERY, UNIV OF CONNECTICUT, HEALTH CE, FARMINGTON, CT; 2) ST. GEORGES HOSPITAL MEDICAL SCHOOL, LONDON, UK; 3) WILLS EYE HOSPITAL, PHILADELPHIA, PA; 4) INTERNATIONAL GLAUCOMA ASSOCIATION, LONDON, UK.

Primary Open Angle Glaucoma is one of the two major causes of blindness worldwide. In our continuous effort to map and clone new POAG genes, in this study we used two extended adult-onset high-pressure glaucoma families and scanned them for the entire genome. The first family had 108 members in four generations (53 sampled) and the second 99 in five generations (40 sampled). A Genome scan was carried out with ABI/CHLC florescent linkage panels. Genotypic data was entered into DMS and subsequently exported to the CYRILLIC program for haplotype analysis. The most likely inherited haplotypes were constructed manually for each chromosome. Genotyping of over 350 polymorphic DNA markers in family-1 and over 1,000 markers in family-2 excluded linkage to all previously reported POAG loci of GLC1A to GLC1F but identified potential regions on chromosomes 1, 3, 5, 6, 7, 8, 10, 15 and 16. However, additional saturation mapping and haplotype analysis ruled out linkage to all of these regions, except for chromosome 5q. Genotypic data from genome wide scan and saturation mapping showed that all 7-living affected members of family-1 consistently shared a common haplotype for 45 consecutive DNA markers from D5S498 to D5S1466. Initially, family-2 shared a smaller portion of this region but further saturation mapping revealed recombination in two affected individuals thus excluding it from this region. Study of additional 7 adult-onset POAG pedigrees with 5 or more living affected subjects per kindred showed that affected members of only 2 families segregate for the same region on 5q. Significant positive LOD scores were obtained for a number of DNA markers (i.e., Z of 3.22 at theta=0 for D5S436). Linkage study of more POAG families to this region is still needed to confirm this initial observation and to narrow down its critical region. In conclusion, a new locus for adult-onset POAG is provisionally mapped to the 5q33-5q35 region. Supported by EY-09947 and M01RR-06192.

**Genome-wide Scan of Reading Ability in Affected Sibling Pairs with Attention-Deficit/Hyperactivity Disorder: Unique and Shared Genetic Effects.** *S.K. Loo<sup>1,2</sup>, S.E. Fisher<sup>4</sup>, C. Francks<sup>4</sup>, M.N. Ogdie<sup>3</sup>, I.L. MacPhie<sup>4</sup>, M. Yang<sup>1,2</sup>, J.T. McCracken<sup>2</sup>, J.J. McGough<sup>2</sup>, S.F. Nelson<sup>3</sup>, A.P. Monaco<sup>4</sup>, S.L. Smalley<sup>1,2</sup>.* 1) Center for Neurobehavioral Genetics, University of California, Los Angeles, CA; 2) Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles; 3) Department of Human Genetics, University of California, Los Angeles; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, U.K.

Attention Deficit/Hyperactivity Disorder (ADHD) and Reading Disability (RD) are common highly heritable disorders of childhood, which frequently co-occur. Data from twin and family studies suggest that this overlap is, in part, due to shared genetic underpinnings. Here, we report the first genome-wide linkage analysis of measures of reading ability in children with ADHD, using a sample of 233 affected sibling pairs who previously participated in a genome-wide scan for susceptibility loci in ADHD. Quantitative trait locus (QTL) analysis of a composite reading factor defined from three highly correlated reading measures, identified suggestive linkage (multipoint maximum lod score,  $MLS > 2.2$ ) in four chromosomal regions. Two regions (16p, 17q) overlap those implicated by our previous genome-wide scan for ADHD in the same sample, one region (2p) provides replication for an RD susceptibility locus, and one region (10q) falls ~35cM from a modestly highlighted region in an independent genome-wide scan of siblings with ADHD. Investigation of an individual reading measure of Reading Recognition supported linkage to putative RD susceptibility regions on chromosome 8p ( $MLS = 2.4$ ) and 15q ( $MLS=1.38$ ). Thus, the data support the existence of genetic factors that have pleiotropic effects on ADHD and reading ability as suggested by shared linkages on 16p, 17q and possibly 10q but also those that appear to be unique to reading as indicated by linkages on 2p, 8p and 15q that coincide with those previously found in studies of RD.

**A common polymorphism in the upstream promoter (P2) of the HNF4 gene on chromosome 20q is associated with type 2 diabetes (T2DM) and appears to account for the evidence for linkage in an Ashkenazi Jewish**

**population.** *L.D. Love-Gregory<sup>1</sup>, J. Wasson<sup>1</sup>, J. Ma<sup>1</sup>, C.H. Jin<sup>2</sup>, B.K. Suarez<sup>2</sup>, M.A. Permutt<sup>1</sup>.* 1) Div of Metabolism; 2) Department of Psychiatry, Washington Univ Sch Medicine, St. Louis, MO.

We reported linkage of T2DM to chromosome 20q in a genome scan of 267 multiplex Ashkenazi Jewish families. To identify a specific locus contributing to the linkage signal, 100 SNPs across a 7.3 Mb region (1 lod) around microsatellite marker D20S107 have been evaluated by an association study. This region encompasses HNF4, a transcription factor that has been shown to play a role in the expression of genes necessary for glucose transport and metabolism. Defects in the HNF4 gene have been shown to cause one type of maturity onset diabetes of the young (MODY). However, mutation analysis in adult T2DM subjects has not identified any association or causative variants. Here, the extent of linkage disequilibrium across 78kb of the HNF4 gene including an alternative upstream promoter (P2), the major regulator of expression in pancreatic  $\beta$ -cells, was determined. Haplotype block structure was assessed by typing 19 SNPs in 35 Ashkenazi trios. Nine haplotype tag SNPs (htSNP) were identified and genotyped in 275 T2DM subjects and 342 non-diabetic controls for case-control analysis. A htSNP 3.9 kb upstream of P2 occurred in 26.9% of cases vs. 20.3% in controls (Odds Ratio 1.45,  $p < 0.008$ ). Variants in absolute linkage disequilibrium with ours were independently found to be associated in a large Finnish T2DM case-control study (Odds Ratio 1.31,  $p < 0.016$ ) (K.L. Mohlke and F. S. Collins, personal communication). Subsequently, linkage to chromosome 20q was re-examined by conditioning on the genotypes of the htSNP near the P2 promoter. A maximum z-score of 2.05 was originally observed at D20S195 and this increased to 3.88 when only those families in which the proband carried at least one risk allele ( $n=91$ ) were considered. Alternatively, a z-score of 0.33 was observed in those families in which the probands did not carry the risk allele ( $n=115$ ). The results of these studies now suggest that this polymorphism, or a variant in linkage disequilibrium with it, may alter expression of HNF4 and predispose to T2DM.

**Follow-Up to a Second Generation Genomic Screen for Multiple Sclerosis.** *S.J. Kenealy<sup>1</sup>, Y. Bradford<sup>1</sup>, N. Schnetz-Boutaud<sup>1</sup>, J.R. Oksenberg<sup>2</sup>, S.L. Hauser<sup>2</sup>, L.F. Barcellos<sup>2</sup>, R.R. Lincoln<sup>2</sup>, S. Schmidt<sup>3</sup>, M.A. Pericak-Vance<sup>3</sup>, J.L. Haines<sup>1</sup>.* 1) Vanderbilt University, Nashville, TN; 2) University of California, San Francisco, CA; 3) Duke University, Durham, NC.

Multiple sclerosis (MS) is a debilitating neuroimmunological disease that affects an estimated 400,000 individuals in the United States. Genomic screens have identified numerous regions of interest for MS loci. However, with the exception of the human leukocyte antigen (HLA) locus, studies have failed to identify genes that modulate MS disease expression.

In conjunction with the French Multiple Sclerosis Genetics Group, we recently completed a second generation genomic screen for MS with 361 microsatellite markers in 245 multiplex families consisting of 344 affected sibpairs and 112 other affected relative pairs. In addition to the HLA-DR locus, the strongest signals from our screen were generated at 1q42, 2q32, 9q34, 13q12, 18p11, and 19q13 (lod scores >2.0 in MLOD or multipoint analyses).

A significant expansion of our MS dataset (an additional 36 families consisting of 50 affected relative pairs) was used for follow-up studies in these six non-HLA regions. Regions 1q42 and 9q34 were prioritized for follow-up based on initial strong results from our screen and congruency with other recent screens for MS and other autoimmune disorders. SNPs located at ~1 cM intervals extending 10 cM to each side of markers exhibiting peak linkage signals from our screen were genotyped in the expanded dataset.

Five SNPs in the 1q42 region generated MLOD scores 1.0, with the highest score being an MLOD=2.52. One SNP in the 1q42 region generated significant P values for allelic association using the PDT (P=0.01) and Transmit (P=0.05). Four SNPs in the 9q34 region generated MLODs 1.0. One SNP in the 9q34 region generated a significant P value using the PDT (P=0.01). These analyses continue to support the localization of MS genes in 1q42 and 9q34. Analysis of additional SNPs is ongoing to narrow intervals of interest in all six follow-up regions.

**Interindividual variation of efficacy of sublingual nitroglycerin is associated with a polymorphism of ALDH2 in Chinese.** *L. Jin<sup>1,2,3</sup>, Y. Li<sup>2</sup>, W. Jin<sup>4</sup>, H. Sheng<sup>3</sup>, Y. Liu<sup>4</sup>, G. Lu<sup>4</sup>, J. Yu<sup>4</sup>, D. Lu<sup>1</sup>, D. Harrison<sup>1</sup>, W. Huang<sup>3</sup>.* 1) Center for Genome Information, Department Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) School of Life Sciences, Fudan University, Shanghai, China; 3) Chinese National Human Genome Center at Shanghai, Shanghai, China; 4) Ruijin Hospital, Shanghai Second Medical University, Shanghai, China.

Nitroglycerin has been the first choice in the treatment and/or management of acute attacks of angina pectoris among antianginal drugs. The mechanism of its vasodilator effect was not fully understood until it was recently showed that its biotransformation is catalyzed by aldehyde dehydrogenase (ALDH2). A well-characterized G-to-A polymorphism at 12th exon of ALDH2, which virtually eliminates the activity of the enzyme in its carriers, has the highest prevalence in Asian populations. We report here that interindividual variation of the efficacy of sublingual nitroglycerin is significantly associated with this ALDH2 polymorphism in Chinese ( $c = 7.59$ ,  $P < 0.01$ ,  $n = 80$ ). We hypothesize that the presence of the A allele (ALDH2\*2) is partially responsible to the failure or reduced response to nitroglycerin; therefore genetic factor should be involved in the consideration of the administration of nitroglycerin especially in oriental populations.

**Association study of polymorphisms in two metabotropic glutamate receptor genes, *GRM3* and *GRM8* with schizophrenia.** H. Shibata<sup>1</sup>, Y. Fujii<sup>1</sup>, M. Takaji<sup>1</sup>, H. Takaki<sup>1</sup>, R. Kikuta<sup>1</sup>, C. Makino<sup>1</sup>, A. Tani<sup>1</sup>, N. Hirata<sup>1</sup>, A. Shibata<sup>1</sup>, H. Ninomiya<sup>2</sup>, N. Tashiro<sup>3</sup>, Y. Fukumaki<sup>1</sup>. 1) Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Fukuoka Prefectural Dazaifu Hospital Psychiatric Center, Fukuoka, Japan; 3) Department of Neuropsychiatry, Grad Sch of Med Sci, Kyushu University, Fukuoka, Japan.

Based on the glutamatergic hypothesis for the pathogenesis of schizophrenia, we have been conducting a systematic study of associations of glutamate receptor (GluR) genes with the disease. Here we report association studies on two metabotropic GluR genes, *GRM3* and *GRM8*. ***GRM3***: We examined 6 iSNPs evenly distributed in the entire *GRM3* region (270 kb) (SNP1-SNP6). We observed a significant association of SNP4 with schizophrenia (allele:  $P = 0.011$ ; genotype:  $P = 0.038$ ), although neither remained significant after Bonferroni correction. We observed highly significant haplotype associations with the disease in multiple combinations including SNP4 ( $P = 8.3 \times 10^{-4}$ ,  $P_{\text{corr}} = 5.0 \times 10^{-3}$  with Bonferroni correction at the lowest). Then we genotyped 10 additional SNPs around SNP4 to examine the LD status of the subregion. We observed significant LD within the 40-kb region containing SNP4. Five out of the 10 SNPs replicated the significant association with schizophrenia ( $P = 0.011$ , at the lowest). We conclude that the susceptibility locus for schizophrenia is located within the 40-kb region in the vicinity of SNP4 in *GRM3*. ***GRM8***: We examined 22 iSNPs evenly distributed in the entire *GRM8* region (800 kb) (SNP1-SNP22). We observed significant associations of schizophrenia with SNP18 (allele:  $P = 0.028$ ; genotype:  $P = 0.012$ ) and with SNP19 (allele:  $P = 0.030$ ; genotype:  $P = 0.013$ ), although neither remained significant after Bonferroni correction. We also observed significant haplotype associations with the disease in the following three combinations: SNP5-SNP6 ( $P = 0.0004$ ,  $P_{\text{corr}} = 0.092$  with Bonferroni correction), SNP4-SNP5-SNP6 ( $P = 0.0075$ ,  $P_{\text{corr}} = 0.015$  with Bonferroni correction) and SNP5-SNP6-SNP7 ( $P = 0.0011$ ,  $P_{\text{corr}} = 0.0022$  with Bonferroni correction). We conclude that susceptibility loci for schizophrenia are situated within or very close to *GRM8*.

**High Density SNP Based Association Study of 21 Candidate Genes in Autism Spectrum Disorder.** *J.L. Stone<sup>1</sup>, S. Tsai<sup>2</sup>, B. Merriman<sup>1</sup>, R.M. Cantor-Chiu<sup>1</sup>, D.H. Geschwind<sup>2</sup>, S.F. Nelson<sup>1</sup>, AGRE Consortium<sup>3</sup>*. 1) Dept. Human Genetics, Gonda, Univ California, Los Angeles, Los Angeles, CA; 2) Dept. Neurology, Program in Neurogenetics and the Neuropsychiatric Institute, Center for Neurobehavioral Genetics; UCLA School of Medicine; 3) Autism Genetic Resource Exchange, Cure Autism Now, Los Angeles, CA.

Autism is a complex disorder identified by impaired language and social skills, restricted repetitive behaviors, and an early childhood onset. Twin and family studies implicate a significant role for genetic etiologies and current evidence suggests that multiple interacting genes are likely causal. We have performed at 10 cM density a whole genome scan in 330 multiplex families from the AGRE consortium (Geschwind et al. 2001). Regions on chromosomes 7q and 17q have presented themselves as likely locations for susceptibility loci, and these regions have been refined by fine mapping with microsatellites. Using these findings as a guide, we chose to test for association to single nucleotide polymorphisms in 21 positional candidate genes. Genes located on chromosome 17 include FLOT2, SLC6A4, CENTA2, NF1, OMG, CDK5R1 and DARPP32. Genes located on chromosome 7 include HIPK2, BRAF, CLECSF5, TBXAS1, CNTNAP2, and ZNF212. We also tested for association in the 5 known or suspected neuroligin genes, since they have been recently implicated in a European sample (Jamain et al. 2003). We performed TDT analysis on 218 parent-child trios obtained through the AGRE Consortium and the NIMH. There are on average 16 SNPs per gene, making an average inter-SNP distance of 5kb with a gene.

**Identification of potential therapeutic targets in complex diseases: evidence for protection from type1 diabetes (T1D) by variants of *CCR2* and *CCR5*.** D. Smyth<sup>1</sup>, J. Howson<sup>1</sup>, R. Twells<sup>1</sup>, P. Badhwar<sup>2</sup>, N. Walker<sup>1</sup>, H. Rance<sup>1</sup>, B.J. Barratt<sup>1</sup>, D. Savage<sup>3</sup>, D. Carson<sup>3</sup>, E. Tuomilehto-Wolf<sup>4</sup>, J. Tuomilehto<sup>4</sup>, C. Guja<sup>5</sup>, C. Ionescu-Tirgoviste<sup>5</sup>, D. Undlien<sup>6</sup>, K. Rønningen<sup>6</sup>, G. Stewart<sup>2</sup>, J.A. Todd<sup>1</sup>. 1) JDRF/WT Diabetes and Inflammation Laboratory, CIMR, University of Cambridge, UK; 2) Westmead Hospital, Sydney; 3) Belfast City Hospital, Northern Ireland; 4) National Public Health Institute, Finland; 5) Clinic of Diabetes, Romania; 6) National Institute of Public Health, Norway.

The association analysis of functional candidate genes still dominates the dissection of complex traits. Classically, the common (major) allele of a variant is considered as the wild type with normal function, and the rarer (minor) allele as the susceptibility allele. However, the minor allele of some variants may, conversely, provide resistance to disease. If the effect of these rare protective variants can be mimicked by therapeutic agents it may be of benefit to a large proportion of the population. Rare functional variants in the closely linked chemokine receptor genes, *CCR5* and *CCR2*, have already been shown to provide resistance to HIV and delay progression to AIDS, respectively. As these genes are involved in chemoattraction in the immune system we consider them to be candidates for immune-mediated diseases such as T1D and, therefore, genotyped the variants *CCR5*-32 and *CCR2*-V64I in approximately 3,700 T1D families. Our results suggest that the minor alleles of these polymorphisms, which are not in strong LD, are associated with lower T1D risk (RR for *CCR5*-32/32 genotype =0.55 [95%CI 0.4-0.8],  $P=0.005$  and OR for I allele of *CCR2*-V64I =0.85 [95%CI 0.7-0.9],  $P=0.006$ ). Stepwise conditional logistic regression indicated that both variants are required to explain the association of the region. The blocking of the interactions of chemokines and their receptors is a major target in the development of drugs against HIV and AIDS. If the association of *CCR5* and *CCR2* with T1D is confirmed in a large, independent data set, anti-*CCR5*/*CCR2* drugs could also be considered in the on-going development of therapeutics to prevent rejection of pancreatic cells in diabetic transplant recipients.

**Serotonin and dopamine system candidate gene studies of novelty seeking, extroversion and neuroticism in a large unselected population-based sample.** *J. Vittum, C.A. Prescott, J. Kuhn, P.F. Sullivan, K.S. Kendler, B. Riley.*  
Dept. of Psychiatry, Virginia Commonwealth University, Richmond, VA.

Serotonin and dopamine systems have been investigated in relation to personality traits with inconsistent results. We attempted to detect association and interaction between 5HT2A T102C, 5HT2C Cys23Ser, HTT promoter long/short and DRD2 Taq1A candidate gene polymorphisms and 3 personality traits. Our sample included 572 unrelated Caucasian participants (male(M)=284, female(F)=288) who were randomly selected from the Virginia Adult Twin Study of Psychiatric and Substance Use Disorders. These individuals had completed a structured psychiatric interview, the 12-item Neuroticism(N) and 8-item Extroversion(E) short forms of the Eysenck Personality Questionnaire and the 18-item Novelty seeking(NS) subscale of the Tridimensional Personality Questionnaire. Participants were unselected for either trait score or clinical criteria. M and F mean scores for NS (m=6.9, f=7.3), E (m=5.0, f=5.2) and N (m=3.4, f=3.1) did not differ significantly. For NS, which is normally distributed, we used general linear modeling (GLM) analysis to test for associations and interactions. We observe significant main effects of DRD2 in M (genotype 1/1 associated with lower NS,  $p=0.048$ ). Models including main effects of DRD2 and 5HT2A in M ( $p=0.026$ ) and DRD2, 5HT2A and HTT in F ( $p=0.017$ ) accounted for more of the variation in NS. In the best fitting model for F, we also detect significant interactions between DRD2 (1/1) and HTT (L/S) increasing NS ( $p=0.035$ ), and HTT (S/S) and 5HT2A (T/T) lowering NS ( $p=0.046$ ). We used logistic regression with recoded categorical trait scores (low vs. all others for E, high vs. all others for N) for skewed and truncated distributions of E and N. For E, we detect a significant main effect of 5HT2A in both M (C/T associated with lower E,  $p=0.011$ ) and F (C/C associated with lower E,  $p=0.028$ ). We also detect a significant main effect of DRD2 in F (2/2 associated with low E,  $p=0.012$ ). For N, we detect a significant main effect of 5HT2C in F only (C/S associated with higher N,  $p=0.012$ ). These results are noteworthy because of our large unselected population-based sample.

**The Role of Gene-Risk Factor Interactions in Predicting Susceptibility to Sporadic Breast Cancer.** *M.D. Ritchie<sup>1</sup>, J.J. Hu<sup>2</sup>, T.R. Smith<sup>2</sup>, J.H. Moore<sup>1</sup>*. 1) Program in Human Genetics, Vanderbilt University, Nashville, TN; 2) Department of Cancer Biology, Wake Forest University, Winston-Salem, NC.

Variability in DNA repair genes may contribute to human cancer risk. An important question is whether breast cancer risk can be predicted by knowledge about variation in DNA repair genes and/or hypothesized breast cancer risk factors. Previous studies suggest that DNA repair genes have minimal main or independent effects. The goal of this study was to determine whether interactions among variations in DNA repair genes and/or risk factors are associated with sporadic breast cancer. We employed the multifactor data reduction (MDR) method to detect interactions in a sample of 162 breast cancer cases and 108 controls without a family history of breast cancer. MDR is a powerful new statistical approach used to detect nonlinear gene-gene interactions. MDR evaluates all possible combinations of genotypes and risk factors for their ability to predict disease status using cross-validation and permutation testing. We measured seven polymorphisms in six DNA repair genes: XRCC\_1, XRCC\_3, APE\_5, XPD\_23, GSTM1, and GSTT1. We also measured three risk factors: age at first live birth, age of menarche, and parity. We detected a statistically significant interaction between the XRCC\_3, APE\_5, and XPD\_23 genes with a prediction error of 39% ( $p=0.027$ ) in addition to an interaction between age of first live birth and parity with a prediction error of 31% ( $p<0.001$ ). Interestingly, the simultaneous analysis of all genes and risk factors identified a single best model with a prediction error of 30% ( $p=0.022$ ) that consisted of the same three genes and two risk factors identified in the separate analyses. These results suggest that combined information about genes and traditional risk factors provides more information for predicting risk of breast cancer than either alone. This study illustrates the importance of considering high-order gene-gene and gene-risk factor interactions in studies of complex diseases such as sporadic breast cancer when the independent main effects of each gene and risk factor are relatively small.

**Fine mapping of 17q25 supports linkage with Gilles de la Tourette Syndrome.** *P. Paschou<sup>1</sup>, A.J. Pakstis<sup>1</sup>, W.C. Speed<sup>1</sup>, M.M.C. DeMille<sup>1</sup>, J.R. Kidd<sup>1</sup>, V. Ruggieri<sup>1</sup>, R. Kurlan<sup>2</sup>, D.L. Pauls<sup>3</sup>, K.K. Kidd<sup>1</sup>.* 1) Department of Genetics, Yale U. School of Medicine, New Haven, CT; 2) Department of Neurology, U. Rochester Medical Center, Rochester, NY; 3) Department of Psychiatry, Massachusetts General Hospital, Boston, MA.

The mode of inheritance of Gilles de la Tourette Syndrome (GTS) is currently thought to involve multiple genes interacting with environmental factors. 17q25 is one of the regions for which indications for linkage with the disorder have been provided by a whole genome scan and unpublished reports by various independent investigators associated with the Tourette Syndrome Association International Consortium for Genetics. We report here results of a high resolution study of 17q25 in an effort to replicate the initial findings and reduce the large candidate susceptibility interval. We studied four large families from Canada, Kansas, Michigan, and Oregon (344 individuals, 120 affected members) using 22 microsatellite markers at an average density of 4 cM. In order to enhance the map density, 12 SNPs were also typed. The region covered at high density extends from D17S933 to 17qter. For the Oregon family and the largest branch of the Canadian family seven additional microsatellite markers spanning the rest of chromosome 17 were also studied. Analyses included TDT and non-parametric linkage analysis (GENEHUNTER). Multipoint analysis for the Oregon family gave a Zall score of 2.2 at D17S928 ( $p=.003$ ). The largest branch of the Canadian family also gave results suggestive for linkage in this region (rs733342, Zall=2,  $p=.02$ ). A smaller broad peak near D17S933, 65 cM upstream, was also found. TDT results in this pedigree indicated an association at D17S784. In analyses combining the Oregon and the largest branch of the Canadian kindred the peak score was even higher and close to rs733342 ( $p=.00007$ ). These results reinforce the evidence of the whole genome scan that distal 17q is one of the regions of interest for GTS. Additional markers and haplotype analysis will help further restrict the candidate region. (Supported in part by NIH NINDS NS40024; P.Paschou is supported by a Tourette Syndrome Association grant.).

**Association of human SCN6A gene with essential hypertension in Chinese.** *K. Zhang<sup>1</sup>, D. Zhu<sup>1</sup>, X. He<sup>1</sup>, G. Wang<sup>1</sup>, W. Huang<sup>2</sup>.* 1) Shanghai Inst Hypertension, Shanghai 2nd Med University, Shanghai, China; 2) Chinese National Human Genome Center, Shanghai, China.

**Objectives** To identify the single nucleotide polymorphisms (SNPs) in the regulatory and coding regions of human SCN6A sodium channel, voltage-gated, type VI, alpha polypeptide gene and to detect the possible relationship between some of these SNPs and essential hypertension (EH) in Chinese. **Methods** The promoter region, exons, as well as part of the introns of SCN6A gene were sequenced by a fluorescent labeling automatic sequencing method to identify and characterize the SNPs in Chinese population. SNP genotyping was performed by PCR-RFLP or direct DNA sequencing in unrelated EH patients and normotensive controls from a Chinese Han population residing in Shanghai area. Case-control studies on seven unlinked SNPs were first carried out in 96 patients and 96 normotensive controls. The positive finding was further verified in an extended study containing 288 patients and 288 controls. **Results** Thirty-two SNPs were identified through a 13132 bp sequencing of SCN6A gene. Among them, seven were in regulatory region, ten in coding regions, one in 3'UTR and fourteen in introns. Thirty SNPs were novel SNPs, and a cSNP in exon 18 (SNP021) was associated with hypertension. **Conclusion** The SNP021 in the gene SCN6A is associated with essential hypertension of Chinese Han population in Shanghai and the role of SCN6A gene in hypertension deserved to be further analyzed.

**Genetic variations in kynureninase gene are associated with essential hypertension in Chinese.** *D. Zhu<sup>1</sup>, X. He<sup>1</sup>, K. Zhang<sup>1</sup>, Y. Zhang<sup>1</sup>, G. Wang<sup>1</sup>, W. Huang<sup>2</sup>.* 1) Shanghai Inst Hypertension, Shanghai 2nd Med. University, Shanghai, China; 2) Chinese National Human Genome Center at Shanghai, Shanghai, China.

Essential hypertension (EH) is a common cardiovascular disorder and occurs as a consequence of a complex interplay of multiple genetic alterations and environmental factors. Our previous genome-wide scan study has mapped a candidate locus for EH on chromosome 2q14-q23. One of the functional candidate genes located within this region is the kynureninase gene (KYNU). In order to investigate whether the nucleotide variations in KYNU are associated with hypertension in Chinese, we first sequenced all 14 coding exons and flanking introns, as well as the promotor region of KYNU. Altogether, fourteen single nucleotide polymorphisms (SNPs) were identified, which included 8 novel SNPs. Further studies were focused on two nonsynonymous SNPs (Arg188Gln and Lys412Glu). For a rare Arg188Gln polymorphism (2.29% for allele 188Gln), a genotype-discordant sib-pair study was performed. In the 39 sibling-pairs discordant for the Arg188Gln polymorphism, the siblings carrying one or two 188Gln allele had significant higher systolic blood pressure (SBP) and diastolic blood pressure (DBP) than the siblings homozygous for the 188Arg allele ( $P < 0.001$  for systolic blood pressure and  $P = 0.001$  for diastolic blood pressure, respectively). For a common Lys412Glu polymorphism, a case-control association study was carried out in a total of 672 unrelated hypertensive patients and 477 unrelated normotensive controls. A borderline association between the Lys412Gly genotypes and hypertensive status was detected ( $P = 0.048$ ). This association was observed in the female group ( $P = 0.042$ ), but was not noted in the male group. We therefore hypothesize that genetic variations within KYNU may account for individuals developing EH in Chinese. Our results suggest that the role of kynureninase pathway on blood pressure modulation needs to be further studied.

**A Two Stage Genome-Wide Linkage Scan for Nonsyndromic Cleft Lip with or without Cleft Palate in 220 Filipino Families Shows Evidence of Linkage to 2p21, 6q23, and 8p21.** *R. Schultz<sup>1</sup>, M. Cooper<sup>2</sup>, B. Riley<sup>1</sup>, T. Goldstein<sup>2</sup>, S. Daack-Hirsch<sup>1</sup>, B. Nepomucena<sup>3</sup>, M. Marazita<sup>2</sup>, J. Murray<sup>1</sup>.* 1) Dept Pediatrics Univ Iowa; 2) School Dental Med Univ Pittsburgh; 3) HOPE Found. Philippines.

Non syndromic CLP is a complex disorder resulting from multiple genetic and environmental factors. NS CLP has a birth prevalence of 1 per 500 in the Philippines where large families provide opportunity for gene localization. A two stage genome-wide linkage scan was done on 220 Filipino families with 2 affecteds. Genotyping on 390 microsatellite markers at 10 cM intervals was done on 109 families with 282 affected and 543 unaffected. A second set of 111 families with 285 affected and 566 unaffected was genotyped to replicate the results from the first group. Two- and multi-point parametric linkage analyses (FASTLINK, SIMWALK2) and nonparametric multipoint and TDT analyses (SIMWALK2, FBAT) were performed. The first scan identified 10 regions with LOD 1.0 or  $p < 0.05$  in one or more test. These regions were also positive in the second scan; the pooled results from all 220 families had the most significance for 2p, 6q and 8p. The 8p region has not been previously identified nor does it contain any of the candidate genes widely studied in CLP. Fine mapping of 8p21 has begun in the first family set using SNP TaqMan markers from eight genes (FZD3, SLC8A1, PPP3CC, EPHX2, BNIP3L, EGR3, PPP2R2A and NAT1) within the 20 cM of 8p with LOD1.0. A SNP in PPP3CC with a two-point recessive LOD of 1.91 in the first 109 families is being tested for transmission distortion in the second family set and an additional 500 parent-case triads. Fine mapping of 2p21 and 6q23 is also underway. A meta-analysis of this genome scan and several other CLP genome scans also had positive results for chromosomes 2 and 6 (ASHG presentation by Marazita et al). In summary, we report the largest NS CLP genome scan to date and identify 3 highly positive regions. PPP3CC, a strong candidate gene on 8p, is under intensive scrutiny by direct exon sequencing. For the first time, fine mapping and gene identification appear feasible for NS CLP. This research was supported by NIH grant DE-08559 and the Center for Inherited Disease Research.

**Genetic variation in the Collagen 6A1 and 6A2 genes in individuals with Down Syndrome with and without atrioventricular septal defects.** *R.E. Pyatt<sup>1</sup>, M. Gupte<sup>1</sup>, C. Torfs<sup>2</sup>, G. Capone<sup>3</sup>, K. Dooley<sup>4</sup>, S.B. Freeman<sup>1</sup>, S.L. Sherman<sup>1</sup>.* 1) Dept of Human Genetics, Emory University, Atlanta, GA; 2) Public Health Institute, Birth Defects Study, Emeryville CA; 3) Dept of Pediatrics, Johns Hopkins Medical Institutions, Baltimore, MD; 4) Sibley Heart Center, Dept of Pediatrics, Emory University, Atlanta, GA.

Approximately 40% of individuals with Down syndrome (DS) are born with a congenital heart defect (CHD). Atrioventricular septal defects (AVSD) are the most common of these accounting for 45% of CHD associated with DS while occurring in only 3-4/10,000 live births in the general population. Collagen VI, a heterotrimer of Collagen 6A1 (COL6A1), Collagen 6A2 (COL6A2), and Collagen 6A3 chains, is expressed in vascular smooth muscle, heart, and the connective tissues. The genes for COL6A1 and COL6A2 are located as a cluster on 21q22.3 within a region of chromosome 21 implicated in the causation of DS-associated CHD. Consequently, alteration in the function of these genes or their expression could contribute to the failure of septation in the heart. We undertook a study to identify the genetic variation in the COL6A1 and COL6A2 genes associated with the development of AVSD in DS individuals using a case (DS with AVSD)/control (DS without CHD) approach. Since Collagen VI is present in human and mouse fetal heart, we initiated our studies with the examination of an STR in the COL6A2 gene. Preliminary findings indicated no difference in the allele distribution in our Caucasian population, but a significant difference in an African-American one ( $p=0.02$ ). To determine if this difference is biologically relevant, we identified 5 haplotype-tag SNPs within COL6A1 and 17 in COL6A2 using the data from Patil et al (Patil et al, 2001, Science 294:1719-1722). These SNPs are being analyzed in 36 DS individuals with verified AVSD, 63 DS individuals without CHD, and all respective parents. We are currently finalizing the analysis and data will be examined using both a case/control genotyping comparison as well as a TDT approach modified to account for the non-independence of alleles contributed by the parent in whom the nondisjunction error occurred.

**Linkage and Association Analysis of Neuregulin-1 Gene Variants with Schizophrenia in the Irish Study of High Density Schizophrenia Families.** *D.L. Thiselton<sup>1</sup>, B.T. Webb<sup>1</sup>, R. Ribble<sup>1</sup>, F.A. O'Neill<sup>2</sup>, D. Walsh<sup>3</sup>, K.S. Kendler<sup>1</sup>, B. Riley<sup>1</sup>.* 1) Dept Psychiatry, Virginia Commonwealth Univ, Richmond, VA; 2) Dept Psychiatry, Queens University, Belfast, N. Ireland; 3) Health Research Board, Dublin, Ireland.

The neuregulin 1 gene (*NRG1*) at chromosome 8p21-22 has been implicated as a schizophrenia susceptibility gene in Icelandic and Scottish populations. A number of genome scans and meta-analyses have reported evidence for linkage of schizophrenia to 8p21-22. Analysis of our Irish high density schizophrenia families generated a linkage signal within this interval. Although ~20cM distal to *NRG1*, the shared ancestry between the Icelandic, Scottish and Irish populations led us to investigate *NRG1* variants and appropriate marker haplotypes for over-representation in our Irish familial cases. Singlepoint linkage analysis using 7 *NRG1* markers including the core Icelandic risk haplotype gave no significant results across 4 diagnostic categories. Multipoint analysis incorporating flanking markers D8S137 and D8S283 produced suggestive evidence for linkage peaking at SNP243177 (NPL Z-score=1.75, p=0.04). However, re-analysis incorporating the *NRG1* genotypes into our existing genome scan data showed the linkage signal from *NRG1* to be part of the original peak centred around LPL-D8S258. Analysis of linkage disequilibrium (LD) across the 251kb 7-marker interval revealed 2 separate 'blocks' of LD within our sample, comprising SNPs 255133, 249130 and 243177 (telomeric) and microsatellites 478B14-428, 420M9-1395, D8S1810 and 420M9-116I12 (centromeric, close to Hs.97362). We therefore sought association with disease by considering haplotypes for the 3 SNPs, then the 4 microsatellites within each block. Single marker analysis gave no evidence for association with schizophrenia. Haplotype analysis for the 3 SNPs in LD block 1 and separately, the 4 microsatellites in LD block 2 (in overlapping 2-marker windows), showed no evidence for overtransmission of specific haplotypes to affected individuals. We thus conclude that if *NRG1* does contain susceptibility alleles for schizophrenia, they play a relatively minor role in our Irish family sample.

**Synergistic effect of multiple risk alleles in association study of ADHD.** *L. Park<sup>1</sup>, K. Nummy<sup>2</sup>, M. Huebner<sup>6</sup>, I. Waldman<sup>5</sup>, M. Rappley<sup>4</sup>, J. Nigg<sup>3</sup>, K. Friderici<sup>1, 2</sup>.* 1) Genetics Program, Michigan State University, East Lansing, MI; 2) Microbiology and Molecular Genetics, Michigan State University, East Lansing, MI; 3) Department of Psychology, Michigan State University, East Lansing, MI; 4) Peds/Hum. Dev., Michigan State University, East Lansing, MI; 5) Department of Psychology, Emory University, Atlanta, GA; 6) Department of Statistics and Probability, Michigan State University, East Lansing, MI.

Attention Deficit Hyperactivity Disorder (ADHD) is a behavior disorder with strong heritability (0.7) and a very high prevalence in children (3-5%). Despite the high heritability, genetic studies reported to date have not shown consistent association with single genetic polymorphisms and two genome-wide scans found inconsistent effects with no clear major gene effect. Lack of a major gene effect reinforces the polygenic nature of ADHD and implies minor contributions from a large number of genes. In this study, we examined 8 polymorphisms on 3 genes using family samples of childhood ADHD (62 control, 115 affected). Diagnostic criteria for ADHD were directly evaluated using structured diagnostic interviews and multi-informant standardized rating scales to assess DSM-IV criteria, severity, onset, duration, and impairment. We found significant associations on the DRD4 gene and the SLC6A3 gene. Most interesting was that we noted associations were strengthened by looking at the combined effect of multiple alleles on three genes (DRD4, SLC6A3 and ADRA2A). Most of the polymorphisms did not show any significance using TDT except one SNP on ADRA2A. Our sample population is not skewed according to ethnicity and shows no admixture. It should be also noted that our parent group of affected children shows significantly biased frequencies of risk alleles. It seems that the suitability of using TDT for detecting the effective polymorphisms highly contributing to this very heritable trait may need further clarification depending on the population. Our result suggests that the synergistic effect among genes must be considered in association studies of complex traits.

**Possible association of a 14 kb haplotype block from the receptor activator of NF-kappa B (RANK) gene with susceptibility to rheumatoid arthritis.** *E. Remmers*<sup>1</sup>, *J. Balow, Jr.*<sup>1</sup>, *W. Li*<sup>2</sup>, *I. Aksentijevich*<sup>1</sup>, *A. Lee*<sup>2</sup>, *A. Damle*<sup>2</sup>, *W. Chen*<sup>3</sup>, *C. Amos*<sup>3</sup>, *P. Gregersen*<sup>2</sup>, *D. Kastner*<sup>1</sup>. 1) Genetics and Genomics Branch, NIAMS, Bethesda, MD; 2) North Shore Long Island Jewish Research Institute, Manhasset, NY; 3) Univ of Texas/MD Anderson Medical Center, Houston, TX.

The North American Rheumatoid Arthritis Consortium has collected 512 multiplex rheumatoid arthritis (RA) families containing 581 independent affected sibling pairs and has completed two genome-wide screens, each with half the sib-pairs. A 15 cM region on chr 18 exhibited suggestive evidence for an RA susceptibility locus in both screens (Jawaheer, et al., *Arthritis Rheum* 48:906-916, 2003). A candidate gene within this susceptibility region is the receptor activator of NF-kappa B (RANK, gene symbol: *TNFRSF11A*), a gene involved in osteoclast differentiation and in regulation of apoptosis of immune cells. To evaluate whether variants within this gene might be associated with RA susceptibility, we undertook a case-control haplotype association study using 414 of the RA probands and 373 ethnically matched controls. We genotyped 15 SNPs in this gene. Two haplotypes were inferred for each individual using an expectation maximization algorithm. Linkage disequilibrium (LD) was then measured between each pair of SNPs. The results demonstrated that the RANK gene was organized into four LD blocks. Within each block there were 3-5 common haplotypes. We evaluated whether any haplotype was more prevalent in the RA probands than in the controls. One haplotype of the second LD block of the RANK gene was found at a frequency of 42% in the RA probands and only 36% in the controls (uncorrected p value = 0.01). The outermost limits of this haplotype block included 14 kb of the RANK gene, encompassing a large portion of the first intron and the second exon. Suggestive evidence for an association of the genotypes of a pair of SNPs located within the block was also found. A pedigree disequilibrium test with genotypes from available family members was also suggestive of an RA susceptibility locus in this region. Further studies will be required to confirm these findings and to identify functional variants that confer susceptibility to RA.

**HAPLOTYPE MAPPING OF A COMPLEX DISEASE: SCHIZOPHRENIA AND CHROMOSOME 5Q. P.**

*Sklar<sup>1, 2</sup>, T. Petryshen<sup>1, 2</sup>, A. Kirby<sup>2</sup>, A. Tahl<sup>2</sup>, K. Aldinger<sup>2</sup>, S. Waggoner<sup>2</sup>, A. Verner<sup>3</sup>, T. Hudson<sup>3</sup>, H. Medeiros<sup>4</sup>, E. Lander<sup>2</sup>, M.T. Pato<sup>4</sup>, M.J. Daly<sup>2</sup>, C.N. Pato<sup>4</sup>.* 1) Harvard Medical School, Boston, MA; 2) MIT/Whitehead Institute for Biomedical Research Cambridge, MA; 3) Montreal Genome Center, Montreal, CA; 4) State University of New York, Syracuse, NY.

We describe the results of an aggressive, haplotype-map based screen to positionally identify a schizophrenia gene on chromosome 5q. Focusing on families of Portuguese descent collected in the Azores, Madeira and the Portuguese mainland, we identified maximum evidence of linkage (NPL = 3.1) at marker D5S820. Simulations suggested that this result was at the threshold required to declare significant genome-wide linkage, and when a handful of additional markers were added, the evidence increased to an NPL = 3.55. Genotyping a second smaller set of families confirmed linkage to this region. In addition, the same region of 5q was recently identified in a meta-analysis of published genome scans (importantly not including our own study) as containing a highly significant risk factor of global importance. However, as in most complex diseases, the region implicated by linkage is quite large (30 Mb) and two strategies for follow-up were pursued. We selected a set of 15 high likelihood positional and functional candidate genes for initial linkage disequilibrium mapping. SNPs were selected at a density of ~1/5kb and genotyped in 98 affected-parent trios and 150 cases and ethnically matched controls. Haplotype maps were constructed across each gene, with individual haplotypes being tested for association with schizophrenia. In the second approach, further fine mapping was undertaken by genotyping an evenly spaced SNP map across the entire 30 Mb region and the data tested for both linkage and association in the original family collection. Data from both of these strategies will be presented and all SNP data is combined to provide a first generation haplotype map of the region.

**Attempt To Maximize Efficiency In Screening Mentally Retarded Males For MECP2 Mutations: Microcephaly, Spasticity and Seizures As Clinical Criteria And Screening For The A140V Mutation.** *F. Lobo-Menendez, R.C. Michaelis, F. Annese, C. Skinner, C.E. Schwartz.* JC Self Research Institute, Greenwood Genetic Center, Greenwood, SC.

The methyl-CpG binding protein 2 (MECP2) gene was first identified as the gene responsible for Rett syndrome (RTT), a neurobehavioral disorder that primarily affects females. RTT is characterized by a 6-12 month period of normal development, followed by the regression of motor, cognitive and language skills, deceleration of head growth leading to acquired microcephaly, onset of seizures and the emergence of autistic behaviors. While MECP2 mutations were originally thought to be lethal in males, recent studies have documented MECP2 mutations in males with mental retardation (MR). The spectrum of phenotypic effects of MECP2 mutations in males ranges from mild nonsyndromic MR to severe encephalopathy and death during infancy, and patients exhibit variable combinations of other phenotypic abnormalities as well.

These findings have prompted efforts to determine the most efficient manner in which to screen mentally retarded males for MECP2 mutations. One study suggested that the most common MECP2 mutation, the A140V substitution, may be common enough in mentally retarded males to warrant routine screening of all males with MR for the A140V mutation. We have tested this suggestion in our population of mentally retarded males, and found no A140V mutations in 525 patients tested. In addition, we selected patients from our MR population who also had microcephaly, seizures or spasticity, to determine the frequency of MECP2 mutations in patients with MR and these additional features. A number of missense variants have been found in these patients. Family members and unrelated controls are being tested to confirm the pathogenic nature of these variants. However, the majority of these variants appear to be benign polymorphisms, and MECP2 mutations appear to be rare in our selected patient population.

**Impact of macro nutrient content of low calory diet on human adipose tissue gene expression.** *I. Dahlman<sup>1</sup>, K. Linder<sup>2</sup>, J. Liden<sup>3</sup>, E. Arvidsson<sup>1</sup>, P. Arner<sup>1</sup>.* 1) Dept Medicine, Karolinska Inst, Huddinge Univ Hosp, Stockholm, Sweden; 2) Center for Molecular Medicine, Karolinska Inst; 3) Center for Biotechnology, Karolinska Inst.

Calorie restriction results in weight loss, however to what extent diet composition, i.e. the relative content of different nutrients, control degree and mechanisms of weight loss are unknown. The aim of this project was to compare the outcome of a high and a low fat diet on the gene expression profile in adipose tissue. Age and weight matched women were randomly selected for high fat (N = 13) or low fat (N = 10) eight week low calory diet. Before initiation of the program and after its termination patients were clinically examined and an abdominal subcutaneous fat biopsy obtained for measurement of fat cell size and gene expression using Affymetrix microarrays containing 8500 of the best characterized human genes. Overall, both groups responded similar with regard to weight loss, blood chemistry phenotypes and decrease in fat cell size. The number of genes altering their expression following diet was relatively small. 40 genes with a relative and significant change of > 25 % in adipose tissue expression before vs after the weight reduction program were detected. There was no diet-specific impact on gene expression, i.e. the same genes were affected in both groups. There was a marked reduction in expression of a number of genes involved in lipid metabolism. In addition, genes regulating carbohydrate metabolism were affected but to a lesser extent. Of interest, the expression of steryl coenzyme A desaturase (SCD) was downregulated 50 %; in response to weight reduction. Mice with a targeted disruption of SCD are protected against obesity. Expression of certain obesity candidate genes correlated with relative weight loss, e.g. NPY Y1 receptor. More detailed studies of SCD and other identified genes are ongoing. We conclude that SCD and other identified genes in lipid metabolism may control important pathways in human body weight regulation and thus represent new therapeutic targets.

**Effects of Activin on Somatic Growth in B Knock-in Mice.** *L. Li<sup>1</sup>, C. Tang<sup>1</sup>, J. Shen<sup>1</sup>, C. Brown<sup>1,2</sup>*. 1) Molecular and Human Genetics; 2) Pediatrics, Baylor College of Medicine, Houston, TX.

To better understand the molecular mechanisms of growth deficiency so that more directed therapies can be developed, we study activins, which are members of the transforming growth factor beta (TGF-) superfamily. They are important for many different biological processes including normal growth and development. Mice that are completely missing one activin family member, activin A, develop cleft palate, fail to form teeth, and do not grow whiskers. Secondary to these and other defects, the mice die shortly after birth. Because of this neonatal lethality, our laboratory has introduced a hypomorphic (activin B knock-in) allele at the activin A locus (BK). Although these mice develop normal craniofacial structures, they grow more slowly than normal, influenced dramatically by the dose of the BK allele. In this study, we are trying to understand the mechanism(s) by which BK mice fail to thrive by carefully measuring growth response to caloric density, metabolic rates, and intake, and also assaying specific analytes that influence somatic growth. We find that high fat diets (HFD) cannot make BK/BK mice grow as well as WT or BK/+ mice on the same diet. However, BK/BK mice on HFD exhibit catch up growth, approximating the weight curves of WT and BK/+ mice maintained on regular diet. Plasma growth hormone levels in 42 day old BK/BK mice on regular diet were not different from controls. In contrast, serum IGF-1 levels of BK/BK mice were significantly less than controls. Major urinary protein levels, an indicator of normal GH secretory patterning, were normal in both male and female BK/BK mice relative to control mice. IGF and GH treatment studies, insulin and glucose tolerance studies, histological and other analyses are in progress. Our results suggest that activin signaling influences many physiological processes, potentially mediated through IGF-1, but not substantially influenced by growth hormone production or release. Additionally, possible reasons for the growth delay in BK/BK mice include reduced intake or increased metabolic rates, as increasing caloric density improves their growth.

**Decreased Mitochondrial tRNA<sup>Lys</sup> Steady-State Levels and Aminoacylation are Associated with the Pathogenic G8313A Mitochondrial DNA Mutation.** *S.R. Bacman, D.P. Atencio, C.T. Moraes.* Neurology, University of Miami, Miami, FL.

Mutations in human mitochondrial tRNA genes cause a number of multisystemic disorders. A G8313A transition in the mitochondrial tRNA<sup>Lys</sup> gene has been associated with a childhood syndrome characterized by gastrointestinal system involvement and encephaloneuropathy. We have used transmitochondrial cybrid clones harboring patient-derived mitochondrial DNA with the G8313A mutation for the study of the molecular pathogenesis. Our results showed that mutant mitochondrial cybrids with 82%, 97% and 100% mutated mtDNA had a severe respiratory chain enzymes activity with a markedly defect in Complex II+III and Complex IV (up to 95% when compared to the homoplasmic wild type). Steady state levels of COX II, a subunit of cytochrome c oxidase and ND1, a subunit of complex I (both mtDNA-encoded subunits), were markedly reduced in the mutant cybrid cell lines. In contrast, a truncated version of COX I was surprisingly stable in mutant cells, as shown by western blot. Mutant cybrids also showed a large number of what appeared to be truncated polypeptides in the mitochondrial protein synthesis experiment, whereas most of the normally-sized bands were decreased or absent. Acid northern blot assays showed that the G8313A mutation affects both steady-state levels and aminoacylation efficiency of the tRNA<sup>Lys</sup>. These observations suggest decrease in functional tRNA<sup>Lys</sup> levels underlie the pathogenesis of the mitochondrial G8313A mutation. They also showed that non-functional truncated polypeptides could be stable in the absence of the holo-complex IV.

**Mitochondria haplogroup B4b1 is associated with an increased risk of familial cholelithiasis in Chinese.** *Z. Niu*<sup>1</sup>, *B. Wen*<sup>2</sup>, *T. Han*<sup>3</sup>, *J. Qin*<sup>3</sup>, *W. Yuan*<sup>1</sup>, *S. Zhang*<sup>3</sup>, *L. Jin*<sup>1,2,4</sup>, *W. Huang*<sup>1</sup>. 1) Chinese Natl Hum Genome Ctr, Shanghai, Shanghai, China; 2) School of Life Sciences, Fudan University; 3) Rui Jin Hospital affiliated to Shanghai Second Medical University; 4) Center for Genome Information, University of Cincinnati.

Cholelithiasis is a condition with strong family predisposition. The incidence of cholelithiasis in China is about 7-10%. The supersaturation of cholesterol in bile leads to its crystallization and formation of a nidus for stone. Cytochrome C oxidase complex is composed of eight subunits including three (COX1, COX2, COX3) that are coded by mitochondrion genome. It plays a crucial role in beta-oxidation and oxidative phosphorylation in fat and steroid metabolism. Therefore, it is reasonable to be explored although the association between haplotypes of mitochondria and familial cholelithiasis has never been reported. In this study, we sequenced the genes of three mitochondrial COX subunits in 101 patients from Shanghai and revealed many SNPs (62 in COX1, 29 in COX2 and 35 in COX3). As a result, three SNPs in COX1 (6023 G to A; 6216 T to C; 6413 T to C) were found to have higher allele frequencies and significant association was only observed at 6413 T to C ( $p < 0.01$ ) and 6023 G to A ( $P < 0.05$ ) with the 535 controls from Shanghai. Furthermore, we sequenced the HVS1 region in all patients and 535 controls from Shanghai. An East Asian specific haplogroup B4b1, which is characterized by 16136C-16189C-16217C motif, showed a strong association with an increased risk of familial cholelithiasis in Chinese population (B4b1,  $p < 0.0001$ ; B4b1a,  $p < 0.00001$ ). The relative risk (RR) of cholelithiasis for individuals carrying B4b1 and B4b1a are 6.778 and 13.049, respectively. To identify the molecular lesion that elevates the risk of this disease in B4b1 haplogroup, we sequenced the complete mtDNA genome in six patients with haplogroup B4b1. Several SNPs which haven't been reported before were found in these patients. The functional role of these potential variants in B4b1 haplogroup responsible for cholelithiasis susceptibility is yet to be found. This is the first observation of a significant association of mtDNA haplotype with cholelithiasis.

**Contribution of mitochondrial genome to hypertension.** *F. Schwartz*<sup>1</sup>, *A. Duka*<sup>1</sup>, *J. Cui*<sup>1</sup>, *H. Gavras*<sup>1</sup>, *F. Sun*<sup>2</sup>. 1) Department of Medicine, Boston University School of Medicine, Boston, MA; 2) University of Southern California, Los Angeles, CA.

Genetic studies of essential hypertension (HTN), a polygenic, multifactorial and highly heterogeneous disorder of unknown etiology, thus far produced inconsistent and often contradictory findings. As the primary focus of molecular genetic analysis is on the nuclear genes, the role of the mitochondrial genome in HTN remains unexplored. Recently, we reported excess maternal transmission in familial HTN, suggesting a possible mitochondrial involvement. In an effort to assess the contribution of the mitochondrial genes to HTN, we initiated a systematic and extended screening of hypertensive individuals to identify potentially pathogenic mtDNA mutations. We applied our newly developed novel class of tests for the detection of mitochondrial mutation involvement in complex diseases (Sun et al. 2003) to the hypertension data set from 350 Caucasian and 98 African American pedigrees ascertained at HTN clinics associated with Boston Medical Center, and identified families with a likely mitochondrial involvement. Thus far, we analyzed the sequence of the entire mitochondrial genome of probands from 19 such pedigrees. They include 10 African Americans, 6 American Caucasians and 3 Greek Caucasians from our collaborating site in Greece. Comparison with the consensus Cambridge sequence revealed multiple base changes in all hypertensive individuals examined, some of which were observed in several individuals (such as 4216C within the ND1 gene and 10398G within the ND3 gene); some appear to be haplogroup-specific (such as 3308C in the ND1 gene and 5655C in the tRNA-Ala gene, both detected only on the L1b1 background); and some found only in one given family (these include many tRNA variants). These data, combined with sequence analysis of additional pedigrees, will serve as a starting point for a large-scale case-control association studies.

**Assessing the role of the mitochondrial genome in type 2 diabetes mellitus and related traits in Finns.** *E.C. Peck<sup>1</sup>, K.L. Mohlke<sup>1</sup>, A.U. Jackson<sup>2</sup>, Y. Suh<sup>1</sup>, L.J. Scott<sup>2</sup>, J. Tuomilehto<sup>3</sup>, R.N. Bergman<sup>4</sup>, M. Boehnke<sup>2</sup>, F.S. Collins<sup>1</sup>, FUSION Study Group.* 1) NHGRI/NIH, Bethesda, MD; 2) U. Michigan, Ann Arbor, MI; 3) National Public Health Institute, Helsinki, Finland; 4) U. Southern California, Los Angeles, CA.

Type 2 diabetes mellitus (T2DM), a complex gene disorder, accounts for approximately 90% of diabetes cases. T2DM has strong genetic and environmental components and is characterized by insulin resistance as well as pancreatic beta cell dysfunction. Since mitochondria play an integral role in ATP production in cells and are involved in glucose metabolism and insulin secretion, variants in the mitochondrial genome are plausible candidates for contributing to diabetes susceptibility. In our study of 793 Finnish families ascertained for T2DM, probands reported affected mothers three times more frequently than they reported affected fathers. To assess whether this apparent excess maternal transmission can be explained by mitochondrial variants, we selected single nucleotide polymorphisms (SNPs) based on phylogenetic networks. We selected 15 SNPs that define the major haplogroups and 18 that subdivide groups H and U, which are common in Finns. We genotyped the SNPs on one T2DM case per family and unaffected controls using primer extension MALDI-TOF mass spectrometry. We were able to assign haplogroups to 789 cases and 414 controls; in addition, we assigned the maternal haplogroup to 480 offspring of genotyped females. We evaluated association with both affected status and 8 to 14 diabetes-related traits for each of the cases, controls, and offspring. One of these traits was glucose effectiveness, which is the ability of glucose to enhance glucose disposal independent of an increment in insulin. The strongest evidence for phenotypic association was reduced glucose effectiveness in offspring from haplogroup V (p-value = 0.0003). No haplogroup, however, showed notable association with T2DM affected status (best p-value = 0.081 for haplogroup J). This study suggests that mitochondrial variants may play a modest role in glucose metabolism in the Finnish population.

**A Mouse Model of Bardet-Biedl Syndrome type 2.** V.C. Sheffield<sup>1,2</sup>, D.Y. Nishimura<sup>1</sup>, C. Searby<sup>1,2</sup>, K. Mykytyn<sup>1,2</sup>, M. Andrews<sup>1,2</sup>, C. Eastman<sup>4</sup>, B. Yang<sup>3</sup>, E.M. Stone<sup>2,4</sup>. 1) Dept of Pediatrics, University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute; 3) Dept of Obstetrics/Gynecology, University of Iowa, Iowa City, IA; 4) Dept of Ophthalmology, University of Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a genetically heterogeneous disorder with the clinical features of obesity, pigmentary retinopathy, polydactyly, hypogenitalism, mental retardation and renal anomalies. Secondary features include diabetes mellitus, congenital heart disease and hypertension. Five BBS genes have been identified on human chromosomes 11 (*BBS1*), 16 (*BBS2*), 15 (*BBS4*), 20 (*BBS6*) and 4 (*BBS7*). Two additional loci have been mapped to chromosomes 3p13-p12 (*BBS3*) and 2q31 (*BBS5*). The BBS genes have a wide pattern of tissue expression and except for *BBS6*, which has similarity to a *Thermoplasma acidophilum* chaperonin, the genes are novel. Although historically thought to be an autosomal recessive disorder, complex inheritance of BBS has been proposed based in part on a family with two discordant siblings homozygous for a nonsense mutation in the *BBS2* gene. In order to further study the genetics and pathophysiology of BBS we are developing animal models of this disorder. We have successfully targeted the *Bbs2* gene in mouse embryonic stem cells resulting in the deletion of exons 5 to 13. Mice homozygous for this knockout mutation (*Bbs2*<sup>-/-</sup>) appear normal at birth but have been obtained at less than the expected frequency (4/48, p<0.005). Electroretinography (ERG) of 11 week old *Bbs2*<sup>-/-</sup> mice revealed a 90% reduction in b-wave amplitude indicating that these mice have the retinopathy component of the human phenotype. Additional studies are underway to further define the *BBS2* phenotype in mice and to determine whether the BBS genes demonstrate genetic interaction.

**Tuberous Sclerosis 2 (TSC2) Gene Variants In Patients With Autism And Seizures.** *R.C. Michaelis<sup>1</sup>, C.E. Steiner<sup>2</sup>, F. Lobo-Menendez<sup>1</sup>, C. Skinner<sup>1</sup>, C.M. Wright<sup>3</sup>, R.J. Schroer<sup>1</sup>.* 1) JC Self Research Inst, Greenwood Genetic Ctr, Greenwood, SC; 2) University of Sao Paulo-Campinas, Campinas, Brazil; 3) Presbyterian College, Clinton, SC.

Despite ample evidence that genetic factors play an important role in the etiology of autism, the genetic causes of autism have been identified in very few cases. Linkage analyses have implicated 16p13 as a potential location for an autism genes. Among the genes in this region is the tuberous sclerosis 2 (TSC2) gene, which encodes the GTPase activating protein tuberin. Tuberin is thought to play an important role in neuronal migration, proliferation and differentiation. TSC2 mutations account for 50-60% of TSC cases. Over 90% of TSC patients demonstrate evidence of CNS involvement, including brain malformations, seizures and/or mental retardation.

The relationship between autism and TSC is particularly intriguing, because of a surprisingly high level of comorbidity between the two disorders. Autism has been estimated to occur in 17-68% of TSC patients. Conversely, TSC has been reported in 1-4% of patients with autism, and 8-14% of patients with autism and seizures. Little is known regarding the pathophysiological mechanism by which autism and TSC may be related, however. Some studies have suggested that autism is associated with tubers in the temporal lobe in TSC patients, but others find no association between autism and tuber location.

The TSC2 gene was screened for mutations in 38 patients with autism and seizures plus 3 patients with autism and TSC. The spectrum of variants found includes at least one nonsense and several missense variants. However, segregation analyses within families suggest that many of these TSC2 mutations, even the nonsense mutation, are not sufficient to produce autism, but may constitute a component of a "multiple-hit" scenario by which autism is produced by dysfunction in several interacting genes and/or environmental factors.

**Apolipoprotein L6 (ApoL6), expression up-regulated in schizophrenia, is a novel BH3-only pro-apoptotic protein.**

Z. Liu<sup>1</sup>, Z. Jiang<sup>2</sup>, H. Lu<sup>1</sup>, C.A. HU<sup>1</sup>. 1) Dept. Biochem. Mol. Biol., Univ. New Mexico Health Sciences Center, Albuquerque, NM; 2) National Center for Genome Resources, Santa Fe, NM.

Apoptosis is a complex and highly regulated physiological process that eliminates unwanted cells. Dysregulation of apoptosis is involved in many human diseases including neuro-degenerative disorders, cancer and atherosclerosis. Members of the Bcl-2 family play pivotal roles in regulating apoptotic pathways in which they are either anti-apoptotic (e.g., Bcl-2) or pro-apoptotic (e.g., PUMA). They possess one to four conserved protein sequences Bcl-2-Homology (BH) domains, designated BH1, BH2, BH3, and BH4. The BH3 domain is the only one conserved in all Bcl-2 family members and is present in pro-apoptotic "BH3-only" proteins. The BH3 domain plays an important role in protein-protein interactions and in regulating dimerization of the Bcl-2 family members in apoptosis. The goal of this study was to identify and characterize novel BH3-containing proteins from the human proteome. The completion of the Human Genome Project and the availability of various public databases allowed us to utilize the bioinformatic data-mining approach to conduct databases search. We employed a 9 amino-acid BH3 domain consensus sequence to screen public databases and identified three novel human BH3-containing proteins, one of which, apolipoprotein L6 (ApoL6), is a 343 amino-acid cytoplasmic protein. ApoL proteins belong to a newly identified, high density lipoprotein family comprised of six members, L1 to L6. The genes encoding ApoLs are localized to chromosome 22q12-13, a high-susceptibility locus for schizophrenia. ApoL1, L2, L4 and L6 have been shown to be significantly up-regulated in schizophrenia (1). To investigate if ApoL6 is a *Boni fide* BH3-only apoptotic protein, we cloned and functionally expressed the full-length human ApoL6 cDNA in a Tet-off inducible cellular model and showed that the overexpression of ApoL6 induces mitochondria-mediated apoptosis-- phenotypes include release of cytochrome c, activation of caspase 9 and nuclear fragmentation. In summary, ApoL6 is a BH3-only pro-apoptotic protein and may be involved in the etiology of schizophrenia.(1) Mimmack et al. (2002) PNAS 99, 4680.

**Candidate genes for myopia - The role of opticin, fibromodulin, PRELP and lumican genes.** *M. Majava<sup>1</sup>, M. Männikkö<sup>1</sup>, P. Bishop<sup>2</sup>, L. Ala-Kokko<sup>1</sup>.* 1) Department of Medical Biochemistry and Molecular Biology, University of Oulu, Finland; 2) Wellcome Trust Center for Cell-Matrix Research, School of Biological Sciences, and Research Group in Eye & Vision Sciences, The Medical School of University of Manchester, UK.

Myopia is the most common eye disease in Western Europe and USA with the incidence of 10-25 %. The environment effects on development of low myopia (physiological), but a strong genetic component has been shown for intermediate and high (pathological) myopia. Three loci have been mapped: Xq (MYP1), 18p (MYP2), and 12q21-23 (MYP3). Human vitreous gel is acellular and highly hydrated extracellular matrix. The gel structure is maintained by a dilute meshwork of collagen fibrils (types II, V/XI and IX). In vitreous degeneration the gel-like structure becomes more liquid as the collagen fibrils collapse. Opticin, fibromodulin, PRELP and lumican belong to a family of extracellular matrix small leucine-rich repeat proteins (SLRP) non-covalently bound to the surface of collagen fibrils. The SLRP proteins have been shown to regulate collagen fibril diameter and spacing through the binding. Opticin is the predominant leucine-rich repeat protein found in vitreous. PRELP, fibromodulin and lumican are expressed in the human sclera. In humans scleral thinning and changes in the collagen fibril diameter are associated with the development of high myopia. In mice null mutations in one or both alleles of the lumican gene result in defects in scleral collagen fibril formation. The genes for human opticin, PRELP and fibromodulin are present in a gene cluster on 1q32. The lumican gene locates in a SLRP cluster at 12q21-23. In the present study a heteroduplex analysis (CSGE) and subsequent sequencing of the exons containing heteroduplexes was performed for opticin, fibromodulin, PRELP, and lumican genes in 86 myopic (> 6 D) patients with family history of the disease. Total of six changes were found, four in lumican and two in fibromodulin gene that were not found in control set of matched population. The results suggest that changes in these genes may be part of the predisposing genetic factors for intermediate and high myopia.

**Assessment cocaine and amphetamine-regulated transcript (CART) gene polymorphism in Korean Alcoholism.**

*M.S. Hong<sup>1</sup>, H.J. Lee<sup>1</sup>, S.Y. Jin<sup>1</sup>, Z.W. Kim<sup>2</sup>, H.J. Park<sup>2</sup>, J.H. Chung<sup>1</sup>.* 1) Department of pharmacology, College of Medicine, Kyung Hee University, Seoul, Republic of Korean; 2) Kowhang Medical Research Institute College of Medicine, Kyung Hee University, Seoul, Republic of Korea.

Cocaine and amphetamine-regulated transcript (CART) peptides are novel gene peptides on putative brain-gut neurotransmitters and co-transmitters that probably have a role in drug abuse, the control of feeding behavior, sensory processing, stress and development. We examined whether single nucleotide polymorphism of the CART gene is associated with a risk for alcohol dependence. Subjects were 100 Korean male alcoholics and 199 age-matched male controls. We performed the distribution of genotypes and frequencies of the AvaII polymorphism. There was significant difference in the genotype distribution of polymorphism between Korean male alcoholics and control group ( $P < 0.05$ ). In further study, more large number of subjects would be required to study whether CART polymorphism is associated with alcohol dependence.

**Impact of IL-1 receptor antagonist gene polymorphism on schizophrenia and bipolar disorder.** *S. Kim<sup>1</sup>, H.J. Lee<sup>2</sup>, J.W. Kim<sup>2</sup>, H.J. Park<sup>2</sup>, S.H. Yoon<sup>3</sup>, M.K. Kim<sup>4</sup>, S.Y. Jin<sup>2</sup>, M.S. Hong<sup>2</sup>, S.V. Yin<sup>5</sup>, D.H. Shin<sup>6</sup>, J. Chung<sup>2</sup>.* 1) College of Life Science & Biotechnology, Korea University, Seoul, Republic of Korea; 2) Kowhang Medical Research Institute, Department of Pharmacology, College of Medicine, Kyung Hee University, Seoul, Republic of Korea; 3) College of Pharmacy, Kyung Hee University, Seoul, Republic of Korea; 4) Seoul National Mental Hospital, Seoul, Republic of Korea; 5) Department of Pharmacology, College of Medicine, Kangwon University, Chunchon, Republic of Korea; 6) Department of Preventive Medicine, School of Medicine, Keimyung University, Daegu, Republic of Korea.

The association between an abnormal immune system and schizophrenia or bipolar disorder was suggested by several studies, and cytokine may be important in those disorder. Especially, the level of proinflammatory cytokines was varied on schizophrenia patients. The IL-1 receptor antagonist(IL-1RA) inhibits IL-1 by competing for receptor binding. In this study, we performed association study of VNTR polymorphism of the IL-1RA gene on schizophrenia and bipolar disorder. A total of 269 patients with schizophrenia, 83 patients with bipolar disorder and 297 Korean healthy control subjects were included. There were a significant difference in the IL-1RA polymorphism between schizophrenia group and controls, and the carriage of IL1RN\*2 allele was associated with the increase risk to schizophrenia. However, there was no association with bipolar disorder with IL-1RA variant. Our results suggest that cytokine alteration in schizophrenia may be a genetic etiology, and IL-1RA could be a candidate gene for susceptibility to schizophrenia.

**Melanocortin-4-Receptor Gene Mutations in Morbidly Obese Finnish Children and Adults.** *K. Valli-Jaakola<sup>1</sup>, M. Lipsanen-Nyman<sup>2</sup>, L. Oksanen<sup>1</sup>, A.N. Hollenberg<sup>4</sup>, K. Kontula<sup>1</sup>, C. Bjørnbæk<sup>4</sup>, C. Schalin-Jäntti<sup>1,3</sup>.* 1) Department of Medicine, University of Helsinki, Finland; 2) The Hospital for Children and Adolescents, Helsinki University Hospital, Finland; 3) Department of Endocrinology, Helsinki University Hospital, Finland; 4) Department of Medicine, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA.

Mutations in the melanocortin-4-receptor (MC4R) gene have been shown to be the most common known monogenic cause of severe early-onset obesity. The aim of the present study was to investigate if morbid obesity in Finns could be explained by mutations in the MC4R gene. We screened the MC4R gene by denaturing high performance liquid chromatography and direct sequencing in 56 children with severe early-onset obesity (relative weight for height +70% before age 10, 29 females / 27 males) and 252 morbidly obese adults (BMI 40 kg/m<sup>2</sup>, 182 females / 70 males). The prevalence of the mutations detected was determined in a background population of 321 healthy blood donors. In one child we identified a pathogenic mutation (S127L) causing severe early-onset obesity. We also detected one novel (I226T) and three previously described (V103I, T112M, I125L) polymorphisms on the coding region of the gene. In addition, two new variations (-439delGC and 1059C>T) outside the coding region of the MC4R gene were identified. The signaling properties of the mutant receptors were studied, in addition to stimulation with the agonist -melanocyte stimulating hormone (-MSH), with desacetyl--MSH, -MSH, <sub>1</sub>-MSH and the antagonist Agouti Related Protein (AGRP). In vitro functional studies of the variants T112M, S127L and I226T demonstrated a severely impaired signaling by the S127L receptor, strongly supporting a pathogenic role for this mutation. The impaired function was due to reduced activation and not a defect of protein expression or transport to the cell membrane. In conclusion, one pathogenic mutation was found in a child with severe early-onset obesity. MC4R sequence variations are found in the Finnish population with similar frequencies as described in other populations.

**Parkin mutation analysis in clinic patients with early-onset Parkinson's disease.** *P. Poorkaj*<sup>1, 2</sup>, *J. Nutt*<sup>3</sup>, *D. James*<sup>3, 4</sup>, *E. Steinbart*<sup>1</sup>, *S. Gancher*<sup>5</sup>, *T. Bird*<sup>1, 2</sup>, *G. Schellenberg*<sup>1, 2</sup>, *H. Payami*<sup>3, 4</sup>. 1) Dept of Medicine, Univ of Washington, Seattle; 2) GRECC, VA, Seattle; 3) Dept of Neurology, OHSU, Portland, OR; 4) Wadsworth Center, Albany, NY; 5) Kaiser, Portland, OR.

Once believed to be non-genetic, Parkinson's disease (PD) has proved to be a heterogeneous disorder with a significant genetic component. In the past seven years, more than ten loci have been linked to PD, four of which (a-syn, UCHL1, parkin and DJ-1) have been identified and mutations characterized. parkin is the most common genetic cause of PD. parkin mutations are found predominantly in early-onset PD (at or before age 40) and are presumed to be recessive. It has been proposed that parkin testing should be a part of clinical work up for young onset PD. The purpose of this study was to assess parkin mutation frequency in a clinic setting, correlate genotype and phenotype, and evaluate the current justification for clinical parkin testing. Patients were selected from a movement disorder clinic based on diagnosis of PD (N=442) and early-onset (39/442). parkin was genotyped by sequence and dosage analysis for all exons. Relatives and controls were screened for mutations. Mutations were found in 7/39 patients and 0/96 controls. Two were compound heterozygous; 5 were heterozygous. Mutations included deletions in E2, E3, E8, duplications in E2-4, E9, and P437L. 70% of mutations were detected by dosage analysis. A novel substitution (R402W) was found in one patient and one control. The phenotype of parkin-positive patients was remarkably similar to patients without parkin mutations. In conclusion, parkin mutations are common in early-onset PD patients (18%). parkin cases cannot be distinguished on the basis of clinical features and require genetic testing. parkin testing is critical for research, but its wide application for diagnosis and counseling is premature. parkin mutations are presumed to be recessive, yet 70% of parkin cases were heterozygous. It is unclear if heterozygous mutations are pathogenic, or another mutation is embedded in parkin. parkin-based diagnosis and counseling requires a better understanding of the mode of inheritance, penetrance and carrier frequencies.

**Growth hormone receptor gene and idiopathic short stature.** *M. Taro, C. La Rosa, A. Citana, M. Baldi, R. Gastaldi, C. Traggiai, C. Bellini, E. Bonioli.* Pediatric Department , State University of Genova, Genova, Italy.

Although several pathological processes can lead to impaired linear growth, many short children do not fit into any clearly defined diagnostic category. These patients are usually classified as having idiopathic short stature (ISS). Although this is an unsatisfactory description, the term ISS is commonly used to describe children with: height < 2 standard deviations (SD); bone age delay > 2 SD; height speed < 25 centile; normal plasma GH level; no evidence of chronic physical or psychological illness. Recently partial Growth Hormon Insensitivity (GHI) has been reported in patients with ISS. GHI is identified as the inability to respond in a normal way to GH. The genetic form of GHI is historically known as Laron Syndrome, it consists of a severe hypostaturalism, and it is associated to a well known typical phenotype. It is due to homozygous mutations of GH receptor gene, resulting in a complete GH insensitivity. Recently, it has been appreciated that abnormalities of the growth hormone receptor (GHR) gene may be associated with relatively modest reduction of height in absence of the classical phenotype. It has also been proposed that partial GHI due to heterozygous mutations of the GHR may account for some cases of short stature previously classified as idiopathic (ISS). We studied GHR gene in 37 ISS patients referred to our Clinic and in 50 controls of normal stature, matched for age, sex and geographical area. Sequence analysis of PCR products of GHR gene revealed in 1 patient a novel heterozygous base pair change c485T>C in exon 6, resulting in mutation V162A. In 13 patients and in 26 controls we found the previously described polymorphism c558A>G, resulting in a silent mutation G186G. In 1 patient a novel polymorphism c336T>C in exon 5 was found, resulting in the silent mutation C112C. Our results suggest that in some patients there may be a correlation between ISS phenotype and GHR gene mutations.

**Analysis of Methyl Binding Domain (MBD) genes in autism risk.** *R. Rabionet<sup>1</sup>, J. Jaworski<sup>1</sup>, M.L. Cuccaro<sup>1</sup>, J.L. Benton<sup>1</sup>, S. Walters<sup>1</sup>, H.H. Wright<sup>2</sup>, R.K. Abramson<sup>2</sup>, G.R. DeLong<sup>1</sup>, J.R. Gilbert<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Duke University Medical Center, Durham, NC; 2) University of South Carolina, Columbia, SC.

Mutations in the methyl-CpG-binding protein 2 (MECP2) gene have been described to cause Rett syndrome and other X-linked mental retardation syndromes. Some cases of Rett syndrome patients have been reported to display autistic features. Recently, mutations in MECP2 have also been reported in autistic disorder cases. The involvement of MECP2 in autism suggests that other genes from the same family might also be involved in autism susceptibility. MECP2 shares the ability to bind to methylated DNA with four other proteins that have a similar Methyl-Binding Domain (MBD), and that are named MBD1-4. The genes encoding these proteins are located on chromosomes 18q21 (MBD1 and 2), 19p13 (MBD3) and 3q21 (MBD4). Preliminary analysis of MBD4 by DHPLC and sequencing in a dataset of 238 autistic families (both multiplex and sporadic (no family history of autism)), and in 32 control samples identified two intronic and 4 exonic variations. The intronic changes consisted of a C to G change at IVS2 -46 and a T to G change at IVS3+50, and were identified in both the case and control datasets. All the exonic variations identified caused amino acid changes. Three of them were identified in multiple cases as well as in controls: a G to T change at position 162 of the coding sequence caused a Met to Ile change, a G to A at 817 caused a Ala to Tre variation, and a T to C change at 1073 caused a Ile to Tre substitution. The fourth coding variant was only identified in two cases, and no controls, and consists of an A to G change at position 1399, causing a substitution of Asn to Ser. The individuals carrying this variant are sporadic autism families thus, screening of additional controls will be necessary to assess the significance of this variant in autism susceptibility. Complete analysis of MBD1-4 genes and their association with autism genetic risk will be presented.

**Variation in the Calpain-10 Gene (CAPN10) is Associated with Age-at-Diagnosis of Type 2 Diabetes in Japanese Subjects.** *N. Iwasaki<sup>1</sup>, Y. Horikawa<sup>2</sup>, T. Nakamura<sup>3</sup>, T. Tsuchiya<sup>4</sup>, M. Ogata<sup>1</sup>, N. Kamatani<sup>3</sup>, N.J. Cox<sup>5</sup>, Y. Iwamoto<sup>1</sup>.*  
1) Diabetes Ctr, Tokyo Women's Medical Univ, Tokyo, Japan; 2) Dept of Cell Biology, Gunma Univ, Maebashi, Japan; 3) Dept of Statistical Genetics, Institute of Rheumatology, Tokyo Women's Medical Univ, Tokyo, Japan; 4) Dept of Biochemistry and Molecular Biology, Univ of Chicago, Chicago, IL; 5) Dept of Human Genetics, Univ of Chicago, Chicago, IL.

Variation in the gene encoding the ubiquitously expressed non-lysosomal cysteine protease calpain-10 has been associated with risk of type 2 diabetes and with diabetes-related traits. Risk is determined by both specific polymorphisms and haplotypes. We have typed three haplotype-tagging SNPs in the calpain-10 gene (SNP-43, -19 and -63) in 205 unrelated Japanese subjects with type 2 diabetes and in 208 controls with normal glucose tolerance. There was no significance difference in frequency of SNP-43 and -19 between cases and controls but the SNP-63 T-allele was present at a significantly higher frequency in cases compared to controls (0.34 and 0.27, respectively,  $P = 0.042$ ). SNP-63 also showed association with area under the curve (AUC) glucose 0-120 min during an oral glucose tolerance test in 281 non-diabetic subjects ( $P = 0.01$ ). Patients with the SNP-63 T/T genotype tended to have a later age-at-diagnosis than those with other genotypes ( $P = 0.075$ ). An effect of calpain-10 genotype on age-at-diagnosis has not been previously observed and we therefore examined this association in a second independent group of patients ( $n = 151$ ). SNP-63 was not associated with type 2 diabetes in this group. However, individuals with the T/T genotype also tended to have a later age-at-diagnosis of type 2 diabetes ( $P = 0.069$ ). A combined analysis of the two patient groups showed a significant difference in age-at-diagnosis of type 2 diabetes: [C/C + C/T] vs T/T; 47.10.7 vs 51.72.0 years, respectively;  $P = 0.037$ . The results suggest that calpain-10 may be a risk factor for type 2 diabetes in Japanese and variation in the calpain-10 gene may modify the age-at-onset of diabetes.

**The contribution of corneodesmosin to androgenetic alopecia.** *R.C. Betz<sup>1</sup>, S. Hanneken<sup>2</sup>, T.G. Schultze<sup>3</sup>, G.M. Kukuk<sup>4</sup>, S. Ritzmann<sup>2</sup>, A.M. Hillmer<sup>4</sup>, C. Metzner<sup>2</sup>, S. Cichon<sup>1</sup>, T. Ruzicka<sup>2</sup>, P. Propping<sup>4</sup>, R. Kruse<sup>2</sup>, M.M. Noethen<sup>1</sup>.* 1) Dept. of Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Dept. of Dermatology, University of Duesseldorf, Duesseldorf, Germany; 3) Central Institute of Mental Health, Mannheim, Germany; 4) Institute of Human Genetics, University of Bonn, Bonn, Germany.

Androgenetic alopecia (AGA, male pattern baldness) is the most common form of hair loss in men and women. Significant AGA affects well over one half of the adult male population. It is characterized by a loss of hair from the scalp that follows a defined pattern. The development of AGA is androgen-dependent and of genetic origin. To date, a very limited number of studies have been performed concerning the molecular genetic basis of AGA.

Recently, we identified corneodesmosin (CDSN) as the responsible gene for hypotrichosis simplex of the scalp (HSS). HSS is an autosomal dominant form of isolated alopecia causing almost complete loss of scalp hair, with onset in childhood. Interestingly, among the known single gene hair disorders, the phenotype in HSS resembles the phenotype in androgenetic alopecia. Furthermore, the histological picture of scalp biopsies from patients with HSS has many features of androgenetic alopecia such as miniaturized follicles of the vellus type and absence of scarring.

Following the identification of the gene for HSS, we thoroughly examined CDSN for a possible contribution to the development of androgenetic alopecia in a sample of 168 trios, 177 single probands and 111 controls. We selected 21 intragenic variants, including 12 SNPs causing amino acid exchanges. Preliminary results at the level of individual polymorphisms in CDSN did not show any significant association with AGA. Further statistical analyses are currently underway.

Program Nr: 2177 from 2003 ASHG Annual Meeting

**Bsm I polymorphism analysis of receptor gene of vitamin D gene (RVD) in venezuelan patients with osteoporosis.**  
*L. Borjas-Fajardo, M. Zambrano, E. Fernandez, L. Pineda, A. Morales-Machin, P. Romero, W. Zabala, AE. Rojas-Atencio, JA. Chacin, W. Delgado.* Unidad de Genetica Medica, Univ del Zulia, Maracaibo, Zulia, Venezuela.

Among genes implied on the study of the osteoporosis genetics, the most studied gene worldwide is the receptor gene of D vitamin (VDR), through the characterization of Bsm I polymorphism. This research had as a main objective to analyze the Bsm I polymorphism of the RVD gene in a sample of 133 postmenopausal women distributed in three groups: 54 with osteoporosis, 24 with osteopenia and 55 normal controls for the disease. PCR and conditions reactions were made like Morrison method. The results showed that 28 of the women with osteoporosis presented the BB genotype, which is related in others countries to DMO decrease, 20 had the Bb genotype, and 6 the bb genotype. Of the control group only 11 women presented the BB genotype, 36 showed the heterozygote genotype and 8 the bb genotype. The frequencies of the B and b alleles in the analyzed population were 0.6 and 0.4 respectively. The BB genotype was found in 52% of the group with osteoporosis, and in 20% of the control group, these findings are statistically significant, which suggest an association between the BB genotype and osteoporosis.

**Association of angiotensin-converting enzyme I/D polymorphism with vitiligo patients of Korea.** *S.Y. Jin<sup>1</sup>, H.H. Park<sup>2</sup>, M.H. Lee<sup>2</sup>, H.J. Lee<sup>1,3</sup>, M.S. Hong<sup>1,3</sup>, H.J. Park<sup>1</sup>, G.Z. Li<sup>3</sup>, J. Chung<sup>1,3</sup>.* 1) Department of Pharmacology, college of Medicine, Kyung Hee University, Seoul, Republic of Korea; 2) Department of Dermatology, college of Medicine, Kyung Hee University, seoul, Republic of Korea; 3) Kohwang Medical Research Institute, College of Medicine, Kyung Hee University, Seoul, Republic of Korea.

Vitiligo (leukoderma) is an acquired idiopathic hypomelanotic disorder characterized by circumscribed depigmented patches. It is a polygenic diseases, and the exact pathogenesis of vitiligo is not yet known. We report the association studies for the angiotensin-converting enzyme (ACE) gene I/D polymorphism in vitiligo patients. The ACE gene was selected as a candidate gene because of the ACE plays an important role in the physiology of vasculature, blood pressure and cutaneous inflammation and which has been widely investigated in its relation with various diseases including autoimmune diseases. ACE gene polymorphism in vitiligo patients has not been reported yet. In this study, ACE gene polymorphism is investigated in 120 Korean vitiligo patients and 429 healthy volunteers. The insertion (I) allele of the ACE gene polymorphism is associated with vitiligo susceptibility. The results ( $P < 0.05$ ) suggest an association of the mutation in ACE with the development of vitiligo in Korean patients.

**Analysis of SNPs reported to be associated with obesity.** *H. Lyon*<sup>1</sup>, *T. Bersaglieri*<sup>1</sup>, *K. Lunetta*<sup>2</sup>, *K. Ardlie*<sup>2</sup>, *J. Hirschhorn*<sup>1,3</sup>. 1) Genetics, Children's Hospital and Harvard Medical School, Boston, MA; 2) Genomics Collaborative Inc., Cambridge, MA; 3) Whitehead Institute Center for Genome Research, Cambridge, MA.

Obesity is now an epidemic in the United States. The increase in obesity will result in an increase in related diseases such as diabetes and heart disease. Understanding the genetic variation that contributes to obesity will be crucial for devising effective interventions. At least 71 single nucleotide polymorphisms (SNPs) in 55 genes have been associated with common obesity phenotypes, but these associations have not been consistently replicated (Chagnon et al 2002). Many of these associations are likely spurious, but some may represent true causal risk factors. To distinguish the true associations from the false leads, association analyses with large populations and well-defined phenotypes are necessary. We genotyped 22 of the SNPs previously reported to be associated with body mass index (BMI) using DNA samples supplied by Genomics Collaborative from a population of 1000 Polish people with BMI at the upper and lower ends of a population distribution. Obese subjects (n=700) had BMI from the 90th-97th percentile, while lean subjects (n=330) had BMI from 5th-12th percentile. A case-control chi square analysis using a SNP with 25% frequency had 97% power to detect a 1.5 fold odds ratio. The use of hypernormal controls further enhanced power to detect alleles with modest effects on BMI. None of the SNPs showed a significant association with obesity after correction for multiple tests. The 697G/C SNP in HT2RC (type 2C serotonin receptor) showed a nominal association of the minor allele (risk ratio for obesity=1.24, p value=0.04). Our study has thus far failed to replicate previously reported associations. This may be due to a high rate of false positive reports, differences between populations, testing alleles that are in linkage disequilibrium with, but not identical to the actual causal variants, or a lack of power for odds ratios below 1.25. To address these issues, we will assess the variants in a larger US Caucasian population of 2000 subjects, and use a comprehensive haplotype-based approach to assess the impact of genetic variation in these candidate genes.

**Analysis of DNA variants in the genes encoding the gastrin releasing peptide (GRP) and its receptor (GRPR) in panic disorder.** *S.P. Hamilton<sup>1</sup>, M. Durner<sup>2</sup>, L. Hodges<sup>1</sup>, M. Bautista<sup>1</sup>, O. Bravo<sup>1</sup>, G.A. Heiman<sup>2</sup>, T.G. Gilliam<sup>2</sup>, S.E. Hodge<sup>2</sup>, J.A. Knowles<sup>2</sup>, A.J. Fyer<sup>2</sup>, M.M. Weissman<sup>2</sup>.* 1) Dept. of Psychiatry, UCSF; 2) Depts. of Psychiatry and Genetics & Development, Columbia University College of Physicians and Surgeons.

Family, segregation, and twin studies imply a genetic component to the predisposition towards panic disorder. Few studies have investigated the potential involvement in panic disorder of genes encoding fear circuitry proteins. Recent animal studies suggest a role for the gastrin-releasing peptide (GRP) and its receptor (GRPR) in anxiety. Additionally, we observed single locus and multipoint heterogeneity lod scores of  $\sim 2.0$  approximately 15cM telomeric to the GRP gene in our recent published genome scan of a panic disorder syndrome. One consequence of the Human Genome Project has been the discovery of large numbers of DNA variations, including single nucleotide polymorphisms (SNPs), localized throughout the genome. The high density of these markers allows the construction of informative haplotypes for linkage disequilibrium mapping studies. Using high throughput methods for genotyping SNPs (FP-TDI and fluorogenic 5-nuclease), we have employed a family-based design to investigate the role of SNPs and simple tandem repeats in the genes for GRP and GRPR. We have genotyped  $\sim 1,200$  individuals in 120 panic disorder pedigrees, as well as 83 parent-proband triads. Subjects were genotyped at 1) 7 informative SNPs over 25kb in or around the GRP gene and 2 informative STRs flanking the GRP gene (18q21); and 2) 6 informative SNPs over 36kb at the GRPR locus (Xp22). These data are currently being analyzed for genetic association and linkage, and the results will be presented. In addition to standard linkage (using recessive/dominant genetic models, three diagnostic models, and tests of heterogeneity) and family-based association (FBAT) analyses, we plan to analyze the data using TRANSMIT, a program that compares the transmission of multilocus haplotypes from parents to affected offspring. Its main advantage is its ability to handle missing parental genotypes or phase-unknown parental genotypes.

**MTHFR C677T GENE MUTATION - A RISK MARKER FOR HEMIPLEGIA RELATED TO**

**VASCULOPATHIES AND COMPLICATIONS OF DIABETES.** *R.A. Varma<sup>1</sup>, S. Movva<sup>2</sup>, V. Mohan<sup>1</sup>, C.*

*Kamalesh<sup>1</sup>, J.R. Chaudary<sup>1</sup>, S. Saharia<sup>2</sup>, Q. Hasan<sup>1,2</sup>.* 1) Dept of Genetics, Kamineni Hospitals, Hyderabad, INDIA; 2) Bhagawan Mahaveer Hospitals and Research Center, Hyderabad, India.

**Introduction:** The enzyme methylenetetrahydrofolate reductase (MTHFR) is pivotal in the metabolism of homocysteine. A mutation (C677T) in the MTHFR gene results in a thermolabile enzyme with reduced activity. More and more studies indicate that polymorphisms in candidate genes, like MTHFR, increase the risk of diseases like hemiplegia, cardiovascular conditions and complications of diabetes. **Aim:** To evaluate the risk assessing potential of C677T mutation in the MTHFR gene in patients with hemiplegia or neurological problems related to vasculopathies and complications of diabetes. **Methods:** Patients problems related to vasculopathies (N=62) and diabetics with diabetic nephropathy and retinopathy (N=25) were included in the study. Controls included individuals having neurological conditions other than hemiplegia (N=15), diabetics of 10-year duration with no overt complications (N=10) and healthy age, sex-matched volunteers (N=35). Genomic DNA was isolated from heparinised blood using DNA isolation kit (Amersham Pharmacia). PCR was carried using specific primers for MTHFR. The amplified product was restriction digested with Hinf I (MBI Fermentas) to identify the mutation by agarose gel electrophoresis. **Results & Discussion:** The gene mutation was identified in 1/35 healthy controls, indicating that the prevalence of the mutation in this cohort is 2.85%. The MTHFR mutation was detected in 19/62 (30.64%) cases with neurological vasculopathies and the incidence of mutation was lower for neurological diseases other than hemiplegia and diabetics with nephropathy/retinopathy. **Conclusion:** There is a significant correlation between MTHFR C677T gene mutation and Neurological Vasculopathies. This can be considered as a risk marker in our population for hemiplegias. However, the sample size for the diabetic group both with and without complications may have to be increased prior to deciding whether the MTHFR gene mutation could be considered as a marker for these conditions.

**A novel approach to analyse genotype combinations in genes of the renin-angiotensin-aldosterone system in type 1 diabetic patients with and without diabetic nephropathy.** *K.J. Pettersson-Fernholm<sup>1</sup>, S. Sammalisto<sup>2</sup>, M.*

*Koivisto<sup>3</sup>, S. Frojdo<sup>1</sup>, M. Perola<sup>2</sup>, K. Sood<sup>3</sup>, M. Rinne<sup>1</sup>, C. Forsblom<sup>1</sup>, J. Fagerudd<sup>1</sup>, L. Peltonen<sup>2</sup>, PH. Groop<sup>1</sup>, FinnDiane Study Group.* 1) Folkhalsan Research Center, Biomedicum, Helsinki, Finland; 2) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 3) Department of Computer Science, University of Helsinki, Finland.

There is evidence for genetic involvement in the pathogenesis of diabetic nephropathy (DN) and the RAAS system, including the ACE, AT1, AT2 and CYP11B2 genes, is a possible candidate system. There are, however, no published data of combining more than 2 loci in DN. Therefore, the aim of this study was to study 9 polymorphisms in the RAAS system by using 3 approaches: 1) Conventional single locus analysis. 2) A novel computer program designed for multi-loci SNP analysis by using a pattern discovery framework called the naive Bayes model. The naive Bayes algorithm attempts to predict the phenotype from the given genotype combinations. 3) A multi-loci search computer program to test all possible 2- and 3-loci combinations. In a cross-sectional case-control study we studied 638 type 1 diabetic patients from 20 centers from the FinnDiane Study. Patients were classified based on their albumin excretion rate: NORMOalbuminuria (n=319) and PROTEinuria (n=319). The frequencies of rare genotypes of ACE I/D, CYP11B2 T-344C, 5 SNPs in the AT1 and 2 SNPs in the AT2 did not differ between the groups in the conventional analysis. However, in multi-loci analyses the naive Bayes model identified a significant deviation between the two groups. Further analyses showed that the following genotype combinations were more common in NORMO than PROT: CC of AT1 A1166C and CC of CYP11B2 T-344C (Fisher exact, p=0.004), ID of ACE I/D, CC of AT1 A1166C and CC of CYP11B2 T-344C (p=0.02) and AC of AT1 A+39C, ID of ACE I/D and CC of CYP11B2 T-344C (p=0.01). These preliminary results suggest that the naive Bayes method combined with a multi-loci search program is a powerful novel approach in the search for genotype combinations in DN and other complex traits.

**Population genetic approaches to Parkinsons disease.** *P.M. Abou-Sleiman<sup>1</sup>, D.G. Healy<sup>1</sup>, K. Ahmadi<sup>2</sup>, D.B. Goldstein<sup>2</sup>, N.W. Wood<sup>1</sup>.* 1) Department of Molecular Neuroscience, Institute of Neurology, Queen Square, London WC1N 3BG, United Kingdom; 2) Department of Biology, University College London, Darwin Building, Gower Street, London WC1E 6BT, United Kingdom.

Parkinsons disease is a neurological conditions of global health significance. A European population-based study estimated the age-dependant prevalence at 1.4, 2, and 3.4%; in those aged 55, 65 and 75 years or over, respectively. Over the past decade major advances have been made in elucidating rare Mendelian forms of the disease, however, very little is known about susceptibility factors influencing the common forms of the disease. We have used a multi-step programme based on linkage disequilibrium mapping to efficiently screen candidate genes for polymorphisms that predispose to PD. For this initial study we have selected 6 candidate genes, these are the two autosomal recessive genes parkin and DJ-1, three autosomal dominant genes -synuclein, NR4A2 and UCH-L1 and MAPT (tau), which has been reported to be associated with PD. We determined the haplotype structure of these candidate genes in a panel of European control trios by direct sequencing. We then determined a minimal set of SNPs that represent most of the observed haplotype diversity (haplotype tagging SNPs). The six genes combined, span a total of 1.7 Mb of genomic DNA, and we were able to capture an estimated 95% of the haplotype diversity within these genes using only 27 SNPs. The tagging SNPs were genotyped in 800 Parkinsons disease patients and a panel of 800 ethnically matched healthy controls using taqman allelic discrimination assays. We then used statistical approaches to identify haplotypes that predispose to PD in each individual gene. Additionally, we looked at possible interactions between the genes under investigation and the incidence of PD. Implicated gene regions were then re-sequenced to identify causal SNPs. These results will not only improve our understanding of this important neurological condition, but may also serve as a framework for the study of other common non-Mendelian diseases which have, to date, remained largely unresolved due to the inadequacy of the available methodologies.

**A range of known risk factors for conduct disorder interact with low MAO-A activity to increase risk. D.L.**

*Foley<sup>1</sup>, B.K. Wormley<sup>2</sup>, H.M. Maes<sup>1</sup>, J.L. Silberg<sup>1</sup>, L.J. Eaves<sup>1</sup>, B.P. Riley<sup>1, 2</sup>.* 1) Dept. of Human Genetics, Virginia Commonwealth Univ., Richmond, VA; 2) Dept. of Psychiatry, Virginia Commonwealth Univ., Richmond, VA.

Low MAO-A activity has been associated with antisocial behavior in boys exposed to maltreatment. We were interested to assess if other known risk factors for conduct disorder (CD) also interacted with low MAO-A activity to increase risk for CD. We therefore genotyped MAO-A polymorphisms in 516 boys from the Virginia Twin Study of Adolescent Behavioral Development and created a quantitative 6 item index of known risk factors for CD, which included parental neglect, exposure to inter-parental violence and inconsistent discipline. There was no main effect of MAO-A on risk for CD (OR= 0.80, CI=0.46, 1.39 P=0.43). Our index is composed of items known to predict CD and as expected we observe a significant main effect on risk for CD (OR=1.62, CI=1.20, 2.19, P=0.002). The bulk of this effect comes from the low activity group (OR=2.51 CI=1.46, 2.49, P=0.0008) although the high activity group is similar (OR=1.34, CI=0.94, 1.91, P=0.10). 27% of children had been exposed to 1+ index items. In an effort to identify those children with more severe risk factors for CD we set a threshold of 2+ index items (8% of the sample). In this more severely exposed group there was no main effect of index on risk for CD (OR=1.48, CI=0.79, 2.75 P=0.22) likely due to reduced power in this sub-sample. Critically, we do detect a statistically significant interaction between low MAO-A activity and the index regardless of the threshold used to define exposure. When exposure is defined by 1 or more index items the association between CD and the interaction between the index and low MAO-A activity is OR=1.87, CI=0.98, 3.56, P=0.03. When exposure is defined by 2 or more index items the association between CD and the interaction between the index and low MAO-A activity is even larger (OR=6.10, CI=1.54, 24.10, P=0.005). Our findings are therefore consistent with the results reported by Caspi et al from the Dunedin study, but they indicate that the low activity genotype interacts with a variety of risk factors for CD.

**Differential allele expression of MPDZ---A candidate gene for alcohol withdrawal liability.** *G. Zhu<sup>1, 2</sup>, P.J. Brooks<sup>1</sup>, D.C. Mash<sup>3</sup>, D. Goldman<sup>1</sup>.* 1) Laboratory of Neurogenetics, NIAAA, NIH, 12420 Parklawn Dr., Room 451, Rockville, MD 20852; 2) Changhai Hospital, Shanghai 200433, P.R. China; 3) Department of Neurology, University of Miami, Miami, FL 33136.

Previous studies show that risk for onset of alcoholism is associated with genetic differences in acute alcohol withdrawal severity. By using an animal model, in which DBA/2J(D2) and C57BL/6J(B6) mouse strains exhibit severe and mild acute alcohol withdrawal, respectively, a quantitative trait locus (QTL) for withdrawal was mapped to mouse chromosomes 4 (Buck et al. 1999). Congenic mapping narrowed the QTL to a 1.8 Mb interval and identified *Mpdz* (multiple PDZ domain protein) as a candidate gene (Fehr et al. 2002), but a causative coding sequence variant was not identified. We hypothesized that a quantitative difference in MPDZ expression might contribute to the difference in alcohol withdrawal. We used MPDZ coding sequence variants as endogenous reporters for MPDZ differential allele expression in brain tissues of both B6/D2 F1 mice and humans. RT-coupled 5 nuclease assays were developed for the SNP markers. Results: (1) In six B6/D2 F1 mouse brains, the B6-specific allele was consistently over-expressed relative to the D2-specific allele, with a mean allele ratio of 1.51 0.12. Real-time RT-PCR quantitation of *Mpdz* mRNA showed that B6 mice expressed 30% more *Mpdz* mRNA in brain than D2 mouse, which is consistent with the differential strain-specific allele expression. (2) In humans, differential MPDZ allele expression was found in 10/27 heterozygous postmortem brain samples, in which one allele is consistently higher expressed than the other allele, with a mean allele ratio of 1.60 0.23. These results indicate: (1) functional variants apparently exist in MPDZ regulatory region(s) in human, and these variants influence gene expression efficiency; (2) differential allele expression of MPDZ gene might be an important mechanism for alcohol withdrawal liability in human, as in mouse. Observation of conditional and dynamic change of *Mpdz* expression in acutely alcohol treated mice and linkage analyses between MPDZ genotype and/or haplotype and alcohol dependence in human are under way.

**Genetic Risk factors for Reduced Lung Diffusing Capacity In Middle Aged And Older Adults.** *M. Matheson<sup>1</sup>, J. Ellis<sup>2</sup>, J. Raven<sup>3</sup>, D. Johns<sup>4</sup>, EH. Walters<sup>4</sup>, M. Abramson<sup>1</sup>.* 1) Department of Epidemiology & Preventive Medicine, Monash University, Melbourne, Vic 3004; 2) Department of Physiology, The University of Melbourne, Vic 3010; 3) Department of Allergy & Respiratory Medicine, The Alfred, Vic 3004; 4) University of Tasmania, Hobart, Tas 7000.

**Introduction:** A reduced carbon monoxide diffusing capacity (DLco) and Kco (DLco/alveolar volume) in people with a significant smoking history is often associated with diseases of the lung parenchyma including emphysema. Emphysema may result from chemical and oxidative damage caused by reactive species present in cigarette smoke or released from neutrophils recruited following cigarette smoke induced injury. The glutathione S-transferase superfamily of detoxification enzymes may protect against such injury through detoxification of cigarette smoke components. The GSTM1 and GSTT1 genes are members of this family and contain polymorphisms that result in no enzyme production (null alleles). Our aim was to investigate the role of the GSTM1 and GSTT1 genes on DLco and Kco in subjects that were part of a cross-sectional study of Chronic Obstructive Pulmonary Disease in Melbourne Australia.

**Methods:** Participants in the study completed a detailed respiratory questionnaire, spirometry, and measurement of DLco and Kco by the single breath technique (n=1221). Polymorphisms in the GSTM1 and GSTT1 genes were determined from PCR analysis from previously published methods.

**Results:** Genotyping for GSTM1 and GSTT1 was completed for 1071 subjects. Individually neither the GSTM1 null nor the GSTT1 null genotypes were associated with reduced DLco or Kco. However inheritance of both the GSTM1 null and GSTT1 null genotype was associated with a significant reduction in diffusing capacity in smokers (p=0.036) allowing for age and gender.

**Conclusions:** These findings would suggest that GSTM1 and GSTT1 may play a role in the development of emphysema in those individuals exposed to cigarette smoke.

Program Nr: 2187 from 2003 ASHG Annual Meeting

**Transcriptional effects of the *EPM1* minisatellite.** L. Hsu, G. Zhang, T. Krontiris. Div Molecular Med, Shapiro Bldg, Beckman Res Inst City of Hope, Duarte, CA.

Expansion mutations of gene-associated minisatellites (VNTRs) are responsible for several human diseases, including myoclonus epilepsy (*EPM1*), insulin-dependent diabetes (*INS*), and neurodegenerative disorders (*5-HTT*, *MAOA*). To study the biological role of these repeat elements, we analyzed the effects of the *EPM1* VNTR on reporter gene activity in murine NIH3T3 fibroblasts and embryonic stem (ES) cells. In a transient transfection system, the expanded *EPM1* VNTR sequence (85 repeats) inhibited the reporter gene promoter activity both *in cis* and *in trans*, whereas the normal VNTR allele (3 repeats) did not alter promoter function. Downregulation of expression *in trans* strongly suggested the titration of certain transcription factors (the VNTR repeat unit bears an SP1 binding site), whereas expression inhibition *in cis* may additionally have resulted from the interaction of higher order VNTR structure with specific DNA-binding proteins. Expression downregulation by an expanded VNTR was also observed when the VNTR was stably incorporated into the 3T3 genome by transfection: Significantly fewer G418-resistant clones were obtained in NIH3T3 cells transfected with the insertion vector carrying an expanded *EPM1* VNTR. Four ES clones containing normal and expanded *EPM1* VNTRs (with 3, 20, 36, and 85 repeat units, respectively) attached to a reporter promoter region were obtained by employing a modified double-targeting strategy at the murine *mnk* locus. In contrast to differentiated 3T3 cells, the effect of VNTR length on *mnk* expression in targeted ES clones assayed by real time PCR was not significant. This result suggested that cell-type or developmental stage specific binding proteins may be involved in the transcriptional regulation by VNTR. We are now using several yeast and murine models to identify cellular DNA binding proteins that may mediate our observed VNTR effects.

**Examination of molecular characteristics of the *FMR1* gene: identifying risk factors for premature ovarian failure among female premutation carriers.** A.K. Sullivan, E.G. Allen, S.L. Sherman. Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Premature ovarian failure (POF), defined as cessation of menses before age 40, occurs in 1% of the general population. *FMR1* female premutation carriers (PC) have a significantly increased risk for POF; however, the cause of their ovarian dysfunction is unknown. We hypothesize that molecular correlates related to the *FMR1* gene may explain this increased risk. Therefore, we examined *FMR1* CGG repeat size, X-inactivation ratio, *FMR1* transcript level, and parental origin of the *FMR1* premutation. We obtained reproductive histories on 403 women (271 with <59 repeats and 132 with 59 repeats) and FSH levels on a subset of these women (N=143). We confirmed previous findings that PC have an increased risk for ovarian dysfunction: they have a higher prevalence of POF (13%) and an earlier age at menopause (mean = 47.10.7). FSH level, an indicator of perimenopause, did not differ between PC and noncarriers under age 30. However, FSH levels were significantly higher in PC than in noncarriers among women in their 30s. Another indicator of ovarian dysfunction among PC was increased dizygotic twinning; however, the miscarriage rate was not increased significantly. Other reproductive measures did not differ between PC and noncarriers including age at menarche and variation in menstrual cycle characteristics. We conducted analyses to determine if repeat size, X-inactivation ratio and parental origin of the *FMR1* allele may explain the risk for POF among PC. We found that PC with 80 repeats had an earlier age at menopause and a higher prevalence of POF compared to those with smaller premutations. Parental origin was not found to be a risk factor for ovarian failure. X-inactivation ratio and transcript level were also not found to be risk factors, although the sample sizes were small for some of these analyses. These findings suggest that 1) PC may not have clinical problems associated with ovarian function in their earlier reproductive years and that 2) premutation size is a risk factor for ovarian dysfunction.

**Investigating Candidate Genes and Novel ESTs in Primary Open Angle Glaucoma.** *K.R. Abramson<sup>1</sup>, M.A. Hauser<sup>1</sup>, O.A. Marks<sup>1</sup>, C. Santiago<sup>1</sup>, F.L. Graham<sup>1</sup>, E.A. del Bono<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>, J.L. Wiggs<sup>2</sup>, J.L. Haines<sup>3</sup>, R.R. Allingham<sup>1</sup>.* 1) Duke University Medical Center, Durham, NC; 2) Massachusetts Eye and Ear Infirmary, Boston, MA; 3) Vanderbilt University, Nashville, TN.

We have previously reported linkage analysis in a set of 86 multiplex POAG families. (Wiggs et al, Hum. Mol. Genet., 9(7);1109-1117). Six genomic regions displayed linkage to POAG, including our strongest regions on 14q11 and 15q11-15q13. Phenotypic stratification using ordered subset analysis (OSA) has identified a subset of families with early onset disease (age at diagnosis less than 45 years) that are linked to the locus on chromosome 15. Candidate genes throughout the minimal candidate interval are being screened both by direct gene sequencing and by family-based association analysis. A sample set of 16 individuals representing 14 early onset families and two controls was used to sequence the known genes. Intron/exon boundaries were determined by BLAT comparison of the cDNA sequence and the UCSC genomic assembly. Each exon was pcr amplified and sequenced on an ABI3700, using standard protocols. The sequences were analyzed using PolyPhred and Sequencher software. Ten known genes in this region have been sequenced: ATP10C, GABRA5, GABRB3, GABRG3, APBA2, KIAA0574, TJP1, NDN, MAGEL2, and SNRPN. We have identified many SNPs, synonymous substitutions, and missense variants, but none of these variants appear to play a primary causative role in POAG. Association studies with 15 SNPs within the GABRA5, GABRB3, GABRG3 genes does not reveal any association with POAG disease status. We have also identified numerous ESTs located in this interval, including several that are expressed in ocular tissue. We present the genomic structure and mutation analysis of a number of ESTs in the 15q11.1-15q13.2 interval. ESTs were extended by 5'-RACE on BD Clontech Marathon-Ready retinal and fetal brain cDNA libraries. Subsequently these extended transcripts were chracterized and screened for mutations by sequencing.

**Evidence for digenic inheritance in adult-onset primary open angle glaucoma.** *M.K. Wirtz<sup>1</sup>, N.D. Gaudette<sup>1</sup>, J.R. Samples<sup>1</sup>, D. Choi<sup>1</sup>, G. Kitsos<sup>2</sup>, E. Economou-Petersen<sup>3</sup>, M. Grigoriadou<sup>4</sup>, G. Aperis<sup>4</sup>, P.L. Kramer<sup>5</sup>, K. Psilas<sup>2</sup>, M.B. Petersen<sup>4</sup>.* 1) Dept Ophthalmology, CE-Res, Casey Eye Inst/OHSU, Portland, OR; 2) Dept Ophthalmology, University of Ioannina, GREECE; 3) National Blood Derivative Center, Athens, GREECE; 4) Dept Genetics, Institute of Child Health, Athens, GREECE; 5) Dept Neurology, OHSU, Portland, OR.

Primary open angle glaucoma (POAG) is the most common form of glaucoma, a blinding disease that may affect as many as 105 million individuals worldwide according to the World Health Organization. Affected individuals have characteristic optic nerve damage with abnormal visual fields, increased optic cup to disc ratios ( $>0.7$ ) and often high intraocular pressures ( $>21$  mm Hg). We have previously mapped a gene for POAG to chromosome 3, *GLC1C*, in two large families. To determine if more than one gene for POAG might be segregating in these families, we screened family members for mutations in *MYOC*, the *GLC1A* gene. *MYOC* variants in the US *GLC1C* family from Oregon included the Y347Y polymorphism in several family members and K398R in a spouse. In the Greek *GLC1C* family from Epirus, *MYOC* base pair changes included T377M, D380H in a spouse, and the Y347Y variant. The T377M change was found in 7 out of 10 affected POAG members. All affected family members carried the *GLC1C* haplotype. Four family members had the T377M *MYOC* variant and a normal haplotype at the *GLC1C* locus. None of these individuals have POAG at this time; all of them appear to have normal cup to disc ratios and only one shows evidence of elevated intraocular pressure. However, the oldest is only 50, thus, it will be important to monitor these individuals over time. The T377M mutation has been identified in Australian families with Greek or Macedonian ancestry. Screening 60 random POAG s Greek patients identified one individual with the T377M variant and four with the Y347Y polymorphism. Haplotype studies are in progress to determine if the T377M variant results from a single founder in the Greek population. This is the first report of potential digenic inheritance in the more common late-onset form of high pressure primary open angle glaucoma.

Program Nr: 2191 from 2003 ASHG Annual Meeting

**Exclusion of TGF Beta-Induced Factor as a Candidate Gene for MYP2 Autosomal Dominant High Myopia.** *T. Young, G. Scavello, P. Paluru, W. Ganther.* Divisions of Ophthalmology and Genetics, Children's Hosp of Philadelphia, Philadelphia, PA.

**PURPOSE:** TGF Beta-Induced Factor (TGIF) is a TALE homeobox gene that maps within the MYP2 high myopia locus interval at chromosome 18p11.31. In a recent report, TGIF was implicated as the MYP2 gene by SNP association studies of exon 3 in 1 transcript variant. (1) We systematically screened for nucleotide variations in the entire TGIF gene, examining an additional 7 transcript variants.

**METHODS:** TGIF was screened for sequence variants in the 7 original MYP2 families by direct DNA sequencing. The TGIF model used was the 4/20/03 human genome NCBI build #33, which has 10 exons and encodes for 8 transcript variants. Polymorphic sequence changes were compared to the previous report.

**RESULTS:** We observed 6 polymorphisms in 8 transcript variants of 10 exons, 3 of which were missense mutations and 3 were silent. The 3 missense variances localized to exon 10 at positions 235CT(ProLeu), 243CT(ProSer), and 244CT(ProLeu). Silent mutations were observed on exon 10 at positions 187AG, 332CT, and 413TG. Five polymorphisms were novel. Of the 25 SNPS published in the earlier report, only one - 187AG (804AG as previously noted) - was observed in our investigation. No sequence alterations co-segregated with the affected disease phenotype.

**CONCLUSIONS:** Mutation analysis of the full TGIF gene for MYP2 autosomal dominant high myopia did not identify sequence alterations associated with the disease phenotype. Further studies of MYP2 candidate genes are needed to determine the gene causative for this potentially blinding disorder.

**A novel missense mutation within the DNA-binding domain of GCMB causes autosomal recessive isolated hypoparathyroidism.** L. Baumber<sup>1</sup>, S. Patel<sup>1</sup>, C.A. Johnson<sup>2</sup>, E.R. Maher<sup>2</sup>, R.C. Trembath<sup>1</sup>. 1) Department of Genetics, University of Leicester, Leicester, UK; 2) Section of Medical & Molecular Genetics, University of Birmingham, Birmingham, UK.

Familial isolated hypoparathyroidism refers to an uncommon metabolic disorder characterized by hypocalcemia and hyperphosphatemia, due either to abnormal activity or deficiency of parathyroid hormone (PTH). We recently identified a consanguineous Pakistani family with multiple affected individuals, each with isolated hypoparathyroidism presenting with seizures soon after birth. Disease segregation was compatible with an autosomal recessive mode of inheritance, so we initially used autozygosity mapping to exclude linkage to the PTH locus in this family. Subsequent microsatellite marker analysis identified a region of homozygosity flanking the *GCMB* (glial cells missing, *Drosophila* homologue B) gene. GCMB belongs to a family of transcription factors containing a novel N-terminal DNA-binding domain. This gcm motif is highly conserved in *Drosophila* and mouse homologues, with human isoforms A and B displaying additional homology to their mouse counterparts outside this region. Mouse GCMB, expressed predominantly in parathyroid tissue, is critical for parathyroid gland development in mice. A deletion within *GCMB* has previously been shown to cause hypoparathyroidism in a single family. Here we report a novel missense mutation within the DNA-binding domain of this gene. Sequencing all five exons of the *GCMB* gene, we have identified a homozygous R47L substitution, present in all affected individuals in this family. Unaffected parents were heterozygous for the mutation, which was not detected in any of 108 chromosomes screened in a control cohort of unrelated Pakistani individuals. This study provides further evidence of a critical role for GCMB expression and activity in parathyroid development in humans. The identification of this novel mutation, the first amino-acid substitution reported within the conserved DNA-binding motif of GCMB, suggests hypoparathyroidism in this family is caused by altered transcriptional regulation of downstream genes, a hypothesis now amenable to direct experimental examination.

**Functional interaction between BMPR2 and Tctex-1, a light chain of Dynein, is isoform-specific and disrupted by mutations underlying primary pulmonary hypertension.** *R.D. Machado*<sup>1</sup>, *N. Rudarakanchana*<sup>2</sup>, *N. Morrell*<sup>2</sup>, *R. Trembath*<sup>1</sup>. 1) Division of Medical Genetics, University of Leicester UK; 2) Department of Medicine, University of Cambridge UK.

Primary pulmonary hypertension (PPH) is characterised by the obstruction of pulmonary arterioles leading to a sustained elevation of pulmonary arterial pressure. PPH is usually fatal, typically as a result of right heart failure. Heterozygous mutations in the bone morphogenetic protein receptor type II (*BMPR2*) gene, a receptor of the TGF family, have been shown to cause PPH. Two isoforms of *BMPR2*, distinguished by the presence of a long cytoplasmic tail encoded by exon 12 of the gene, transduce signal by phosphorylating cytoplasmic mediators upon forming heteromeric complexes with type I receptors. A third of PPH mutations occur in the long C-terminal cytoplasmic tail, a domain of unknown function and unique to *BMPR2*. As the generation of the short isoform, lacking exon 12, is unlikely to be affected by these mutations, we investigated the cellular function of the cytoplasmic domain. Using a yeast two-hybrid screen and *in-vitro* binding assays we have identified Tctex-1, a light chain of the multi-subunit cytoplasmic dynein microtubule motor, as a binding partner to the *BMPR2* cytoplasmic tail. Dynein is required for the intracellular trafficking of protein cargo, the specificity for which depends on the composition and phosphorylation of sub-units in the complex. We demonstrate that the binding affinity of the short isoform of *BMPR2* for Tctex-1 is much lower than that of the long variant. Through kinase assays, we have shown that Tctex-1 is phosphorylated by *BMPR2*. Predictably, kinase mutation removed the ability of *BMPR2* to phosphorylate Tctex-1. Cytoplasmic tail *BMPR2* mutant constructs, both truncating and missense, were able to bind Tctex-1 at similar levels to the long isoform but unable to phosphorylate it. These data emphasise the requirement of the cytoplasmic domain of *BMPR2* in mediating functional activity. As interaction with Tctex-1 is disrupted by PPH causing mutations in *BMPR2*, further investigation of the role of the light chain in the regulation of *BMPR2* signalling is now required.

Program Nr: 2194 from 2003 ASHG Annual Meeting

**Pendrin Syndrome - A Complex Disease.** *T. Yang*<sup>1</sup>, *K. Kolln*<sup>1</sup>, *S. Enerback*<sup>2</sup>, *R. Smith*<sup>1</sup>. 1) Department of Otolaryngology and Interdepartmental PhD Program in Genetics, University of Iowa, Iowa City, IA 52242, USA; 2) Medical Genetics, Department of Medical Biochemistry, Goteborg University, Goteborg, Sweden.

Pendred syndrome (PDS) is the most common form of syndromic deafness. It is an autosomal recessive disorder characterized by severe-to-profound sensorineural hearing loss (SNHL), thyroid goiter and temporal bone malformations. Mutations in SLC26A4 are the major genetic cause of PDS, contributing approximately 50% to the PDS genetic load. An additional 10% of persons with PDS segregate mutations in FOXI1. This gene is an important regulator of SLC26A4 expression in the inner ear. Based on murine experiments, Foxi1 acts upstream of Slc26a4; homozygous mouse mutant knockouts of either gene show identical phenotypes (Hulander et al., 2003). In many families segregating a PDS phenotype, only a single disease-causing mutation is found in either FOXI1 or SLC26A4. This finding suggests that other genes modify the PDS phenotype. We hypothesize that many cases of PDS represent double heterozygosity. To test this hypothesis, we are screening the promoter region of SLC26A4 for mutations that may affect binding of FOXI1. In addition, we are completing a yeast-two-hybrid study to identify interacting partners of Foxi1, using as preys E9 and P9 cochlear libraries. This research was supported by R01-DC02842 (RJHS).

**DFNB1-Causing Mutations Outside the Coding Region of GJB2.** *H. Azaiez<sup>1</sup>, R. Tom Taggart<sup>2</sup>, I. Del Castillo<sup>3</sup>, S. Prasad<sup>1</sup>, C. Nishimura<sup>1</sup>, G. Van Camp<sup>4</sup>, R.J.H. Smith<sup>1</sup>.* 1) Dept Otolaryngology, Univ Iowa, Iowa City, IA, USA; 2) Dept of Pediatrics, School of Medicine, SUNY at Buffalo, NY, USA; 3) Unidad de Genetica Molecular, Hospital Ramon y Cajal, Madrid, Spain; 4) Dept of Medical Genetics, University of Antwerp, Antwerp, Belgium.

Mutations in GJB2, encoding the protein Connexin 26 (Cx26), account for half of recessive deafness in many different populations, making deafness at the DFNB1 locus one of the worlds most common genetic conditions. Frequently, only a single deafness-causing allele variant of the coding region of GJB2 is identified. This finding is not uncommon and implies the presence of a missed mutation outside the coding region of GJB2 or coincidental carrier status in a person with deafness of another etiology. To address this question, we screened 1088 deaf persons lacking two non-complementary mutations of GJB2. Of these persons, 100 carried a single GJB2 allele variant of exon 2; 988 persons carried two wild-type alleles. Within the group of 100 carriers, we found compound heterozygosity for IVS1+1G-A (n=5) and (GJB6-D13S1830) (n=7), the two most frequently reported DFNB1 mutations outside the coding region of GJB2. Of the remaining 88 deaf persons in whom a second GJB2 deafness-causing mutation could not be found, 37 were 35delG heterozygotes. Based on a 35delG carrier rate of 2.5%, in a cohort of 1076 deaf persons we would anticipate identifying 27 deaf 35delG carriers. This discrepancy suggests the existence of at least one additional DFNB1-causing mutation outside the coding region of GJB2. To screen for this putative mutation, we sequenced GJB6, the promoter and intron of GJB2, and select genomic regions conserved between human and mouse. No obvious disease-causing mutations were identified. We then typed several SNPs uniformly distributed throughout the interval bounded by GJB2 and CRYL1 in these patients and in 35delG homozygotes and normal-hearing controls. Comparison of the SNP distribution in these three populations suggests the existence of at least one additional DFNB1-causing mutation outside the coding region of GJB2. This research was supported by R01-DC02842 (RJHS).

**Relative frequencies of the mitochondrial A1555G and 961 del T mutations in the 12SrRNA gene in a large sample of deaf probands from the United States.** *K. Arnos<sup>1</sup>, X.J. Xia<sup>2</sup>, G. Norris<sup>1</sup>, B. Landa<sup>2</sup>, R. Falk<sup>3</sup>, R. Erdenetungalag<sup>4</sup>, B. Dangasuren<sup>4</sup>, W.E. Nance<sup>2</sup>, A. Pandya<sup>2</sup>.* 1) Dept Biology, Gallaudet Univ, Washington, DC; 2) Dept of Human Genetics, Virginia Commonwealth Univ, Richmond, VA; 3) Dept of Medical Genetics, Cedar Sinai Med Ctr. Los Angeles; 4) Maternal & Child Health Research Ctr,Ulaanbataar, Mongolia.

Mitochondrial mutations are being recognized to be of growing importance as a cause for deafness. The A1555G mutation in the 12SrRNA gene is a well established cause of deafness due to aminoglycoside ototoxicity. Its prevalence varies in different ethnic groups, with high frequencies among deaf from East Asia and Spain, and a lower frequency in the US. Since some individuals with the A1555G mutation do not develop hearing loss (HL) while others develop HL without exposure to aminoglycosides, additional genetic modifiers have been suggested to alter the phenotype. Casano et al.(1999) reported a second mutation in the 12SrRNA gene, the deletion of a thymidine at bp 961 also associated with aminoglycoside ototoxicity, independent of A1555G mutation. Others have reported the co-occurrence of both mutations in deaf probands from China (Bacino 1995, Li 2002). Screening of 1173 anonymized newborn blood spots in Texas yielded incidences of 0.08 and 0.59 for the A1555G and 961 del T mutations respectively (Tang, 2002). The hearing status of these newborns, however, is not known. We have determined the frequency of these variants in 721 DNA samples in a national repository of deaf probands from the US along with samples from 713 deaf probands from Mongolia. We did not identify a single proband with the A1555G mutation but the 961 del T mutation occurred with a frequency of 1.2% in the US. A matrilineal transmission was evident in one of the families. A definite history of aminoglycoside use was not present in most. In contrast, the incidence of 961 del T in Mongolia was 2.8%, and 16 of these subjects also carried the A1555G mutation. These data raise questions about the independent contribution of the 961 del T mutation to HL. A prospective study on newborns with both physiologic and molecular screen for HL, may help resolve some of these questions.

**Second DFNA11 mutation found in *MYO7A* gene.** *M.W.J. Lijndijk*<sup>1</sup>, *E. van Wijk*<sup>2</sup>, *E. Krieger*<sup>3</sup>, *A.M.L.C. Bischoff*<sup>2</sup>, *C.W.R.J. Cremers*<sup>2</sup>, *F.P.M. Cremers*<sup>1</sup>, *H. Kremer*<sup>2</sup>. 1) Human Genetics, Univ Med Cntr Nijmegen, Nijmegen, Netherlands; 2) Otorhinolaryngology, Univ Med Cntr Nijmegen, Nijmegen, Netherlands; 3) Center for Molecular and Biomolecular Informatics, Univ Med Cntr, Nijmegen, Netherlands.

Myosin IIVA is an unconventional myosin that has been implicated in Usher syndrome type 1B, in non-syndromic recessively inherited (DFNB2) and dominantly inherited (DFNA11) hearing impairment. Unconventional myosins are actin-based motor molecules that transduce chemical energy derived from ATP into a force enabling them to move along actin filaments.

A family presenting with autosomal dominant bilateral hearing loss most progressive in the higher frequencies was studied. The clinical data suggested DFNA11 to be the type of hearing loss inherited in this family. Linkage analysis confirmed this and mutation analysis of the *MYO7A* gene was performed.

When compared to the published sequence 11 changes were found. Seven polymorphisms were found in the protein coding sequence of the gene and three polymorphisms were intronic changes that were predicted not to cause significantly altered splicing. A c.1373 AT transversion that is heterozygously present in all affected family members, co segregates with the disease and was not found in 300 control individuals. The nucleotide change results in the amino acid substitution N458I.

N458 is located in a region of the myosin VIIA motor domain that is highly conserved throughout species and myosins. To estimate the likelihood that the observed N458I mutation is indeed responsible for the patients symptoms, a molecular model of myosin VIIA was built based on the known structure of the myosin II heavy chain from *Dictyostelium discoideum*. In the model, N458 is a conserved residue that is part of the switch II -helix and fulfills an important structural role by attaching the helix to the preceding switch II loop. In the model, the N458I mutation has severe effects.

**A novel connexin 26 (GJB2) mutation in a case of sensorineural hearing loss, keratoderma and knuckle pads.** *N. Leonard<sup>1</sup>, A.L. Krol<sup>2</sup>, S.M. Hasse<sup>1</sup>, K. Sprysak<sup>1</sup>, M.J. Somerville<sup>1</sup>*. 1) Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada; 2) Oregon Health and Science University, Portland, OR, USA.

We report on an eight-year-old girl who developed striate linear lesions of keratoderma on the palms and knuckle pads on the dorsum of her fingers. Striate linear lesions were developing on the soles. She had mild hyperkeratosis over one elbow. She showed no evidence of restricting lesions or diffuse keratoderma as seen in Vohwinkel syndrome (MIM 124500). Her teeth, hair and nails were normal with no evidence of leukonychia. She was diagnosed with a non-progressive congenital mild sloping to severe sensorineural hearing loss bilaterally. She otherwise was healthy. There are no other individuals in family history with hearing loss or dermatologic changes. In particular her parents and sister were unaffected. Sequencing of the connexin 26 (GJB2) gene showed a single mutation G59R (175G>C) in exon 2. This mutation had not been described before, however a similar mutation within the same codon (G59A) had previously been reported to cause an autosomal dominant syndrome of hearing loss and palmoplantar hyperkeratosis without knuckle pads (Heathcote K et al., J Med Genet 2000;37:50-51). The G59R mutation seen in our case was not detected in either parent. Paternity was confirmed by a genome-wide multiplex analysis of 15 tetranucleotide repeat loci. Our patient shows overlap of clinical features with palmoplantar keratoderma with deafness (MIM 148350). She does not show severe features as seen in Vohwinkel (Deafness, congenital, with keratopachydermia and constrictions of fingers and toes - MIM 124500). Both of these conditions have shown connexin 26 mutations. Bart-Pumphrey (Knuckle Pads, leukonychia, and sensorineural deafness - MIM 149200) shares features of deafness and knuckle pads similar to our patient. She however did not have leukonychia. To date a gene mutation has not been described for this condition or for conditions involving knuckle pads. The connexin 26 mutation in our patient suggests there may be overlap amongst the keratodermas, stemming from different mutations in the connexin 26 (GJB2) gene.

**GJB2 mutations in Indian families with Autosomal Recessive Nonsyndromic Sensorineural Hearing Loss (ARNSHL).** *R. Vijaya, M. Kabra, P.S.N. Menon, R.C. Deka\**. Genetics Unit, Department of Pediatrics and \*Department of Otorhinolaryngology, All India Inst Medical Sci, New Delhi, India.

Mutations in the gene GJB2 are responsible for more than 50% cases of prelingual nonsyndromic deafness in Caucasian populations. The aim of the study was to characterize the GJB2 mutations in Indian families with Autosomal Recessive Nonsyndromic Sensorineural Hearing Loss (ARNSHL). Totally 437 deaf individuals belonging to 202 families with ARNSHL (123 multiplex families and 79 simplex families) were screened for mutations in the coding region of the GJB2 gene and 211 ethnically matched controls were screened to estimate the carrier frequency of the various mutant alleles. GJB2 mutations account for 28.8% of the mutant alleles in the multiplex families, 12% of the mutant alleles in the simplex families and 25.7% of all GJB2 deafness alleles studied. Six previously reported mutations W24X, W77X, Q124X, del313-326, 35delG & V37I and one novel mutation E147X were identified. In addition, three polymorphisms R127H, V153I and R165W were also detected. The most common mutation was W24X contributing to 87.55% of the GJB2 mutated alleles and was found to be a major cause for nonsyndromic deafness in Indian families with a carrier frequency of 1.4% in general population. The high prevalence of W24X indicates a founder effect rather than a mutational hot spot in the Indian population. The most common mutation in Caucasian population, the 35delG, occurs as a rare allele but the other common mutations 167delT, R143W and 235delC were not found. All individuals with GJB2 mutations had significant prelingual, usually bilateral, sensorineural, non-progressive and severe to profound hearing loss. The present study reveals that approximately 25% of the ARNSHL families including the simplex cases are due to mutations in the GJB2 gene and indicate that mutations in GJB2 gene are an important contribution to nonsyndromic recessive deafness in Indian ethnic groups. Though the other mutations are less frequent, the high prevalence of W24X helps in evolving a strategy to screen for the mutations in the GJB2 gene in patients with ARNSHL as part of the genetic testing.

**Heterozygous mutation in promoter region of SPR results in Dopa-responsive dystonia.** *U. Muller<sup>1</sup>, N. Blau<sup>2</sup>, D. Goriounov<sup>2</sup>, J. Bitsch<sup>1</sup>, S. Hummel<sup>3</sup>, D. Steinberger<sup>1,4</sup>.* 1) Inst Human Genetics, Justus-Liebig Univ, Giessen, Germany; 2) Division of Clinical Chemistry and Biochemistry, University Childrens Hospital, Zurich, Switzerland; 3) Neurologische Unisversitatsklinik Freiburg, Freiburg, Germany; 4) Center for Human Genetics Ingelheim, Ingelheim, Germany.

In about 50 % of patients with Dopa-responsive dystonia (DRD) no mutations in the GCH1 gene can be detected. GCH1 codes for GTP-cyclohydrolase I, the rate-limiting enzyme in the biosynthesis of tetrahydrobiopterin. We argued that at least some of the GCH1-negative cases of DRD are caused by mutations in other genes involved in the biosynthesis of biopterin. One of these genes, SPR, codes for sepiapterin reductase (SR [E.C.1.1.1.153]) that converts 6-pyruvoyl-tetrahydropterin (PTP) to tetrahydrobiopterin (BH4). We tested for mutations in SPR in 95 GCH1-negative DRD cases and found the heterozygous base exchange ga at position 13 of the promoter region of one patient, a 26 year-old woman. She had developed fixed pes equinovarus during childhood. The symptoms disappeared before puberty and at age 15 she noticed abnormal movements of 4th and 5th digits of the left hand, at age 19 she developed gait anomalies with internal rotation, adduction, and extension of the left leg. Presently, the major findings are gait anomalies primarily caused by dystonia of left leg, tremor of the left arm, dystonia of digits 4 and 5 of the left hand, and involvement of the vocal cords. There was a positive response of signs and symptoms to L-dopa (3x200mg Madopar/die). Analysis of SR in patients fibroblasts showed significant reduction in activity consistent with a pronounced negative effect of the SPR mutation on SR production.

Program Nr: 2201 from 2003 ASHG Annual Meeting

**Region specific changes of gene expression in a transgenic mouse model for Huntington disease.** *F. Oyama, H. Miyazaki, N. Sakamoto, N.R. Jana, S.E. Kotliarova, N. Nukina.* Lab CAG Repeat Dis/Molec Neuro, RIKEN Brain Science Inst, Saitama, Japan.

Huntington disease is a hereditary neurodegenerative disorder caused by expansion of the CAG repeat in the exon 1 of the huntingtin (htt) gene. We established transgenic line expressing truncated form of human Nhtt (tNhtt) with 180 poly Q tract fused with EGFP (HD180) and analysed altered gene expressions by GeneChip technology profiling from brain of HD180. We found that a large number of gene expressions in the brain are changed in HD180 comparing with their control littermates. Majority of differentially expressed genes were down-regulated. We further confirmed the altered gene expression especially related to the nervous system function by RT-PCR assay, followed by in situ hybridization and found that vasopressin, oxytocin, enkephalin, prodynorphin, substance P mRNAs and several ESTs are down-regulated in the HD180. The results suggest that these changes are due to the region-specific degeneration and dysfunction of hypothalamic nuclei as well as striatum in the brains of HD180.

**Tyrosinase gene mutations in oculocutaneous albinism 1 (OCA1): definition of the phenotype.** *R. King<sup>1</sup>, J. Pietsch<sup>1</sup>, J.P. Fryer<sup>1</sup>, S. Savage<sup>1</sup>, M.J. Brott<sup>1</sup>, I. Russell-Eggitt<sup>2</sup>, C.G. Summers<sup>3</sup>, W.S. Oetting<sup>1</sup>.* 1) Medicine/Institute of Human Genetics Univ Minnesota, Minneapolis, MN; 2) Great Ormond Street Hospital for Children, London, UK; 3) Ophthalmology, Univ Minnesota, Minneapolis, MN.

Oculocutaneous albinism (OCA) is a common human genetic disease resulting from mutations in at least ten different genes. OCA1 results from mutations of the tyrosinase gene and presents with the life-long absence of melanin pigment after birth (OCA1A) or with the development of minimal-to-moderate amounts of cutaneous and ocular pigment (OCA1B). Other types of OCA have variable amounts of cutaneous and ocular pigment. We hypothesized that white hair at birth indicates OCA1 and tested this hypothesis in a sample of 120 probands with OCA who had white hair at birth. We found that 102(85%) of the probands had OCA1. Most probands were compound heterozygotes, and 169 of the 204 OCA1 tyrosinase gene alleles had identifiable mutations, while 35(17%) had cryptic or hidden mutations that were not identified with standard sequencing techniques that analyzed the coding, splice junction or proximal promoter regions of the gene. The cryptic mutations were more common in OCA1B (24/35,69%) than in OCA1A (11/35,31%). Tyrosinase gene mutations were distributed across exons 1-4 with few in exon 5. Seven probands with no tyrosinase gene mutations were found to have OCA2 with one or two P gene mutations, and eleven probands had no mutations in either the tyrosinase or the P genes. We conclude that the presence of white hair at birth is a useful clinical tool that suggests OCA1 in the initial evaluation of a child or adult with OCA, but that some probands with OCA2 may also have this presentation, indicating that molecular analysis of the tyrosinase and P genes are necessary for accurate diagnosis. Furthermore, the presence of cryptic mutations of the tyrosinase gene, particularly in OCA1B, suggests that more complex mutation mechanisms of this gene exist in OCA.

**Loss-of-function of an *N*-acetylglucosaminyltransferase, POMGnT1, in muscle-eye-brain disease.** *K. Kobayashi*<sup>1</sup>, *H. Manyá*<sup>2</sup>, *T. Toda*<sup>1</sup>, *T. Endo*<sup>2</sup>. 1) Div Functional Genomics, Dept Post-Genomics and Diseases, Osaka Univ Grad Sch Med, Osaka, Japan; 2) Glycobiol Res Gr, Tokyo Metropolitan Inst of Gerontol, Tokyo, Japan.

Muscle-eye-brain disease (MEB) is an autosomal recessive disorder characterized by congenital muscular dystrophy, ocular abnormalities, and lissencephaly. Mammalian *O*-mannosyl glycosylation is a rare type of protein modification that is observed in a limited number of glycoproteins of brain, nerve, and skeletal muscle. We isolated a human cDNA for protein *O*-mannose 1,2-*N*-acetylglucosaminyltransferase 1 (POMGnT1). POMGnT1 participates in the synthesis of *O*-mannosyl glycan, a modification that is known to be a laminin-binding ligand of -dystroglycan. Although 13 disease-causing mutations of the *POMGnT1* gene have been identified in patients with MEB, only the protein with the most frequently observed splicing site mutation has been studied previously. This protein was found to have no activity. In the present study, we expressed the remaining mutant POMGnT1 and found all mutants lost activity entirely. The results clearly demonstrate that MEB is inherited as a loss-of-function of POMGnT1. Since the MEB phenotype overlaps substantially with those of Fukuyama-type congenital muscular dystrophy (FCMD) and Walker-Warburg syndrome (WWS), these three diseases are thought to result from a similar pathomechanism, post-translational disruption of dystroglycan-ligand interactions. Our findings would propose a novel pathomechanism, glycosylation, on muscular dystrophy as well as neuronal migration disorder. Future studies will expand this new glycopathology field.

**Male infertility due to germ cell apoptosis in mice lacking the thiamin carrier, *Tht1*: a new insight into the critical role of thiamin in spermatogenesis.** *K. Oishi*<sup>1</sup>, *M. Barchi*<sup>2</sup>, *B.D. Gelb*<sup>1</sup>, *G.A. Diaz*<sup>1</sup>. 1) Department of Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Cell Biology Program, Memorial Sloan-Kettering Cancer Center, New York, NY.

Thiamin-responsive megaloblastic anemia (TRMA) is an autosomal recessive syndrome with megaloblastic anemia, sensorineural deafness, and diabetes mellitus. The disease gene, *SLC19A2*, encodes the high affinity thiamin carrier, THT1. A mouse model of TRMA lacking functional *Slc19a2* has been generated and showed a similar phenotype when maintained on a thiamin-free diet. In mice maintained on standard chow, an unexpected male-specific sterility phenotype was observed, while females reproduced normally. We characterized the testis-specific effects of absence of the high-affinity thiamin transporter, Tht-1. Null males were infertile due to aspermia and found to have hypoplastic testes (*Slc19a2*<sup>-/-</sup>: 36.31.5 vs. *Slc19a2*<sup>+/+</sup>: 72.54.0 mg;  $P < 0.00001$ ). Morphologic and testis-specific gene expression analyses revealed that spermatocyte development was completely arrested at the pachytene stage under conditions of standard thiamin intake, while tissues affected in the syndrome (pancreatic  $\beta$ -cell, hematopoietic cells, auditory nerve) maintained normal function. Using TUNEL and phospho-histone-H3 staining assays, we confirmed the stage of spermatogenesis arrest and determined that the lack of Tht1 in testis caused germ cell apoptosis. After thiamin deficiency challenge for 16 days, the apoptotic cell loss extended to earlier stages of germ cells but spared Sertoli and Leydig cells. Intraperitoneal injection of high-dose thiamin (1 mg/day for 20 days) was effective in reversing the spermatogenesis failure and mature sperm were produced, suggesting that the absence of the thiamin carrier could be overcome by diffusion-mediated transport at supranormal thiamin concentrations. These observations demonstrated that male germ cells, particularly those beyond the blood-testis barrier, are more susceptible to apoptosis triggered by intracellular thiamin deficiency than any other tissue type. The findings highlight an unexpected and critical role for thiamin transport and metabolism in spermatogenesis.

**Exclusion of candidate genes in four families with autosomal dominant multiple epiphyseal dysplasia.** *M. Czarny-Ratajczak*<sup>1,3</sup>, *P. Rogala*<sup>4</sup>, *A. Latos-Bielenska*<sup>3</sup>, *L. Ala-Kokko*<sup>1,2,5</sup>. 1) Center for Gene Therapy, Tulane University, New Orleans, LA; 2) Department of Medicine, Tulane University, New Orleans, LA; 3) Department of Medical Genetics, Karol Marcinkowski University of Medical Sciences, Poznan, Poland; 4) Department of Orthopedics, Karol Marcinkowski University of Medical Sciences, Poznan, Poland; 5) Collagen Research Unit, Biocenter and Department of Medical Biochemistry and Molecular Biology, University of Oulu, Finland.

Multiple epiphyseal dysplasia (MED) is a disorder of the skeletal system limited to cartilage and manifested as disturbance in the development of the epiphyses. The first symptoms of MED occur in childhood and include joint pain, waddling gait as well as restriction of joint mobility. Thus far mutations in five genes, COL9A1, COL9A2, COL9A3, COMP and MATN3 have been identified in MED. However, mutations in these five genes are only found in about half of the patients. We studied here four families with autosomal dominant MED. The families had six to fourteen affected members. A detailed clinical and radiological examination was performed on all the probands and affected family members. Four intragenic markers and nine microsatellite markers were used for linkage analysis of the COL9A1, COL9A2, COL9A3, COMP, MATN3 genes in four families. Linkage analysis of markers showed recombination between the five candidate genes and the phenotype in three families. Recombinations were observed between the COL9A1, COL9A2 and COMP genes in the fourth family. The proband of the fourth family was analyzed for mutations in the COL9A3 and MATN3 genes. Mutation analysis consisted of sequencing of the candidate exons, exon 2 of the MATN3 gene and exons 2 to 4 of the COL9A3 gene. The analysis failed to identify mutations. The results suggest the presence of additional locus/loci for MED. We are currently performing genome-wide screening in these families to identify new loci for MED.

**Novel mutations in EVC and EVC2 in Ellis-van Creveld Syndrome.** *M. Galdzicka<sup>1</sup>, G.E. Graham<sup>2</sup>, J.F. Cai<sup>1</sup>, S. Patnala<sup>1</sup>, M.G. Hirshman<sup>1</sup>, E.I. Ginns<sup>1</sup>.* 1) Brudnick Neuropsych Res Inst, Psychiatry Dept, Univ of Massachusetts Med Sch, Worcester, MA; 2) Childrens Hospital of Eastern Ontario and Univ of Ottawa, Ottawa, Ont. Canada.

Ellis-van Creveld (EvC) syndrome is an autosomal recessive disorder presenting with dwarfism, polydactyly, ectodermal dysplasia, congenital heart abnormalities (~60%) and rarely nephronophthisis. The absence of EVC gene mutations in some patients suggested genetic heterogeneity in this syndrome. Involvement of a second gene was demonstrated by identification of mutations in exons 17 and 18 of the contiguous EVC2 gene in an Ashkenazi individual with EvC, and subsequently confirmed by reports of mutations in Gypsy, Ecuadorian and Brazilian families. We now report mutations in both EVC and EVC2 in a 20-month-old caucasian EvC patient of French and English Canadian origins. The proband has marked shortening of the extremities (but normal chest circumference), radiographic features compatible with EvC, mild facial dysmorphism (midface hypoplasia with a glabellar nevus flammeus), abnormal frenulae, peg teeth with abnormal enamel, absence of one index finger phalanx, bilateral 4th finger clinodactyly, bilateral post-axial polydactyly, nail hypoplasia, renal dysplasia and an unbalanced AVSD requiring a bidirectional Glenn shunt. The EVC gene (117.1 kb) has multiple RNAs up to ~7,500 nucleotides in length, has four transcription start sites, 21 coding exons, three alternative 3' untranslated regions and tissue specific alternative splicing. The EVC2 gene (166.4 kb) has multiple RNAs up to ~4,800 nucleotides in length, has one transcription start site, 21 coding exons, two alternative 3' untranslated regions and alternative splicing characterized by long and short variants of several exons. Sequence analysis of EVC and EVC2 in this patient showed a deletion in exon 8 and an acceptor splice site mutation of exon 20 in one allele of the EVC gene, and a donor splice site mutation of exon 13 of the EVC2 gene. Inheritance of these mutations was confirmed by sequence analysis of parental alleles. Thus, the possibility of mutations in either or both EVC and EVC2 must be considered in counseling for this disorder.

**The Mutation P392L of the Sequestosome 1 Gene in Paget's Disease of Bone is frequent in the French Population.**

*L Michou<sup>1, 7</sup>, JL. Laplanche<sup>2</sup>, P. Orcel<sup>3</sup>, P. Hilliquin<sup>5</sup>, P. Quillet<sup>6</sup>, T. Bardin<sup>1,3</sup>, E. Vicaut<sup>4</sup>, JM. Launay<sup>2</sup>, F.*

*Cornelis<sup>1,7</sup>.* 1) CLinical Genetics Unit, Lariboisière Hospital, Paris, France; 2) Bichemistry department, Lariboisière Hospital, Paris, France; 3) Rheumatology department, Lariboisière Hospital, Paris, France; 4) Clinical Research Unit, Lariboisière Hospital, Paris, France; 5) Rheumatology department, Sud-Francilien Hospital, Evry, France; 6) Biology department, Sud-Francilien Hospital, Evry, France; 7) Clinical Genetics Unit, Sud-Francilien Hospital, Evry, France.

**Purpose.** Paget's disease of bone (PDB) is a late onset chronic disease of the skeleton that affects 3 % of the Caucasian population aged over 55 years. Paget's lesions exhibit an excess of bone turn-over and can be treated by biphosphonates, which inhibit osteoclast resorption. PDB often segregates as an autosomal dominant trait. Genetic heterogeneity has been demonstrated, with 7 PDB loci reported. At the PDB3 locus on chromosome 5, Laurin et al. (1) identified the first of Paget's genes, sequestosome 1 (SQSTM1), part of the RANK (Receptor Activator of NF-kB) pathway involved in osteoclast regulation. A recurrent mutation (P392L) was found in 16 % of the sporadic PDB patients and 46 % of the familial cases in the French Canadian population. This mutation was also found in the British population, in 9 % of sporadic and 19 % of familial cases, as well as two additional mutations: E396X and IVS7+1 G-A in 6 % and 1 % of the familial cases, respectively. Genetic testing in families carrying the PDB mutation is clinically relevant, leading to early radiological diagnosis at the clinically asymptomatic stage, when complications can be prevented by early treatment. The aim of this study was to evaluate the frequency of those SQSTM1 mutations in the French Caucasian population.

**Patients and methods.** Nineteen French Caucasian patients with sporadic PDB underwent genetic testing. The search for the P392L mutation relied on a Sac-I PCR-RFLP assay. Sequencing was performed for the two others mutations.

**Results.** Only the P392L mutation of SQSTM1 was detected, in 2 patients out of 19 (11%).

**Conclusion.** The P392L mutation of the SQSTM1 gene is frequent in the French Caucasian PDB population. Genetic testing of PDB patients in France is indicated, aiming at early diagnosis to prevent complications in relatives of patients carrying the mutation. **Analysis of *FLNA* as a candidate gene for Terminal Osseous Dysplasia with Pigmentary Defects and Focal Dermal Hypoplasia.** *D. Sharma*<sup>1</sup>, *C. Bacino*<sup>2</sup>, *I.B. Van den Veyver*<sup>1, 2</sup>. 1) Obstetrics and Gynecology; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

We previously described a novel, male-lethal X-linked dominant developmental disorder, TODPD (Terminal Osseous Dysplasia with Pigmentary Defects), and mapped the candidate locus to Xq27.3-qter. Affected females have distinct facial anomalies in conjunction with skeletal (limb) deformities and skin pigmentation defects. This phenotype overlaps with that of Goltz syndrome (Focal Dermal Hypoplasia; FDH), another X-linked dominant disorder with limb anomalies and skin defects. A recent report describes missense and in-frame deletions in exons 3, 5, 11, 22, and 29 of the *FLNA* gene in four congenital malformation disorders (OPD1, OPD2, MNS, and FMD) with skeletal and limb abnormalities. *FLNA*, encoding a 280 kDa protein (Filamin A) that regulates re-organization of the actin cytoskeleton, comprises 48 coding exons and localizes to the candidate region of TODPD in Xq28. To test *FLNA* as a candidate gene for TODPD and FDH, we performed PCR amplification followed by direct sequencing of exons 3, 5, 11, 22, and 29 from peripheral blood leukocyte or lymphoblast derived DNA of 8 unrelated FDH patients and 2 TODPD females from a previously reported large multigenerational pedigree. An unaffected female from the TODPD family and an anonymous random male and female sample were included as normal controls. Results so far do not reveal any mutations in these exons in TODPD and Goltz patients. Analysis of the other coding exons of *FLNA* in these patients is in progress.

**Mutational, histologic and gene expression analysis in spondyloepiphyseal dysplasia tarda (SEDL).** *G.E. Tiller<sup>1</sup>, C. Baird<sup>1</sup>, T. Aigner<sup>2</sup>*. 1) Department of Pediatrics, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Pathology, University of Erlangen-Nuremberg, Erlangen, Germany.

Spondyloepiphyseal dysplasia tarda (SEDL) is an X-linked skeletal dysplasia characterized by disproportionate short stature and early-onset osteoarthritis. The SEDL gene, *sedlin*, is located at Xp22.2, and a transcribed retropseudogene exists on chromosome 19. Mutational analysis of *sedlin* in SEDL patients has revealed over 25 unique mutations, including a recurrent splice mutation (IVS3+5GA) and a hot spot for recurrent 2-5bp deletions in exon 5. With rare exceptions, all mutations are predicted to generate premature stop codons and truncate the protein product. Immunohistochemical analysis of residual articular SEDT cartilage revealed normal staining for cartilage collagens. Real-time RT-PCR experiments failed to demonstrate nonsense-mediated mRNA decay of mutant *sedlin* transcripts. However, immunohistochemical analysis of cultured SEDL fibroblasts, using an anti-*sedlin* antibody, demonstrated no staining above background, compared to controls. These data suggest that truncated *sedlin* proteins are unstable and are degraded, and that the pseudogene, while transcribed, is not translated. We hypothesize that the pathophysiology of SEDL may involve an intracellular pathway previously unappreciated in chondrocytes, whose dysfunction interferes with extracellular matrix homeostasis.

**Hallervorden Spatz syndrome (HSS) in two families from southern Italy: a clinical and genetic study.** *I. Cirò*

*Candiano<sup>1</sup>, F. Annesi<sup>1</sup>, D. Civitelli<sup>1</sup>, P. Tarantino<sup>1</sup>, P. Spadafora<sup>1</sup>, S. Carrideo<sup>1</sup>, E.V. De Marco<sup>1</sup>, F. Naso<sup>3</sup>, D. Consoli<sup>3</sup>, A. Quattrone<sup>1,2</sup>, G. Annesi<sup>1</sup>.* 1) Inst of Neurol Sciences, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, University of Magna Graecia, Catanzaro, Italy; 3) Azienda Ospedaliera, Vibo Valentia, Italy.

**Background and Objective.** Hallervorden Spatz syndrome (HSS) is an autosomal recessive disorder characterized by dystonia, parkinsonism, and iron accumulation in the brain. Many patients with HSS have mutations in the gene encoding pantothenate kinase2 (PANK2) located in chromosome 20p13. The aim of the current study was to investigate patients with HSS for mutations in the PANK2 gene. **Material and Methods.** Patients with HSS were classified as having the classic disease (characterized by early onset with rapid progression) or atypical HSS (later onset with slow progression). Primers were designed to amplify each of the seven exons of PANK2. Polymerase-chain-reaction-amplified DNA was sequenced in both the forward and the reverse directions and compared with control DNA. **Results.** One patient from the first family was affected by classic disease while two individuals in the other family presented with atypical disease. In all patients T2-weighted magnetic resonance imaging of the brain showed a specific pattern of hyperintensity within the hypointense medial globus pallidus. A novel mutation in the PANK2 gene in homozygous state was identified in two patients from the family with atypical HSS. This mutation was a missense mutation (C1069T) which resulted in an amino acid substitution (Arginine to Tryptophane at position 357), and was not found in 100 control chromosomes. No mutation in the coding regions of the PANK2 gene was found in the family with classic HSS. **Conclusion.** We identified a new mutation in the PANK2 gene in two patients with atypical HSS whereas no mutation was found in one patient with classic HSS. Our findings suggest that classic form of HSS is not always due to mutations in the coding region of the PANK2 gene.

**Agenesis of the corpus callosum and frontonasal dysplasia associated with a balanced translocation that disrupts the *FLJ21877* gene.** *J.J. Dowling*<sup>1</sup>, *M. Kato*<sup>2</sup>, *J. Chung*<sup>2</sup>, *D.K. Manchester*<sup>3</sup>, *E. Sujansky*<sup>3</sup>, *D.H. Ledbetter*<sup>2</sup>, *W.B. Dobyns*<sup>2</sup>. 1) Neurology, CHOP, Philadelphia, PA; 2) Human Genetics, U of Chicago, Chicago, IL; 3) Genetics, Children's Hospital, Denver, CO.

Agenesis of the corpus callosum (ACC) is a common human brain malformation, with an incidence estimated at 0.25 per 1000 livebirths. It can occur in isolation or be associated with other brain and somatic abnormalities. Among the latter, craniofacial anomalies are particularly common. While many different syndromes with ACC are known, fewer than ten causative genes have been identified.

Here we describe disruption of a novel gene in a male patient with ACC, frontonasal dysplasia, and a balanced translocation t(2;15)(p21;q14). Clinical evaluation documented mild mental retardation, hypertelorism, broad forehead, midfacial hypoplasia, prominent jaw, radioulnar synostosis, and mild webbing of fingers and toes. The father has a similar facial appearance, but chromosome analysis was not performed. Physical mapping of the translocation using FISH, southern blot analysis and PCR from somatic cell hybrids led to localization of the 2p breakpoint within an intron of a previously uncharacterized gene designated *FLJ21877*. The 15q breakpoint was localized to a region that contained no known or predicted genes. *FLJ21877* is a gene of unknown function that was initially identified as a large cDNA highly enriched in brain (Nagasi et al., DNA Res 2000;7:347). It codes for an approximately 2 kb transcript with 12 alternatively spliced exons that span greater than 300 kb of genomic DNA. Given the location of the breakpoint within the coding region, we believe alteration of *FLJ21877* expression is likely responsible for the abnormal phenotype in this patient via either haploinsufficiency or a dominant negative effect. *FLJ21877* is therefore one of the first genes implicated in ACC associated with frontonasal dysplasia.

**APRATAXIN, THE CAUSATIVE GENE FOR EARLY-ONSET ATAXIA WITH OCULAR MOTOR APRAXIA AND HYPOALBUMINEMIA (EAOH), IS A MEMBER OF SSDNA REPAIR MACHINERY. -IMPLICATION OF IMPAIRED DNA REPAIR SYSTEMS IN NEURODEGENERATION-. H. Date<sup>1</sup>, S. Igarashi<sup>1</sup>, T. Takahashi<sup>1</sup>, H. Takano<sup>1</sup>, O. Onodera<sup>1</sup>, M. Nishizawa<sup>1</sup>, Y. Sano<sup>2</sup>, S. Tsuji<sup>3</sup>. 1) Dept Neurology, BRI Niigata Univ, Niigata, Japan; 2) Dept Neurology, Yamaguchi Univ, Yamaguchi, Japan; 3) Dept Neurology, Univ of Tokyo, Tokyo, Japan.**

Early-onset ataxia with ocular motor apraxia and hypoalbuminemia (EAOH/AOA1) is one of the most frequent form of autosomal recessive spinocerebellar ataxias in the Japanese population. This disease has unique clinical presentations characterized by ocular motor apraxia, cerebellar ataxia, peripheral neuropathy and hypoalbuminemia. Interestingly, some of these clinical presentations overlap with those of Friedreich's ataxia and ataxia-telangiectasia. By a positional cloning approach, we have recently identified the causative gene for EAOH/AOA1 and designated as aprataxin (APTX). Aprataxin has two major mRNA species as a result of alternative splicing of exon 3. Although both forms of aprataxin mRNAs are expressed at comparable levels in various human tissues, the long form of APTX (LAPTX) has been found to be a major form in human central nervous system based on Western blot analysis. These results suggest that the loss of function of LAPTX underlies the neurodegenerative processes in this disease. The N-terminus portion of LAPTX shows a homology to the polynucleotide kinase-3'phosphatase (PNKP), which plays an important role in single-strand DNA (ssDNA) break repair in collaboration with XRCC1, DNA polymerase  $\beta$ , poly (ADP-ribose) polymerase and DNA ligase III. Here we demonstrate that long form APTX interact with XRCC1 in a yeast two-hybrid system and a co-immunoprecipitation experiment. Furthermore, poly (ADP-ribose) polymerase has been shown to co-immunoprecipitate with LAPTX, but not with the short form of APTX. These observations strongly suggest that the LAPTX is involved in single strand DNA break repair as a member of a complex together with XRCC1 and poly (ADP-ribose) polymerase, and that the gradual accumulation of DNA damages underlies the neuronal dysfunction in EAOH/AOA1.

**Microarray analysis of compensatory changes in gene expression in Frataxin deficient mouse brain.** *S-H. Choi<sup>1</sup>, D. Tentler<sup>1</sup>, M.M. Santos<sup>2</sup>, M. Pandolfo<sup>2</sup>, D.H. Geschwind<sup>1</sup>*. 1) Program in Neurogenetics, Department of Neurology, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Department of Medicine, Centre Hospitalier de le Universite de Montreal, Hopital Notre-Dame, Montreal, PQ, Canada.

Friedreichs ataxia is one of the most common forms of autosomal recessive ataxia and is caused by reduced expression of the frataxin gene. The clinical features include neurological, cardiovascular, skeletal and endocrine abnormalities. Frataxin deficiency leads to iron accumulation within mitochondria, increasing free radical production by fenton chemistry, and altering oxidative metabolism. The direct pathway(s) by which this results in cell death are not known. We applied microarray analysis of gene expression to identify specific pathways affected by reduced frataxin level, which lead to neurodegeneration in Friedreichs ataxia. To identify the early alterations caused by frataxin deficiency and the cellular compensatory response to this stress, we analyzed gene expression in mice expressing 25 to 36% of wild-type frataxin levels, which have no observable neurological phenotype or neuropathology (Miranda et al., 2002). A custom 10K-element cDNA microarray was probed with cDNA from 4 replicates of 3 brain regions affected in Friedreichs ataxia. We identified upregulation of a number of genes in a variety of signaling pathways and biological processes. The absence of neurodegeneration in these mice has allowed us to identify the specific cellular response to frataxin deficiency, rather than detecting changes due to cell loss or inflammation. In this context, the differentially expressed genes obtained in our study likely reflect the true cellular dysregulation and compensation for frataxin loss, as the cell struggles for continued survival. These putative compensatory pathways become novel therapeutic targets.

**Molecular studies of chorein, the protein altered in chorea-acanthocytosis.** C. Dobson-Stone, A. Velayos, A.P. Monaco. Wellcome Trust Centre for Human Genetics, Oxford University, Roosevelt Drive, Oxford OX3 7BN, UK.

Chorea-acanthocytosis (ChAc) is an autosomal recessive neurological disorder, whose characteristic features include hyperkinetic movements and abnormal red blood cell morphology, caused by alteration of the *CHAC* gene on 9q21. To date, 71 different mutations, distributed throughout the gene, have been reported. *CHAC* encodes a large, novel protein called chorein. It shares significant homology with the yeast protein Vps13p, implicated in protein sorting. No known localisation signals, structural motifs or domains are detected in this protein. We have undertaken the functional characterisation of chorein, focussing our efforts on i) its subcellular localisation and ii) the identification of proteins that interact with it.

i) An N-terminal portion of chorein, overexpressed in bacteria as a glutathione-S-transferase-fusion protein and then cleaved and purified, was used to raise a polyclonal antibody (anti-chor1) in rabbit. Using Western blot analysis and immunofluorescence techniques, we have shown that this antibody detects chorein. To determine the subcellular location of chorein, we tagged chorein with myc, FLAG or EGFP epitopes. Chorein was visualised using immunofluorescent labelling in a number of mammalian cell lines after transient (cos-1, HEK293, HeLa and MRC5) or stable (HEK293) transfection, and it was detected in vesicular-like structures.

ii) In order to identify proteins that may interact with chorein, we have performed yeast two-hybrid analyses using different regions of chorein as baits. We have identified several putative interactors, including MAP kinase kinase kinase 7 interacting protein 2 (MAP3K7IP2, TAB2). Co-immunoprecipitation and GST-pulldown techniques will be used in the further analysis of this interaction.

These studies provide the first steps in the functional characterisation of chorein that will eventually provide some clues as to how the absence of chorein leads to the clinical features seen in ChAc.

**Prevalence of SCA14 and spectrum of PKC mutations in a large panel of ataxia patients.** *D.H. Chen<sup>1</sup>, P.J. Cimino<sup>2</sup>, L. Ranum<sup>4</sup>, I. Yabe<sup>5</sup>, H. Sasaki<sup>5</sup>, M. Matsushita<sup>2</sup>, T.D. Bird<sup>1,3</sup>, W.H. Raskind<sup>2,3</sup>.* 1) Depts of Neurology and; 2) Medicine, Univ Washington; 3) MIRECC, SVAMC, Seattle, WA; 4) Institute of Human Genetics, Univ Minnesota; 5) Dept of Neurology, Hokkaido Univ Graduate School of Medicine, Japan.

SCA is a group of hereditary neurodegenerative disorders with at least 20 autosomal dominant forms. Nine of the 10 SCAs for which the genes are known result from nucleotide expansions. We recently discovered a new genetic mechanism for SCA mutations in protein kinase C gamma (*PRKCG*; PKC; MIM 179680), a serine/threonine kinase primarily expressed in the central nervous system. Of 89 SCA samples screened, four different mutations in *PRKCG* were identified in one sporadic case and three familial cases, including the Japanese family in which SCA14 was originally described. To investigate the prevalence of SCA14, the spectrum of mutations in *PRKCG*, and genotype-phenotype correlations, we screened a large collection of samples from ataxia patients who were negative for SCA DNA expansions. Of the 236 samples, 78 were familial, 134 were apparently sporadic and 24 were not specified. Because all previously detected mutations were clustered in exon 4, we speculated that it may be a hotspot for mutations in SCA14. Therefore, we initiated the screening with exon 4. A six base-pair deletion, predicting omission of lysine 100 and histidine 101, was found in a sporadic case. The mutations all affect highly conserved residues in the regulatory region of the gene (H101Y, S119P, Q127R, G128D, and del. 100K-101Y). Axial myoclonus was a feature in early onset cases in the Japanese family, but all other affected individuals manifested uncomplicated ataxia. To date, exon 4 mutations in *PRKCG* account for 3/149 familial and 2/176 sporadic or unknown ataxias without an identified repeat expansion. Although SCA14 represents a small fraction of ataxia cases, it is reasonable to sequence exon 4 in this subset of ataxia patients. Ongoing screening of the remaining 17 exons will further our understanding of the genotype-phenotype correlations and the functional role of PKC in SCA14. These new results will be presented.

**A splice-junction mutation in Sbf2 gene causes autosomal recessive Charcot-Marie-Tooth disease (CMT4B2) in a family from southern Italy.** *F. Conforti<sup>1</sup>, R. Mazzei<sup>1</sup>, A. Patitucci<sup>1</sup>, P. Valentino<sup>2</sup>, A. Magariello<sup>1</sup>, T. Sprovieri<sup>1</sup>, F. Bono<sup>2</sup>, J. Senderek<sup>3</sup>, A. Gabriele<sup>1</sup>, G. Peluso<sup>1</sup>, R. Nistico<sup>2</sup>, C. Bergmann<sup>3</sup>, M. Muglia<sup>1</sup>.* 1) ISN-CNR, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) Department of Human Genetics, Aachen University of Technology, Aachen, Germany.

Autosomal recessive Charcot-Marie-Tooth disease type 4 (CMT4) comprises a group of clinically and genetically heterogeneous disorders of the peripheral nervous system. At least 10 loci are responsible for autosomal recessive CMT and six genes have identified so far. In this study, we report a small pedigree with a recessive form of CMT (CMT4B) from Southern Italy in which the linkage to chromosome 11q23 was excluded. There were six individuals in two generations with two affected subjects. We performed haplotype analysis using highly polymorphic microsatellite markers located on chromosome 11p15. Subsequently, the coding region of the Sbf2 gene was sequenced by using primers flanking intron-exon boundaries. Using 7 microsatellite markers located on chromosome 11 (D11S4186, D11S909, D11S932, D11S4149, D11S1329, D11S1999 and D11S1346), the haplotype analysis revealed a suggestive linkage to chromosome 11p15. Direct sequencing of the Sbf2 gene showed a GC exon 32/intron 32 splice-junction mutation. In the current study we identify a splicing mutation in SBF2 gene in a small family with CMT4B linked to chromosome 11p15. Mutational screening of Sbf2 revealed a homozygous mutation in the splice-junction donor-acceptor site of exon 32 (+1GC) in the affected patients. The variation was also confirmed by digestion with restriction enzyme Alu I, which cleaved the wild-type PCR product of 370 bp into 210 bp and twice 80 bp digestion fragments. The corresponding region of the Sbf2 gene in our affected patients was cleaved into 210 bp, 80 bp, 68 bp and 12 bp digestion fragments. This mutation was absent in 100 control chromosomes examined. This is the first finding of a mutation in the Sbf2 gene that alters the correct splicing of the gene. Furthermore, these data confirm that mutations in the Sbf2 gene are causative of CMT4B2.

**Generation and characterization of mouse models of spastic paraplegia caused by mutation of SPG4 gene. C.**

*Fassier<sup>1</sup>, A. Tarrade<sup>1</sup>, D. Charvin<sup>1</sup>, S. Betuing<sup>1</sup>, N. Fonknechten<sup>2</sup>, G. Millet<sup>1</sup>, S. Courageot<sup>1</sup>, N. Roblot<sup>1</sup>, A. Dierich<sup>3</sup>, J. Melki<sup>1</sup>.* 1) Molecular Neurogenetics Laboratoty, INSERM E-223, Evry, France; 2) Genoscope, CNS, Evry; 3) IGBMC, Illkirch, France.

Hereditary spastic paraplegia (HSP) is a progressive neurodegenerative disorder characterized by axonal degeneration of corticospinal tracts and posterior columns. The most prevalent form of autosomal dominant HSP is linked to the SPG4 locus encoding spastin (Sp), a member of the AAA protein family. In order to elucidate the pathophysiology of HSP, mouse models have been generated. A targeting vector that includes two loxP sites flanking exons 5 to 7 of the murine Sp gene (Spf) and a NeoR gene was constructed. Through homologous recombination, (Spf/+) heterozygous mice were created. To generate mice carrying heterozygous deletion of Sp exons 5 to 7 in all cell types, (Spf/+) mice were crossed to CMV-Cre transgenic mice. Mice heterozygously deleted in all cell types (Spdel/+) are viable and fertile. Transcript analysis revealed a marked reduction of full-length (FL) Sp transcripts in brain of mutant mice associated with truncated transcripts lacking exons 5 to 7 when compared to control. Surprisingly, less than the expected half dose of FL Sp transcripts was observed in brain of (Spdel/+) mice when compared to that found in other mutant tissues. To determine whether HSP was caused by defect of Sp in neurons, transgenic mice expressing the Cre recombinase transgene under the control of the NSE promoter were used (NSE-Cre). Using Rosa 26 reporter mice, Cre-mediated activity of -galactosidase was observed in spinal cord and in several regions of the brain including motor cortex, the region affected in HSP. (NSE-Cre,Spf/+) mice were generated and transcript analysis of Sp revealed results similar in brain to those found in (Spdel/+) mice. Molecular analysis of these two mice models suggest that, in brain, Sp could play a direct or indirect role on its transcription. Further characterization of both types of mutant mice including behavioural and morphological studies should allow us to validate mutant mice as mouse models of HSP and should provide new insights into pathogenic mechanisms leading to HSP.

**LMNA, MTMR2 and GDAP1 : implication in autosomal recessive Charcot-Marie-Tooth disease.** A. DeSandre-Giovannoli<sup>1</sup>, T. Hamadouche<sup>2</sup>, R. Bernard<sup>3</sup>, M. Tazir<sup>4</sup>, M. Chaouch<sup>5</sup>, I. Boccaccio<sup>1</sup>, V. Delague<sup>6</sup>, JM. Vallat<sup>7</sup>, C. Desnuelle<sup>8</sup>, A. Megarbane<sup>6</sup>, D. Grid<sup>9</sup>, N. Levy<sup>1,3</sup>. 1) INSERM U491, Genetique Medicale et Developpement, Marseille, France; 2) Institut Pasteur d'Algerie, Algiers; 3) Departement de Genetique Medicale, Hopital Timone, Marseille, France; 4) Service de Neurologie, CHU Ben-Aknoun, Algiers; 5) Service de Neurologie, CHU Mustafa, Algiers, Algeria; 6) Service de Genetique, Universit Saint-Joseph, Beyrouth, Lebanon; 7) Service de neurologie, Hopital l'Archet, Nice, France; 8) Neuropathologie, CHU Dupuytren, Limoges, France; 9) Genethon III, Evry, France.

Charcot-Marie-Tooth (CMT) disorders are the most frequent inherited peripheral neuropathies. Electrophysiological criteria serve to classify patients as presenting demyelinating (CMT1), axonal (CMT2) or intermediate neuropathies. Autosomal recessive forms are less frequent, more severe and early onset forms. We report homozygous mutations in LMNA, MTMR2 and GDAP1 causing respectively axonal (CMT2B1), demyelinating (CMT4B1) and mixed (CMT4A) neuropathies in families affected with autosomal recessive CMT. We identified the LMNA c.892C>T founder mutation segregating in 11 Algerian families affected with axonal CMT. MTMR2 sequencing revealed a nonsense change and a 1bp insertion, respectively in two families affected with a demyelinating phenotype. Finally, GDAP1 splicing and nonsense mutations in Algerian and Lebanese families, caused very severe mixed CMT. LMNA encodes Lamins A/C, major structural proteins of nuclear laminae. MTMR2 encodes a member of the myotubularin phosphatase multigenic protein family, with specific activity towards phosphatidylinositol 3-phosphate. On the other hand, GDAP1 structure and expression pattern locate it at the crossroads between gangliosides and Gluthatione S-Transferases diverse functions. While GDAP1 is mainly expressed in nervous tissues, LMNA and MTMR2 are ubiquitously expressed. Additionally, different mutations in LMNA cause a series of only partially related hereditary disorders. Unraveling the functional interplays underlying the pathophysiology of CMT diseases is today the main issue, focusing on the structure-function-phenotype relationships.

**Mutation analysis of the TSC2 gene in 23 TSC families from India.** *M. Ali*<sup>1</sup>, *M. Markandaya*<sup>1</sup>, *S.C. Girimaji*<sup>2</sup>, *A.K. Shukla*<sup>3</sup>, *S. Sacchidanand*<sup>4</sup>, *A. Kumar*<sup>1</sup>. 1) MRDG, Indian Institute of Science, Bangalore, Karnataka, India; 2) Dept. of Psychiatry, NIMHANS, Bangalore, India; 3) Department of Radiology, KIMS, Bangalore, India; 4) Department of Dermatology, Bangalore Medical College, Bangalore, India.

Tuberous sclerosis complex (TSC) is an autosomal dominant neuro-cutaneous disorder with loci on chromosome 9q34.3 (TSC1) and chromosome 16p13.3 (TSC2). Genes for both loci have been isolated and characterized. Pathologically, tuberous sclerosis complex is a disorder of cell proliferation, differentiation and migration. Clinical symptoms of TSC include cortical tubers, subependymal nodules, mental retardation, seizures, autism, shagreen patches and angiofibromas on the skin, cardiac rhabdomyomas, retinal hamartomas, ungual and peringual fibromas, and cysts and angiomyolipomas in the kidneys. More than 350 mutations have been reported in both TSC genes in patients mainly from the western and Japanese populations. However, there is no report on the mutation analysis of TSC genes in patients from the Indian population. We report here the mutational analysis of the TSC2 gene in 23 TSC families from India. Using PCR-SSCP and DNA sequence analyses, we have screened all 41 exons and promoter region of the TSC2 gene in seven familial and 16 sporadic TSC cases. We have identified a total of 12 mutations representing 25% and 75% of familial and sporadic cases respectively. Of these, eight mutations are novel. Of 12 mutations, 3 are deletions, 2 are insertions, 4 are missense, 2 are splice site and 1 is a nonsense mutation. In addition, we have also detected nine single-nucleotide polymorphisms (SNPs) in the TSC2 gene. Of these, three are novel SNPs. There was no correlation between the types of mutations (missense, nonsense, etc.) and the severity of the disease. The mutations were distributed across the gene without any clustering, suggesting that mutation analysis requires scanning of the complete coding sequence of the TSC2 gene (This work was financially supported by a grant from DBT, New Delhi to AK and SCG and a CSIR JRF to MA).

**The SPG3 disease gene atlastin: new mutations and the characterization of its murine orthologue.** A. Abel<sup>1</sup>, A. Hofer<sup>1</sup>, D. Del Turco<sup>2</sup>, S. Klimpe<sup>3</sup>, T. Deller<sup>2</sup>, G. Auburger<sup>1</sup>. 1) Section Molecular Neurogenetics, Department of Neurology, Johann Wolfgang Goethe University, Frankfurt/Main, Germany; 2) Institute for Clinical Neuroanatomy, Department of Neurology, Johann Wolfgang Goethe University, Frankfurt/Main, Germany; 3) Department of Neurology, Johannes Gutenberg University, Mainz, Germany.

Mutations in the large GTPase atlastin cause autosomal dominant spastic paraplegia. Atlastin is encoded in 15 exons and comprises 558 amino acids. In cooperation with clinical specialists around Germany we have performed a mutation screening by sequencing all coding exons and adjacent intron sequences in samples from 22 individuals or pedigrees, and identified two novel missense mutations. The F151S (ttt tct, exon 5) mutation, just two amino acids downstream from the conserved DxxG motif of the GTPase domain, was found in a 4-generation pedigree with DNA samples available from 10 affected and 7 unaffected individuals. A new MnlI restriction site resulting from this mutation was used to confirm complete cosegregation of the spastic paraplegia phenotype with the F151S mutation in this family and to exclude the mutation from 100 normal control chromosomes. The I315S (atc agc, exon 10) mutation was found in an affected individual with a positive family history, yet access to DNA samples of other family members could not be obtained.

We have also cloned and sequenced the murine Atlastin full-length cDNA. In situ hybridization of murine brain sections revealed atlastin expression in selected neuronal, but not glial cell populations. We will also present subcellular localization data derived from our current immunohistochemical studies of murine brain with a polypeptide antibody against a carboxy-terminal epitope.

**SOD1 Gene Mutations in Amyotrophic Lateral Sclerosis Italian Patients.** *C. Gellera<sup>1</sup>, D. Testa<sup>1</sup>, P. Passariello<sup>1</sup>, R. Mineri<sup>1</sup>, L. Morandi<sup>1</sup>, M. Sabatelli<sup>4</sup>, E. Munerati<sup>2</sup>, M. Corbo<sup>3</sup>, C. Mariotti<sup>1</sup>, V. Silani<sup>3</sup>, S. Di Donato<sup>1</sup>, F. Taroni<sup>1</sup>.* 1) Istituto Nazionale Neurologico IRCCS Carlo Besta, Milano, Italy; 2) Ospedale San Raffaele, IRCCS, Milano, Italy;; 3) Istituto Auxologico Italiano IRCCS, University of Milan Med. School, Milano, Italy; 4) Universit del Sacro Cuore, Roma, Italy.

Amyotrophic Lateral Sclerosis (ALS) is a progressive neurodegenerative disorder (incidence 1:100.000). Only a small percentage of patients (10%) shows an inherited form. Molecular studies have allowed to identified at least 8 loci (ALS1, 2, 4, 5, 6, ALSX, ALS-FTD and ALS-NFHC). The causative gene has been identified in 3: ALS1-SOD1, ALS2-Alsin and ALS-NFHC. Mutations in the SOD1 gene are present in 10-20% of familial cases with more than hundred mutations described so far. Our work has been focused to the identification of mutations in SOD1 gene in a cohort of Italian ALS patients. Previous studies have shown that the disease progression may be due by the specific SOD1 mutation, although a great variability in disease duration has been observed among and within families with the same mutation. A great variability in the percentage and distribution of SOD1 specific mutations has also been observed in populations with different ethnic backgrounds. We have screened 310 Italian patients including 54 familial cases and found mutations in 12/54 (22%) unrelated families and in 4/256 (1.5%) sporadic patients. Eight FALS patients carried previously described mutations in heterozygous form: A4V (4 families), L84F (3 families), and G93D (1 family), while the remaining 4 FALS patients carried different new mutations. In two sporadic patients we have found two previously described SOD1 gene mutations: the homozygous D90A mutation and the heterozygous I113T, respectively. In the two additional sporadic cases we have found new heterozygous mutations: A95T and V97L. It is interesting to note that 58% (7/12) of SOD1 mutated Italian FALS patients harbour two prevalent mutations. A subset of patients (95/310) have also been screened for deletions in SMN2 gene: we do not have found a significative number of patients with deletions respect to controls.

**A reduced activity of the Na-K ATPase is responsible for Familial Hemiplegic Migraine.** *G. Casari<sup>1</sup>, M. De Fusco<sup>1</sup>, P. Aridon<sup>1</sup>, L. Silvestri<sup>1</sup>, L. Atorino<sup>1</sup>, L. Rampoldi<sup>1</sup>, A. Ballabio<sup>3</sup>, R. Marconi<sup>2</sup>.* 1) Dept. of Neuroscience, San Raffaele Scientific Institute, Milan, Mi, Italy; 2) Div. of Neurology, Misericordia Hospital, Grosseto, Italy; 3) TIGEM, Naples, Italy.

Headache attacks and autonomic dysfunctions characterize migraine, a very common disabling disorder with a 12 percent prevalence in the general population of western countries. Approximately 20% of migraineurs experience aura, a visual or sensory-motor neurological dysfunction, which usually precedes or accompanies the headache. Although the mode of transmission is controversial, population-based and twin studies indicate that genetic factors are implicated, prevalently in migraine with aura. Familial hemiplegic migraine (FHM) is a hereditary form of migraine with aura and some degree of hemiparesis. Two chromosomal loci are associated to FHM: FHM1, on chromosome 19, and FHM2 on chromosome 1q21-23. Mutations of the alpha-1A subunit of the voltage gated calcium channel (CACNA1A) are responsible for FHM1. We narrowed the FHM2 locus by linkage analysis on two large Italian families affected by pure FHM. The new critical region covers a small area of 0.9 Mb in 1q23 and renders feasible a positional candidate approach. Furthermore, we demonstrate that mutations of the alpha 2 subunit of the Na,K pump are responsible for the familial hemiplegic migraine form associated to chromosome 1q23 (FHM2, MIM 602481). Functional data show that a putative pathogenetic mechanism is triggered by a loss-of-function of a single allele of the Na,K pump.

**Aprataxin mutations are not a significant cause of recessive ataxia in the Mexican Mestizo population. M.**

*Gomez*<sup>1</sup>, *L. Hern*<sup>1</sup>, *T. Ashizawa*<sup>2</sup>, *E. Alonso*<sup>3</sup>, *A. Rasmussen*<sup>3</sup>, *S.I. Bidichandani*<sup>1</sup>. 1) Dept Biochem & Molec Biol, Oklahoma Univ Health Sci Ctr, Oklahoma City, OK; 2) Neurology, UTMB Galveston, TX; 3) National Institute of Neurology, Mexico City, Mexico.

Friedreich ataxia is the most common recessive ataxia, accounting for 75% of all recessive ataxias among Indo-Europeans. East Asians and Native Americans do not develop Friedreich ataxia because they lack the mutagenic *FRDA* alleles that cause the abnormal GAA triplet-repeat expansion seen in the vast majority of patients. Recently it was shown that the most common cause of recessive ataxia in Japan includes loss-of-function mutations in the *APTX* gene that encodes aprataxin. *APTX* mutations were also shown to be the second most common cause of recessive ataxia in Portugal. We have previously shown that Friedreich ataxia accounts for approximately 10% of all recessive ataxias in the Mexican Mestizo population and that this is largely due to the preponderance of non-mutagenic Native American *FRDA* genes among this population. Given the phenotypic overlap between patients with *APTX* and *FRDA* gene mutations, as exemplified by the Japanese and Portuguese studies, we decided to evaluate the role of *APTX* mutations as a cause of recessive ataxia in the majority of Mexican Mestizo patients without *FRDA* mutations. We screened all seven exons of the *APTX* gene in 90 Mexican Mestizo recessive ataxia patients who had previously tested negative for Friedreich ataxia and found no disease causing mutations. A parallel analysis of 13 Caucasian recessive ataxia patients referred for Friedreich ataxia testing, but who tested negative for *FRDA* mutations, revealed one patient who was homozygous for the Portuguese founder *APTX* mutation (W279X). We detected two common polymorphisms previously described in the Portuguese population, consisting of deletions in poly(T) stretches preceding the acceptor splice sites of exons 4 and 6; 41.4% and 55.5% were heterozygous, respectively. These data indicate that *APTX* mutations are not a significant cause of recessive ataxia in the Mexican Mestizo population, and that the cause of their ataxia remains largely unknown.

Program Nr: 2224 from 2003 ASHG Annual Meeting

**Mutations in POMT1 are a rare cause of Walker Warburg Syndrome.** *S.C. Currier<sup>1</sup>, B.S. Chang<sup>1</sup>, C.K. Lee<sup>1</sup>, A. Hassan<sup>1</sup>, A.L. Bodell<sup>1</sup>, W.B. Dobyns<sup>2</sup>, C.A. Walsh<sup>1</sup>.* 1) Howard Hughes, Beth Israel Deaconess Medical Center, Department of Neurology, program in Neuroscience, and Harvard Medical School, Boston, MA, 02115, USA; 2) Department of Human Genetics, Neurology and Pediatrics, The University of Chicago, Chicago, IL, USA.

Walker Warburg Syndrome (WWS) is an autosomal recessive disorder of infancy diagnosed by hydrocephalus, agyria, retinal dysplasia, and congenital muscular dystrophy and characterized by over migration of cortical neurons. Previous work (D.B.Valero de Bernab et al, Am J Hum Genet, 2002) identified mutations in the o-mannosyl transferase, POMT1, in six out of thirty unrelated WWS families. In order to investigate the genetic cause of WWS we performed a 10 cm genome wide screen in seven additional families. None of these families demonstrate linkage to the POMT1 locus. We have begun sequencing the POMT1 gene in more than thirty new WWS patients. Our preliminary results have not yet revealed any POMT1 mutations suggesting that they are a rare cause of WWS. Supported by: NIH RO1 NS35129.

**Functional analyses of the *NIPA1* gene with dominant negative mutations in hereditary spastic paraplegia (SPG6) and mapping within the Prader-Willi/Angelman syndrome region.** *J-H. Chai*<sup>1</sup>, *S. Rainier*<sup>2</sup>, *J.K. Fink*<sup>2</sup>, *R.D. Nicholls*<sup>1</sup>. 1) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 2) Department of Neurology, University of Michigan, Ann Arbor, MI.

Hereditary spastic paraplegias (HSPs) are a genetically heterogeneous group of disorders characterized by progressive lower limb spasticity and weakness, with degeneration of the long corticospinal tracts. Although 20 spastic gait (SPG) loci have been genetically mapped, only 8 causative genes have been identified, and the molecular pathogenesis is poorly understood. SPG6, an autosomal dominant HSP, maps proximally within chromosome 15q11-q13, a region associated with Prader-Willi/Angelman syndromes (PWS/AS). We have identified a missense mutation (T45R) in a novel non-imprinted gene within the PWS/AS region, *NIPA1*, as responsible for SPG6. PWS/AS patients with chromosome deletions are hemizygous for *NIPA1* but do not show an SPG6 phenotype, indicating that T45R is a dominant negative mutation. Previous studies showed that *NIPA1* is predicted to encode a polypeptide with 9 transmembrane (TM) domains, suggestive of function as a transporter or receptor, and is highly expressed in mammalian brain. Extensive phylogenetic analysis now indicates that a *NIPA1*-related superfamily occurs in vertebrates, invertebrates, plants and bacteria. Immunohistochemical studies using anti-Nipa1 antisera shows expression of mouse *NIPA1* in neurons of cortex, hippocampus and spinal cord. In HeLa cell fusion gene studies, Nipa1-EGFP is in cytoplasmic vesicles that co-localization with -Lamp1 shows are late endosomes/lysosomes. Western blot analyses using anti-*NIPA1* and anti-GFP antisera with total or membrane protein fractions from transfected HeLa cells or mouse tissues detected ~90 kD and ~70 kD isoforms of Nipa1-EGFP or an ~40 kD Nipa1 protein, respectively, with an ~23 kD processed isoform in brain. Membrane fraction enrichment in each case confirms *NIPA1* functions as a TM protein. Identification of the *in vivo* subcellular localization, ligand, and development of animal models will reveal the role of *NIPA1* in axonal maintenance and may lead to therapeutic approaches in the HSP neurodegenerative disorders.

**MRI studies in SCA8: Cerebellar atrophy in unaffected expansion carriers partially explains reduced penetrance.** *J.W. Day, H. Liu, J. Dalton, Y. Ikeda, L.P.W. Ranum.* Inst Human Genetics, MMC 206, Univ MN, Mpls, MN.

We previously reported that an untranslated CTG expansion causes spinocerebellar ataxia type 8 (SCA8). In the large MN-A family we initially characterized ( $Z=6.8$ ,  $=0.0$ ), affected individuals have longer repeats (mean=117 CTGs,  $n=13$ ) than unaffected carriers (mean=90 CTGs,  $n=21$ ,  $p=1 \times 10^{-8}$ ). The reduced penetrance seen in the MN-A family also occurs in other SCA8 families. The observation of SCA8 expansions on control chromosomes suggests that in addition to the CTG repeat expansion other environmental or genetic factors may play a role in disease pathogenesis. To better characterize SCA8, and to investigate the causes of reduced penetrance, we performed volumetric, functional and spectroscopic MRI studies of genetically normal, clinically affected and unaffected expansion carriers in the MN-A family. Volumetric studies show that cerebellar volume of clinically affected SCA8 subjects ( $n=4$ ) is ~50% of normal ( $n=4$ ; mean=57cm<sup>3</sup> vs. 116cm<sup>3</sup>), without cerebral or brainstem atrophy. Functional MRI studies show a dramatic loss of cerebellar but not cerebral response during repetitive finger-tapping. Spectroscopy shows a significant reduction in the choline:creatine ratio in cerebellum and cerebrum. Combined MRI data may prove useful in comparing disease characteristics in unrelated SCA8 families.

A clinically unaffected MN-A family member with 140 CTGs, well above the family's pathogenic threshold, had an entirely normal clinical exam; on repeated evaluation she was able to stand or hop on one foot for >30s, and to tandem walk backwards and forwards, all with her eyes closed. Surprisingly her MRI showed dramatically (~50%) reduced cerebellar volume (53cm<sup>3</sup>). Marked cerebellar atrophy has also been seen in other clinically unaffected MN-A and Japanese expansion carriers. The use of MRI screening is clearly more sensitive than neurological exams in assessing the pathogenic effects of the SCA8 CTG expansion and may explain some of the apparent reduced penetrance that has been reported. Remarkably, significant cerebellar atrophy is not necessarily associated with ataxia in this slowly progressive degenerative disease.

**Genomic multiplication of the alpha-synuclein gene in three kindreds with familial Lewy body disease. M.**

*Farrer<sup>1</sup>, D. Wang<sup>1</sup>, S. Lincoln<sup>1</sup>, J. Kachergus<sup>1</sup>, W.J. Langston<sup>2</sup>, D. Dickson<sup>1</sup>.* 1) Neuroscience, Mayo Clinic Jacksonville, Jacksonville, FL; 2) Parkinson's Institute, Sunnyvale, CA.

The Spellman-Muenter (Iowa) kindred, in which affected individuals present clinically with early-onset parkinsonism, has been followed by Mayo Clinic for >90 years. At autopsy, patients have diffuse Lewy body disease. Recent genome-wide linkage analysis identified alpha-synuclein as the locus that segregates with disease ( $z=3.65$ , D4S2460). Genomic triplication of a 2.1Mb region results in alpha-synuclein gene/protein over-expression (Singleton, Farrer et al., 2003). We now present genetic, clinical and pathological comparisons of this and two unrelated kindreds with familial Lewy body disease, in which genomic multiplication of alpha-synuclein locus is causal for disease. Haplotype analysis demonstrates that these families are independent and not related to a common ancestral founder. Our analysis serves to highlight the intrinsic genomic instability of the region. mRNA and protein studies from brain tissue also clearly demonstrate upregulation of alpha-synuclein gene and protein expression. Genomic, clinical and pathological correlates of disease, within these families will be compared. The profound implications for idiopathic Lewy body disorders will be discussed.

**A complex neurocristopathy results from dominant-negative *SOX10* mutations that escape nonsense mediated decay.** *K. Inoue*<sup>1</sup>, *M. Khajavi*<sup>1</sup>, *T. Ohyama*<sup>1</sup>, *S. Hirabayashi*<sup>2</sup>, *J. Wilson*<sup>3</sup>, *J.D. Reggin*<sup>4</sup>, *P. Mancias*<sup>5</sup>, *I.J. Butler*<sup>5</sup>, *M.F. Wilkinson*<sup>6</sup>, *M. Wegner*<sup>7</sup>, *J.R. Lupski*<sup>1</sup>. 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Div Pediatric Neurology, Nagano Children's Hospital, Nagano, Japan; 3) Dept Neurology, Great Ormond Street Children's Hospital, London, UK; 4) Meritcare Neuroscience Clinic, Fargo, ND; 5) Dept Neurology, Univ of Texas Houston, Houston, TX; 6) Dept Immunology, University of Texas M.D. Anderson Cancer Center, Houston, TX; 7) Institut für Biochemie, Universität Erlangen-Nürnberg, Erlangen, Germany.

We investigated whether mutations in an open reading frame can dictate disease severity by a mechanism other than affecting the protein product. In particular, we investigated whether mutations that trigger the nonsense-mediated decay (NMD) RNA surveillance pathway and thereby decrease mRNA levels can decrease disease severity. As a test case, we examined patients with mutations in the *SOX10* gene, who have either a complex neurological disease phenotype termed PCWH (peripheral demyelinating neuropathy, central dysmyelinating leukodystrophy, Waardenburg syndrome and Hirschsprung disease) or a more restricted phenotype termed Waardenburg-Shah syndrome. We found that while all nonsense mutations that prematurely terminate translation generate mutant truncated *SOX10* proteins with potent dominant-negative activity, the more severe disease phenotype is prevented by mutations in internal exons, as these mutations elicit the NMD pathway. Our findings suggest that NMD functions to mitigate the harmful effects of a major subset of truncating mutations and thus has the potential to moderate the symptoms of many genetic diseases.

**Characterization of the breakpoints of PLP1 duplication in three cases of Pelizaeus-Merzbacher disease. A.**

*Iwaki<sup>1</sup>, J. Kondo<sup>1</sup>, M. Ototsuji<sup>1</sup>, K. Kurosawa<sup>2</sup>, Y. Fukumaki<sup>1</sup>.* 1) Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Kanagawa Children's Medical Center, Yokohama, Japan.

Duplication of the proteolipid protein gene (PLP1) on chromosome Xq22 causes Pelizaeus-Merzbacher disease (PMD), an X-linked disorder characterized by dysmyelination in the central nervous system. The size of the duplicated genomic segments varies, yet the orientation of duplication is tandem in the most cases. To understand the nature of PLP1 duplication, we examined the precise sequences of the duplication breakpoints of three newly identified PMD patients at nucleotide levels. The extent of duplication was examined using various PAC probes along the Xq22 region by interphase FISH. We mapped approximate location of the centromeric and/or telomeric ends of the duplicated segments by quantitative multiplex PCR using sequence-tagged site primers. After detecting the rearranged restriction fragments by Southern blot hybridization, junction fragments were amplified by either oligocassette-mediated PCR or inverse-PCR. Sequence analysis revealed that the duplicated segments, arranged in a head to tail manner, were estimated to be 245 kb, 285 kb and 565 kb in length. The telomeric ends resided in different repetitive elements, L1PA7, AluSp, and L1ME3B, and one of them was located in an X-chromosome specific low-copy repeat (LCR) rich region. There was no homology between the sequences around the centromeric and the telomeric ends except for three to five nucleotides of AT stretch in all three cases. Therefore, it is likely that non-homologous end joining causes PLP1 duplications in these cases.

**Cytoplasmic polyglutamine aggregates are associated with lysosomal proteases.** *K. Ishikawa<sup>1</sup>, T. Makifuchi<sup>2</sup>, H. Fujigasaki<sup>1</sup>, M. Li<sup>1</sup>, S. Toru<sup>1</sup>, T. Kato<sup>3</sup>, K. Nagashima<sup>4</sup>, N. Ohkoshi<sup>5</sup>, E. Kominami<sup>6</sup>, Y. Komatsuzaki<sup>7</sup>, H. Mizusawa<sup>1</sup>.*  
1) Dept Neurology, Tokyo Medical & Dental Univ, Tokyo, Japan; 2) Dept Laboratory Medicien, National Saigata Hospital, Niigata, Japan; 3) 3rd Dept Internal Medicine, Yamagata Univ, Yamagata, Japan; 4) Dept Molecular & Cellular Pathology, Hokkaido Univ, Sapporo, Japan; 5) Dept Neurology, Inst Clinical Medicine, Univ Tsukuba, Ibaraki, Japan; 6) Dept Biochemistry, Juntendo Univ, Tokyo, Japan; 7) Dept Internal Medicine, Hatsuishi Hospital, Chiba, Japan.

Polyglutamine diseases are a group of dominantly-inherited, progressive neurodegenerative diseases caused by expansions of CAG repeat that encode polyglutamine in causative genes. Mutant proteins form aggregations both in nucleus and cytoplasm of neurons, usually undergo degeneration. Although there is an ample evidence that nuclear aggregations of mutant protein is important for pathogenic mechanism of many polyglutamine diseases, nuclear aggregations are very few compared to cytoplasmic aggregations in some polyglutamine diseases, such as SCA2 and SCA6. This might imply that cytoplasmic aggregations could have pathogenic role different from nuclear aggregation. As the first step to elucidate the role of cytoplasmic aggregations, we studied human brains affected with either three polyglutamine diseases, Machado-Joseph disease (MJD; n=5), dentatorubral-pallidoluysian atrophy (DRPLA; n=2), SCA6 (n=5), and analyzed the subcellular location of cytoplasmic aggregates immunohistochemically. The polyglutamine aggregates were detected with anti-expanded polyglutamine antibody, 1C2, and the Golgi apparatus and lysosomal protease were detected with G58K (Sigma) and anti-cathepsin-D antibody, respectively. The cytoplasmic aggregates were more often seen in MJD and SCA6 brains compared to DRPLA. Cytoplasmic polyglutamine aggregates were colocalized with cathepsin-D, but not obviously with G58K. Cytoplasmic aggregates were not obviously labelled with anti-ubiquitin antibody. The present observation may indicate that cytoplasmic aggregates are formed in lysosomes. This process may be a common step in formation of aggregation in polyglutamine diseases.

**Linkage analysis in a large Israeli Bedouin kindred with a unique form of a congenital contractural syndrome.** *G. Narkis*<sup>1,2</sup>, *E. Manor*<sup>2</sup>, *D. Landau*<sup>2</sup>, *K. Elbadour*<sup>2</sup>, *R. Carmi*<sup>2</sup>, *R. Ofir*<sup>1</sup>, *O. Birk*<sup>1,2</sup>. 1) Department of Molecular Genetics, Ben-Gurion University of the Negev, Beer-Sheva, Israel; 2) Genetics Institute, Soroka Medical Center, Ben-Gurion University of the Negev, Beer-Sheva, Israel.

We have recently described a new lethal form of an autosomal recessive multiple contractural syndrome in a large Israeli Bedouin kindred. The phenotype is lethal in the neonatal period and is unique in the presence of a markedly distended urinary bladder. In the present study we set out to determine the genetic locus harboring the gene defective in this disease. We excluded linkage to two known candidate regions associated with autosomal recessive arthrogyrosis (5q35 related to arthrogyrosis multiplex congenita in a large Israeli-Arab inbred family, and 9q34 in the Finnish type of lethal arthrogyrosis). We then performed Genome-wide linkage analysis using the ABI PRISM Linkage Mapping Set. Analysis of 400 polymorphic markers demonstrated linkage to a 6 cM homozygosity region between markers D12S1604 and D12S83 on chromosome 12q13. The maximum Lod score obtained was 3.5 at a recombination fraction of 0. Based on recombination events, the interval harboring the disease-associated locus was further narrowed to a chromosomal region spanning 6.5 Mb between D12S1618 and D12S1072. The linkage established provides means for molecular prenatal diagnosis of the disease in the affected families. Identification of the specific gene defect within the defined region is underway.

**Loss of Neto1, a component of the NMDA receptor complex, is associated with decreased synaptic plasticity and impaired extinction of memories.** *D. Ng<sup>1</sup>, A. Sertie<sup>1</sup>, R.K. Szilard<sup>1</sup>, G.M. Pitcher<sup>2</sup>, S. Clapcote<sup>3</sup>, L.V. Kalia<sup>2</sup>, M.W. Salter<sup>2</sup>, J.C. Roder<sup>3</sup>, M.A. Cortez<sup>2</sup>, R.R. McInnes<sup>1</sup>.* 1) Prog in Devel Biol and; 2) Brain & Behav, Hosp for Sick Children and; 3) Lunenfeld Res Instit, Toronto ON, Canada.

Neto1 & Neto2 are neuronal proteins with two CUB domains and an LDLa domain located extracellularly, and a cytoplasmic tail. Mouse Neto1 & Neto2 have overlapping embryonic and adult expression, being most abundantly expressed in the cerebral cortex and hippocampus, which is essential for memory. The brain of Neto1<sup>-/-</sup> mice is grossly & histologically normal but the mice have myoclonic seizures & defects in some axon projections. To define the functions of Neto1, we first sought its cytoplasmic binding partners. Since Neto1 localizes to the postsynaptic density (PSD) of synapses, and has a C-terminal PDZ binding ligand, we predicted that Neto1 binds to PSD-95, a PSD scaffolding protein. We confirmed this prediction by 2-hybrid assays and co-IPs from crude synaptosomal fractions. Since the NMDA receptor is also assembled by PSD-95, we hypothesized that Neto1 associates with this receptor, which is critical for activity-dependent synaptic plasticity in the hippocampus. Neto1 and components of the NMDA receptor co-IP, and Neto1 interacts directly with the NR1 subunit of the receptor, as shown by 2-hybrid and co-IP studies. To determine whether NMDA receptor function is disrupted in Neto1<sup>-/-</sup> mice, we measured LTP, a test of synaptic strength, in hippocampal slices, and identified a decrease in LTP amplitude. To test whether the LTP defect impairs memory, we examined Neto1 mutants in the Morris water maze. Neto1<sup>+/-</sup> and Neto1<sup>-/-</sup> mice acquired new memories as well as Neto1<sup>+/+</sup> mice, but had difficulty extinguishing memories, a phenomenon seen in some patients with psychiatric disorders. We conclude that 1) Neto1 is a component of the NMDA receptor complex and directly binds NR1; 2) Neto1<sup>-/-</sup> mice have defects in synaptic plasticity; 3) Neto1 is required for memory extinction; 4) human NETO1 is a candidate for CNS diseases, particularly the bipolar disorder locus at 18q22, epilepsy, and other disorders affecting the synapse.

Program Nr: 2233 from 2003 ASHG Annual Meeting

**Pro-survival effects of wild-type huntingtin *in vivo*.** *B.R. Leavitt, D. Rogers, J. vanRaamsdonk, C.J. Opina, E. Chan, C.L. Wellington, M.R. Hayden.* CMMT, Univ British Columbia, Vancouver, BC, Canada.

A pro-survival function for huntingtin was first postulated by Nasir and colleagues in 1995, based on the presence of neurodegeneration in mice heterozygous for deletion of the Hdh gene. We developed cell culture based assays in which we model the pro-survival effects of huntingtin in several types of cell death. These assays allow us to elucidate the cellular mechanisms by which wild-type huntingtin exerts its pro-survival effects. In addition to our *in vitro* studies we have found that over-expression of wild-type huntingtin confers dramatic protection against caspase activation and apoptotic neurodegeneration in transgenic mice. Following kainic acid-induced seizures, YAC transgenic mice expressing 2-3 times the endogenous levels of wild-type htt averaged approximately 50-fold less degenerating hippocampal neurons than control animals (81 vs. 3708,  $p < 0.006$ ). Significantly less hippocampal caspase activation was also evident by DEVDase assay in transgenic mice compared to wild-type mice (14.5 vs. 20.8,  $P = 0.02$ ). Transgenic mice that over-express the mutant form of huntingtin are not protected. Activation of caspases and cleavage of full-length huntingtin leads to decreased neuronal huntingtin levels and apoptotic death of hippocampal neurons following kainic acid-induced seizures. This neuronal cell death is completely blocked by ZVAD-fmk an inhibitor of caspases. These data provide *in vivo* evidence that huntingtin levels can modulate neuronal sensitivity to excitotoxic neurodegeneration. We propose that reduced levels of wild-type huntingtin and the resultant loss of pro-survival huntingtin function may contribute to the increased vulnerability of striatal neurons to excitotoxic degeneration in Huntingtons disease.

**Genotype-phenotype correlation of hereditary sensory neuropathy type 4: Extension of the phenotype. C.**

*Oddoux*<sup>1</sup>, *C. Maayan*<sup>3</sup>, *R. Cilio*<sup>4</sup>, *F. Axelrod*<sup>2</sup>. 1) Div Human Genetics, New York Univ Sch Medicine, New York, NY; 2) Pediatrics, New York Univ Sch Medicine, New York, NY; 3) Hadassah Hospital, Mt Scopus, Jerusalem, Israel; 4) Ospedale Pediatrico Bambino Gesù, Piazza S. Onofrio, Rome, Italy.

Hereditary sensory and autonomic neuropathies (HSAN) are a group of genetic disorders with overlapping characteristics. HSAN types 2, 3, 4, and 5 are inherited as autosomal recessive traits. Mutations in the *IKAP* gene have been associated with HSAN type 3 (also known as familial dysautonomia) and mutations in the *NTRK1* gene (nerve growth factor receptor) have been associated with HSAN type 4 (also known as CIPA). The genes responsible for HSAN types 2 and 5 have yet to be discovered.

The overlap in phenotypic characteristics of these disorders can make their delineation difficult. HSAN 4 is distinguished from the other disorders in the group by a decreased ability to sweat. Some patients classified as having HSAN 4 by these criteria have a milder phenotype retaining partial pain perception and partial ability to sweat. In an effort to correlate diagnostic criteria used to delineate HSAN 4 with genetic causative agents, we sequenced the *NTRK1* gene in a series of patients characterized with HSAN type 4 including some that had what appeared to be a milder phenotype. All seventeen exons and intron-exon boundaries were sequenced. Not all patients classified as having HSAN4 had detectable mutations. Mutations were detected in some patients displaying the milder phenotype and some patients with the classical phenotype had no detectable mutations. Our results are consistent with a broader phenotypic spectrum for HSAN4 and genetic etiologies for this disorder other than *NTRK1* coding region mutations.

**Full-length DRPLA protein suppresses CREB- and p53- dependent transcriptional activation.** *T. Shimohata<sup>1</sup>, K. Ogura<sup>1</sup>, S. Naruse<sup>1</sup>, S. Igarashi<sup>2</sup>, T. Sato<sup>3</sup>, O. Onodera<sup>2</sup>, M. Nishizawa<sup>1</sup>, S. Tsuji<sup>4</sup>.* 1) Department of Neurology, Brain Research Institute, Niigata University; 2) Resource Branch for Brain Disease Research, Center for Bioresource-based Researches, Brain Research Institute, Niigata University, Niigata, Japan; 3) Animal Resources Branch, Center for Bioresource-based Researches, Brain Research Institute, Niigata University, Niigata, Japan; 4) Department of Neurology, University of Tokyo, Graduate School of Medicine, Tokyo, Japan.

At least nine neurodegenerative diseases, including dentatorubral pallidoluysian atrophy (DRPLA), have been known to be caused by expanded CAG repeats encoding polyglutamine (polyQ) stretches. Recently, it has been demonstrated that interference with CREB-dependent transcription due to the binding of expanded polyQ stretches with transcriptional co-activators, such as TATA-binding protein associated factor (TAFII130) or CREB-binding protein (CBP), is involved in the pathogenetic mechanisms underlying neurodegeneration. It remains, however, unclear whether full-length DRPLA proteins have physiological functions on transcriptional regulation. To investigate the effects of DRPLA proteins on transcriptional regulation, we performed a reporter assay (dual luciferase assay) using cultured cells expressing full-length or truncated DRPLA proteins containing 19 or 82 glutamines, and found that full-length DRPLA proteins suppressed CREB-dependent transcriptional activation. There are no apparent differences of the suppression levels between the cells expressing DRPLA proteins containing 19 or 82 glutamines. We also found that p53-dependent transcriptional activation was suppressed by full-length DRPLA proteins, while AP1- or NF $\kappa$ B-dependent transcriptional activation was not suppressed. Taken together, these results raise the possibility that physiological function of DRPLA proteins is the transcriptional regulation that depends on CREB or p53.

**Autosomal dominant cerebellar ataxia with sensory neuropathy maps to the spinocerebellar ataxia 25 (SCA25) locus on chromosome 2p15-p21.** *G. Stevanin<sup>1</sup>, N. Bouslam<sup>1</sup>, E. Broussolle<sup>3</sup>, L. Ravaux<sup>1</sup>, A. Boland<sup>4</sup>, A. Durr<sup>1,2</sup>, A. Brice<sup>1,2</sup>.* 1) INSERM U289-NEB, Institut Federatif des Neurosciences, Paris, France; 2) Departement de Genetique, Cytogenetique et Embryologie, AP-HP, Groupe hospitalier Pitie-Salpetriere, Paris, France; 3) Service de Neurologie, Hopital Neuro-chirurgical Pierre Wertheimer, Lyon, France; 4) Centre National de Genotypage, Evry, France.

Autosomal dominant cerebellar ataxias constitute one of the most clinically, neuropathologically and genetically heterogeneous group of neurodegenerative disorders. Approximately 50-80% of the families do not have mutations in genes known to be implicated in spinocerebellar ataxias (SCA). Numerous SCA loci have also been mapped, often in single families, but the responsible genes have not been identified yet. This suggests further genetic heterogeneity. We have ascertained 18 individuals from a large French family in which cerebellar ataxia and prominent sensory neuropathy segregated as an dominant trait. Interfamilial variability was great regarding age at onset (17 months to 39 years), severity and the clinical picture, ranging from sensory neuropathy to Friedreichs ataxia-like phenotype. After excluding known SCA mutations, linkage was detected, in a genome wide screen, with markers on chromosome 2p, thereby defining a new locus that we designated SCA25. For confirmation of linkage and fine mapping of the genetic interval, 18 additional markers were tested. A maximum two-point lod score of 3.15 was obtained at D2S2378. Haplotype analysis defined a critical 12.6-cM-region between D2S22174 and D2S2736. This interval contains several genes that could be responsible for the disease. One of these genes, CRIPT, encodes a post-synaptic protein. No mutations were found in its entire coding region, excluding it as a candidate. Furthermore, CAG repeat expansions are often involved in SCA pathogenesis, but no pathological expansions were found at the protein or at the DNA level using the 1C2 antibody and the Repeat Expansion Detection method, respectively. The gene responsible for SCA25 remains to be determined.

**Mutation of the Paired-like Homeobox 2B gene (PHOX2B) in congenital central hypoventilation syndrome**

**(CCHS): vertical transmission and phenotype/genotype correlations.** *D. Trochet<sup>1</sup>, K. Waters<sup>2</sup>, H. Trang<sup>3</sup>, B. Laudier<sup>1</sup>, L. de Pontual<sup>1</sup>, A. Munnich<sup>1</sup>, C. Gaultier<sup>3</sup>, S. Lyonnet<sup>1</sup>, J. Amiel<sup>1</sup>.* 1) INSERM U393, Hopital Necker, Paris, France; 2) Respiratory Support Service, The Children's Hospital at Wesmead, Sydney, Australia; 3) Service de Physiologie, Hopital Robert Debre, Paris, France.

CCHS (Ondine's curse, MIM209880) is a life-threatening disorder involving an impaired ventilatory response to hypercarbia and hypoxaemia. This core phenotype is associated with lower penetrance anomalies of the autonomic nervous system (ANS) including Hirschsprung disease (Haddad syndrome, MIM142623) and tumours of the sympathetic nervous system. Considering that the development of ANS reflex circuits is Phox2b-dependent in mice, we showed that most CCHS cases are ascribed to mutations of its human ortholog PHOX2B\*. We further screened the PHOX2B gene in a series of 43 patients including 30 isolated CCHS, 13 Haddad syndrome, and 3 patients with CCHS and neuroblastoma or ganglioneuroma. Heterozygous de novo PHOX2B mutations were found in 24/30 sporadic CCHS and 8/13 Haddad syndrome cases respectively, suggesting that isolated CCHS and Haddad syndrome are allelic conditions at the PHOX2B locus. Most PHOX2B mutations consisted in 5-9 alanine expansions within a 20 alanine tract likely to result from non-homologous recombination (28/32). The four remaining mutations were frameshift mutations resulting in an elongated (3/4) or shortened putative protein (1/4) with a preserved homeodomain. Although no genotype/phenotype correlation can be established as far as the length of the polyalanine expansion is concerned, frameshift mutations may predispose to tumors, as opposed to polyalanine expansions. Finally, we identified a 5-alanine expansion of the PHOX2B gene in a familial case where the affected father transmitted a stable mutant allele to his affected daughter further supporting an autosomal dominant inheritance with de novo PHOX2B mutations at the first generation. Combined with our expression study, our data support the crucial role of PHOX2B in the patterning of the autonomous ventilation system and ANS in human.\*Nat Genet 2003;33:459-61.

**An intragenic modifier of hereditary spastic paraplegia due to spastin gene mutation suggests a role for cyclin-dependent kinase 5 in HSP pathogenesis.** *I.K. Svenson<sup>1</sup>, M.T. Kloos<sup>1</sup>, P.C. Gaskell<sup>1</sup>, M.A. Nance<sup>2</sup>, J.Y. Garbern<sup>3</sup>, M.A. Pericak-Vance<sup>1</sup>, A.E. Ashley-Koch<sup>1</sup>, D.A. Marchuk<sup>1</sup>.* 1) Duke University Medical Center, Durham, NC; 2) Park Nicollet Clinic, Minneapolis, MN; 3) Wayne State University School of Medicine, Detroit, MI.

Hereditary spastic paraplegia (HSP) is a genetically heterogeneous neurodegenerative disease characterized by wide variability in phenotypic expression, both within and among families. The most common cause of autosomal dominant HSP is mutation of the gene encoding spastin, a protein of unknown function. Almost all reported missense mutations in spastin are located in the C-terminal half of the protein, which contains the highly conserved AAA domain. The sole exception is a serine to leucine substitution at amino acid residue 44. This mutation was found previously in only one individual, in whom it occurred homozygously, and it was speculated to be a rare, recessively acting mutation. We have now identified S44L as a North American population polymorphism. In addition, we identified a family in which S44L segregates independently of D470V, a missense mutation in the AAA domain of spastin. S44L was associated with a striking decrease in age at onset and increase in severity of symptoms in the presence of the D470V mutation in this family. S44L is located in the poorly characterized amino-terminal half of the protein. Using a bioinformatics approach, we found that this highly conserved serine residue is predicted to be a site of phosphorylation by the proline-dependent serine/threonine cyclin-dependent kinase 5 (Cdk5). Cdk5 is abundant in the brain, where it is associated with complexes of cytoskeletal proteins including tubulins, consistent with a previously reported role for spastin in regulating microtubule dynamics. In addition, Cdk5 plays a major role in the molecular path leading to neurodegeneration. Thus, our identification of S44L as a modifier of the HSP phenotype has led to new insights into the biochemical pathways involved in the neurodegeneration in HSP due to spastin mutation.

**FMR1 Testing in Subjects with Undiagnosed Ataxia Disorders.** *K.J. Steenblock<sup>1</sup>, S.A. Adams<sup>1</sup>, S.N. Thibodeau<sup>1</sup>, N.M. Lindor<sup>2</sup>.* 1) Division of Laboratory Genetics, Mayo Clinic, Rochester, MN; 2) Department of Medical Genetics, Mayo Clinic, Rochester, MN.

Fragile X Ataxia Syndrome (FXAS) is a newly defined tremor and ataxia syndrome in male FMR1 premutation carriers. Symptoms of this disorder include progressive intention tremor, ataxia, cognitive decline, and characteristic MRI findings. Elevated FMR1 mRNA levels are hypothesized to cause buildup of inclusions, resulting in the distinct MRI findings and phenotype. Initial studies reported these features in males with known family histories of Fragile X syndrome. Recent studies identified gray zone FMR1 alleles (40-60 CGG repeats) in a subset of patients with multiple system atrophy (MSA). To date, the proportion of male ataxia patients with either etiology is unknown. In this study, PCR analysis was performed on 286 males over age 40 who were tested for Dentatorubral-Pallidoluysian Atrophy (DRPLA) (N=3), Spinocerebellar Ataxia (SCA) (1,2 and 3 or 1,2,3,6 and 7) (N=269), or both (N=14). Clinical information was obtained on each of the 286 patients. Features most commonly identified in subjects were gait ataxia, dementia, tremor, tingling and/or numbness, spasticity, muscle weakness, and neuropathy. Of the 286 subjects tested, one premutation (100 CGG repeats) and 16 "gray zone" alleles were identified. Although the premutation rate in this study is roughly equivalent to that of the general population, the results yield pertinent clinical applications. Of the subjects studied, 54% had only one of the three cardinal FXAS features, 21% had two of the three, and 4% had all three. Gait ataxia associated with clinical features not typically described in FXAS was found in 46% of subjects. These findings suggest that gait ataxia in the absence of tremor and dementia is less likely to result in the identification of an FMR1 premutation than if all three features were present. It is possible, however, that a higher frequency of FMR1 premutations would be identified in a more select population. Further research is necessary to define specific clinical features of this syndrome to allow for more effective use of FMR1 testing.

**Huntington's disease-like 2 (HDL2): A CTG repeat expansion in Junctophilin-3 leads to a loss of function.** *D. Rudnicki<sup>1</sup>, S.E. Holmes<sup>1</sup>, E. O'Hearn<sup>2,3</sup>, J. Troncoso<sup>4</sup>, J. Hwang<sup>1</sup>, O. Pletnikova<sup>4</sup>, C.A. Ross<sup>1,2,3,5</sup>, H. Takeshima<sup>6</sup>, T.H. Moran<sup>1</sup>, R.L. Margolis<sup>1,2,5</sup>.* 1) Psychiatry; 2) Neurology; 3) Neuroscience; 4) Pathology; 5) Program in Cellular and Molecular Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Department of Biochemistry, Tohoku University, Japan.

HDL2 is a devastating neurological disorder with clinical and pathological findings essentially indistinguishable from Huntington's disease (HD). The causative mutation is a CAG/CTG expansion in the CTG orientation within a variably spliced exon of junctophilin-3 (JPH3). We hypothesize that the expansion results in a loss of JPH3 function through interference with transcription or splicing. To test this hypothesis, we performed RT-PCR across the JPH3 repeat in frozen HDL2 brain tissue. The normal repeat, but not the expanded repeat, was amplified in each case, though both repeats could be amplified from each case in genomic DNA. RT-PCR across the full-length JPH3 transcript suggested the presence of abnormal splice variants in patient genomic, consistent with expansion-induced alterations in JPH3 splicing. To further test the loss-of-function hypothesis, we investigated knockout mice hemizygous for the junctophilin-3 gene. These mice were motorically impaired, as measured by the rotarod, and gradually became hypoactive. Preliminary immunohistochemical evidence suggests that these mice have neuronal intranuclear inclusions, similar to those seen in HDL2 brain, stained by anti-polyglutamine and anti-ubiquitin antibodies. In combination, this evidence suggests that the JPH3 repeat expansion in HDL2 results in a decrease in junctophilin-3 expression. How this loss of expression leads to neuronal inclusions and neurotoxicity remains to be determined. Funding sources: This work was supported by a Lieberman Award from the Hereditary Disease Foundation.

**Astrocytic expression of the cerebral cavernous malformations type 1 gene, *KRIT1*, and its interaction partner *ICAP1* suggests a role in formation or maintenance of the blood-brain barrier.** *J.S. Zawistowski*<sup>1,3</sup>, *N.W. Plummer*<sup>1,3</sup>, *D.D. Chang*<sup>2</sup>, *D.A. Marchuk*<sup>1</sup>. 1) Dept of Molec. Genetics and Microbiology, Duke University, Durham, NC; 2) Dept of Medicine, UCLA School of Medicine, Los Angeles, CA; 3) contributed equally.

Cerebral cavernous malformations (CCM) are vascular lesions of the central nervous system consisting of clusters of greatly enlarged, thin-walled blood vessels without intervening brain parenchyma. Hemorrhaging of the lesions can result in migraines, seizures, or lethal stroke. Three forms of autosomal dominant cerebral cavernous malformations have been mapped, and CCM1 is caused by loss-of-function mutations in a novel gene termed *KRIT1*. The *KRIT1* protein contains ankryin repeats and a FERM domain in the carboxyl half of the protein, but the amino half of the protein is unique. It remains unclear how loss of *KRIT1* contributes to CCM pathogenesis, and even if the pathology is intrinsic to vascular endothelial cells. *In-situ* analyses have suggested that *KRIT1* is expressed in neurons, whereas an antibody raised against a C-terminal peptide has shown *KRIT1* expression in cultured endothelial cells. In order to resolve these issues, we have generated an antibody to a GST-fusion protein consisting of the unique N-terminal 272 amino acids of *KRIT1* which harbor the motif critical for binding to the  $\alpha_1$  integrin-associated protein *ICAP1*. We have used our *KRIT1* antibody and a previously described *ICAP1* antibody to investigate the expression pattern of both genes.

Our analyses demonstrate that *Krit1* and *Icap1* are not expressed in neurons, nor in the vascular endothelium of adult mouse brain. Instead, both proteins show strong expression in astrocytes. Since interaction between astrocytes and vascular endothelial cells is known to be required for formation of the blood-brain barrier (BBB), this expression pattern suggests a role for *KRIT1* in formation or maintenance of the BBB. These data are also consistent with previously reported observations that endothelial cell tight junctions are defective in cavernous malformations, and suggest that the interaction between astrocytes and endothelial cells depends on  $\alpha_1$  integrin.

**Molecular analysis of NAIP gene in Iranian Spinal Muscular Atrophy families.** *I. Salahshouri<sup>1</sup>, Y. Safagati<sup>1,2</sup>, Z. Golkar<sup>2</sup>, H. Najmabadi<sup>1,2</sup>.* 1) The Social Welfare and Rehabilitation Sciences University, Evin, Tehran, Iran; 2) 2 Kariminejad/Najmabadi genetics and pathology center.

**Abstract:** Spinal muscular atrophy (SMA) is an autosomal recessive disorder characterized by degeneration of anterior horn cells in the spinal cord leading to progressive muscular weakness and atrophy. The three candidate genes for SMA were mapped to the 5q13 region. SMA-determining genes including SMN (survival motor neuron), (the major gene in SMA phenotype), NAIP (neuronal apoptosis inhibitory protein) and BTF2P44, all of which are located on chromosome 5q13 in two highly homologous copies (telomeric and centeromeric) within the SMA region. The objective of this study was to investigate the NAIP gene deletion in SMA patients and families. NAIP gene deletion analyzed in 34 SMA families as mentioned above, in which exon 7 of SMNt gene before confirmed and in 75% exon 7 of SMNt gene was deleted. We found 60% (12/20) NAIP gene deletion in SMA I-III (77%; SMA-I, 29% SMA-II or III), 6.6% (2/30) carrier parents and none of the normal parents. The NAIP gene deletion in SMA-I was higher other than SMA-types. In this study consanguinity rate was 65% (22/34). **Key words:** Spinal Muscular Atrophy; the SMN gene; the NAIP gene; P44 gene.

**Molecular genetic analysis in Moebius syndrome.** *B. van der Zwaag*<sup>1</sup>, *H.T.F.M. Verzijl*<sup>1</sup>, *D. Beltran Valero de Bernabe*<sup>2</sup>, *J. Veltman*<sup>2</sup>, *H.G. Brunner*<sup>2</sup>, *G.W. Padberg*<sup>1</sup>, *H. van Bokhoven*<sup>2</sup>. 1) Neurology, UMC Nijmegen, Nijmegen, Gelderland, The Netherlands; 2) Human Genetics, UMC Nijmegen, Nijmegen, Gelderland, The Netherlands.

Moebius syndrome (MBS) is a rare autosomal dominant disorder characterized by paralysis of the 7<sup>th</sup> cranial nerve (facialis). Additional clinical features in MBS are dysfunction of other cranial nerves, limb- and musculoskeletal malformations, and mental retardation. Several loci for MBS have been uncovered by linkage studies and cytogenetic analysis. We initiated a positional candidate gene analysis for MBS2 (3q21-q22) and MBS3 (10q21-q22), the loci identified in our lab in two large non-related Dutch MBS families. Several positional candidate genes were excluded, including *EGR2*, *GATA2*, *PGT*, and *SOX14*. Recently, we identified a new candidate gene: *PLEXIN-D1*. RNA *in situ* hybridization during mouse embryogenesis revealed that *PLEXIN-D1* is expressed in regions involved in MBS (brain and cranial ganglia), and in developing blood vessels. Mutation analysis in the MBS2 family and in a cohort of over 40 isolated MBS patients identified 19 nucleotide changes in the coding sequence and splice sites of the gene. However, all of these were present in the normal population and should be considered polymorphisms. RT-PCR analysis showed no aberrations in splicing, and the co-segregating nucleotide changes were heterozygously present in the RNA, demonstrating promoter activity for both alleles. Therefore *PLEXIN-D1* can be excluded as the causative gene for MBS2. To select new candidate genes for MBS2, we are currently performing large scale RNA *in situ* analysis for 22 genes from the critical region. Transcripts showing expression in MBS affected tissues are considered new candidate genes. Selection of candidate genes will be followed by mutation analysis, to identify the causative mutation for MBS2. In addition, DNA samples from over 40 isolated MBS patients are being hybridized to a newly developed genomic microarray to detect possible chromosomal aberrations (deletions or duplications) in MBS patients. The array contains over 3600 BACs, resulting in a 5 to 10 times higher resolution than routine karyotyping.

**MUTATION DETECTION OF SOME NEUROMUSCULAR DISEASES IN MOLDOVA.** *V.C. Sacara.* Medical genetics Centre, Scientific Research Institute , Kishinau, Moldova.

Progress in molecular genetics has greatly improved our understanding of the molecular basis of many inherited neurological diseases and to provide practical help for the clinical neurologist to make appropriate use of the possibilities of molecular diagnosis of neurologic disorders in Moldova. In our data base we have 120 families with high genetic risk of Duchenne/Becker muscular dystrophy (DMD), 30 families with Spinal muscular atrophy (SMA), 15 families with Charcot-Marie-Tooth disease(CMT1A). Most of these families are Moldavian by origin. DNA analysis of the DMD families consists of detects deletions in 13 different exons of dystrophin gene and pERT87-8/TaqI, pERT87-15/BamH1 and 16 intron/TaqI polymorphisms. About 76 % of probands were proved to be carriers of dystrophin gene deletion by MPCR. The algorithm of MDD molecular researches allows to define informative in 93% cases. Molecular analysis was efficiently applied to 11 fetuses. Five male fetuses were no affected, two male fetuses were affected, in one case the risk remained 50% and in 3 cases it were heterozygous carriers. Molecular studies at the SMNI - homozygous deletions of exons 7 and 8 were found in 21 patients (91%). In 3 patients was observed only exon 8 deletions. The feasibility of indirect diagnosis was evaluated using microsatellite polymorphic locus D5S557. Four alleles (148bp, 160bp, 166bp, 172bp) were exposed. The most frequent allele in control group had 160 bp length. This allele accounted 52% of all alleles. The observed heterozygosity rate was 0,54. A total 23 DNA samples from patients and 40 relatives, were analyzed. 74% of families were informative and allele marked mutant chromosome was detected. In the most case it was allele 166 bp length with frequency 0,48. In 5 cases we performed prenatal diagnosis SMA. In 3 out of 4 fetuses we detected heterozygous deletion of the exons. We use of STRs for diagnosis of CMT1A duplication. Two markers (17dup5 and 17dup4) were amplified by PCR using standard conditions. We found duplication in 8 CMT1A families. DNA-analysis supplements considerably clinic-laboratorial methods of diseases investigation, permits to use for effective and rapid carrier detection and prenatal diagnosis in at-risk families.

**Analyses of biochemical function of aprataxin in DNA single-strand break repair.** *T. Takahashi*<sup>1</sup>, *S. Igarashi*<sup>1,2</sup>, *H. Date*<sup>1</sup>, *O. Onodera*<sup>1,2</sup>, *M. Nishizawa*<sup>1</sup>, *S. Tsuji*<sup>3</sup>. 1) Department of Neurology, Brain Research Institute, Niigata University, Niigata, Japan; 2) Department of Molecular Neuroscience, Brain Research Institute, Niigata University, Niigata, Japan; 3) Department of Neurology, The University of Tokyo, Tokyo, Japan.

Aprataxin (APTX) has been identified as the causative gene for Early-onset ataxia with ocular motor apraxia and hypoalbuminemia (EAOH). The physiological functions of aprataxin, however, remains to be elucidated. APTX has two splicing variants, long form(LAPTX) and short form. LAPTX has a homology to polynucleotide kinase-3' phosphatase (PNKP) and interacts with XRCC1, which is required for single-strand DNA break repair(SSBR), in a yeast two-hybrid study. To investigate the functions of the aprataxin in SSBR, we conducted in vitro reconstituted SSBR assay using oligonucleotide duplex with a 1 bp gap and three recombinant SSBR-related proteins (DNA polymerase(Pol), DNA ligase III (Lig3) and T4 polynucleotide kinase(T4 PNK). The short fragment of the oligonucleotides was end-labelled with fluorescein isothiocyanate, and the length of ligated oligonucleotide products was analyzed by an automated DNA sequencer. In this experiment, reconstituted SSBRs were completed by recombinant lig3, Pol and T4 PNK ,however, ligation products were undetectable by using LAPTX substituted for T4 PNK. This data suggested that LAPTX does not have any polynucleotide kinase activity in spite of its homology. To elucidate the physiological roles of aprataxin in SSBR ,further investigations on other SSBR systems will be needed.

**Autosomal dominant hypoceruloplasminemia associated with extrapyramidal signs due to a novel heterozygous 4-bp deletion mutation in the Ceruloplasmin gene.** *Y. Watanabe<sup>1</sup>, Y. Yamashita<sup>1</sup>, T. Yamamoto<sup>2</sup>, E. Nanba<sup>3</sup>, M. Nakashima<sup>1</sup>, I. Yoshida<sup>1</sup>, T. Matsuishi<sup>1</sup>, M. Yoshino<sup>1</sup>.* 1) Department of Pediatrics, Kurume University, Fukuoka, Japan; 2) Division of medical genetics, Kanagawa children's medical center, Kanagawa, Japan; 3) Division of Functional Genomics, Research Institute of Bioscience and Technology, Tottori University, Tottori, Japan.

We identified a novel 4-bp deletion in exon 14 at position 2520 of the Ceruloplasmin(CP) gene in a Japanese family with hypoceruloplasminemia, resulting in a premature termination at amino acid 892. The proband was a 12-year-old boy who was presented with a history of refusing attending school because of his motor clumsiness and tremor which had been noticed since age four years. He had mild mental retardation and extrapyramidal signs including dysarthria and cogwheel rigidity. Serum ceruloplasmin and copper were 10 mg/dl (normal 22-44) and 41 g/dl (normal 80-130), respectively. Wilson disease was excluded by normal urine copper excretion and normal copper content in the liver tissue. Hypoceruloplasminemia and heterozygous mutation of the 4-bp deletion were identified in four individuals in this family (father: CP 13, Cu 52; younger brother: CP17, Cu 65; paternal grandmother: CP 17, Cu 56). Abnormal extrapyramidal signs as well as abnormal brain MRI findings with high signal intensity in globus pallidus were identified only in the proband and his father. The other two relatives were found asymptomatic. We report a familial hypoceruloplasminemia, due to a novel heterozygous 4-bp deletion mutation of the CP gene, resulting in abnormal neurological findings in a father and a son. Hypoceruloplasminemia due to the deletion mutation at nucleotide 2520 showed autosomal dominant inheritance with variable expression in neurological symptoms. Although onset of neurological symptoms in hypoceruloplasminemia was believed to be between 3<sup>rd</sup> and 4<sup>th</sup> decades, this familial cases suggest that onset of neurological symptoms can be significantly earlier (as early as age four years) than it was thought.

**Paraplegin mutations are associated to complex I deficiency and increased sensitivity to oxidative stress in Hereditary Spastic Paraplegia.** *L. Silvestri<sup>1</sup>, L. Cassina<sup>1</sup>, L. Atorino<sup>1</sup>, M. Koppen<sup>2</sup>, A. Ballabio<sup>3</sup>, R. Marconi<sup>4</sup>, T. Langer<sup>2</sup>, G. Casari<sup>1</sup>.* 1) Neuroscience, San Raffaele Scientific Instit, Milan, MI, Italy; 2) Institute for Genetics and Center for Molecular Medicine, University of Cologne, Cologne, Germany; 3) Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy; 4) Division of Neurology, Ospedale Misericordia, Grosseto, Italy.

Mutations in paraplegin, a putative mitochondrial metallopeptidase of the AAA family, cause an autosomal recessive form of hereditary spastic paraplegia (HSP). We analyze the function of paraplegin at the cellular level and characterize the phenotypic defects of HSP patients cells lacking this protein. Paraplegin and the homologous protein AFG3L2 are integral proteins of the inner mitochondrial membrane; by coimmunoprecipitation and FPLC experiments, we demonstrate that paraplegin interacts with AFG3L2 to form a high molecular weight complex of about 900 kDa, which is aberrant in HSP fibroblasts. The loss of this complex causes a reduced complex I activity in mitochondria and an increased sensitivity to oxidant stress, which can be both rescued by exogenous expression of wild type paraplegin. The impaired complex I activity correlate to a reduced amount of complex I in HSP cells, we therefore conclude that the paraplegin/AFG3L2 complex is required for the efficient assembly of complex I. Furthermore, complementation studies in yeast demonstrate functional conservation of the human paraplegin/AFG3L2 complex with the yeast m-AAA protease and also assign proteolytic activity to this structure. Taken together, our findings shed new light on the molecular pathogenesis of HSP. We show how paraplegin mutations suppress the human m-AAA protease formation and generate complex I deficiency in HSP cells, which may lead to additional production of ROS causing oxidative stress in the particular subset of neurons affected by HSP. Therefore, the initial pathogenic mechanism is likely to stem from the combined effects of misfolded peptide accumulation and the lack of chaperon activity on complex I assembling.

**Somatic mosaicism in Fanconi anemia: Investigation of the dynamics of phenotype correction.** *Y. Akkari, Y. Torimaru, M. Grompe, S.B. Olson.* Department of Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR.

Fanconi anemia (FA) is an autosomal recessive disease characterized by congenital anomalies, bone marrow failure, and an increased risk for neoplasia. Cells from FA patients are hypersensitive to DNA crosslinking agents, such as mitomycin C (MMC), and display genomic instability. Recently, it has been recognized that the genomic instability seen in FA cells may increase the opportunity for correction of the genetic error in a proportion of the patient's blood cells by a phenomenon known as somatic reversion. In order to simulate somatic reversion seen occasionally in FA, tissue samples from several FA patients were mixed in different proportions with like material from sex-unmatched healthy individuals, and treated with and without MMC. Breakage analysis and fluorescent in situ hybridization (FISH) were performed to assess the resulting sensitivity and the proportion of male and female cells in the mixed samples, respectively. Our results suggest that in all blood, marrow, and fibroblast samples treated with MMC, the presence of only 5% healthy cells can decrease the radial percent reading to normal ranges (ie. >20% radials). In contrast to untreated mixed cultures, blood cultures treated with MMC revealed that FA cells were more prone to cell death which is consistent with the selective advantage of the reverted cell population. In addition, breakage analysis of FA cells in the normal cell milieu, as followed by FISH for female versus male cells, revealed no evidence for intercellular correction for MMC hypersensitivity. These findings have implications for the treatment of FA in general, as well as for the longterm survival of FA patients following a somatic reversion event.

**Identification of the Gene Causing CM-AVM, a Heretofore Undescribed Clinical Entity, Characterized by Defects in Capillary Morphogenesis, Arterial/Venous Identity and Control of Local Tissue Growth.** *I. Eerola<sup>1</sup>, L.M. Boon<sup>1, 2</sup>, J.B. Mulliken<sup>3</sup>, P.E. Burrows<sup>4</sup>, R. Vanwijck<sup>2</sup>, M. Vikkula<sup>1</sup>.* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology & Université catholique de Louvain, Brussels, Belgium; 2) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 3) Vascular Anomalies Center, Division of Plastic Surgery, Children's Hospital, Harvard Medical School, Boston, MA 02115, USA; 4) Vascular Anomalies Center, Division of Interventional Radiology, Children's Hospital, Harvard Medical School, Boston, MA 02115, USA.

Defects in cutaneous vascular development manifest as vascular malformations that vary in size, location, blood flow, and clinical severity. Capillary malformation (CM), (port-wine stain), (OMIM#163000) is the most common one, occurring in 0.3% of newborns. Arteriovenous malformation (AVM) and arteriovenous fistula (AVF) are fast-flow vascular anomalies that arise in skin, muscle, bone, internal organs and brain, and can cause life-threatening complications, such as bleeding, congestive heart failure, or neurologic consequences. Multiple micro-AVFs co-occur with cutaneous stain, and soft tissue and skeletal hypertrophy of the affected limb in Parkes Weber syndrome. Using linkage analysis and positional candidate gene screening, we have identified a gene, at the CMC1 locus on chromosome 5q, mutations of which can cause CM, AVM, AVF and Parkes Weber syndrome. This data delineates a new phenotypic and genetic entity that we named CM-AVM. The variability in phenotype can be explained by the involvement of the identified mutated gene in signaling of various growth factor receptors that control proliferation, migration, and survival of several cell types, including vascular endothelial cells. (vikkula@bcm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

**INCIDENCE OF TRANSTHYRETIN VAL122ILE AMYLOID MUTATION IN AFRICAN-AMERICANS BORN IN INDIANAPOLIS, INDIANA, USA.** *M. Benson, M. Yazaki, T. Yamashita, K. Hamidi Asl.* Dept Path & Lab Medicine, Indiana Univ, Indianapolis, IN.

Hereditary transthyretin amyloidosis is associated with 85 different mutations in transthyretin. While the most common type of transthyretin amyloidosis in the world is caused by the TTR Val30Met mutation, one particular TTR mutation (Val122Ile) is found predominantly in Americans of African descent. This mutation causes late-onset restrictive cardiomyopathy (after age 60). In previous reports allele frequencies of 0.014 (148 subjects) and 0.020 (1688 subjects) were found. Those studies, however, used DNA samples obtained for genetic analysis of other diseases in various geographic areas. The present study determines the gene frequency in newborns in a mid-American city (Indianapolis, Indiana). Cord bloods were collected from 1,973 subjects. Val122Ile was detected by PCR-RFLP.

Race	Number Tested	Number Positive	% Positive
African-American	1,000	30	3%
Caucasian	453	2	.004%
Hispanic	490	0	
Other (Asian, etc.)	30	0	

Conclusion: In a population selected only by ethnicity and birth in an urban community the finding of 3% incidence of the TTR Val122Ile mutation associated with late-onset cardiac amyloidosis is higher than previously reported. The amyloidosis caused by this mutation is often clinically mistaken for other types of cardiac disease in the African-American population. Demonstration of the high incidence of this mutation in African-Americans is important for the education of individuals giving care to this population.

**Compound heterozygous mutation of both and subunits of IKs associated with Romano-Ward Syndrome.** *E. Estrella, T. Miller, L.J. You, W. Lanier, M.L. Young, R. Myerburg, N. Bishopric, L. Baumbach.* Univ. Miami Sch. Med., Miami, FL.

Inherited forms of Long QT Syndrome (LQTS) are caused by over 200 mutations in seven genes. Mutations are predominantly found as dominant mutations (Romano Ward Syndrome, RWS) and less frequently as homozygous recessive mutations (Jervell Lange-Neilsen Syndrome, JLNS) with hearing loss. Compound heterozygosity in single LQTS genes is reported in both RWS and JLNS. Reports of individuals with pathogenic mutations in different LQTS genes are difficult to find. Consequently, it is not known how mutations in multiple LQTS genes may affect phenotype. We describe a RWS family with heterozygous missense mutations in 3 different LQTS genes, including biallelic mutations at both the and subunits of IKs. The proband, an 8yo Caucasian male, diagnosed with RWS after 3 episodes of exercise-induced syncope. His mother had a cardiac arrest at age 17 and an AICD at age 29 for syncope. No other family members were symptomatic. The family was screened at 5 LQTS loci for mutations by exon-specific PCR, SSCP and DNA sequencing. Three mutations were identified in KCNQ1 and KCNE1, encoding IKs and subunits respectively, and in the subunit of IKr(KCNE2). These mutations were inherited in various combinations. Two of these (KCNE1-D76N & KCNE2-Q9E) have been associated with different forms of LQTS. The Q9E mutation has not previously been observed in Caucasians. The third mutation is novel, and resides in a highly mutable pore region of KCNQ1. This mutation was not found in 77 control samples, and exhibited concordance with the disease phenotype in this family. Molecular analysis revealed the following genotype-QTc correlations: proband, KCNQ1 +/- and KCNE1 +/-, (0.405 s); mother, KCNQ1 +/- and KCNE2 +/- (paced); father, KCNE1 +/- (0.433 s); sister 1, KCNQ1 +/- (0.472 s); sister 2, KCNE1+/-, KCNE2 +/- (0.467 s); sister 3, KCNQ1 +/-, KCNE1 +/- (0.478 s). Because the proband and sister 3 have normal hearing, we conclude that heterozygous mutation of both IKs subunits is not an obligatory JLNS genotype, and that sufficient normal IKs channels can be constituted in the presence of both mutations.

**Defective elastogenesis causing lethal pulmonary artery occlusion.** *M. Dasouki*<sup>1</sup>, *D. Markova*<sup>2</sup>, *R. Garola*<sup>3</sup>, *M-L. Chu*<sup>4</sup>. 1) Sec of Medical Gen & Molec Med, Children's Mercy Hospitals & CLinics, Kansas City, MO; 2) Department of Dermatology and Cutaneous Biology, Thomas Jefferson University, Philadelphia, PA; 3) Department of Pathology, Children's Mercy Hospitals & Clinics, Kansas City, MO; 4) Department of Dermatology and Cutaneous Biology, Thomas Jefferson University, Philadelphia, PA.

Disorders of elastogenesis may involve any of the proteins that comprise the microfibrillar and amorphous components of elastic fibers. Mutations involving fibrillin-1 and-2, elastin and fibulin-5 genes result in a broad spectrum of elastic tissue phenotypes affecting skin, skeleton, ocular and vascular structures. Frameshift mutations in the elastin gene have been reported in three families with autosomal dominant cutis laxa. A fibulin-5 gene homozygous missense mutation and a 22-kb internal duplication were reported in two autosomal recessive and autosomal dominant cutis laxa families respectively. A 27-day old Caucasian female had respiratory distress since birth requiring positive pressure ventilation. Family history was negative. were seen on echocardiography. Echocardiography showed dilated & tortuous pulmonary artery and aorta "causing tracheal compression", enlarged right ventricle and atrium and pulmonary hypertension. She also had mild cutis laxa and arachnodactyly. Skin biopsy was significant for markedly reduced elastic fibers. Her respiratory status continued to deteriorate due to the pulmonary vascular abnormalities and additional RSV infection. Post mortem examination showed biventricular hypertrophy, tortuous aneurysmal dilatation of ascending aorta and main pulmonary artery and wall dissection involving large segments of the great vessels with markedly reduced elastic fibers in the media. Skin fibroblast chromosomal and FISH analyses of the elastin gene were normal. DNA sequencing of the elastin and fibulin-5 genes showed an IVS3,+15 t->g heterozygous nucleotide change. RT-PCR products of the fibulin-5 mRNA transcript were of normal sizes excluding aberrant splicing. Northern analysis of mRNA for elastin, fibulin-2 and fibulin-5 showed a decreased fibulin-5 expression compared to control. This is of unknown significance.

**Localization of a familial cardiac conduction defect with adolescent onset to chromosome 3p21-p24. P.J.**

*Laitinen<sup>1</sup>, P. Mäkynen<sup>2</sup>, S. Yli-Mäyry<sup>2</sup>, V. Virtanen<sup>2</sup>, K. Kontula<sup>1</sup>, K. Aalto-Setälä<sup>2</sup>.* 1) Department of Medicine and Biomedicum Helsinki, University of Helsinki, Finland; 2) Tampere University Hospital, Finland.

Several inherited electrical cardiac diseases including the long QT syndrome type 3, Brugada syndrome, and both progressive and isolated form of cardiac conduction defect have been shown to result from mutations in the SCN5A gene which is located in chromosome 3p21-p24 and encodes a cardiac sodium channel. This study aimed to investigate whether in a large Finnish family an inherited cardiac conduction defect with onset in adolescence is linked to this chromosomal locus and whether SCN5A gene is involved in pathogenesis of the disease. A total of 44 family members were examined at the Department of Medicine, Tampere University Hospital. Affected individuals presented with progressive intracardial conduction delay, principally displayed by a widened QRS complex. Progressive atrio-ventricular (av) conduction delays up to a complete av-block appeared especially during exercise. The hearts of the affecteds were structurally normal. None of the affected individuals had any symptoms under the age of 12 years, but required pacemaker installation in their teens. No sudden cardiac deaths have been reported. Microsatellite markers D3S1298, D3S3527, D3S3623 and an intragenic SNP C5607T were genotyped in 15 family members (6 affected, 9 non-affected). In linkage analysis, lod score of 3.09 was obtained at marker D3S1298 and haplotype constructed of the markers co-segregated in the family with the disease but showed reduced penetrance. This indicates that SCN5A gene may play a role in this disease. Tan et al. (Nature 2001) reported a family with similar conduction defect and demonstrated a mutation in exon 12 of the SCN5A gene to underlie the phenotype. The main difference between the two families is the age at onset of symptoms: the index case described by Tan et al. was only 3 years of age while none of our patients have had their first symptoms before teenage. We are currently sequencing the SCN5A gene, but have not found mutations in the exons analyzed this far (including exon 12). In conclusion, SCN5A locus shows linkage to an exercise-induced conduction defect with onset in youth.

**Mutations in the SOX18 Transcription Factor Underlie Recessive and Dominant Forms of Lymphedema with Hypotrichosis and Telangiectasia.** *A. Irrthum*<sup>1</sup>, *K. Devriendt*<sup>2</sup>, *D. Chitayat*<sup>3</sup>, *G. Matthijs*<sup>2</sup>, *A. Mertens*<sup>2</sup>, *C. Glade*<sup>4</sup>, *P.M. Steijlen*<sup>4</sup>, *J.P. Fryns*<sup>2</sup>, *M.A.M. Van Steensel*<sup>4</sup>, *M. Vikkula*<sup>1</sup>. 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology & Université catholique de Louvain, Brussels, Belgium; 2) Center for Human Genetics, University of Leuven, Leuven, Belgium; 3) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Canada; 4) Department of Dermatology, University Medical Center Nijmegen, The Netherlands.

Hereditary lymphedema is a developmental disorder characterized by chronic swelling of the extremities due to a dysfunction of lymphatic vessels. Two responsible genes have been identified: VEGFR3, implicated in congenital lymphedema and FOXC2 causing lymphedema-distichiasis. Here we report three families with patients showing an unusual association of lymphedema, hypotrichosis and telangiectasia. Using microsatellite analysis, we first excluded both VEGFR3 and FOXC2 as causative genes. We then evaluated various murine phenotypes that present a combination of hair and cardiovascular anomalies including symptoms of lymphatic dysfunction as likely counterparts of the human disease. With this approach, we identified homozygous missense mutations in the gene encoding the SOX18 transcription factor in affected individuals from the two first families that present consanguinity. Two amino acid substitutions affect conserved residues in the first alpha-helix of the DNA-binding domain of the transcription factor. In the third family, both the affected child and his brother who died in utero presented a heterozygous nonsense mutation that truncates the protein in its trans-activation domain. This substitution was not found in the genomic DNA of either parent and hence constitutes a de novo germline mutation. This data shows that mutations in the SOX18 transcription factor gene cause both recessive and dominant lymphedema with alopecia and telangiectasia, suggesting that, in addition to its established role in hair and blood vessel development in mouse, the transcription factor is necessary for development and/or maintenance of lymphatic vessels.(vikkula@bchm.ucl.ac.be).

**Malignant familial cardiac fibrosis, without dilatation or hypertrophy, due to a novel exon-1 lamin A/C gene deletion: recognition of a distinct lamin related cardiomyopathy.** *W.S. Kerstjens-Frederikse<sup>1</sup>, J.P. van Tintelen<sup>1</sup>, R.A. Tio<sup>2</sup>, Y.J. Vos<sup>1</sup>, A.J.H. Suurmeijer<sup>3</sup>, L.G. Boven<sup>1</sup>, G.J. te Meerman<sup>1</sup>, M.P. van den Berg<sup>2</sup>, D.J. van Veldhuisen<sup>2</sup>, C.H.C.M. Buys<sup>1</sup>, R.M.W. Hofstra<sup>4</sup>, Y.M. Pinto<sup>5</sup>.* 1) Dept Clinical Genetics, Univ Hospital Groningen, Netherlands; 2) Dept Cardiology, Univ Hospital Groningen, Netherlands; 3) Dept Pathology, Univ Hospital Groningen, Netherlands; 4) Dept Medical Genetics, Univ Groningen, Netherlands; 5) Dept Experimental and Molecular Pathology, Univ Hospital Maastricht, Netherlands.

A large family with autosomal dominant cardiac fibrosis -without cardiac hypertrophy or dilatation- not fulfilling criteria of any known form of cardiomyopathy allowed us to identify a gene causing cardiac fibrosis. In affected family members, cardiac fibrosis manifested between 20 and 63 years of age by first degree AV block, (supra-) ventricular arrhythmias, rapidly progressive heart failure and a high rate of sudden death at relatively young ages. No neurological abnormalities were noted and echocardiography revealed neither dilatation nor (asymmetric) cardiac hypertrophy. Post mortem examination or myocardial biopsy in clinically affected subjects revealed massive interstitial fibrosis. Twelve family members were proven affected by histological evaluation. To identify the gene we collected DNA from consenting family members for linkage analysis studies. Genome wide linkage analysis yielded linkage in the vicinity of the LMNA gene, a LOD score of 3.46 at marker D1S1595 (5% recombination and 90% penetrance) with exclusion of other loci. The LMNA gene was analysed by DGGE and direct sequencing but no mutations were found. Subsequent Southern blot analysis of the gene revealed a deletion of exon 1 co-segregating with the disease. A non-penetrant 42-year-old family-member explained the lack of linkage with the LMNA locus itself. Conclusion: We describe a novel exon 1 deletion in the LMNA gene, that cannot be found by routine sequencing, which expands the phenotype of laminopathies with a non-dilating strictly fibrotic, yet highly malignant form of cardiomyopathy, not fulfilling the criteria for established forms of cardiomyopathy.

Program Nr: 2256 from 2003 ASHG Annual Meeting

**Mutation of Muscle LIM Protein is an Uncommon Genetic Cause for Familial Dilated Cardiomyopathy.** *D. Li, P. Jakobs, S.B. Parks, M. Bestwick, J. Kushner, E. Burkett, S. Ludwigsen, M. Litt, R. Hershberger.* Dept Medicine/Cardiology, Oregon Health & Sciences Unive, Portland, OR.

Familial dilated cardiomyopathy (FDC) is a primary cardiac muscle disease clinically characterized by enlarged cardiac chambers and decreased contractility, and commonly leads to heart failure and cardiac transplantation. FDC is usually inherited as an autosomal dominant trait. Although mutations in more than 10 genes have been identified using positional cloning or candidate gene approaches, the molecular cause of the majority of FDC remains unknown. These genes encode cytoskeletal or contractile proteins or their regulators. Muscle LIM protein (MLP) is enriched in striated muscle and is located in Z disc, a sarcomeric and cytoskeletal anchoring site. Mice with targeted disruption of the MLP gene exhibited a phenotype suggestive of dilated cardiomyopathy and heart failure. Thus, MLP was considered as a promising candidate gene for FDC. We sequenced the coding region of MLP in 92 FDC index cases; one mutation was identified in a 46 year old male with dilated cardiomyopathy (left ventricular ejection fraction 25%), atrial fibrillation and heart failure. The DNA sequence variant (T to C at nucleotide 55, GenBank NM\_003476) was predicted to substitute a highly conserved tryptophan at residue 4 with arginine (W4R). The missense mutation resulted in a charge change at the affected region of MLP and was predicted to alter the protein structure. This sequence variant was neither observed in other FDC index patients nor among 100 control chromosomes. Our finding provided further evidence to support a recent report that mutations in MLP though infrequent may cause FDC.

**Genetic study of Japanese patients with familial and sporadic primary pulmonary hypertension.** *T. Morisaki<sup>1,2</sup>, H. Morisaki<sup>1</sup>, S. Kyotani<sup>3</sup>, N. Nakanishi<sup>3</sup>*. 1) Dept Bioscience, Natl Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Dept Molecular Pathophysiology, Osaka Univ Grad Sch Pharm Sci, Suita, Osaka, Japan; 3) Dept Cardiovasc Med, Natl Cardiovasc Ctr, Suita, Osaka, Japan.

Primary pulmonary hypertension (PPH) is a potentially lethal disorder, in which heterozygous mutations within the bone morphogenetic protein type II receptor (BMPRII) gene (BMPR2) have been identified. We report the molecular study of BMPR2 mutations in 3 Japanese families with familial PPH and in 31 Japanese patients with sporadic PPH as well as in 15 cases with secondary pulmonary hypertension (SPH). We have identified 11 mutations, including 2 missense mutations, distributed throughout the BMPR2 gene, in PPH but not in SPH. The majority of mutations are predicted to lead to a premature termination codon. Most of these mutations were novel and other additional synonymous nucleotide substitutions were also found. In all families with familial PPH studied, missense mutation or mutations resulting in premature termination of BMPR2 were found. In one case, the nucleotide substitution, resulting in a very short peptide of BMPRII terminated at the fourth amino acid residue, was found, strongly supporting that haploinsufficiency could account for the pathogenesis of PPH. We also tried to investigate genotype-phenotype relationships to elucidate the mechanisms contributing to pathogenesis of this important vascular disease. Regarding characteristics of nucleotide changes found in patients with PPH, there were similarities as well as differences between Japanese and other ethnic groups. These results indicate the considerable heterogeneity of BMPR2 mutations that cause PPH, and additional genetic and/or environmental factors will have to be identified.

**Mutation screening of the Thymopoietin gene (TMPO) in dilated cardiomyopathy.** *M. Taylor<sup>1</sup>, P. Fain<sup>1</sup>, E. Carniel<sup>1</sup>, A. Di Lenarda<sup>2</sup>, G. Sinagra<sup>2</sup>, M. Boucek<sup>3</sup>, L. Ku<sup>1</sup>, S. Graw<sup>4</sup>, J. Feiger<sup>1</sup>, D. Slavov<sup>1</sup>, X. Zhu<sup>1</sup>, D. Dao<sup>1</sup>, D. Feguson<sup>1</sup>, L. Mestroni<sup>1</sup>.* 1) Adult Medical Gen Program, Univ Colorado Health Sci Ctr, Denver, CO; 2) Division of Cardiology, University of Trieste, Italy; 3) Division of Cardiology, The Children's Hospital, Denver, CO; 4) Eleanor Roosevelt Institute, Denver, CO.

**Background:** Familial dilated cardiomyopathy (FDC) is a genetic disease caused by mutations in several FDC genes, including the lamin A/C gene (LMNA). Colocalization of and binding between the rat lamin-associated polypeptide-2 gene (LAP2) and LMNA gene products has been previously shown. The thymopoietin (TMPO) gene is the human counterpart to the rat lamin-associated polypeptide-2 gene (LAP2). Based on this data we believed TMPO to be a suitable candidate FDC gene and performed screening of TMPO in FDC families. **Methods:** Denaturing high-performance liquid chromatography heteroduplex analysis was used to screen 101 subjects from 75 families (49 FDC and 21 sporadic and 5 unclassified) with dilated cardiomyopathy (DCM). To date, over 90% of the coding region has been screened. **Results:** A putative TMPO mutation has been identified in one FDC pedigree in 2 severely affected male siblings. The older sibling developed cardiac symptoms at age 31 and was diagnosed at age 33 with a severe idiopathic DCM. The younger sibling presented with symptoms at age 22 and was diagnosed with idiopathic DCM at age 24. Neither subject had evidence of skeletal muscle dystrophy. In addition, a paternal cousin died unexpectedly at age 40. No additional family members were available for study. Both affected siblings inherited a CT transition in exon 4, encoding the TMPO alpha isoform, predicting an arginine (hydrophilic, charged residue) to cysteine (hydrophobic, uncharged residue) substitution at codon 690. The mutation is predicted to alter the C-terminal protein secondary structure (GOR IV software) and was absent in 300 control chromosomes (and a total of over 450 chromosomes). **Conclusion:** These results suggest that mutations in TMPO may represent a rare cause of FDC.

**Dilated Cardiomyopathy and the Microsatellite Polymorphism of Heme Oxygenase 1.** *J. Pohorence Ferguson, Y. Liu-Stratton, G. Cooke, P.F. Binkley.* The Ohio State University Davis Heart and Lung Institute, Columbus OH.

Heme oxygenase 1 (HO-1) is upregulated by stimuli that produce reactive oxygen species, and plays a protective role in cardiovascular diseases involving oxidative stress. Oxidative stress is a major source of damage in both ischemic (ICM) and dilated cardiomyopathy (DCM). Because a loss of HO-1 activity increases tissue susceptibility to oxidative damage, the hypothesis of this study was that protective actions of HO-1 are inhibited in patients with cardiomyopathy due to a microsatellite polymorphism in the promoter that reduces transcriptional activity. Sequence analysis was performed on 43 patients with ICM and 58 patients with DCM to identify the presence of this microsatellite polymorphism (L) that consists of 29 dinucleotide repeats. The frequency distribution for the presence of at least one L allele is shown below. These data indicate that patients with DCM possess the L allele in a significantly ( $p = 0.01$ ) higher proportion than ICM patients. An ELISA specific for the HO-1 protein was run on 14 DCM and 17 ICM sequenced patients, and the results showed that DCM patients with an L allele have lower HO-1 protein levels than DCM patients lacking an L allele ( $p = 0.11$ ). Therefore, despite the absence of significant coronary disease, patients with DCM may be susceptible to progressive ventricular dysfunction due in part to an inability to protect against myocardial oxidative stress.

Etiology	L Absent	L Present
ICM	30	13
DCM	26	32

**Preliminary Results of Lamin A/C Mutation Screening in a Large Cohort of Familial Dilated Cardiomyopathy Patients.** *S.B. Parks, P. Jakobs, D. Li, J. Kushner, E. Burkett, S. Ludwigsen, M. Litt, R. Hershberger.* Department of Medicine/Cardiology, Oregon Health & Science University, Portland, OR.

Heart failure, which typically results from dilated cardiomyopathy (DCM), is responsible for 260,000 deaths per year in the US. One third or more of all patients with non-ischemic (idiopathic) dilated cardiomyopathy have a positive family history, referred to as familial dilated cardiomyopathy (FDC). Mutations in several genes have been linked to FDC, including lamin A/C (*LMNA*), -myosin heavy chain, cardiac troponin T, cardiac actin, desmin, and others. We have previously reported *LMNA* mutations in 3 of 16 FDC kindreds (19%). Other reports have suggested that *LMNA* mutations may account for 5-10% of FDC. It is still unclear what proportion of FDC cases are attributable to *LMNA*, or if a reliable genotype-phenotype correlation will emerge. In addition, mutations in *LMNA* can cause a variety of diseases, including Emery-Dreifuss muscular dystrophy, Charcot-Marie-Tooth disease, familial partial lipodystrophy and progeria, among others.

To better define the nature of *LMNA* mutations causing FDC, we have begun a mutation screening protocol in 122 of our FDC kindreds. With approximately 7% of the protocol completed, we have identified a novel *LMNA* missense mutation, a G to C transversion at nucleotide 302. The G302C mutation is predicted to replace the wildtype arginine with proline at residue 101 within the central rod domain of the protein. This domain, an helical coiled coil, is formed by hydrophobic residues in the center and charged amino acids on the surface. Replacement of a positively charged arginine with a hydrophobic proline is expected to have a dramatic affect on polypeptide structure, and to likely alter protein function. The subject carrying the G302C mutation developed DCM and atrial fibrillation in his 30s, progressing to heart failure and eventual cardiac transplantation. His brother and at least four other relatives have been similarly affected. We anticipate that the discovery of this and other FDC associated *LMNA* mutations in our cohort will help to advance the status of mutation detection in dilated cardiomyopathy.

***COL3A1* mutations in Japanese patients with Ehlers-Danlos syndrome type IV (EDSIV).** A. Watanabe<sup>1,2</sup>, N. Sakai<sup>1</sup>, T. Wada<sup>3</sup>, M. Fujimoto<sup>4</sup>, Y. Fukushima<sup>3</sup>, T. Shimada<sup>1,2</sup>. 1) Dept Molec & Medical Genet, Nippon Medical Sch, Tokyo, Japan; 2) Div Clinical Genet, Nippon Medical Sch Main Hosp, Tokyo, Japan; 3) Div Clinical & Molecular Genet, Shinshu Univ Hosp, Nagano, Japan; 4) Dept Dermatology, Jichi Medical Univ, Tochigi, Japan.

Ehlers-Danlos syndrome type IV (EDSIV), the vascular type, is an autosomal dominant disorder and results from mutations in the genes for type III procollagen (*COL3A1*). Affected patients are at risk for arterial, bowel, and uterine rupture.

We analyzed four unrelated Japanese patients with the features of EDSIV. In order to identify mutations in patients RNA, the 3.3 kb reverse transcriptase polymerase chain reaction (RT-PCR) product containing triple-helical domain of *COL3A1* was prepared from cultured skin fibroblast and sequenced directly. Our results showed four heterozygous mutations, three novel missense base substitutions (Gly220Trp, Gly727Asp, Gly877Asp) and a 24 bp insertion mutation in 1440th nt of position of *COL3A1*. In this insertion mutation, eight amino acids added to in frame *COL3A1* but had no glycine, supposed to be decreased the normal mature type III collagen. Further analysis of the genomic structure of the insertion type is in progress. We also discuss the genotype-phenotype correlations in these individuals.

**Role of PTEN in lipid signaling in breast cancer.** *C. Alvarez-Breckenridge, K.A. Waite, C. Eng.* Human Cancer Genetics, The Ohio State University, Columbus, OH.

The tumor suppressor gene PTEN encodes a dual specificity phosphatase that recognizes both protein and phosphatidylinositol lipid substrates and modulates cellular functions such as migration and proliferation. Germline, but more importantly somatic, mutations in PTEN have been shown to play a role in breast cancer. Since its discovery, the role of PTEN as a negative regulator of the phosphatidylinositol-3-kinase/Akt pathway has been intensely investigated. In contrast, little is known about the role of PTEN in regulating other lipid signaling pathways by modulating phosphatidylinositol(4,5)bis-phosphate (PIP<sub>2</sub>; PTENs product) and phosphatidylinositol(3,4,5)tri-phosphate (PIP<sub>3</sub>; PTENs substrate). Within the last two decades, and underscored by the discovery that PTEN is a lipid phosphatase, phospholipids have been shown to play a critical role in signal transduction, and are key players in determining whether a cell divides. With the continued work of lipid signaling events and metabolism, it is becoming clear that the modulation of PIP<sub>2</sub> and PIP<sub>3</sub> levels is a theme in cellular regulation. As a consequence, PTEN may be a master regulator of cellular regulation due to its ability to modulate the levels of these lipids. Based upon these findings, we hypothesize that PTEN regulates lipid signaling and lipid homeostasis. We found that in unstimulated MCF-7 cells, increased expression of PTEN, through an inducible vector, results in a 51% increase in phosphatidic acid (PA), a product of phospholipase D (PLD), suggesting that PTEN may regulate PLD. Further, overexpression of PTEN results in a 1.3-fold increase in PLD activity in unstimulated cells, with a concomitant decrease in phosphatidylcholine, the PLD substrate. This activation appears to be dependent upon the lipid phosphatase activity as overexpression of mutated PTEN protein that does not have lipid phosphatase activity results in a decrease in basal PLD activity. Further work along these lines will allow us to understand the role of PTEN in lipid-mediated signaling events and may provide novel targets for cancer therapy and prevention.

**Functional exploration of A type lamins and associated proteins in patients affected with Hutchinson-Gilford Progeria Syndrome caused by G608G mutation in LMNA.** *N. LEVY*<sup>1,2</sup>, *C. Navarro*<sup>1</sup>, *I. Boccaccio*<sup>1</sup>, *A. Boyer*<sup>2</sup>, *P. Negre*<sup>2</sup>, *K. Devriendt*<sup>3</sup>, *Y. Shafeghaty*<sup>4</sup>, *J. Bridger*<sup>5</sup>, *N. Progeria is a rare, typical and severe premature aging disorder. Death usually occurs around 13.4 years, due to stroke or coronary artery disease. Recently, we and others identified the a single point mutation in LMNA encoding Lamin A as the cause of progeria. To further explore the mechanisms underlying progeria, we performed genomic transcriptional and functional analysis in 7 patients affected with HGPS. The c.1824C>T (p.G608G) mutation was detected in all cases. Transcript splicing and/or protein expression levels for lamins A/C, lamins B and emerin were analyzed by RT-PCR and western blotting on patients lymphoblasts or fibroblasts. In all cases, a 150 bp heterozygous deletion was identified due to the aberrant use of a cryptic donor splice site. Western blotting showed a decreased amount of Lamin A with or without truncated Lamin A. Immunocytochemistry with antibodies to Lamin A/C, A, B1, B2, emerin and nup62 was performed. Nuclear sizes were highly variable; herniations and interruptions of the nuclear envelopes with chromatin extrusion were observed. Lamin A/C and emerin were often lacking on one pole of the nuclei, being delocalized to the nucleoplasm into foci or with homogeneous patterns. Lamins B were delocalized as voluminous foci in the nucleoplasm. These findings underscore the implication of perturbed nuclear functions in the pathogenesis of progeria and orientate the research towards specific molecular interplays being impaired.

**Defining Branchio-Oto-Renal syndrome and determining the contribution of EYA1 mutations to this phenotype.**

*E.H. Chang*<sup>1</sup>, *N.C. Meyer*<sup>1</sup>, *V.S. Vervoort*<sup>2,3</sup>, *C.E. Schwartz*<sup>2,3</sup>, *R.J.H. Smith*<sup>1</sup>. 1) Molecular Otolaryngology, University of Iowa, Iowa City, IA; 2) Department of Genetics and Biochemistry, Clemson University, Clemson, SC 29654; 3) Greenwood Genetic Center, Greenwood, SC 29646.

Background: BOR syndrome is an autosomal dominant disorder with an estimated prevalence of 1:40,000. It affects ~2% of profoundly deaf children and has a variable phenotype that typically involves the branchial arches, ears, and kidneys. EYA1 mutations are known to cause BOR syndrome and are reported in ~18% of families segregating a BOR phenotype. Objective: To refine the diagnostic criteria for BOR by analyzing phenotypic data from 33 families in which disease-causing EYA1 mutations have been found; to develop a novel screening method to detect large insertions/deletions of EYA1. Methods: Literature review of phenotypic data from persons with documented EYA1 mutations and the presentation of 9 novel disease-causing mutations and their phenotypes. Intervention: Mutation screening of EYA1 was completed on DNA by single-strand conformational polymorphism (SSCP) analysis. Samples were sequenced bi-directionally if shifts were observed on MDE gels. A semi-quantitative based screen was developed to detect large insertions and deletions in EYA1, which were confirmed via sequence-based or single nucleotide polymorphism (SNP) analysis. Results: Of 33 disease-causing EYA1 mutations with adequate phenotypic data, 16 are nonsense or frameshift, 8 are missense, 6 are splice site, and 3 are large deletions. The most common resulting phenotype includes deafness (98.5%), preauricular pits (83.6%), branchial anomalies (68.5%), renal anomalies (38.2%) and external ear abnormalities (31.5%). Based on these phenotypic data, we developed strict diagnostic criteria for BOR syndrome and found that 30% of families fulfilling these criteria had mutations in EYA1 detectable by SSCP analysis. Our semi-quantitative PCR screen identified an additional 4 of 17 patients with large insertions/deletions of EYA1. This result means that ~50% of persons with a BOR phenotype will have mutations in EYA1, although 40% of the identified EYA1 mutations will be large insertions/deletions.

Fragile X (FraX) premutation, defined as the presence of 55-200 CCG repeats in the FMR1 gene, is known to contribute to the FraX phenotype through expansion to full mutation allele (>200 CCG). There is emerging evidence that premutation alleles may cause in older male carriers a syndrome presenting with intention tremor, ataxia and a peculiar neuroimaging pattern. We examined for FraX premutation two series of clinically ascertained male patients: i) 114 subjects (belonging to 71 families) diagnosed as having definite essential tremor (ET) (mean age 62.5, SD 17.7); ii) 51 individuals (48 families; mean age 57.8, SD 15.1) referred as having spinocerebellar ataxia (SCA), who resulted negative for SCA1, SCA2, SCA3, SCA6, DRPLA repeat expansions. No premutation allele was found in the ET cohort (82 patients were older than 50 years). Conversely, we identified two SCA patients carrying the premutation (84 and 86 repeats, respectively). This corresponds to a rough 4% proportion (2/51), which raises up to 7.1% if only subjects older than 50 are included (2/28). The first patient (aged 55 at examination) presented with gait ataxia, dysarthria, muscle weakness and atrophy of lower limbs. The second patient (71 ys.) had severe kinetic tremor, along with cerebellar atrophy and signal alteration of the middle cerebellar peduncles on MRI. These observations were consistent with the clinical profile reported in affected male carriers. In summary, these findings allowed to rule out FraX premutation as genetic risk factor for ET. On the other hand, the excess of premutation carriers among SCA individuals further confirms that the presence of a premutation allele contribute to a distinct movement disorder and should be investigated in patients with such a clinical presentation.

**Three novel SACS mutations in Italian patients with Autosomal Recessive Spastic Ataxia of Charlevoix-Saguenay type.** *C. Casali<sup>1</sup>, G. Grieco<sup>2</sup>, A. Malandrini<sup>3</sup>, M. Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) is an early-onset form of cerebellar ataxia with spasticity and axonal neuropathy, which occurs frequently in the Charlevoix-Saguenay-Lac-Saint-Jean region of Quebec, but is believed to be rare elsewhere. ARSACS is associated with mutations in the SACS gene, which encodes saccin, a protein of unknown function. In two Italian ARSACS families, we identified three novel SACS mutations resulting in premature translation termination of saccin. Apart from the absence of retinal striation, the phenotype of the Italian patients closely resembles that of French Canadian cases. While lending definitive support to the notion that SACS mutations are not confined to the Quebec region, our data also expand the number of genetic alterations that must be considered in patients with cerebellar ataxia.

**Fibroblast expression profile analysis in the human progeroid syndrome (MAD) associated to LMNA mutations.**

D'Adamo<sup>2</sup>, A. Nardone<sup>1</sup>, K. Margiotti<sup>1</sup>, M. Lewis<sup>3</sup>, G. Novelli<sup>1</sup>.* 1) Dept Hum Genetics, Tor Vergata Univ, Rome, Italy; 2) Dept Int Medicine, Tor Vergata Univ; 3) Dept Psychology, Univ of Texas at Austin, USA.

MAD (Mandibuloacral dysplasia OMIM\*248370) is a rare autosomal recessive disorder characterized by mandibular and clavicular hypoplasia, acroosteolysis, delayed closure of cranial sutures, joint contractures, mottled cutaneous pigmentation and partial lipodystrophy. MAD is caused by a mutation in the LMNA gene (R527H). The LMNA gene is also implicated in a wide spectrum of genetic disorders called laminopathies. It is reasonable that laminopathies arise from alteration and/or disturbance in differentiation, maintenance, repair or regulation of mesenchymal cells. Three possible mechanisms have been suggested to explain the extreme phenotypic variability induced by LMNA mutations, such as nuclear fragility, alteration of gene expression patterns, and knock-on effect on the complement of proteins found in the endoplasmic reticulum. To understand the molecular pathogenesis of this disorder, we performed an expression analysis of 5184 genes using a cDNA microarray (DermArray, Integriderm). Cultured fibroblasts were obtained from skin specimens derived from two patients (a 37 yrs old male and a 22 yrs old female) and from three control subjects (a 40 yrs man and two females with a mean age of 21 yrs old). Microarray analysis was performed by Pathways 4-Universal Microarray Software (ResGen). A total of 119 genes show a differential expression in MAD fibroblasts. Fifty genes were upregulated (ratio > 3) and 69 downregulated (ratio < 0,3). Only 15 of them showed a common behavior in both patients. The six upregulated genes include structural, ribosomal and carrier proteins; the nine downregulated genes encode for enzymes, transcription factor and structural, contractile and heat shock proteins. The altered expression of 8 of these 15 genes was confirmed by Q-RT PCR. Among the upregulated genes, we found COL3A1, while among the downregulated genes we detected POLR2B. Both these proteins could play an important role in MAD pathogenesis.

**Expression of the Hutchinson Gilford Progeria Mutant Lamin A Causes Abnormal Nuclear Morphology and Lamin A Mislocalization.** *M.W. Glynn, T.W. Glover.* Dept of Human Genetics, Univ of Michigan, Ann Arbor, MI.

Hutchinson-Gilford Progeria Syndrome (HGPS) is a rare disease that affects children in the first decade of life and causes a remarkable phenotype resembling many aspects of aging. Affected children have an aged appearance, a lack of subcutaneous fat, growth retardation and severe atherosclerosis. The average life span of progeria patients is 13 years, with most dying from complications due to atherosclerosis. Virtually all HGPS patients have the same mutation creating an abnormal splice donor site in exon 11 of the LMNA gene. The result of the mis-splicing creates a protein missing 50 amino acids near the C-terminus. The deleted region includes a protein cleavage site that normally removes 18 amino acids including a CAAX box farnesylation site. The LMNA gene codes for lamin A and lamin C proteins, which are a component of the nuclear lamina, a fibrous matrix located at the interior of the nuclear membrane, responsible for nuclear integrity and organization. We have created GFP-tagged normal and HGPS-mutant lamin A expression constructs and have transfected normal and HGPS fibroblasts. As expected, the normal protein localizes at the periphery of the nucleus in normal cells. Expression of the GFP-tagged mutant lamin A in normal fibroblasts causes an abnormal nuclear morphology including mislocalization of the GFP-tagged mutant lamin A to foci at the nuclear periphery, and nuclear blebbing similar to that seen in HGPS fibroblasts. Expression of normal lamin A in HGPS fibroblasts did not significantly correct the nuclear blebbing phenotype. Furthermore, the normal GFP-lamin A was mislocalized indicating that the presence of the endogenous mutant can cause mislocalization of the normal GFP-tagged lamin A in a dominant-negative fashion. These results show that the mutant HGPS cellular phenotype can be recreated in normal cells and that the mutant phenotype is not easily corrected by over-expression of the normal protein. In addition, they provide evidence for the mislocalization of the HGPS-specific form of lamin A, which may affect lamin A function in an array of nuclear processes including transcription, replication and cell cycle functions.

**Phenotypic variability in Friedreich ataxia: spastic paraplegia in the absence of point mutations in the FRDA gene.** *E. Andermann*<sup>1,2</sup>, *A. Badhwar*<sup>1,2</sup>, *M.H. Seni*<sup>1,2</sup>, *M. Pandolfo*<sup>3</sup>, *F. Andermann*<sup>2</sup>. 1) Neurogenetics Unit, McGill Univ, Montreal, PQ, Canada; 2) Department of Neurology and Neurosurgery, Montreal Neurological Hospital and Institute, McGill Univ, Montreal, PQ, Canada; 3) Centre Hospitalier de l'Universit de Montral, Montreal, PQ, Canada.

Friedreich ataxia (FA) is an autosomal recessive disease with onset before the age of 25. The majority of FA cases are due to mutations in the Frataxin gene (FRDA) on 9q13. 96% of patients with FA have homozygous expansions of an intron 1 GAA repeat. 4% have an expansion on one allele and a point mutation on the other. Point mutations (particularly D122Y and G130V) may give rise to an atypical FA phenotype with slow disease progression, minimal or no ataxia, and gait spasticity (Durr et al, 1999). We report a male patient with late onset, slowly progressive spastic paraplegia, in a FA family with 3 affected siblings and marked intra-familial phenotypic variability. The 43-year old proband(P1) first presented with cardiomyopathy at age 16. He developed progressive spasticity, bilateral lower limb weakness and mild ataxia at age 25, and was wheelchair-bound at age 40. His sister(P2) was diagnosed with FA at age 29, exhibiting ataxia, bilateral lower limb weakness and dysarthria. She initially presented with insulin dependent diabetes at age 21. His brother(P3) developed progressive ataxia and leg weakness in early childhood. By age 24, he had developed diabetes, optic atrophy, hearing loss and cardiomyopathy. He died at age 31. Autopsy revealed slight atrophy of the cerebellum at the level of the vermis and atrophy of the dorsal roots. Mutation analysis in P1, 2 and 3 confirmed the diagnosis of FA in this family. P1 had expansions in both FRDA alleles, each with 750 GAA repeats. P2 had 850 and 450 repeats, while P3 had 1050 and 790 repeats. Marked intra-familial phenotypic variability with respect to age of onset and mode of presentation exists in this FA family, despite average size GAA expansions in both alleles, demonstrating the importance of modifying genes. Our proband is unusual in having atypical FA with spastic paraplegia with equal GAA expansions in both alleles and without point mutation in D122Y and G130V.

**Functional studies of the RNA component of RMRP in Cartilage Hair Hypoplasia.** *P. Hermanns*<sup>1,3</sup>, *A. Bertuch*<sup>1</sup>, *M. Schmitt*<sup>4</sup>, *B. Zabel*<sup>3</sup>, *B. Lee*<sup>1,2</sup>. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Children's Hospital, University of Mainz, Germany; 4) Biochemistry and Molecular Biology, SUNY Upstate Medical University, Syracuse, NY.

RNase mitochondrial RNA processing endoribonuclease (RMRP) is a nuclear encoded, ubiquitously expressed pol III RNA transcript. It is part of a large ribonuclear protein complex with multiple functions in yeast including processing of the pre-rRNA, cleavage of mitochondrial RNA for priming DNA replication, and perhaps cell cycle control. However, its function in vertebrate development is completely unknown. Mutations in RMRP cause a skeletal malformation syndrome CHH affecting chondrogenesis, hematopoiesis, and hair development. Four single base pair substitutions were found in our cohort of CHH patients (70AG, 124CT, 180GA, 262GT) and while the fifth mutation was a 2 bp deletion mutant (267,268). We have introduced these five mutations in the essential RMRP yeast ortholog NME1 to understand effects of human mutations on NME1 function. The *nme1* mutants were all viable and their growth rates were indistinguishable from wild type control, with the exception of the 2 bp deletion, which showed a significant growth delay. Since RMRP is involved in mitochondrial replication we also looked for loss of mitochondrial function in the mutant strains at different temperatures. No differences were found in mutant vs. wild type strains. Furthermore, we did not detect evidence of cell cycle delay in four of the *nme1* mutants via FACS analysis. RNase MRP is required for production of the 5.8S<sub>S</sub> rRNA species. Mutations in yeast cause failure to process the 5.8S<sub>L</sub> rRNA to 5.8S<sub>S</sub> rRNA. Two of the *nme1* mutants (70AG and the 2bp deletion mutant) showed an alteration of the 5.8S<sub>S</sub>/5.8S<sub>L</sub> rRNA ratio. These data show that a subset of CHH mutations can affect ribosomal RNA processing while more severe mutations are likely lethal. Together these studies will provide insight into the pathogenesis of the pleiotropic effects observed in CHH.

**Causative Malignant Hyperthermia mutations excluded in the pathophysiology of South African clubfoot**

**patients.** *C. Mouton*<sup>1</sup>, *B. Semete*<sup>1</sup>, *H. Brand*<sup>2</sup>, *A. Olckers*<sup>1,3</sup>. 1) Centre for Genome Research, Potchefstroom University for CHE, Pretoria, South Africa; 2) Department of Anesthesiology, University of Pretoria, South Africa; 3) DNAbiotec (Pty) Ltd, Pretoria, South Africa.

Malignant hyperthermia (MH) is a pharmaco-induced syndrome, characterised by skeletal muscle calcium dysregulation, hypermetabolism and elevated body temperatures. This autosomal dominant genetic predisposition is a response to individual exposure to inhalational anaesthetics or depolarising muscle relaxants. If not treated immediately, MH results in severe tissue damage, organ failure and death. Although treatment has led to a significant decline in mortality associated with MH, it still remains the most common cause of death from general anaesthetic. At present the diagnosis of MH based on clinical phenotypes alone is invasive, and cumbersome. For this reason the molecular diagnosis of this disorder needs to be embraced. Various mutations in the skeletal muscle ryanodine receptor (RYR1) gene located on chromosome 19q13.1, and encoding the calcium release channel of skeletal muscle, can account for susceptibility to MH. A number of mutations have been reported within the RYR1 gene, although only seventeen have been demonstrated to be causative. This study included three infants, aged three to eight months, who had typical clubfoot phenotypes and a Clinical score of six (performed according to Larach et al., 1994). With their first exposure to anaesthesia which was during surgery for clubfoot, these patients developed an MH episode. The anaesthetic agents included Sevoflurane or Halothane. All three patients were screened for seventeen causative mutations via RFLP and automated sequencing. None of the mutations investigated were detected in these individuals. This result was not unexpected, although, these mutations had to be excluded. Their absence implies that these seventeen mutations do not contribute towards the MH phenotype of these three clubfoot patients. This study is the first to investigate the link between the clubfoot and MH phenotypes concurrently observed in this group of patients.

**Examination of the mitral valve prolapse locus on chromosome 11p15.4.** *M. Leyne*<sup>1</sup>, *F. Nesta*<sup>1,2</sup>, *D. Dai*<sup>1</sup>, *J. Acierno*<sup>1</sup>, *L. Freed*<sup>1,2</sup>, *R. Levine*<sup>1,2</sup>, *S. Slaugenhaupt*<sup>1,2</sup>. 1) Harvard Inst Human Genetics, Massachusetts General Hosp, Boston, MA; 2) Harvard Medical School, Boston, MA;

Mitral valve prolapse (MVP) is a very common cardiac disorder in humans, occurring in approximately 2.4% of the general population. The condition is characterized by systolic billowing of the mitral leaflets into the left atrium, often accompanied by mitral regurgitation. Early attempts at establishing a genetic basis for MVP were limited by difficulties in diagnosis; however, recent advances in echocardiography have significantly increased the diagnostic specificity. We have recently identified a novel MVP locus, *MMVP2*, on chromosome 11p15.4 by genetic linkage mapping in a single large pedigree. The *MMVP2* locus was originally defined as a 4.3-cM region between the markers *D11S1923* and *D11S1331*. This region contained several large sequence gaps and 46 RefSeq genes. Initial examination of the known genes in the large candidate interval revealed a potential candidate, matrix metalloproteinase-26 (*MMP26*). *MMP26* was screened for mutations since MMPs are known to function in the degradation of the extracellular matrix and several MMPs have been shown to be over-expressed in myxomatous valve tissue. No coding sequence or splice site changes were identified in MVP patients in this family, suggesting that this gene is not likely to be involved in MVP. We have now used haplotype analysis with new informative genetic markers to narrow the candidate interval from 4.4 Mb to 2.7 Mb between the markers *PNM1104* and *D11S1331*. This smaller region has no sequence gaps and contains only 38 RefSeq genes, which are currently being prioritized and screened for MVP mutations. Determination of the genetic basis of MVP is important because the disease often manifests clinically in the 5th or 6th decade of life through presentation as a severe cardiac event. Earlier intervention in genetically susceptible individuals could potentially prevent progression to a clinically severe stage.

**Human spastin (SPG4): Functional characterization of potential nuclear localization sequences and N-terminal deletion mutants.** *J. Schickel<sup>1</sup>, M. Brodhun<sup>2</sup>, K. Moutzouris<sup>1</sup>, T. Deufel<sup>1</sup>.* 1) Inst Klinische Chemie, FSU Jena, Jena, Germany; 2) Inst Pathologie, FSU Jena, Jena, Germany.

The SPG4 locus at 2p21-p22 has been shown to account for approximately 40-50 percent of all families with autosomal dominant hereditary spastic paraplegia (HSP); the SPG4 gene is ubiquitously expressed in adult and fetal tissues and encodes for spastin, an 616-amino-acid ATPase belonging to the AAA protein family. It was shown that overexpressed wild-type spastin interacts transiently with microtubules and is likely to be involved in microtubule dynamics; in this model, spastin association with the microtubule cytoskeleton is mediated by the N-terminal region of the protein and regulated through the ATPase activity of the AAA domain. In a recent report, however, immunolabeling experiments using polyclonal antibodies suggest that spastin protein is localized in the nucleus outside the nucleolus. Our study was aimed at characterizing functional domains in the N-terminal part of spastin, specifically 1) testing the functionality of putative nuclear localization sequences (NLS), and 2) mapping the tubulin-binding region. Constructs containing four predicted NLS fused to green fluorescent protein (GFP) were generated and transiently expressed in cultured cells. Our results indicate that none of these sequences in neither C-terminal nor N-terminal fusions was sufficient for nuclear targeting. A set of deletion mutants of both wild-type spastin and the K388R mutant spastin, the latter known to irreversibly associated with microtubule, were fused to GFP and transfected. Binding to MT is tested by immunofluorescence and will allow to fine-map the MT interacting domain.

**Identification of two novel mutations of the human elastin gene in Korean patients with SVAS.** *S.M. Park<sup>1</sup>, E.J. Seo<sup>1,2</sup>, Y.H. Kim<sup>1</sup>, H.W. Yoo<sup>1,3</sup>, Y.H. Kim<sup>1,3</sup>, J.K. Ko<sup>1,3</sup>, I.S. Park<sup>1,3</sup>.* 1) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center, Seoul, Korea; 2) Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

The human elastin gene (ELN) has 34 exons and spans an approximately 45 kb of genomic region at chromosome 7q11.23, encoding tropoelastin, an elastin precursor of 72 kDa. Elastin is composed largely of glycine, proline, and other hydrophobic residues and contains multiple lysine-derived crosslinks, such as desmosines, which link the individual polypeptide chains into a rubber-like network. The resilience of many tissues, such as vascular walls, skin, ligaments, and lungs are maintained by elastic fibers in the extracellular matrix. Genetic defects of ELN are known to be associated with the development of supravalvular aortic stenosis (SVAS), a cardiovascular disease with the characteristic thickening of the aorta media and intima. We have identified two novel mutations of ELN, 890\_922del and 2260C>A, in two unrelated Korean patients with SVAS. The 890\_922del mutation causes deletion of 11 amino acids at exon 17, which corresponds to the hydrophilic region involved in cross-linking of this protein. The 2260C>A mutation substitutes Trp for Arg at codon 754 in exon 34, which encodes a hydrophobic domain. Functional characterization of these mutations will be helpful in understanding the molecular causes of SVAS and, furthermore, in developing therapeutic treatments of this cardiovascular disease.

**Muscle proteins alteration in patients with mutations in the Fukutin-Related Protein gene.** *L.U. Yamamoto, M. Canovas, R.C.M. Pavanello, B.L. Lima, F. de Paula, N. Vieira, M. Zatz, M. Vainzof.* Human Genome Research Center, IBUSP, University of Sao Paulo, SP, Brazil.

The fukutin-related protein (FKRP) has been recently identified, with sequence similarities to a family of proteins involved in the glycosylation of cell surface molecules. Mutations in the FKRP gene were identified in limb-girdle muscular dystrophy type 2I (LGMD2I) and congenital muscular dystrophy type 1C (CMD1C), both previously mapped to an identical region on chromosome 19q13.3. CMD is characterized by onset of symptoms within the first few months of life, and in the 1C form, there is inability to walk. LGMD2I has a milder and variable course, a slower progression, and the age at onset varying from the first to the fourth-fifth decade of life. Both show preserved intelligence and elevated serum CK. Secondary protein abnormalities such as a variable reduction in the expression of  $\alpha$ -dystroglycan and 2-laminin have been described in the CMD1C form. Here we report the results of the analysis of muscle proteins associated to the sarcolemma (dystrophin, sarcoglycans, dysferlin) extracellular matrix (2-laminin, collagen VI), from the sarcomere (telethonin) and from the muscle cytosol (calpain 3) in muscle biopsies from 13 unrelated patients with molecular diagnosis of LGMD2I. We observed that eight patients, five with the common C826A mutation, showed a variable degree of deficiency of 2-laminin, through immunofluorescence analysis; three patients showed calpain 3 and two patients, deficiency of dystrophin, through western blot analysis. The present study shows that in our population, mutations in the FKRP gene can lead to secondary reduction of several muscle proteins, and the deficiency of 2-laminin on sections is clearly prevalent in the milder form. Financial support: FAPESP-CEPID, PRONEX, CNPq.

**Deficiency of myotilin in skeletal muscle of a patient with limb-girdle muscular dystrophy: a primary or a secondary defect?** *M. Vainzof<sup>1</sup>, L.U. Yamamoto<sup>1</sup>, P.M. Kossugue<sup>1</sup>, L.L.Q. Fogaca<sup>1</sup>, J. Gurgel-Giannetti<sup>2</sup>, M. Moza<sup>3</sup>, P. Salmikangas<sup>3</sup>, O. Carpen<sup>3</sup>.* 1) HGRC-IBUSP, University of Sao Paulo, SP, Brazil; 2) UFMG, Belo Horizonte, Brazil; 3) Dep of pathology, University of Helsinki, Helsinki, Finland.

Myotilin is a thin filament-associated Z-disc protein, that binds to -actinin, actin and filamin C. Mutations in the myotilin gene lead to a rare autosomal dominant limb-girdle muscular dystrophy 1A form (LGMD1A), characterized by proximal muscle weakness, a dysarthric speech and high serum CK levels. On muscle biopsy myopathic alterations and rimmed vacuoles are observed. Up to now, only two families with T57I and S55F missense mutations have been described; the former mutant allele is transcribed and normal levels of correctly localized myotilin protein are seen. Here we identified a 14-year-old patient, with severe proximal muscle weakness, with difficulties to climb stairs, to get up from the floor, or to raise the arms. Serum CK is 15X increased and EMG is myopathic. Muscle biopsy analysis showed degeneration, variation in fiber size, fiber splitting, connective tissue replacement and a large number of rimmed vacuoles. Muscle protein analysis revealed normal expression for dystrophin, sarcoglycans, calpain 3, dysferlin, telethonin and 2-laminin. On the other hand, western blot analysis using three different myotilin antibodies showed a clear reduction in the amount of the 57 kDa myotilin band, in comparison to other cytoskeletal proteins and to control muscle biopsies. Lymphocyte DNA analysis for the myotilin gene is ongoing to verify if this deficiency is a primary or a secondary defect. This patient is an isolated case, but she has an unaffected identical twin sister. Therefore, any identified gene mutation is probably a post-zygotic event. Additionally, the possibility of a somatic mosaic in the patient must also be considered. In any case, this is the first description of a deficiency of myotilin in a dystrophic patient, compatible with the formation of the sarcomeric structure in muscle fibers. **Mutations in the potassium channel gene KCNJ2 constitute a rare cause of long QT syndrome.** *H.M. Fodstad<sup>1</sup>, H. Swan<sup>2</sup>, M. Auberson<sup>3</sup>, I. Gautschi<sup>3</sup>, J. Loffing<sup>4</sup>, L. Schild<sup>3</sup>, K. Kontula<sup>1</sup>.* 1) Biomedicum, University of Helsinki, Finland; 2) Department of Cardiology, University of Helsinki, Finland; 3) Institute of Pharmacology and Toxicology, University of Lausanne, Switzerland; 4) Institute of Anatomy, University of Zurich, Switzerland.

Mutations of six different genes (KCNQ1, HERG, KCNE1, KCNE2, SCN5A, ankyrin-B) have been shown to cause long QT syndrome (LQTS). Andersens syndrome (AS), a rare form of periodic paralysis, associated with dysmorphic features and cardiac arrhythmias, was recently established to result from mutations of KCNJ2, a strong inward rectifying potassium channel regulating resting cell membrane potential in heart, brain and skeletal muscle. We conducted a search for KCNJ2 mutations among 185 unrelated probands with LQTS. The screening was performed by denaturing high-performance liquid chromatography and DNA sequencing. Two novel mutations of the KCNJ2 gene were detected in two families: a missense threonine to alanine mutation (T75A) in the N-terminal region (family 1) and an in-frame deletion of two amino acids (FQ163-164) in the M2 transmembrane region (family 2). In addition, a previously described silent polymorphism C1146T was detected. In family 1, some of the affected family members had a history of periodic muscle weakness characteristic of AS, but no dysmorphic features. The mean QTc interval of the affected members were 444.24 ms (family 1, n=7) and 456.8 ms (family 2, n=2). These two mutations were not found in 231 healthy control individuals. The mutations affect functionally important regions of the KCNJ2 channel protein: upon transfection of the *Xenopus* oocytes with the wild type and mutant KCNJ2 constructs, the channel proteins were correctly synthesized and addressed at the cell surface, but no measurable inward K<sup>+</sup> current could be detected for the mutant KCNJ2 constructs. In conclusion, we report two novel loss-of-function mutations of the KCNJ2 channel, affecting different domains of the channel protein. Our data also suggest that the KCNJ2 mutations found likely result in these families in a LQTS phenotype without overt manifestations of AS.

**Expression profiling reveals involvement of the GABA<sub>A</sub> receptor subunit in the fragile X syndrome. I. Gantois<sup>1</sup>, J.**

*Vandesompele<sup>2</sup>, F. Speleman<sup>2</sup>, R. D'Hooge<sup>3</sup>, L.-A. Severijnen<sup>4</sup>, R. Willemsen<sup>4</sup>, F. Tassone<sup>5</sup>, R.F. Kooy<sup>1</sup>.* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Dept Medical Genetics, Ghent University Hospital, Ghent Belgium; 3) Dept Neurochemistry and Behavior, Univ Antwerp, Antwerp, Belgium; 4) Dept Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 5) Dept Biological Chemistry, University of California, Davis, School of Medicine, Davis, CA.

Despite intense research it is still unclear why absence of the fragile X protein (FMRP) leads to the mental retardation, macroorchidism and specific behavior problems observed in fragile X patients. A decade of research demonstrated that FMRP, the protein missing in fragile X patients, is an RNA binding protein that shuttles between the nucleus and cytoplasm. In neurons, the protein may transport certain brain mRNAs towards the actively translating ribosomes near the synapses.

In an attempt to unravel the mechanism leading to the disorder, we performed global gene expression analysis using differential display on neurons from the fragile X mouse model, a validated model for the disorder. To verify differential expression we used microarray technology and real-time PCR. We revealed 3 differentially expressed cDNAs that showed consistent underexpression in the fragile X knockout mouse. In addition, we identified 5 genes that showed differentially expression dependent on the sample of RNA analysis, and we consider their differential expression as provisional. This list of 3 differentially expressed sequences contains a GABA<sub>A</sub> receptor subunit, a Rho guanine exchange factor 12 and an EST BU563433. It is possible that the differential expression of these genes play a role in the fragile X syndrome. E.g., absence of rho guanine exchange factor 6 causes mental retardation in patients and mice lacking the GABA<sub>A</sub> receptors subunit subunit have an increased sensitivity to epileptic seizures, like fragile X patients. Differential expression of the GABA<sub>A</sub> subunit delta receptor was shown to be restricted to the hippocampus and cortex.

**Clinical and cellular phenotype of two Italian sibs with ATLD.** *L. Chessa<sup>1</sup>, M. Piane<sup>1</sup>, S. Palmeri<sup>2</sup>, C. Savio<sup>1</sup>, G. Buscemi<sup>3</sup>, P. Lulli<sup>1</sup>, A.M.R. Taylor<sup>4</sup>, D. Delia<sup>3</sup>.* 1) Dpt. Experimental Medicine Pathology, II Faculty Medicine, Hosp S Andrea, Roma, Italy; 2) Dpt. Neurological Sciences, University of Siena, Italy; 3) Dpt. Experimental Oncology, Istituto Nazionale Tumori, Milano, Italy; 4) The University of Birmingham CRC Institute for Cancer Studies, UK.

We studied two sibs with a slowly progressive neurological syndrome mimicking ataxia telangiectasia. The neurological features appeared during infancy with unsteadiness and progressed to ataxic gait, oculomotor apraxia, nystagmus and cerebellar dysarthria. The two sibs, now 34 and 33, are still able to walk for few steps unaided. In both patients laboratory investigations, including immunoglobulins, alpha-fetoprotein, lysosomal enzymes, vitamin E and lipoproteins, resulted normal. EMG revealed a slight motor sensory neuropathy. Brain CT scan and MRI showed cerebellar atrophy with a moderate increase in the size of the fourth ventricle. Tests performed on X-irradiated peripheral blood lymphocytes at G2 phase showed mild radiosensitivity, intermediate between classical Ataxia Telangiectasia patients and controls. Western analysis revealed normal levels of ATM but markedly reduced amounts of NBS1, Mre11 and Rad50. No mutations in ATM and NBS1 genes were found. By cDNA sequence of Mre11 gene the mutated maternal allele (1442C>A) was identified, while the second allele was actually null, possibly due to nonsense-mediated mRNA decay. The sequencing of genomic DNA revealed a single base change C>T in exon 15, i.e. nucleotide 1714 in the cDNA sequence, that changes the normal codon CGA (Arg) into the stop codon TGA and reduces the Mre11 protein size from 81 to 65KDa. The patients were classified as Ataxia Telangiectasia Like Disorder (ATLD). To better understand the effects of their mutations on the function of the NMR complex we analysed the radiation induced Mre11 nuclear foci. While before irradiation ATLD cells showed a more diffuse Mre11 staining than wild-type cells, after irradiation they failed to form Mre11 nuclear foci. Moreover, the radiation induced Chk2 phosphorylation in the ATLD fibroblasts appeared defective. These results contribute to clarify the pathway of the cellular response to IR-induced DNA damage.

**AN UNUSUALLY MILD TUBEROUS SCLEROSIS PHENOTYPE ASSOCIATED WITH A MISSENSE MUTATION IN TSC2.** *M.D. D'Agostino<sup>1,2,3</sup>, A. Badhwar<sup>1,2,3</sup>, G. Gobbi<sup>3</sup>, R. Wilkinson<sup>3</sup>, D. Melanson<sup>2,3</sup>, R. Koenekoop<sup>3</sup>, M. Gans<sup>3</sup>, G. Li<sup>3</sup>, M.H. Seni<sup>1,2,3</sup>, D. Tampieri<sup>2,3</sup>, F. Andermann<sup>2,3</sup>, F. Dubeau<sup>2,3</sup>, M. Pandolfo<sup>2,4</sup>, D. Kwiatkowski<sup>5</sup>, E. Andermann<sup>1,2</sup>.* 1) Neurogenetics Unit, McGill University, Montreal, QC., Quebec, Canada; 2) Department of Neurology and Neurosurgery, Montreal Neurological Hospital and Institute, McGill University, Montreal, Quebec, Canada; 3) McGill University Hospital Centre, Montreal, Quebec, Canada; 4) Centre Hospitalier de l'Universite de Montreal, Quebec, Canada; 5) Hematology, Brigham and Womens Hospital, Boston, MA.

Tuberous sclerosis(TSC) is an autosomal dominant disorder caused by mutations in the TSC1(9q34) or TSC2(16p13) genes. The disease phenotype was found to be more severe in sporadic TSC2 patients. We analyze the genotype/phenotype correlations in a 3-generation family (202 individuals) presenting with familial epilepsy and suspicion of TSC. 58 family members were genotyped for TSC1 and TSC2 markers. We demonstrated linkage to the TSC2 locus. 28 affected individuals had a missense mutation in exon 23(2714G to A, 905R to Q). Epilepsy was diagnosed in 15/28(54%) individuals with the mutation. Seizures occurred mainly during childhood, were easily controlled, and frequently remitted spontaneously. In 24/28(86%) we detected ash-leaf or confetti spots. No facial angiofibromas, periungual fibromas or rhabdomyomata were found. Eye exams in 11/28 patients demonstrated cataract in two; glaucoma, minor intraretinal lesions, and retinal hamartoma in one individual each. Neuroimaging studies (21/28) revealed sub-ependymal giant cell astrocytoma and sub-ependymal nodules in one patient each, and hypersignal in the cerebral white matter in 7. Abdominal ultrasound detected renal angiomyolipoma in 1/14. The most frequent psychiatric diagnoses were learning disabilities (6/28) and anxiety disorder (4/28). This study expands the phenotypic spectrum of familial TSC2 and demonstrates extremely mild clinical features, in particular a benign prognosis of epilepsy. This in contrast with the more severe phenotypes described in a large series of sporadic TSC2 cases, indicating co-segregation of a modifying gene(s).

**Novel IRF6 mutations in Japanese patients with Van der Woude Syndrome: Two missense mutations (R45Q and P396S) and a 17-kb deletion.** *S. Kayano*<sup>1,2</sup>, *K. Kanno*<sup>1,2</sup>, *A. Yamada*<sup>1</sup>, *S. Kondo*<sup>3</sup>, *B.C. Schutte*<sup>3</sup>, *J.C. Murray*<sup>3</sup>, *Y. Suzuki*<sup>2</sup>, *S. Kure*<sup>2</sup>, *Y. Matsubara*<sup>2</sup>. 1) Plastic/Reconstructive Surg, Tohoku Univ Sch Medicine, Sendai Miyagi, Japan; 2) Dept. Medical Genetics, Tohoku Univ Sch Medicine, Sendai Miyagi, Japan; 3) Dept. Pediatrics, Iowa Univ, Iowa City, IA, USA.

Three Japanese families with Van der Woude syndrome (VWS) were screened for mutations in the interferon regulatory factor 6 gene (IRF6) by sequencing its entire coding region. Two novel missense mutations, R45Q in exon 3 and P396S in exon 9, were identified in families 1 and 2, respectively. In family 3, no causative base change was found by the sequencing analysis, but a deletion involving exons 4-9 was suggested by multiplex PCR analysis. To confirm the deletion and to determine its 5- and 3-boundaries, we amplified a DNA fragment containing a heterozygous polymorphic site in exon 2 by using a 5-upstream forward PCR primer and eight different reverse primers located 3 downstream of exon 2. The amplified product was subjected to nested PCR to generate a DNA fragment containing the polymorphic site. When a reverse primer located within the deletion was used for the first PCR amplification, only the non-deletion allele was detected after the second PCR. Repeated analyses with eight different reverse primers allowed us to map the boundaries of the deletion and subsequently a heterozygous 17,162-bp deletion involving exons 4-9 was identified. Since IRF6 mutations in a significant portion of VWS patients remain undetected by conventional sequencing analysis, it may be important to search for a large deletion in those patients. Our simple methods to identify deletions and to determine the boundaries of a deletion would facilitate the identification of such patients.

**Novel *de novo* mutations in *JAG1* gene.** *P.S. Lai*<sup>1</sup>, *S.L. Low*<sup>1</sup>, *W.S. Lee*<sup>2</sup>, *M. Aw*<sup>1</sup>, *S.C. Quek*<sup>1</sup>, *S.H. Quak*<sup>1</sup>. 1) Dept Pediatrics, National Univ Singapore, Singapore, Singapore; 2) Dept Pediatrics, Universiti Malaya, Malaysia.

Alagille syndrome (AGS, MIM 118450) is a multisystem developmental disorder affecting 1 in 70,000 newborns. It is characterized by bile duct paucity leading to liver disease, with involvement of other major organs. There is highly variable phenotypic expressivity, and diagnosis in mildly presenting patients can be difficult without molecular characterization. In this study, eight AGS patients of Chinese, Malay and Indian ethnic origins were identified based on histologic findings on liver biopsy with the presence of at least three of the five major clinical presenting features. Involvement of *JAG1* gene, which encodes a ligand in the Notch signalling pathway, was confirmed in all the patients. Insetion/deletion and point mutations were identified in exons 6, 10, 12, 14, 17 and 21 of *JAG1*. No deletion of the the entire *JAG1* gene was observed. All these mutations affect the evolutionarily conserved EGF-like motifs of the *JAG1* protein. One nonsense and six frameshift mutations are predicted to result in truncated protein products. A heterozygous missense mutation is expected to severely affect interactions with Notch receptor. Screening of parental genomic DNA samples indicate *de novo* origin of all the mutations. In most cases, parents of the proband did not have any clinical features consistent with a diagnosis of AGS except for one mother with features suggestive of AGS microform. Our results show a high degree of novel and *de novo* mutations occurring in the EGF-like repeats of *JAG1* in our patients.

**Novel *ENAM* mutation responsible for autosomal recessive amelogenesis imperfecta and localized enamel defects.**

*T.C. Hart*<sup>1</sup>, *P.S. Hart*<sup>2</sup>, *M.C. Gorry*<sup>1</sup>, *M.D. Michalec*<sup>2</sup>, *O. Ryu*<sup>1</sup>, *C. Uygur*<sup>3</sup>, *D. Ozdemir*<sup>3</sup>, *S. Firatli*<sup>3</sup>, *G. Aren*<sup>3</sup>, *E. Firatli*<sup>3</sup>. 1) Craniofacial Genetics, University of Pittsburgh, Pittsburgh, PA; 2) School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) School of Dentistry, University of Istanbul, Istanbul, Turkey.

The amelogenesis imperfectas (AI) are a clinically and etiologically heterogeneous group of heritable conditions characterized by qualitative or quantitative anomalies of enamel. While genetic loci have been identified for autosomal dominant and X-linked forms of AI, the genetic bases of nonsyndromic autosomal recessive forms of AI (ARAI) are unknown. The aim of this study was to evaluate five candidate genes for an etiologic role in nonsyndromic ARAI. By proband ascertainment, we identified 20 consanguineous families with AI consistent with autosomal recessive transmission. Family members were genotyped for genetic markers spanning 5 candidate genes: *AMBN* and *ENAM* (4q13.3), *TUFT1* (1q21), *MMP20* (11q22.3-q23), and *KLK4* (19q13). Genotype data were evaluated to identify loci inherited identical by descent in affected individuals. Mutational analysis was performed by genomic sequencing. Results: Homozygosity linkage studies were consistent for localization of an AI locus in three families to the chromosome 4q region containing the *ENAM* gene. *ENAM* sequence analysis in these families identified a 2 bp insertion mutation that introduced a premature stop codon in exon 10. All 3 probands were homozygous for the same g.13185\_13186insAG mutation, consistent with inheritance of the mutation from a common ancestor. These 3 probands presented with a generalized hypoplastic and undermineralized AI phenotype and a class II openbite malocclusion. All heterozygote carriers of the g.13185\_13186insAG mutation manifested localized, circumscribed hypoplastic enamel pitting defects, but none had AI nor openbite malocclusion. Conclusion: These findings demonstrate that the phenotype associated with the g.13185\_13186insAG *ENAM* mutation is dosage dependent with ARAI and openbite malocclusion segregating as a recessive trait, and enamel pitting segregating as a dominant trait.

**Identification of cryptic mutations in *IRF6* using real time deletion assays and genomic sequencing.** *N. Miwa, M. Johnson, S. Hoper, S. Kondo, T. Zuccherro, J.C. Murray, B.C. Schutte.* Pediatrics, Univ Iowa, Iowa City, IA.

We recently showed that mutations in *IRF6* cause Van der Woude syndrome (VWS). To date, we sequenced all exons and flanking intronic sequence in samples from 129 unrelated cases and identified missense (M), protein truncation (PT) and splicing (S) mutations in 84 cases (65%).

Exon	1	2	3	4	5	6	7	8	9	10
M	0	0	8	15	0	2	16	4	1	0
PT	0	1	5	6	1	9	5	2	8	0
S	0	0	1	0	0	0	0	0	0	0

There is minimal evidence for locus heterogeneity in VWS, and two large pedigrees that lack a mutation were linked to *IRF6*. Consequently, we sought evidence for point mutations that might be located outside the exons and for deletions in the 35% of samples with no mutation. We performed a real time PCR deletion assay for exons 2 and 7 on 24 samples and disclosed three likely deletions. One family appeared to be deleted at both probes. Complete genomic sequence of the 23 kb gene identified 67 SNPs. In addition, six mutations were identified in single individuals but were not identified in 90 control samples. In summary the missing mutations in VWS appear to be caused in part by the presence of genomic deletions of as yet indeterminate size and occasional mutations located within regulatory regions outside the exons. No evidence for locus heterogeneity has yet been established. These findings will provide improved genetic counseling and a better understanding of functional elements for *IRF6*.

**RFNG: a candidate gene in Russel-Silver syndrome.** *M. Ulijamperl<sup>1</sup>, D. Galron<sup>2</sup>, T. Harel<sup>1</sup>, U. Bar-yosef<sup>1</sup>, R. Ofir<sup>1</sup>, O.S. Birk<sup>1,2</sup>.* 1) Molecular Genetics, Ben-Gurion University, Beer-Sheva, Israel; 2) Soroka University Medical Center, Beer-Sheva, Israel.

Russel-Silver syndrome (RSS, OMIM #180860) occurs sporadically and is characterized by primordial growth failure, normal head circumference, a triangular face, right-left asymmetry, and fifth finger clinodactyly with normal intelligence. Approximately 10% of SRS cases show maternal uniparental disomy for chromosome 7. Less than 5% of SRS cases are caused by defects in the GRB10 gene located on chromosome 7. However, the genetic defect underlying most cases of this syndrome is unknown.

There have been two separate reports of RSS appearing in conjunction with a chromosomal breakpoint in the long arm of chromosome 17 at band 17q25, suggesting that this locus might harbor the gene defective in this disorder. Radical fringe (RFNG) is an interesting candidate gene for RSS that resides at this precise chromosomal location. RFNG is similar to *Drosophila* fringe (*fng*), which is known to participate in the evolutionarily conserved Notch receptor signaling pathway. Fringe genes encode pioneer secretory proteins with weak similarity to glycosyltransferases. Both expression patterns and functional studies support an important role for Fringe genes in patterning during embryonic development and an association with cellular transformation. The potential relevance to RSS stems from three experiments: a. fruitflies lacking functional *fng* have short legs. B. Notch has been implicated in right-left asymmetry in *C. elegans*. C. *fng* normally activates Notch by glycosylating it. Thus, in the absence of active RFNG, one would expect a phenotype of short stature and possible asymmetry, two of the hallmarks of RSS.

We have amplified by PCR and sequenced the 8 exons of RFNG and their flanking intronic regions. Thus far, of 8 RSS patients studied, none exhibited RFNG mutations. Analysis of additional RSS patients is underway.

**Mutation in GPIb impairs assembly of the platelet von Willebrand factor receptor and causes Bernard-Soulier syndrome.** *J. Tang<sup>1</sup>, S. Stern-Nezer<sup>1</sup>, P. Liu<sup>1</sup>, L. Matyakhina<sup>2</sup>, N. Luban<sup>3</sup>, S.G. Kaler<sup>1</sup>.* 1) Unit on Pediatric Genetics, LCG, NICHD/NIH, Bethesda, MD; 2) Section on Genetics and Endocrinology, DEB, NICHD/NIH, Bethesda, MD; 3) Children's National Medical Center, Washington, DC.

Haploinsufficiency for contiguous genes on chromosome 22q11 is associated with velocardiofacial (VCF) syndrome. Glycoprotein Ib (GPIb), a component of the platelet membrane receptor for the von Willebrand factor (vWF), lies within the 22q11 critical region. Isolated deficiency or impaired function of GPIb causes the bleeding disorder Bernard-Soulier syndrome (BSS) in which the platelet vWF receptor complex (GPIb-GPIb-GPIX) does not properly assemble at the platelet cell surface. Consequences range from troublesome bleeding episodes to serious hemorrhage. Treatment approaches include transfusions, desmopressin (DDAVP) to shorten bleeding time, recombinant activated factor VII, and bone marrow transplant. We identified and characterized a novel GPIb mutation in a patient with VCF and BSS. FISH in transformed lymphoblasts revealed a 22q11 deletion in the proband and neither parent. Flow cytometry showed absence of platelet surface GPIb and GPIX in the proband, and reduced levels in the patient's father. Proband DNA sequence showed normal GPIb and GPIX, and a CT transition in the GPIb coding region, predicting a proline to serine substitution (P96S) in a carboxy-terminus cystine loop. The mutation destroys a BanI site, enabling screening of other family members and normal controls. As expected from platelet flow data, the father was heterozygous for P96S. Fifty normal chromosomes did not harbor the mutation. We characterized P96S GPIb by expression experiments in a cell line (CHOIX) that stably surface-expresses human GPIb and GPIX. Flow cytometry and confocal imaging of transfected CHOIX cells demonstrated that P96S GPIb entirely abrogates surface assembly of the platelet vWF receptor complex. Based on these and other data, we propose a model of GPIb protein structure. Our results shed light on the critical importance of P96 for non-covalent association of GPIb with GPIX. Since estimated carrier frequency is 1:500, BSS may represent an under-appreciated co-morbid feature of VCFS.

**Reciprocal crossovers and a positional preference for strand exchange in recombination events resulting in deletion/duplication 17p11.2.** *W. Bi<sup>1</sup>, C.J. Shaw<sup>1</sup>, M.A. Withers<sup>1</sup>, S.-S. Park<sup>1</sup>, P.I. Pragnal<sup>1, 3</sup>, J.R. Lupski<sup>1, 2, 4</sup>.* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatrics; 3) Neurology; 4) Texas Children Hospital, Houston, Texas, 77030, USA.

Smith-Magenis syndrome (SMS) is caused by an ~3.7 Mb heterozygous interstitial deletion in 17p11.2 in about 80-90% of patients. The SMS common deletion interval is flanked by large (~200 kb), complex, and highly homologous (~98%) low-copy repeat (LCR) gene clusters-the proximal and distal SMS-REPs. These LCRs act as substrates for nonallelic homologous recombination (NAHR) resulting in both the deletion associated with SMS and the reciprocal duplication-dup(17)(p11.2p11.2). What potentially stimulates the recombination events and whether or not strand exchanges are distributed evenly throughout the regions of homology are presently unknown. Using restriction enzyme cis-morphism analyses and direct sequencing we mapped the regions of strand exchange in 16 hybrids that harbor only the recombinant SMS-REP. Our analyses showed that the sites of strand exchanges distribute widely throughout the region of homology. However, 50% of the recombinant junctions occurred in an ~12 kb region within the *KER* gene cluster of the SMS-REP. Through DNA sequencing of this hotspot, the sites of crossing-over in 7 recombinant SMS-REPs were precisely located in an ~8 kb interval. Interestingly, 4 occur in a 1.7 kb region rich with polymorphic nucleotides that could potentially reflect frequent gene conversion. For further evaluation of the strand exchange frequency in patients, novel junction fragments from the recombinant SMS-REPs have been identified in both SMS and dup(17)(p11.2p11.2) patients as predicted by the reciprocal recombination model. Putative recombination promoting sequences human minisatellite core sequence and -like sequence were identified within the hotspot. Interestingly, there is an ~2.1 kb AT-rich inverted repeat flanking the proximal and middle *KER* gene clusters but not the distal one. We hypothesize that this inverted repeat structure may stimulate double-strand breaks around this positional recombination hotspot and facilitate the unequal crossing-over.

**Rapid screening of large genomic rearrangements in the cystic fibrosis transmembrane conductance regulator (CFTR) gene by quantitative multiplex polymerase chain reaction of short fluorescent fragments (QMPSF)**

**analysis: high detection rate and diverse mutational mechanisms.** *C. Férec<sup>1</sup>, J.M. Chen<sup>1</sup>, O. Raguénès<sup>1</sup>, N.A.*

*Chuzhanova<sup>2</sup>, K. Giteau<sup>1</sup>, S. El Mouatassim<sup>3</sup>, C. Le Maréchal<sup>1</sup>, I. Quéré<sup>1</sup>, M.P. Audrézet<sup>1</sup>.* 1) INSERM 01 15, Génétique Moléculaire et Génétique Epidémiologique, Université de Bretagne Occidentale, Etablissement Français du Sang-Bretagne, Centre Hospitalier Universitaire de Morvan, Brest 29220, France; 2) Department of Computer Science, Cardiff University, Cardiff, United Kingdom; 3) Laboratoire Marcel Mérieux, Service de Génétique Humaine, Lyon, France.

Cystic fibrosis, the most common life-shortening autosomal recessive disorder in Caucasians, is caused by mutations in the CFTR gene. Despite the extensive and enduring effort of many CF researchers worldwide over the past 14 years, 1 to 30% of the disease alleles still remain to be identified. Although it has long been suggested that gross genomic rearrangements may account for these unidentified alleles, only several simple large deletions have been found by Southern blotting; and only three of them have been fully characterized. Here we reported the first systematic screening of the 27 exons of the CFTR gene for large genomic rearrangements, using the simple and rapid QMPSF technique. We analysed a well-characterized cohort of 39 patients: all had classical CF and carried at least one unidentified allele after extensive and complete screening of the CFTR gene by our well-established DGGE and DHPLC techniques. A total of 6 novel mutations including 2 simple large deletions and 4 complex large indel mutations were found, accounting for about 16% of the previously uncharacterized CF chromosomes. This represents a further significant step in understanding the molecular pathogenesis of the disease. Moreover, that all these mutations were fully characterized (ie, the breakpoints were determined) enabled us to investigate in detail their underlying mechanisms and, in particular, to trace the origin and follow the formation of the inserted sequences in the 4 complex indel mutations. This has revealed amazing new aspects of the diverse mechanisms underlying large genomic rearrangements that cause human disease.

**Fine mapping of balanced translocation breakpoints in 4 patients with non-syndromic mental retardation. L.**

*Crisponi<sup>1</sup>, S. Rassu<sup>2</sup>, C. Floris<sup>1</sup>, L. Boccone<sup>3</sup>, D. Gasperini<sup>3</sup>, G. Pilloni<sup>3</sup>, A. Cao<sup>1</sup>, G. Pilia<sup>1</sup>.* 1) Istituto di Neurogenetica e Neurofarmacologia (INN), CNR, Cagliari, Italy; 2) Università degli Studi di Cagliari, Cagliari, Italy; 3) Ospedale Regionale per le Microcitemie Cagliari, Italy.

Mental Retardation (MR) is a common disorder affecting about 3% of the human population. While several X-linked non-syndromic mental retardation loci and genes have been identified, few autosomal loci have been mapped so far. We collected 4 patients, 3 males and 1 female, with non-syndromic mental retardation associated with balanced translocations. With cytogenetic analysis we positioned the corresponding breakpoints as follow: t(X;3)(Xq13.1; 3p22.3); t(5;8)(5q14.3; 8q23.3); t(6;8)(6q14; 8q23.3); and t(7;9)(7q11.2; 9q33.3). We used Fluorescent In Situ Hybridization (FISH) analysis with Bacterial Artificial Chromosomes (BACs) as probes to map the exact position of the breakpoints in order to identify the genes affected by the translocations. In the t(X;3) patient we have been able to identify BAC clones containing the breakpoints on both chromosomes. The genomic sequence analysis of the DNA surrounding the breaks indicated that no gene had been interrupted. However, 4 candidate genes map on the 150 kb region around the Xq13 breakpoint. On 3p22.3 there is only one candidate gene about 100kb downstream to the break. For the t(5;8) and t(6;8) translocations we focused on the 8q23.3 region which contains both breakpoints. FISH analysis revealed that the two breakpoints lie 4 Mb apart. Several potential genes map in the genomic DNA around the breakpoints. It is notable that this region has been involved in the Langer Giedion Syndrome (tricho-rhino-phalangeal syndrome, type II, MIM150230) whose affected patients show mental retardation associated with other typical malformations. The MR patient with t(7;9) have been studied only in its 9q33.3 breakpoint and we mapped it in a 500 kb region. Mutation analysis in non-syndromic MR patients, functional studies, and the creation of animals with selective inactivation of candidate genes mapping at these breakpoints could lead to the identification of new genes involved in MR.

**Multiplex Ligation-Dependent Probe Amplification (MLPA): A promising technology in the detection of subtelomeric rearrangements.** *P. Hilbert, M-N. Michel, D. Sartenaer, S. Rombout, B. Parmentier, Y. Gillerot, L. Van Maldergem.* Human Genetics Center, Inst Pathologie et Genetique, Loverval, Belgium.

Unbalanced subtelomeric rearrangements can now be considered as a major cause of mental retardation and /or malformation syndrome since they are identified in up to 10 % of selected populations of mentally retarded patients . If some of the rearrangements result in a specific phenotype easily recognised by clinicians and confirmed by a single FISH analysis, the majority of subtelomeric defects produce an aspecific phenotype and require a general subtelomeres screen to be identified. Different methods of screening are available (Multiplex FISH, polymorphic markers, microarray CGH, ..) but the majority of them present important technical and /or financial limitations. Recently, two new technologies , Multiplex Amplifiable Probe Hybridisation (MAPH) and Multiplex Ligation-Dependent Probe Amplification (MLPA) were developed . They allow a rapid and inexpensive screen of all the subtelomeres from a few nanograms of DNA. The MLPA being commercially available as a kit ([www.mrc-holland.com](http://www.mrc-holland.com)) we decided to evaluate the method by testing a panel of normal patients as well as a serie of positive cases previously ascertained by cytogenetics and /or FISH in our centre. On a total of 24 rearrangements, we were able to confirm 11 duplications (probes 3 qter, 7 qter, 9 pter, 19 pter, 19 qter, 21 pter, 21q21, 21 qter, Xq11, X pter and X qter) and 11 deletions (probes 2 qter, 6 qter, 9 pter, 9 qter, 18 pter, 21 pter, 21q21, X qter, Y pter, Y q11, Y qter). Two rearrangements were missed : a 9 qter deletion and a 6 pter deletion. False positive results were also obtained with the 6 pter probe. In conclusion, our results suggest that the MLPA technology represents an interesting method, usefull in the subtelomeric rearrangements screening of mentally retarded and/or malformed patients.

**Single-sided haplotype conservation in BCM patients suggests the activation of a cryptic mutant opsin gene copy through unequal homologous recombination.** *B. Wissinger*<sup>1</sup>, *S. Tippmann*<sup>1</sup>, *J. Nathans*<sup>2</sup>. 1) Molecular Genetics Laboratory, University Eye Hospital, Tuebingen, Germany; 2) HHMI, Johns Hopkins University School of Medicine.

Blue Cone Monochromacy (BCM) is a rare X-linked visual disorder. It results from the simultaneous functional loss of middle (green) and long wavelength sensitive (red) cone photoreceptors due to mutations in the opsin gene cluster on Xq28. In normal subjects the opsin gene cluster is composed of a single red cone opsin gene and one up to five copies of the green cone opsin gene. In the majority of BCM patients there is only a single red-green hybrid opsin gene left that harbours a common missense mutation, C203R. In order to investigate this particular genotype we performed marker analysis and comparative sequencing of the opsin gene cluster in 33 independent Caucasian BCM patients. Marker analysis revealed a striking difference in haplotype conservation between flanking centromeric and telomeric chromosomal segments. There were mostly unique haplotypes centromeric to the opsin gene cluster while there were only a few common haplotypes on the telomeric side. Indeed 20 patients share a common telomeric haplotype. This difference in haplotype segment conservation is reflected also within the locus itself. Comparative sequencing of the opsin gene(s) in the BCM patients revealed high sequence variability proximal to the C203R mutation but mostly conserved sequences distal to it. This indicates that the formation of single hybrid genes carrying the C203R mutation have occurred multiple times. Analysis of 500 unselected male controls revealed a frequency of ~ 1.5% for the C203R mutation in the Caucasian population. In all controls the mutated gene copy occupies the most telomeric position within the gene cluster and thus has no or only a mild phenotypic effect (cryptic mutant allele). Intriguingly these controls show telomeric haplotype segments identical to those seen in the BCM patients. We therefore argue that the formation of the most common BCM genotype occurs through unequal homologous recombination involving a frequent founder chromosome harbouring a cryptic mutant allele.

**HOMOZYGOUS MYOTONIC DYSTROPHY CLINICAL EVALUATION, MOLECULAR ANALYSES AND GENETIC COUNSELING.** *N. Lannoy<sup>1</sup>, I. Abinet<sup>1</sup>, M. Freund<sup>1</sup>, C. Hubinont<sup>2</sup>, P. Van Den Berghe<sup>3</sup>, K. Dahan<sup>1</sup>, Ch. Verellen-Dumoulin<sup>1</sup>.* 1) Dept Genetics, UCL , Saint-Luc Hospital, Brussels, Belgium; 2) Dept of Obstetrics and gynecology, UCL, Saint-Luc Hospital, Brussels, Belgium; 3) Dept of Neurology, UCL, Saint-Luc Hospital, Brussels, Belgium.

Myotonic dystrophy (DM) is the most common autosomal dominant form of adult muscular dystrophy caused by an expansion of CTG repeat in the 3'UTR of a protein kinase gene. In the literature, 6 homozygous DM patients have been described with a phenotype similar than usually reported in heterozygotes. The purpose is to report the clinical and molecular studies of 3 additional MD homozygotes from 2 non consanguineous Belgian families and the apparent stability of intergenerational transmission. In the first family, the homozygotes are 2 sisters (aged 21 and 28) with two expanded alleles (respectively 108-607 repeats and 108-178 repeats). These 2 individuals belong to large families with a maternal and paternal history of DM. In the second family, the propositus is an 68 year old female who has bilateral cataract at 43 years of age as the only symptom of DM. The CTG expansion analyses show the presence of an apparently homozygous expanded allele (128 repeats) without normal allele. The description of DM homozygous cases in country with low consanguinity rate may be useful for clinical purposes in particular for genetic counseling and prenatal diagnosis. Furthermore, these presentation raises the question of a real appreciation of DM prevalence in Belgium.

**Deletions of the pseudoautosomal region encompassing the SHOX gene in Leri-Weill dyschondrosteosis. A.R.**

*Zinn<sup>1</sup>, B. Luo<sup>1</sup>, J.L. Ross<sup>2</sup>.* 1) McDermott Center for Human Growth and Development, The University of Texas Southwestern Medical School, Dallas, TX; 2) Department of Pediatrics, Thomas Jefferson University, Philadelphia, PA.

Leri-Weill dyschondrosteosis is characterized by short stature, mesomelia, and Madelung deformity of the wrist. Heterozygous deletions of the pseudoautosomal gene SHOX are the most frequent cause of Leri Weill dyschondrosteosis and imply that haploinsufficiency is the genetic mechanism underlying this disorder. The pseudoautosomal region (PAR1) encompassing SHOX may be prone to undergo deletions because of its high frequency of recombination during male meiosis and its abundance of repetitive DNA sequences. In order to better understand the nature of SHOX deletions, we are characterizing PAR1 microdeletions in subjects with dyschondrosteosis using a combination of FISH and somatic cell hybrids. We have examined 14 subjects with normal karyotypes (in some cases inferred from the karyotype of an affected relative) and a SHOX deletion confirmed by FISH with cosmids LLNCOYC03-M34F5 or LLNCOYC03-M15D10. Twelve of the 14 deletions break within PAR1, as judged by FISH with PAC clone RPCI3-431I1 near the proximal PAR1 boundary, whereas two of the deletions extend beyond PAR1. Thus most SHOX microdeletions lie entirely within PAR1, consistent with the hypothesized propensity of sequences within this region to undergo deletions. Because few other robust FISH probes for PAR1 sequences are readily available, we are using human/rodent somatic cell hybrids retaining the deleted X chromosome to refine the mapping of deletions. Preliminary results using PCR assays for the PPP2R3B gene distal to SHOX and the ANT3 gene proximal to SHOX demonstrate that both terminal and interstitial PAR1 deletions occur. Further characterization of these deletions will reveal whether low-copy repeat sequences in PAR1 create hotspots for SHOX deletions, as is the case for other chromosomal deletions such as Prader-Willi/Angelman and DiGeorge syndromes.

**Autosomal dominant Pterygium of the conjunctiva: a report of an India family.** *R. Meda<sup>1</sup>, R. Singh<sup>2</sup>, R.M. Memon<sup>3</sup>, J.V. Solanki<sup>4</sup>, U. Ratnamala<sup>1</sup>, U. Radhakrishna<sup>1</sup>.* 1) Genetics Laboratory, Green Cross Blood Bank & Genetic Centre, Paldi; 2) Dr. P.L. Desai Eye Center, Navrangpura; 3) Department of Zoology, Gujarat University, Ahmedabad; 4) Department of Animal Genetics & Breeding, Veterinary college, Gujarat Agriculture University, Anand, India.

The conjunctiva is the thin, transparent tissue that covers the outer surface of the eye. It begins at the outer edge of the cornea, covering the visible part of the sclera, and lining the inside of the eyelids. It also secretes oils and mucous that moistens and lubricates the eye. Pterygium, a wing-like growth of the conjunctiva is most common in people who live in tropical climates or spend a long time in sunny, windy or dusty climates. In most cases it develops late in life and in rare instances at birth. The growth of pterygium usually remains dormant; however, in some cases it grows over the central cornea and blocks light entering the eye. It also affects the vision by altering the shape of the cornea. Environmental factors may influence the penetrance. Small families with autosomal dominant modes of inheritance have been reported but no mutation-causing gene has yet been identified. We have studied a large four generation Indian pedigree with Pterygium of Conjunctiva (OMIM 178000) in which the anomaly segregates as an autosomal dominant trait. The pedigree consists of 21 individuals including seven affecteds (five males and two females). All affecteds had bilateral pterygia. The age of onset ranged from 30-35 years. Surgical excision was done in three affecteds. There was 100% penetrance in this family. The family did not have a history of long exposure to solar radiation, dust or wind, and they live in a pollution free environment. To the best of our knowledge this is only hereditary Pterygium reported with male to male transmission and provides further evidence that genetic factors make a few individuals susceptible to Pterygium of Conjunctiva. **Linkage analysis of polycystic kidney disease in Persian cats.** *L.A. Lyons<sup>1</sup>, A.E. Young<sup>1</sup>, H.R. Roberts<sup>2</sup>, D.S. Biller<sup>3</sup>.*  
1) Population Health and Reproduction, School of Veterinary Medicine, University of California, Davis, Davis, CA; 2) Sierra College, 5000 Rocklin Road, Rocklin, CA 95677; 3) Department of Clinical Sciences, College of Veterinary Medicine, Kansas State University, Manhattan, KS 66506.

Autosomal dominant polycystic kidney disease (ADPKD) is a common inherited disorder (1/1000) in humans that is characterized by the formation of fluid-filled cysts in the kidneys. Defects in the PKD1 and PKD2 genes cause 85% and 15% of human ADPKD cases, respectively. Mutations in a single gene, PKHD1, are responsible for autosomal recessive PKD (ARPKD). Mutations in several genes, including the recently described gene Nck8, cause PKD in mice. Although a number of cases of feline PKD have been described, a causative gene has not been identified. PKD affects approximately 38% of Persian cats worldwide. Forty-two microsatellites were chosen from the feline linkage and radiation hybrid maps based on known homology with human chromosomal regions that contain the PKD1, PKD2, PKHD1 and Nck8 genes. Through the use of seven extended Persian cat pedigrees, a linkage analysis has shown strong linkage, with a significant LOD score ( $Z = 5.83, = 0$ ), between a marker on feline chromosome E3, which is within 10 cM of the PKD1 gene, and the PKD disease phenotype. Further investigation into the cause of PKD will be valuable for feline health as well as provide insights into human ADPKD. The PKD1 gene is now being scanned for causative mutations.

**Characterization of early onset of retinal degeneration in Persian cats.** *H. Rah*<sup>1</sup>, *D.J. Maggs*<sup>2</sup>, *T. Blankenship*<sup>3</sup>, *L.A. Lyons*<sup>1</sup>. 1) Population Health & Reproduction, School of Veterinary Medicine, University of California Davis, Davis, CA; 2) Surgical and Radiological Sciences, School of Veterinary Medicine, University of California Davis, Davis, CA; 3) Cell Biology and Human Anatomy, School of Medicine, University of California Davis, Davis, CA.

A rapid, complete, early-onset retinopathy has been noted in Persian cats. To date, only end-stage inherited retinal degeneration (15 weeks of age) has been described. Our pedigree suggests an autosomal recessive mode of inheritance. We have characterized the inheritance, clinical, histologic, and genetic features of this disease. Kittens with known disease genotypes were produced by mating homozygous affected and heterozygous normal carriers. Seventeen cats (9 affected; 8 phenotypically normal carriers) from 4 litters were ophthalmically examined weekly from eye-opening until 16. Extent and speed of pupillary light reflexes were diminished in affected cats by 2 weeks of age and decreased further with age. Dazzle reflex was lost in affected animals by 3 weeks. Retinal vascular attenuation was first suspected at 4 weeks. Horizontal pupil diameter was greater in affected cats (7 mm) than in normal phenotype cats (4 mm) at 5 weeks. Altered tapetal reflectivity was first observed at 6 weeks of age and was generalized by 9 weeks. At 15 weeks, marked generalized retinal degeneration was seen in all affected cats. Behavioral testing confirmed total blindness in affected individuals by 16 weeks. Histological examinations suggest that photoreceptors were present and quickly degenerated between 3-15 weeks. We have identified ten genes (RPE65, RHO, PDE6B, PDE6A, RDS, RP1, CRX, CRB1, RGPR1 and GUCY2D) that we are isolating from the feline BAC library in order to screen for mutations and to isolate gene-associated microsatellite markers. Particular regions of six candidate genes with known mutations causing inheritable retinopathies in other species have been scanned. One missense mutation was identified in RP1; however, the mutation did not segregate with disease phenotype. Linkage mapping is being performed on the pedigree. We have described an autosomal recessive, rod cone dysplasia of Persian cats.

**Molecular analysis of the dysferlin gene and phenotypic spectrum of dysferlinopathies.** *K. Nguyen<sup>1</sup>, G. Bassez<sup>3</sup>, V. Labelle<sup>1</sup>, D. Figarella-Branger<sup>1</sup>, F. Leturcq<sup>2</sup>, J. Pouget<sup>1</sup>, B. Eymard<sup>3</sup>, N. Levy<sup>1</sup>.* 1) Hopital de la Timone, Marseille, France; 2) Hopital Cochin, Paris, France; 3) Hopital de la Pitie-Salpetriere, Paris, France.

Dysferlinopathies are autosomal recessive muscular dystrophies, caused by defects in the dysferlin gene. Two well-described phenotypes can result from the same defects in the dysferlin gene: limb-girdle muscular dystrophy type 2B (LGMD2B) and Miyoshi myopathy (MM). The dysferlin gene is composed of 55 coding exons in a total genomic region of 150 kb. A relatively small number of mutations was reported so far. In order to analyse gene mutations in patients with dysferlin deficiency, we performed SSCP screening of each of the 55 exons of the gene followed by sequencing. Furthermore, to investigate the phenotypic spectrum of the dysferlinopathies, we examined clinical, pathological, biological features and protein expression of 55 french patients with either LGMD2B or MM. We identified 20 novel mutations in 16 patients; one novel splicing mutation was found in three unrelated patients. We identified in majority non-sense and frameshift mutations. All these mutations were widely distributed along the coding sequence; mutational hot spots were absent. The phenotypic study revealed that 36% of the patients (from 15 families) were of maghrebian origin; 26% of the patients could not be classified as MM or LGMD2B and presented at onset with a combination of proximal and distal weakness and atrophy in the lower limbs. We introduced the term "proximodistal" for this major group. Two patients had an isolated hyperCKaemia, one of them was still asymptomatic at age 55. A minority of patients had a particularly severe progression of the disease with confinement to wheelchair in less than 5 years after onset. Misdiagnosis was frequent with diagnosis of polymyositis for 28% of the patients. The presence of inflammatory changes on muscle biopsy was significantly correlated to the severity of the disease. Finally, we established a database (Universal Dysferlin Mutations Database) in order to collect the mutational and phenotypical data and to study genotype/phenotype correlations.

Program Nr: 2298 from 2003 ASHG Annual Meeting

***MutationView* : Addition of Automatic Extraction System for Disease-associated Knowledge.** *M. Ohtsubo, S. Mitsuyama, T. Kawamura, S. Minoshima, N. Shimizu.* Department of Molecular Biology, Keio University School of Medicine, Japan.

One of the important purposes of genome research is to elucidate the genes responsible for monogenic as well as multigenic diseases. In order to better understand correlation between disease and genetic diversity, we developed the integrated database system *MutationView*, which at present mainly deals with monogenic diseases (<http://mutview.dmb.med.keio.ac.jp>). *MutationView* is the system which can search, display and analyze the mutation data with graphical environment. The characteristic features of the *MutationView* include the followings. (1) Various data display and analysis functions are available with regard to genomic/cDNA structure of normal gene, functional domain structure of protein, zooming-in and -out of the nucleotide and amino acid sequences, plotting mutations with the histogram of case number, changes in the nucleotide sequence and restriction sites, classification based on mutation type, case number, dominant/recessive and symptom, experimental information such as PCR primers and reaction conditions. (2) To date, we have collected 8476 entries of mutations from 1531 literatures dealing with 211 genes involved in 199 distinct diseases focused on nine categories of diseases, such as those related to ophthalmology, brain, muscle, otolaryngology, heart, syndrome, autoimmunity and familial tumor. (3) Several ways are available to access to the gene of interest through the chromosomal map, anatomical chart of disease-associated organ or tissue and diagram of causative gene product, but they are mainly gene-oriented manner. Currently, we are developing a support system to automatically extract disease-associated knowledge from the literature. Using categorized dictionary for various fields such as clinical medicine, histology and anatomy, significant relations are being extracted by statistical language analysis from OMIM.

Computer demonstration will be performed at the meeting.

**Six Families with Van Der Woude and/or Popliteal Pterygium Syndrome: All with a Mutation in the IRF6 Gene.**

*M. Ghassibe*<sup>1</sup>, *N. Revencu*<sup>2</sup>, *B. Bayet*<sup>3</sup>, *Y. Gillerot*<sup>2</sup>, *R. Vanwijck*<sup>3</sup>, *C. Verellen-Dumoulin*<sup>2</sup>, *M. Vikkula*<sup>1</sup>. 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology & Université catholique de Louvain, Brussels, Belgium; 2) Center for Human Genetics, Cliniques universitaires St-Luc and Université catholique de Louvain, Brussels, Belgium; 3) Centre Labiopalatin, Division of Plastic Surgery, Cliniques universitaires St-Luc, Brussels, Belgium.

Cleft lip with or without cleft palate (MIM#119530) (OFC) is the most frequent craniofacial malformation in humans. It results from failure of fusion of the fronto-nasal and maxillary prominences with failure of palatal shelf fusion. Its aetiology is likely multifactorial; some are a result of genetic mutations, while others may be due to environmental factors. Since 20% of OFC patients have a positive family history, genetic factors are thought to play an important role in the onset of this birth defect. Yet, the mode of inheritance of OFC remains controversial. We have initiated our genetic study of cleft lip and/or palate on syndromic OFC. We have collected 6 families with individuals affected by Van der Woude syndrome (VWS). VWS (MIM#119300) is a dominantly inherited disorder characterized by pits and/or sinuses of the lower lip, with cleft lip and/or cleft palate. It is the most common cleft syndrome. Recently, the Interferon regulatory factor-6 (IRF6) gene, localized to the VWS1 locus on 1q32.2, was shown to harbor mutations in patients with van der Woude and/or popliteal pterygium syndrome (PPS, MIM 119500). In this study, we analysed six novel VWS families, with or without PPS, for possible mutations in the IRF6 gene. Screening revealed a novel heterozygous substitution in each family. The mutations affected either the DNA-binding domain, or the protein-binding domain of the transcription factor. This data confirms that mutations in the IRF6 gene are responsible for VWS and PPS syndromes, and suggests IRF6 to be the major causative gene. (vikula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be>).

**A further Locus for Congenital Central Hypoventilation Syndrome (CCHS).** *S. Mc Cabe*<sup>1,2</sup>, *L. Doherty*<sup>3</sup>, *W.T. McNicholas*<sup>3</sup>, *A.J. Green*<sup>1,2</sup>, *S. Ennis*<sup>1,2</sup>. 1) Department of Medical Genetics / Conway Institute of Biomolecular and Biomedical Research, University College Dublin, Crumlin, Dublin 12, Ireland; 2) National Centre for Medical Genetics, Our Ladys Hospital for Sick Children, Crumlin, Dublin 12, Ireland; 3) Department of Respiratory Medicine / Conway Institute of Biomolecular and Biomedical Research, St Vincents Hospital, Dublin 4, Ireland.

Congenital central hypoventilation syndrome (CCHS) also known as Ondines curse, is a rare disorder of unknown etiology characterised by the failure of autonomic control of ventilation. CCHS has been associated with the neurocristopathies neuroblastoma, ganglioneuroma, and most frequently Hirschsprung disease (HSCR) which appears in 16-50% of CCHS patients, thought to be due to defective neural crest cell migration or differentiation. We describe a family, with a clinical diagnosis of CCHS comprised of a mildly affected mother, an affected father, four affected siblings, two male and two female and one unaffected female sibling, none of whom has Hirschsprung disease. Approximately 200 patients worldwide have been diagnosed with CCHS, with most reported cases being sporadic. Family cases are rare and to our knowledge this is the largest affected family reported to date and the only other case of familial recurrence without the association of HSCR. Analysis of candidate genes for Hirschsprung disease (HSCR) was carried out. Both dHPLC mutational analysis and sequencing of the candidate genes RET and GDNF together with linkage analysis of RET GDNF, EDN3, EDNRB, BDNF, SOX10, ECE1 and NRTN showed no evidence of association with the disease. The more recently described hASH1 gene on chromosome 12 (de Pontual et al) and the PhoX2b gene on chromosome 4 reported to be involved in CHSS (Amiel et al), have also been excluded in this family indicating a further disease locus for CCHS in this family. *E. J. Hum. Genet.* 2002; 10 suppl 1 :61. *Nat. Genet.* 33: 459-460, 2003.

**Exclusion of two regional candidates in MFS2, the second gene implicated in Marfan syndrome.** *C. Boileau<sup>1,3</sup>, A. Derré<sup>1</sup>, G. Jondeau<sup>2</sup>, G. Delorme<sup>2</sup>, O. Dubourg<sup>2</sup>, J-P. Bourdarias<sup>2</sup>, C. Junien<sup>1,3</sup>, G. Collod-Beroud<sup>1,4</sup>.* 1) Hôpital Necker-Enfants Malades, INSERM U383, Paris, France; 2) Service de Cardiologie and; 3) Laboratoire central de Biochimie, dHormonologie et de Génétique moléculaire, Hôpital Ambroise Paré, Boulogne, France; 4) Laboratoire de Génétique moléculaire, IURC, Montpellier, France.

Marfan syndrome is an autosomal dominant disorder presenting with genetic heterogeneity. *FBN1*, the first gene implicated in this syndrome, accounts for 80% of cases and encodes fibrillin-1, the major component of extracellular microfibrils. *MFS2*, the second gene implicated, is still unknown. It has been located in a region of less than 0.5 Mb mapped at 3p24.2-p25 between markers D3S2336 and D3S2466. The transcriptional map of the critical region contains only 2 known genes that are poor candidates (*RAR*, and *TOP2B*). We have been studying the 2 mRNAs coding for human homologs of genes known in other species and located in the region: FLJ11005 (encoding N-glycanase 1, *NGLY1*) and FLJ20604 (similar to beta-ketoacyl synthase). The expression of these candidates observed in a range of 13 different tissues is consistent with the features observed in MFS. Large and small rearrangements, point mutations as well as qualitative or quantitative transcript abnormalities were investigated. No abnormality was found excluding implication of these two genes in MFS. We are currently studying 3 predicted genes (gene models reconstructed solely from mRNA and EST evidence) in order to identify the *MFS2* gene.

**Atypical Friedreich ataxia in a carrier of a premutation length allele.** *S.I. Bidichandani*<sup>1,2</sup>, *M. Gomez*<sup>1</sup>, *S. Li*<sup>2</sup>, *T. Ashizawa*<sup>3</sup>. 1) Dept Biochem/Mol Biol, and; 2) Pediatrics, Oklahoma Univ Hlth Sci Ctr, OK; 3) UTMB Galveston, TX.

Friedreich ataxia (FRDA), the most common recessive ataxia, is caused by abnormal expansions of a GAA triplet-repeat sequence in intron 1 of the *FRDA* gene. This repeat is highly polymorphic; normal alleles contain 5-30 triplets and disease-causing alleles contain 100-1700 triplet-repeats. The carrier frequency in the Indo-European population is approximately 0.5%, consequently the vast majority of patients inherit fully expanded alleles with 600-1200 triplet-repeats. Rare alleles with 30-65 triplet-repeats, termed premutations, do not normally cause disease, but may expand into the pathogenic range when transmitted from parent to child. Equally rare intermediate alleles, ranging in size from 66-100 triplet-repeats, may be associated with mild disease. We describe a Caucasian patient (OK99) with clinical features compatible with atypical Friedreich ataxia who had one fully expanded allele (696 triplet-repeats) and another allele in the premutation size range (44 triplet-repeats). Most patients with FRDA have onset of disease at <25 y, however, approximately 15% of patients have late-onset or very late-onset Friedreich ataxia (LOFA or VLOFA), depending on whether they develop disease between 26-39 y or >40 y, respectively. OK99 first experienced difficulty with her balance at age 43. Five years after the onset of symptoms OK99 had mild, mainly cerebellar ataxia, dysarthria, hyperreflexia, loss of vibration sense, intact position sense, and slight scoliosis. The clinical severity in FRDA is mainly regulated by the length of the shorter of the two expanded alleles, and indeed most patients with VLOFA have at least one allele with <300 triplet-repeats. OK99 was tested and found to be negative for frataxin and aprataxin point mutations. Repeat expansions responsible for autosomal dominant ataxias (SCA1, 2, 3, 6, 7) were excluded, and OK99 had a normal karyotype (46,XX). These data indicate that carriers of premutation length alleles may themselves develop clinical disease in their lifetime. This study blurs the distinction between premutation and disease-causing alleles and complicates genetic counseling and phenotypic prediction in FRDA.

**Update of the FBN1 mutation database and creation of a FBN1 polymorphism database.** *G. Collod-Beroud*<sup>1,2</sup>, *I. Dehaupas*<sup>3</sup>, *S. Grey*<sup>3</sup>, *G. Matyas*<sup>4</sup>, *C. Junien*<sup>2,3</sup>, *B. Steinmann*<sup>4</sup>, *M. Claustres*<sup>1</sup>, *C. Beroud*<sup>1,2</sup>, *C. Boileau*<sup>2,3</sup>. 1) Laboratoire de Génétique moléculaire, IURC, Montpellier, France; 2) Hôpital Necker-Enfants Malades, INSERM U383, Paris, France; 3) Laboratoire central de Biochimie, dHormonologie et de Génétique moléculaire, Hôpital Ambroise Paré, Boulogne, France; 4) Division of Metabolism and Molecular Pediatrics, University Children's Hospital, Zurich, Switzerland.

We have created, in 1995, a human FBN1 mutation database, UMD-FBN1. Mutations in the FBN1 gene (encoding fibrillin-1, the major structural component of microfibrils) were first associated with Marfan syndrome (MFS) and subsequently with a large spectrum of related disorders. Aim of this database is to facilitate the mutational analysis of FBN1 mutations and the identification of structure/function and phenotype/genotype relationships. It gives access to a software package that provides specific routines and optimized multicriteria research and sorting tools. For each mutation, information is provided at gene, protein, and clinical levels. The current update shows 600 entries, of which 463 are new ones. UMD-FBN1 is accessible at <http://www.umd.be/>. The global molecular analysis reveals 2 classes of mutations. The first one, (38.6%), corresponds to mutations predicted to result in shortened fibrillin-1 molecules. They act as dominant negative but display a highly variable clinical phenotype, of which severity is directly related to the quantitative expression of the mutant allele and to the percentage of truncated or shortened proteins incorporated in the microfibrils. The second one (60.3%) correspond to missense mutations, among them mostly are located in cbEGF-like modules (78%). They can be subclassified in (a) mutations creating or substituting cysteine residues potentially implicated in disulfide bonding and consequently in the correct folding of the monomer and (b) amino acids implicated in  $Ca^{2+}$  binding and subsequently in interdomain linkage, rigidification of monomer and in protease susceptibility. Recently, we have also developed a FBN1 polymorphism database in order to facilitate diagnostics. This database list 84 reported or contributed polymorphisms.

Program Nr: 2304 from 2003 ASHG Annual Meeting

**More than 125 *FOXL2* mutations and variants in BPES and POF patients in the Human *FOXL2* Allelic Variant Database.** *D. Beysen, J. Vandesompele, F. Pattyn, A. De Paepe, L. Messiaen, E. De Baere.* Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Blepharophimosis-ptosis-epicanthus inversus syndrome (BPES, MIM 110100) is an autosomal dominant genetic condition in which an eyelid malformation is associated (type I) or not (type II) with premature ovarian failure (POF). In 2001, mutations in the *FOXL2* gene, encoding a forkhead transcription factor, have been shown to cause BPES type I and II. Since then a number of publications appeared describing *FOXL2* mutations in BPES patients. In addition, there have been reported a few *FOXL2* variants in POF patients and XX males. Previously, our group has reported the existence of two mutational hotspots in *FOXL2* and of intra- and interfamilial phenotypic variability in BPES families. Moreover, we have demonstrated genotype-phenotype correlations for a number of mutations in BPES patients. Here we describe a new locus-specific Human *FOXL2* Allelic Variant Database (<http://allserv.ugent.be/~jvdesomp/foxl2/>), created using the MuStaR software (on which the *PAX6*, *PAX2*, *SHOX* and *MLYCD* Allelic Variant Databases have been based similarly). Our database contains general information about the *FOXL2* gene, as well as details about more than 125 intragenic mutations and variants of *FOXL2*, obtained from published papers and abstracts of meetings, and also from unpublished data of our group. Not included in the current version of the database are complete *FOXL2* deletions, microdeletions and cytogenetic rearrangements of the *FOXL2* region on 3q23. The aim of this database is to provide an online resource, allowing remote users to do queries by selecting options on a web form and to submit new mutations to the database by means of a submission form. We believe this database will be a useful tool as it contains prevalence data about disease-causing mutations and a catalogue of polymorphisms. In addition, it will also allow to make more accurate genotype-phenotype correlations.

**Huntingtin and huntingtin-associated protein 1 influence neuronal calcium signaling mediated by inositol-(1,4,5) triphosphate receptor type 1.** *E.Y. Chan<sup>3</sup>, T. Tang<sup>1</sup>, H. Tu<sup>1</sup>, A. Maximov<sup>2</sup>, Z. Wang<sup>1</sup>, C.L. Wellington<sup>4</sup>, M.R. Hayden<sup>3</sup>, I. Bezprozvanny<sup>1</sup>.* 1) Department of Physiology and; 2) Center for Basic Neuroscience, University of Texas Southwestern Medical Center at Dallas, Dallas, Texas, USA; 3) Center for Molecular Medicine and Therapeutics, Department of Medical Genetics Children's and Women's Hospital and; 4) Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, British Columbia, Canada.

Calcium (Ca<sup>2+</sup>) has long been regarded to play a critical role in the pathogenesis of Huntington's disease (HD). Dysfunctional neuronal Ca<sup>2+</sup> homeostasis caused by Huntingtin (Htt) with polyglutamine expansion (exp) has been previously described to involve ionotropic glutamate receptors (e.g. NMDA receptors) and the mitochondria. The type 1 inositol (1,4,5)-triphosphate receptor (InsP3R1) is an intracellular Ca<sup>2+</sup> release channel that plays an important role in neuronal function. In a yeast two-hybrid screen with the InsP3R1 carboxy terminus, we isolated Htt-associated protein-1A (HAP1A). We have demonstrated that an InsP3R1-HAP1A-Htt ternary complex is formed *in vitro* and *in vivo*. InsP3R1 activation by InsP3 *in vitro* is sensitized by Httexp, but not normal Htt. Transfection of full-length Httexp or caspase-resistant Httexp, but not normal Htt, into medium spiny striatal neurons facilitates Ca<sup>2+</sup> release in response to threshold concentrations of the selective mGluR1/5 agonist 3,5-DHPG. Our findings identify a novel molecular link between Htt and InsP3R1-mediated neuronal Ca<sup>2+</sup> signaling and provide an explanation for the derangement of cytosolic Ca<sup>2+</sup> signaling in HD patients and mouse models.

**Nonsense mediated decay mitigates the effect of *MPZ* mutant alleles responsible for a more severe peripheral neuropathies.** *M. Khajavi*<sup>1</sup>, *T. Oyama*<sup>1</sup>, *K. Inoue*<sup>1</sup>, *J.R. Lupski*<sup>1,2</sup>. 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Texas Children's Hospital, Houston, TX.

Charcot-Marie-Tooth disease (CMT) is a clinically and genetically heterogenous group of inherited neuropathies that is traditionally classified into two major types, CMT type 1 (CMT1) and CMT type 2 (CMT2). In most CMT1 patients (~70%) the disease phenotype results from a 1.5-Mb DNA duplication on chromosome 17p11.2-p12 (CMT1A) whereas other patients have mutations in one of several genes such as peripheral myelin protein 22 (*PMP22*), myelin protein zero (*MPZ*), connexin 32 (*Cx32/GJB1*), early growth response 2 (*EGR2*), periaxin, and neurofilament light chain gene. Protein Po, encoded by the *MPZ* gene, is the major structural protein of peripheral myelin and functions as a homophilic adhesion molecule in myelin compaction. Mutations in the *MPZ* gene cause dominantly inherited peripheral neuropathies with various severity from CMT disease (mild alleles) to Dejerine-Sottas syndrome/congenital hypomyelinating neuropathy (severe alleles). Various nonsense and frameshift mutations in *MPZ* result in both mild and severe forms of peripheral myelinopathy, but no functional consequences have been delineated to effectively explain the association between mutation and disease severity. Interestingly, most mutations in *MPZ* that results in PTCs in downstream exons in which the nonsense-mediated decay (NMD) pathway is insensitive, appear to result in more severe forms of peripheral neuropathy. Such severe disease-associated alleles do not retain the transmembrane domain, suggesting that the toxic effects of these mutant proteins do not require positioning in the plasma membrane where the normal tetrameric *MPZ* proteins localize and function. Considering the location of truncation in the gene, here we investigated whether mutations that could possibly trigger the NMD RNA surveillance pathway and therefore decrease mRNA levels can decrease disease severity. To address this, we have introduced such disease associated mutations in an expression vector and used a transiently transfected HeLa cell lines to study the potential role for NMD in the abrogation of aberrant effect of selected mutant alleles.

**Molecular genetic study of patients with BOR Syndrome: Current status of mutation analysis and issue of genetic heterogeneity.** *S. Kumar<sup>1</sup>, M. Hare<sup>1</sup>, B. Berrigan<sup>1</sup>, C.W.R.J. Cremers<sup>2</sup>, W.J. Kimberling<sup>1</sup>*. 1) Dept Genetics, Boys Town Natl Research Hosp, Omaha, NE; 2) Department of Otolaryngology, University Hospital Nijmegen, The Netherlands.

Branchio-oto renal syndrome (BOR) is a human developmental disorder characterized by (1) branchial cleft, fistulas or cysts (2) various ear anomalies such as malformed pinnae, pre-auricular pits, structural defects of the external, middle and/or inner ear (3) hearing loss and (4) renal anomalies. It is inherited as an autosomal dominant pattern and affect at least 2% of profoundly deaf children and have estimated prevalence of 1 in 40,000. The phenotypic expression of the BOR gene is extremely variable from one family to another. The first BOR gene has been localized to chromosome 8q13 and has been shown to be caused by mutations in the EYA1 gene. A second genetic locus associated with BOR syndrome has been localized to chromosome 1q. We have performed mutation analysis on more than eighty five BOR families by WAVE followed by sequence analysis of sixteen EYA1 exons. To date, using this approach, we have identified nineteen novel mutations. At least 55% of our large data set of BOR families do not show mutations in the EYA1 gene. This further complicates the issue and suggests that either most of the mutations lie in the untranslated region or several genes are involved in the branchiogenic disorder. We have performed genetic linkage analysis on several multigenerational BOR type families with 8q and 1q markers to explore the possibility of further genetic heterogeneity. The present results, together with mutation screening and genetic linkage study, demonstrate genetic heterogeneity. A genome-wide search is being performed for the localization of third locus. Also, a candidate gene analysis is underway to identify genes in the critical region of second BOR locus on chromosome 1q. These results provide the basis for a molecular genetic testing and genetic counseling of members of BOR families. Further characterization of EYA1 mutation and identification of other BOR genes will significantly help in defining the spectrum of defects associated with branchial and hearing anomalies.

**The molecular basis of classical Ehlers-Danlos Syndrome (EDS).** *A. de Paepe, F. Malfait, S. Symoens, B. Loeys, L. Nuytinck, P. Coucke.* Depart. Medical Genetics, 0 K5, University Hospital Gent, Ghent, Belgium.

The classical form of EDS is characterized by fragile and hyperextensible skin, poor wound healing, atrophic scarring and joint hypermobility. Mutations in the COL5A1 and the COL5A2 gene encoding the 1 and 2 chain of type V collagen have been shown to cause the disorder, but it is unknown which proportion of classical EDS patients carries a mutation in these genes. We have studied fibroblast cultures from 52 patients with classical EDS for the presence of type V collagen defects. First, a biochemical analysis was performed by SDS-PAGE of metabolically labeled collagens produced by dermal fibroblasts. An abnormal collagen pattern was detected in only 4/52 cell lines, making this method not conducive for diagnostic evaluation. Secondly, a test that permits us to detect the presence of a non-functional COL5A1 allele (null-allele) was developed. In 36% of informative patients a null-allele was found (15/42). Finally molecular analysis of the COL5A1/A2 gene was performed by SSCP, CSGE and DHPLC. Six structural mutations in the COL5A1 gene and 3 in the COL5A2 gene were detected. In addition 10 mutations, either nonsense, frameshift or splice site mutations, all leading to a premature termination codon, were identified. Overall, the presence of a molecular defect in type V collagen could be confirmed in 26/52 patients (50%) with classical EDS. Variability in severity of the phenotype was observed. Two patients, harbouring exonskipping mutations in the COL5A1 and the COL5A2 gene respectively, had a particularly severe phenotype with bilateral hip dislocation. The relatively low mutation detection rate, despite exhaustive mutation analysis, suggests that other genes are involved in classical EDS. This is validated by our findings of a COL1A1 mutation (Arg134Cys) in 2 unrelated patients with the classical EDS phenotype. In addition, mutations in Tenascin X have been demonstrated to cause an autosomal recessive condition similar to classical EDS. Studies in transgenic mice have suggested genes encoding small leucine-rich proteoglycans (SLRP) as candidate genes for EDS. However no human examples have been documented for these mouse models at present.

**Refinement of the ichthyosis-prematurity locus on chromosome 9q34.** *M. Larsson<sup>1</sup>, J. Klar<sup>1</sup>, M. Pigg<sup>1</sup>, B. Carlsson<sup>1</sup>, A. Vahlqvist<sup>2</sup>, T. Gedde-Dahl JR.<sup>3</sup>, N. Dahl<sup>1</sup>.* 1) Dept Genetics & Pathology, Uppsala Univ, Uppsala, Sweden; 2) Dept Medical Science, Uppsala Univ, Uppsala, Sweden; 3) Institute of Forensic Medicine, Rikshospitalet, Oslo, Norway.

Autosomal recessive congenital ichthyosis (ARCI) is a heterogeneous group of skin disorders. Ichthyosis-Prematurity Syndrome (IPS), is a rare form of ARCI with a relatively high prevalence in the Norwegian population. Key features are thick caseous desquamating epidermis and complicated pregnancies due to polyhydramnion and an opaque amnion fluid caused by the shedding of large amount of epidermally derived cells. This results in premature birth of the affected child.

We recently reported the mapping of a novel IPS locus in thirteen families related to a defined region in middle-Norway and Sweden. The results showed a maximum cumulative lod-score of 3.73 on chromosome 9q34.

Here we present five additional families and the refinement of the critical interval using a denser map of microsatellite markers and SNPs. Haplotype analysis resulted in the identification of two separate ancestral haplotypes associated with the disease. The minimal shared haplotype region spans a 21-kb region containing a single gene.

**Acquired Pseudoxanthoma Elasticum-like syndrome in  $\alpha$ -Thalassemia Patients.** *O. Le Saux*<sup>1</sup>, *N. Hamlin*<sup>1</sup>, *K. Beck*<sup>1</sup>, *B. Bacchelli*<sup>2</sup>, *P. Cianciulli*<sup>3</sup>, *I. Pasquali-Ronchetti*<sup>2</sup>. 1) Pacific Biomed Research Ctr, University of Hawaii, Honolulu, HI; 2) Dept Biomed Sci, University of Modena and Reggio Emilia, Modena, Italy; 3) S. Eugenio Hospital, Rome, Italy.

A marked frequency of patients diagnosed with  $\alpha$ -thalassemia develop clinical and histopathologic manifestations of a disease called pseudoxanthoma elasticum (PXE). These manifestations include the calcification of elastic fibers in the skin, eyes, and cardiovascular system. PXE is also an inherited disorder, however, it is caused by mutations in an ATP-binding cassette gene called ABCC6 localized on the short arm of chromosome 16. Haplotype analysis of the ABCC6 locus in Italian  $\alpha$ -thalassemia/PXE patients and their family members revealed no co-segregation with the PXE phenotype. Moreover, SSCP analysis and direct sequencing were used to screen all 31 exons of the ABCC6 gene in 10 patients presenting both  $\alpha$ -thalassemia and PXE symptoms. This mutational analysis did not detect any of the 81 disease-causing mutations known thus far. Furthermore, an RT-PCR showed the expression of ABCC6, in skin fibroblasts from a  $\alpha$ -thalassemia/PXE patient, was similar to that of control individuals. These results revealed that the PXE phenotype present in  $\alpha$ -thalassemia/PXE patients is not likely caused by known mutations of ABCC6, suggesting that some  $\alpha$ -thalassemia patients have a susceptibility to developing an acquired form of PXE as a consequence of their altered metabolism.

**Genome Scans Provide Evidence for Keloid Susceptibility Loci on Chromosomes 2q23 and 7p11. E.**

*Reichenberger*<sup>1</sup>, *A. Marneros*<sup>2</sup>, *J.E.C. Norris*<sup>3</sup>, *S. Watanabe*<sup>4</sup>, *B.R. Olsen*<sup>2</sup>. 1) Dept BioStructure & Function, Univ Connecticut Health Ctr, Farmington, CT; 2) Dept Cell Biology, Harvard Medical School, Boston; 3) St.Luke's/Roosevelt Hospital Center, New York; 4) Dept of Plastic and Reconst. Surgery Showa University School of MedicineTokyo, Japan.

Keloids are proliferative fibrous growths that result from an excessive tissue response to skin trauma. They often occur sporadically, but in some families a genetic predisposition to keloids has been observed. Here we studied two families with an autosomal dominant inheritance pattern of keloids. One African-American family showed a high degree of variability in the extent of keloid formation between family members, whereas the second family from Japan showed a pattern of full penetrance and formation of only small keloids. We performed a genome wide linkage search for genes predisposing to keloid formation in these two families. We identified linkage to chromosome 2q23 (maximal two-point LOD-score 3.01) for the Japanese family from Japan. The African-American family showed evidence for a keloid susceptibility locus on chromosome 7p11 (maximal two-point LOD score of 3.16). The observed locus heterogeneity in autosomal dominant keloid disease is consistent with the clinical heterogeneity of this wound healing disorder. Dense microsatellite analysis in these two loci was performed and candidate genes were identified. This study provides the first genetic evidence for keloid susceptibility loci and serves as a starting point for the identification of responsible genes.

**A Novel Homozygous Recessive Mutation in the Galactosyltransferase-I (B4GALT7) Gene in Individuals Resembling the Progeroid Type of Ehlers-Danlos Syndrome.** *M.F. Ul Haque<sup>1</sup>, A.S. Teebi<sup>1,3</sup>, M. Al-Ali<sup>2</sup>, M.S. Al-Mureikhi<sup>2</sup>, S. Kennedy<sup>1,3</sup>, G. Al-Thani<sup>2</sup>, S.H.E. Zaidi<sup>1</sup>, L-C. Tsui<sup>1,4</sup>.* 1) Dept Genetics, Elm Wing, Hosp Sick Children, Toronto, ON, Canada; 2) Dept Pediat, Hamad Med Corp, Doha, Qatar; 3) Clin Genet and Dymorp, Hosp Sick Children, Toronto, ON, Canada; 4) Univ of Hong Kong, Pokfulam Rd, Hong Kong.

Ehlers-Danlos syndrome (EDS) comprised of a heterogeneous group of inheritable disorders that exhibit skin hyperextensibility, joint hypermobility and tissue fragility. In addition to these classical features of EDS, the Progeroid type displays wrinkled loose facial skin, fine curly hair, and scanty eyebrows and eyelashes. Several genes have been implicated to produce EDS phenotypes. In the present study, two individuals from two sibships of a large consanguineous family from Qatar exhibiting the phenotype that resembles the Progeroid type of EDS, were analyzed for linkage to the genes that have been implicated in EDS. Homozygosity was observed for only two markers on chromosome 5q35.2 that are associated with the B4GALT7 gene, in which compound heterozygous mutations have previously been reported in a single case of Progeroid-like EDS. The entire coding region and exon/intron boundaries of B4GALT7 gene were sequenced and a missense, C to T substitution at nucleotide 808 in the coding region was discovered in the DNA from both affected individuals. While this mutation was not found in control subjects of same ethnicity, carrier parents were heterozygous for this change. Pedigree analysis further confirmed the recessive mode of inheritance in this type of EDS. The C to T substitution translates into an arginine to cysteine change at the amino acid residue 270 of galactosyltransferase-I (encoded by the B4GALT7 gene). This change in the catalytically active, extracellular, C-terminal domain is likely to produce an abnormal protein due to misfolding or aberrant interaction with other extracellular proteins. The resulting abnormal protein product could alter the normal organization of extracellular matrix of connective tissues where the galactosyltransferase-I is expressed, thus conferring the Progeroid like phenotype in affected subjects.

**Mutations of the RNA-specific adenosine deaminase gene (*DSRAD*) are involved in Dyschromatosis Symmetrica Hereditaria.** T. Suzuki, Y. Miyamura, K. Inagaki, M. Kono, S. Ito, N. Suzuki, Y. Tomita. Department of Dermatology, Nagoya University School of Medicine, Nagoya, Aichi, JAPAN.

Dyschromatosis symmetrica hereditaria (DSH, reticulate acropigmentation of Dohi) has been reported mainly in Japan, although it occurs in families of every ethnic origin all over the world. The patients have pinpoint, pea-sized hyper- and hypo-pigmented macules on the back of the hands and the top of the feet. These abnormalities are otherwise asymptomatic and do not affect the general health. DSH generally shows an autosomal dominant pattern of inheritance with high penetrance. Many clinical and morphological investigations have been reported, but the cause and the pathogenesis as well as the *DSH* gene have not yet been clarified. Accordingly, we mapped and positionally cloned the *DSH* gene. We performed a genome-wide search in three families (39 affected and 41 unaffected), and mapped the *DSH* locus to chromosome 1q21.3. To further refine the localization, we identified novel single nucleotide polymorphisms and integrated the genetic and physical maps of the region. The final genetic interval was approximately 500 kb in which 9 genes were mapped. To detect the pathological mutations, affected individuals from each of the Pedigrees 1, 2 and 3, plus new pedigree, named Pedigree 4, were screened by PCR-SSCP and direct sequencing. The results showed that they were heterozygous for mutation alleles of double-strand RNA-specific adenosine deaminase gene (*DSRAD*), R474X, L923P, K952X and F1165S respectively. None of these four mutations were found in 55 unaffected individuals in any of the four pedigrees or in 116 unrelated normally pigmented Japanese adults that were surveyed. Thus, we concluded that those four mutations are not polymorphic but are the pathologic ones causing the disease. *DSRAD* catalyzes the deamination of adenosine to inosine in double-stranded RNA substrates which results in the creation of alternative splicing sites. We speculate that the failure of correct RNA editing may induce differentiation of melanoblasts to hyper- or hypo-active melanocytes colonizing in an irregular distribution in the skin lesions during the development.

**Frequency of Mitochondrial DNA (T/C) 16189 Polymorphism among Filipinos with Type 2 Diabetes Mellitus. E.**

*Paz-Pacheco*<sup>2</sup>, *E. Cutiongco*<sup>1</sup>, *C. Halili-Manabat*<sup>3</sup>, *M.A. Lim-Abrahan*<sup>2</sup>, *C. Padilla*<sup>1</sup>, *K.D.S. Corvera*<sup>2</sup>. 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines, Manila; 2) Section of Endocrinology, Diabetes, and Metabolism, Department of Medicine, College of Medicine, University of the Philippines Manila; 3) Department of Physiology, College of Medicine, University of the Philippines Manila.

Mitochondrial DNA polymorphisms, implicated in the development of type 2 diabetes mellitus, have a reported prevalence that is higher among Asian diabetics than their normal counterparts. To determine the frequencies of mitochondrial DNA (T/C) 16189 polymorphism among Filipino type 2 diabetic patients and normal controls, we extracted DNA from peripheral blood obtained from 31 type 2 diabetic patients and 31 normal controls. We subjected these samples to polymerase chain reaction, restriction enzyme digestion, and gel electrophoresis techniques. Preliminary analysis of DNA was performed. Among the 29 diabetics, 14 presented with the wild type allele, while 4 had the (T/C) 16189 polymorphism. Interestingly, 17 of the 38 study subjects showed a restriction enzyme digestion pattern different from either the wild type or the (T/C) 16189 polymorphism. Type 2 diabetics who possess the said polymorphism had lower body weights, body mass indices, and abdominal circumferences, but had higher mean arterial pressures than the type 2 diabetics with the wild type allele. The wild type allele was present in 48.3 percent of the type 2 diabetics as compared to 22.22 percent of the controls. Only 4 of the 29 diabetics (13.8 percent) and 1 of the 9 controls (11.1 percent) had the (T/C) 16189 polymorphism. Different restriction enzyme digestion patterns were found in 44.8 percent of the study population. Additional molecular studies need to be performed among the latter group of subjects to further elucidate these observed variations.

**Mutation spectrum at the ALADIN locus in Allgrove syndrome: founder mutation and neurodegenerative phenotypes.** *A. Tullio-Pelet, D. Trochet, F. Begeot, A. Munnich, S. Lyonnet.* INSERM U393 Dept Genetique, Hopital Necker Enfants Malades, Paris, France.

Triple-A syndrome (Allgrove syndrome, MIM 231550) is a rare autosomal recessive disorder characterized by adrenal insufficiency with adrenocorticotropin hormone (ACTH) resistance, achalasia of the oesophageal cardia and alacrima. Several lines of evidence indicate that triple-A syndrome results from the abnormal development of the nervous system including late-onset progressive neurological symptoms such as peripheral neuropathies and anisocoria. Moreover, the central nervous system may also be involved as cerebellar ataxia and mild dementia have been reported. In 2000, we showed that mutations of the *AAAS* gene, encoding a nucleoporin protein (ALADIN), was disease causing in triple A syndrome. We have screened the 16 exons of *AAAS* gene in 49 patients using DHPLC and direct DNA sequencing. In 42 patients (86%) we have identified the causing mutation (missense, nonsense, insertion or deletion). Among them, 35/42 (83%) patients were true homozygous and 24/35 carried the IVS14+1G A founder mutation, characterized in Northern African population. Only 7 patients were compound heterozygous. In the remaining 7 patients (14%), no mutation could be found ; among these, the diagnosis of triple A syndrome was regarded as unlikely for 4 cases. These data suggest genetic homogeneity in Allgrove syndrome. They support a Mediterranean founder effect for mutation IVS14+1G A that extended to France and to Puerto Rican population. Finally, both expression studies and this study underline the involvement of the *AAAS* gene in the central and peripheral nervous system.

**PABPN1 (GCN) expansion mutations in OPMD are likely due to unequal crossovers during recombination. B.**

*Brais<sup>1</sup>, Q.D. Trinh<sup>1</sup>, H. Lavoie<sup>1</sup>, A. Saint-Denis<sup>1</sup>, C. Alexander<sup>1</sup>, F.M.S. Tomé<sup>2</sup>, M. Fardeau<sup>2</sup>, B. Eymard<sup>2</sup>, A. Pou Serradell<sup>3</sup>, M. Medici<sup>4</sup>, C. Camejo<sup>4</sup>, M. Rodriguez<sup>4</sup>, J. Mathieu<sup>5</sup>, J.P. Bouchard<sup>6</sup>, G.A. Rouleau<sup>7</sup>.* 1) CHUM, Université de Montréal, Qc, Canada; 2) Institut de Myologie, Groupe Hospitalier Pitié-Salpêtrière, Paris, France; 3) Hospital Universitari del Mar, Barcelona, Spain; 4) Hospital de Clínicas, Montevideo, Uruguay; 5) Carrefour de Santé, Jonquière, Qc, Canada; 6) Hôpital de l'Enfant-Jésus, Quebec, Qc, Canada; 7) McGill University Health Center, Montreal, Qc, Canada.

Autosomal dominant oculopharyngeal muscular dystrophy (OPMD, OMIM 164300) causes late-onset progressive eyelids ptosis and dysphagia. It is particularly frequent in French Canadians (FC). It is caused by (GCN) expansions in the PABPN1 gene (14q11.1). Slippages during replication and unequal crossovers during recombination have been proposed as mutation mechanisms. Purpose. Determine what is the likely mechanism responsible for the genesis of OPMD mutations. Methods. We sequenced PABPN1 mutations in 66 cases from 49 ethnic backgrounds. We constructed haplotypes for in 42 cases with the shared (GCG)<sub>9</sub> FC mutation, four FC cases in which the size of the mutation has increased and 62 carrier chromosomes from 54 ethnic backgrounds. Results. The lengthening of the (GCG) repeat causes OPMD in 80% of families. In the other 20%, cryptic addition of combinations of (GCA) and (GCG) codons are the causal mutations. Lengthening of the (GCG) repeat was uncovered in the four FC cases with larger size mutations. The ancestral FC haplotype was lost, likely through unequal recombinations, on one side of the mutation in at least 3 of the 4 families. Haplotype clustering of cases from different ethnic backgrounds identified three groups of at least three families sharing telomeric or centromeric haplotypes. In these groups, different sizes of mutations were observed and two included cryptic mutations. Conclusion. This study demonstrates that 20% of OPMD PABPN1 mutations are due to cryptic (GCN) mutations. Together our results suggest that unequal crossovers during recombination are responsible for the appearance and subsequent expansions of (GCN) PABPN1 mutations in OPMD.

**Screening for mutations in the connexin 31 gene in Brazilian patients with non-syndromic deafness. E.L.**

*Sartorato<sup>1</sup>, F. Alexandrino<sup>1</sup>, C.A. Oliveira<sup>1</sup>, A.T. Maciel-Guerra<sup>2</sup>.* 1) Lab de Genetica Humana/CBMEG, Universidade Estadual de Campinas, SP, Brasil; 2) Departamento de Genetica Medica/FCM, Universidade Estadual de Campinas, SP, Brasil.

Deafness is a complex disorder that involves a high number of genes and environmental factors. At this moment, there has been enormous progress in non-syndromic deafness research, with the identification of 90 loci and 33 nuclear and 2 mitochondrial genes. Mutations in the GJB3 gene encoding the gap junction protein connexin 31 (Cx31) have been pathogenically linked to erythrokeratoderma variabilis and non-syndromic autosomal recessive or dominant hereditary hearing impairment. To determine the contribution of connexin 31 to sporadic deafness, we analysed the entire gene of connexin 31 in 67 families with non-syndromic hearing impairment and no mutation in the connexin 26 gene. Single coding exon of connexin 31 was amplified from genomic DNA and then sequenced. We reported three amino acid changes, Y177D, 49delK and R32W, and two nucleotides variants which represents a silent mutation. The R32W substitution has been previously described, and its involvement in hearing impairment remains uncertain. We presume that mutations in connexin 31 gene are an infrequent cause of non syndromic deafness.

Program Nr: 2318 from 2003 ASHG Annual Meeting

**Detailed analysis of the unstable region of the ZNF9 gene causing DM2/PROMM in normal chromosomes.** *M. Baiget, L. Martorell, I. Cusco, M. Calaf.* Genetics Department, Hosp Santa Creu i Sant Pau, Barcelona, Spain.

It has been recently demonstrated that large expansions in the intron 1 of the ZNF9 gene, located on chromosome 3q21.3 cause myotonic dystrophy type2 (DM2/PROMM). The aim of this study is to analyze the structure/size of the unstable repeat track containing the CCTG sequence in normal chromosomes. We have studied 30 unrelated alleles. DNA was amplified as previously described (Liquori et al 2001). PCR products were cloned using a commercial kit (Invitrogen) and subsequently sequenced. To investigate the pattern of inheritance of the unstable sequence, we have also studied two transmissions of the repeat sequence in a control family. The PCR products from the members of this family were analyzed using FAM as a fluorescent dye and processed in an ABI Prism 310 (Gene Scan software, Perkin Elmer-Applied Biosystems). In control alleles, the (CCTG)<sub>n</sub> ranged from 7 to 22, the CCTG13 being the most frequently observed. All tracks except one were interrupted by GCTG and TCTG. In control alleles, the size of the (TG)<sub>n</sub>(TCTG)<sub>n</sub>(CCTG)<sub>n</sub> repeat track ranged from 106 to 180 base pairs, 128bp, 138bp and 140 bp being the most frequently observed alleles. This complex region has been transmitted in a stable manner in the studied control family. Sequence and Gene Scan analysis demonstrate the presence of mosaicism in the (TG)<sub>n</sub>(TCTG)<sub>n</sub>(CCTG)<sub>n</sub> repeat track in somatic DNA samples from normal subjects.

**SCA8 BAC Transgenic Mice: Pathogenic CTG Expansion and Expression Models.** *M. Moseley, M. Weatherspoon, D. Jin, H.B. Clark, J.W. Day, L.P.W. Ranum.* Institute of Human Genetics, University Minnesota, Minneapolis, MN.

Spinocerebellar ataxia type 8 is caused by an untranslated CTG expansion. To better understand SCA8 pathogenesis we have created a transgenic mouse model of the disease by replacing the normal repeat tract (11 CTGs) of an SCA8-containing bacterial artificial chromosome (BAC) with a pathogenic expansion of 107 CTGs. The BAC contains approximately 115 kb of sequence flanking the SCA8 gene, which should be sufficient to regulate transgene expression in the mouse to mirror human temporal and tissue specific expression patterns. Seven expansion and 3 control lines were obtained (copy # 1-10). SCA8 expression, detected by RT-PCR in all lines, generally mimics the human expression pattern with low levels of transcripts found in the CNS. Three expansion lines had poorer rotarod performance at 26-wks than BAC control and non-transgenic littermates. Two of the highest copy number lines have a progressive, severe phenotype in which animals have difficulty in locomotion, lose weight and die (14 to >52 wks). In contrast, the five lower copy number expansion lines develop a milder, slowly progressive phenotype much later in life (~18 mos) in which an uncoordinated and unsteady gait is observed. Similar phenotypes have not been observed in BAC transgenic control lines with the normal repeat tract. No evidence of Purkinje cell or CNS neurodegeneration has been found, suggesting that the progressive neurological phenotype observed in the mice is caused by neuronal dysfunction rather than neurodegeneration. To better understand the pathology of the SCA8 transcript we are generating a second BAC transgenic expression model in which -gal reporter expression is driven by the endogenous human promoter contained on the BAC. Temporal and cell specific expression patterns of the human SCA8 promoter are being characterized and correlated with molecular and functional changes in the CNS of affected mice containing pathogenic CTG expansions. Our data provide the first evidence in a model organism that SCA8 transcripts containing an expanded repeat cause a progressive neurological phenotype, and support an RNA gain of function model of SCA8 pathogenesis.

**Myotonic Dystrophy Type 2: Founder Haplotype and Evidence for Loss of Sequence Interruptions on a Premutation Allele.** *Y. Ikeda<sup>1</sup>, C.L. Liquori<sup>1</sup>, M. Weatherspoon<sup>1</sup>, K. Ricker<sup>2</sup>, B.G.H. Schooser<sup>3</sup>, J.C. Dalton<sup>1</sup>, J.W. Day<sup>1</sup>, L.P.W. Ranum<sup>1</sup>.* 1) Inst of Human Genet, Univ of Minnesota, Minneapolis, MN; 2) Univ of Wurzburg, Germany; 3) Ludwig-Maximilians-Univ, Munich, Germany.

Myotonic dystrophy (DM), the most common form of muscular dystrophy in adults, can be caused by a mutation on either chromosome 19 (DM1) or 3 (DM2/PROMM). In 2001 we demonstrated that DM2 is caused by a CCTG expansion in intron 1 of the *zinc finger protein 9 (ZNF9)* gene. To investigate the ancestral origins of the DM2 expansion, we compared haplotypes of 71 genetically-confirmed DM2 families using 19 short tandem repeat markers we developed that flank the repeat tract. All of the families are Caucasian, with the majority of Northern European/German descent and a single family from Afghanistan. Several conserved haplotypes spanning more than 700 kb converge into a single haplotype near the repeat tract. The common interval immediately flanking the repeat in all DM2 families extends up to 216 kb telomeric and 119 kb centromeric of the CCTG expansion. Although estimates of haplotype age are difficult because rare ancestral recombination events are unlikely to be evenly distributed from generation to generation, and microsatellite mutation rates vary from marker to marker, conservation of a native Tajik Afghan haplotype allows us to speculate that DM2 was introduced into Afghan gene pool sometime between 2000 and 1000 B.C. when the ancient Aryan tribes of Indo-European extraction settled Aryana (ancient Afghanistan). The DM2 repeat tract contains the complex repeat motif  $(TG)_n(TCTG)_n(CCTG)_n$ . The CCTG portion of the repeat tract is interrupted on normal alleles, but as in other expansion disorders these interruptions are lost on affected alleles. We examined haplotypes of 228 control chromosomes and identified a potential premutation allele with an uninterrupted  $(CCTG)_{20}$  on a haplotype that was identical to the most common affected haplotype. Our data suggest that the predominant Northern European ancestry of DM2 families resulted from a common founder and that the loss of interruptions within the CCTG portion of the repeat tract may predispose alleles to further expansion.

**Expansion to full mutation of a FMR1 gray zone allele over two generations.** *A. Terracciano, M.G. Pomponi, G.M.E. Marino, G. Neri.* Institute of Medical Genetics, Catholic University, Rome, Rome, Italy.

The fragile X syndrome is due to an expansion of the CGG repeat sequence at 5' UTR of the FMR1 gene. According to size of the CGG sequence, one can distinguish four allele categories: normal (40 CGG), protomutated or grey zone (40-59 CGG), premutated (60-200 CGG) and full mutated (200 CGG). However, the boundaries among these categories are blurred, especially those of the grey zone. This uncertain classification makes it difficult to recognize truly unstable alleles and to accurately estimate the risk of expansion. We report on a family in which the proband presented with mental retardation and hyperactivity. Southern blot analysis showed a 1,2 kb methylated full mutation. PCR analysis of other members of the family showed two alleles of 29 and 61 CGG respectively repeats in the mother. Sequencing of the 61 CGG allele showed no AGG interruptions. Both mother's sisters had two alleles of 31 and 43 CGGs respectively, and the daughter of one of these had two alleles of 24 and 43 repeats, demonstrating stable transmission of the 43 CGG allele. The maternal grandmother had two alleles of 29 and 31 CGGs. The maternal grandfather had died several years before. Molecular analysis confirmed paternity with a probability of 99,97 for all three sisters. According to these findings it is likely that the maternal grandfather carried the 43 CGG allele, showing unstable transmission, because it expanded first to 61 CGGs in one daughter, and then to full mutation in her grandchild. On the other hand, the allele remained stable in three other persons we could observe (maternal aunts and cousin of the proband). Therefore, genetic counselling is difficult for female carriers in this family. Although we cannot exclude paternal mosaicism, it is likely that a rare event of progression from protomutation to premutation occurred in this family .

**Mapping genes for Autosomal Dominant Keratoconus.** *B.A Bejjani*<sup>1,2</sup>, *M. Gajecka*<sup>1</sup>, *A. Molinari*<sup>3</sup>, *J. Pitarque*<sup>3</sup>, *S.M. Leal*<sup>4</sup>, *R.A. Lewis*<sup>4</sup>. 1) Wash State Univ, Spokane; 2) Sacred Heart Med Ctr, Spokane; 3) Hospital Metropolitano, Quito, Ecuador; 4) Baylor Col Medicine, Houston, TX.

Keratoconus (KC) is a non-inflammatory thinning and anterior protrusion of the cornea that results in steepening and distortion of the cornea, altered refractive powers and altered visual acuity. The cause(s) of KC are unknown. We identified an Ecuadorian population among whom isolated KC seems to segregate in an autosomal dominant trait with reduced penetrance. We have examined, collected blood, and purified DNA from 104 individuals from 28 multiplex families with KC. We excluded *VSX1* as a candidate for KC in these families by sequence analysis of *VSX1*-coding exons in 18 KC individuals. We identified three single nucleotide polymorphisms (SNPs) in the *VSX1* coding region: 18GT, 174GT and 542AG. These are presumed to be benign SNPs because none induces a putative amino-acid change in the sequence of *VSX1*, and two of them (18GT and 542AG) were found in matched normal control samples sequenced in parallel. We are confirming these results with targeted genotyping with markers at the *VSX1* locus on 20p11q11. Additional markers on chromosome 16q22.3-q23.1 are being examined to evaluate a KC locus there described in a Finnish population. To evaluate whether the pedigree data have sufficient power to detect linkage, we performed a simulation study with the following assumptions: an autosomal dominant model; a polymorphic marker with 5 alleles of equal frequency (Heterozygosity = 0.8); a disease allele frequency of 0.001; and a penetrance of 0.70 for homozygous and heterozygous disease allele carriers and 0.0 for homozygous wild-type genotypes. The marker and the disease locus were generated in complete linkage ( $= 0.0$ ). The data were generated both with all families linked to one locus and under linkage heterogeneity where only a proportion of the families, , segregates the same disease locus. We used a variety of values and analyzed data with the ELODHET program. These simulation studies show that sufficient power exists to establish linkage even if only 60% of the families are linked to a single locus. A genome-wide screen is in progress.

**A novel locus for autosomal dominant hypodontia involving incisors and premolars.** *P. Das*<sup>1</sup>, *A. Rohr*<sup>1</sup>, *R.M. Scarel-Caminaga*<sup>3</sup>, *E. Aguiar*<sup>4</sup>, *S.M. Leal*<sup>2</sup>, *E.L. Figuerido*<sup>4</sup>, *S.R.P. Line*<sup>3</sup>, *P.I. Patel*<sup>1, 2</sup>. 1) Dept Neurology, Baylor Col Medicine, Houston, TX; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Faculty of Odontology of Piracicaba-UNICAMP, Brazil; 4) Federal University of Alagoas, Maceio, Brazil.

Familial hypodontia is a genetically heterogeneous condition characterized by the congenital absence of primary and/or permanent teeth, ranging in severity from mild, involving the absence of one or two teeth, to severe, where the majority of teeth can be missing. Autosomal dominant (AD) hypodontia has been localized to at least three chromosomal loci: *MSX1*, *PAX9*, and an unknown locus on chromosome 10. A missense mutation in *MSX1* has been associated with AD hypodontia involving the second premolars and third molars while frame-shift, nonsense and missense mutations in *PAX9* as well as a submicroscopic deletion involving the *PAX9* gene have been seen in families with AD hypodontia involving primarily molar teeth. A third locus associated with hypodontia involving the absence of a few to the entire set of permanent teeth has been mapped to chromosome 10q11.2. A distinct unknown locus underlying hypodontia involving incisors and premolars has been previously implicated based on exclusion mapping of candidate genes. We have identified a large family segregating AD hypodontia involving incisors and premolars, and studied 31 members of whom 15 are affected. A total genome scan assuming autosomal dominant inheritance with complete penetrance has allowed mapping of the hypodontia locus to a 1.6 cM (730 Kb) interval on chromosome 17q23. This interval contains 16 genes. Sampling of additional family members and fine mapping will allow narrowing of the candidate region. High-throughput sequencing of all candidate genes is expected to allow identification of this novel hypodontia locus. (Supported by NIH grant DE14102 and Center for Inherited Disease Research).

**Familial juvenile hyperuricaemic nephropathy (FJHN): Linkage analysis in 17 families, transcriptional characterization of the FJHN critical region on chromosome 16p11.2 and the analyzes of uromodulin and other candidate genes.** *K. Hodanova<sup>1</sup>, M. Kalbacova<sup>1</sup>, B. Stiburkova<sup>1</sup>, J. Majewski<sup>2</sup>, A. Marinaki<sup>3</sup>, A. Simmonds<sup>3</sup>, G.*

*Matthijs<sup>4</sup>, J. Fryns<sup>4</sup>, J. Ott<sup>2</sup>, S. Kmoch<sup>1</sup>.* 1) Charles University, Inst of Inher Metab Diseases, Prague, Czech Republic; 2) Laboratory of Statistical Genetics, Rockefeller University, New York, NY, USA; 3) Purine Research Unit, GKT, Guys Hospital, London, UK; 4) Center for Human Genetics, University of Leuven, Leuven, Belgium.

FJHN is an autosomal dominant renal disease characterized by juvenile onset of hyperuricaemia, gouty arthritis, and progressive renal failure at an early age. Recent studies showed linkage of a gene for FJHN to the same genomic region on chromosome 16p11.2, where the gene for the phenotypically similar medullary cystic disease type 2 (MCKD2) has been localized. In our study of 17 families we found in 8 of them linkage of FJHN to 16p11.2, which suggests that, in a large proportion of FJHN kindreds, the disease is likely to be caused by a gene(s) located outside of 16p11.2. Haplotype analysis of all analyzed families provided two non-overlapping critical regions on 16p11.2 FJHN1, delimited by markers D16S499-D16S3036 and FJHN2, delimited by markers D16S412-D16S3116. Considering MCKD2 to be a distinct molecular entity, the analysis suggested that as many as three kidney disease genes may be located in close proximity on 16p11.2. From genomic databases we compiled transcription maps of whole critical genomic region in which 122 known genes and predicted loci have been localized. We selected, analyzed and found no pathogenic mutations in ten candidate genes. Following recent publications of Uromodulin (UMOD) mutations in FJHN and MCKD2 we analyzed UMOD coding sequence including exon/intron boundaries in seven 16p11.2 linked FJHN families. FJHN causing mutations (Cys126Arg, Met229Arg, and Cys317Tyr) were found in only three of them. Further investigations are aimed at sequencing of UMOD 6 kbp promotor and large deletions detection. This effort should finally answer question of FJHN and MCKD2 genetic heterogeneity on 16p11.2.

**Two novel severe mutations in the pancreatic secretory trypsin inhibitor gene (SPINK1) cause familial or/and hereditary pancreatitis.** *C. Le Maréchal<sup>1</sup>, J.M. Chen<sup>1</sup>, C. Le Gall<sup>2</sup>, G. Plessis<sup>3</sup>, J. Chipponi<sup>4</sup>, N.A. Chuzhanova<sup>5</sup>, O. Raguénès<sup>1</sup>, C. Férec<sup>1</sup>.* 1) INSERM 01 15, Génétique Moléculaire et Génétique Epidémiologique, Etablissement Français du Sang-Bretagne, Université de Bretagne Occidentale, Centre Hospitalier Universitaire de Morvan, Brest, France; 2) Hépatogastroentérologie Nutrition, Hôpital Édouard Herriot, Lyon, France; 3) Département Génétique et Reproduction, Centre Hospitalier Universitaire de Caen, Caen, France; 4) Service de Chirurgie Générale et Digestive, Centre Hospitalier Universitaire, Clermont-Ferrand, France; 5) Department of Computer Science, Cardiff University, Cardiff, United Kingdom.

Mutations in the pancreatic secretory trypsin inhibitor (PSTI/SPINK1) gene have recently been found to be associated with chronic pancreatitis. The aim of this study was to identify novel severe SPINK1 mutations with a view to expanding the gene's mutational spectrum and providing further insights into SPINK1's role in pancreatitis. 46 unrelated families, each including at least two pancreatitis patients and carrying neither cationic trypsinogen mutations or the frequent SPINK1 N34S mutation, participated in this study. The four exons and their flanking sequences of the SPINK1 gene were screened by denaturing high performance liquid chromatography analysis; and mutations were identified by direct sequencing. A heterozygous microdeletion mutation (27delC), which occurs within a symmetric element, was identified in two families. In one family, 27delC showed segregation with the disease across two generations, with a penetrance of up to 75%. But in the other family, however, the same mutation manifested as a low-penetrance susceptibility factor. In addition, a novel heterozygous splicing mutation, IVS2+1G>A, was found in one family with familial pancreatitis. Our results demonstrated that genetic testing for SPINK1 mutations in pancreatitis families wherein no cationic trypsinogen mutations were found is warranted; and suggested that the differing views about SPINK1's role (ie, disease-causing vs. disease) in pancreatitis should be discussed in the context of specific mutations.

**Cirhin, the protein mutated in North American Indian childhood cirrhosis (NAIC) is a novel nucleolar protein.**

*B. Yu, G. Mitchell, A. Richter. Génétique Médicale, Hôpital Sainte-Justine, Montréal, Canada.*

NAIC (MIM 604901) is a severe, pediatric onset intrahepatic cholestasis, frequent in the Natives of NE Quebec. A C->T mutation in *cirhin* (NM\_032830) changes a conserved Arg to Trp at codon 565 (R565W) in patients, altering the predicted secondary structure of the 686 aa protein. As a step in the elucidation of the function of cirhin, we used bioinformatics to predict organellar localization. These showed multiple targeting signals including a bipartite nuclear localization signal (BNLS, aa 328-344) and a C-terminal nuclear localization signal (C-NLS, aa 677-686). To test the predictions we transfected EGFP and His tagged fusion constructs of wild type (wt) and R565W cirhin into HeLa cells. Our results show that both proteins locate to the nucleolus. Thus, cirhin is a nucleolar protein lacking obvious RNA and DNA binding motifs. To investigate its function within the plurifunctional nucleolus we mutated the predicted targeting signals. The C-NLS (PPPIKKKK) conforms to the consensus for monopartite NLS, a helix-breaking N-terminal proline followed 3 or more basic residues in an array of 7-9 aas. To isolate the function of the NLS we used a construct that initiates at M487. As expected, it localizes to the nucleus. Changing the second Lys to Ala (PPPIKAKK) causes loss of nuclear localization, indicating the importance of this residue for NLS function. Truncation of the C-NLS does not completely abolish nucleolar localization, but its presence improves efficiency. We have evidence of a nucleolar localization signal (NrLS) of ~170 aas (M315-M487). This includes the predicted BNLS. With truncation and mutagenesis we are defining the minimal sequence of this NrLS. The nuclear and nucleolar localization signals are functionally additive, suggesting that different transport mechanisms may be necessary for correct and efficient nucleolar targeting of cirhin. Yeast 2 hybrid studies underway may reveal the effect of other interacting proteins on targeting of cirhin to this organelle. Cirhin is a nucleolar protein with a unique NLS and an NrLS having a more complex structure than others previously described. Supported by the Canadian Institutes of Health Research.

**Recent development studies in MTMR13, the gene implicated in a demyelinating Autosomal Recessive form of Charcot-Marie-Tooth (AR-CMT) disease associated with Early Onset Glaucoma (EOG).** *H. Azzedine*<sup>1</sup>, *A. Bolino*<sup>2</sup>, *A. Chojnowski*<sup>1</sup>, *K.H. El hachimi*<sup>3</sup>, *C. Blondin*<sup>4</sup>, *P. Hamard*<sup>4</sup>, *P. Fragner*<sup>1</sup>, *G. Stevanin*<sup>1</sup>, *A. Brice*<sup>1</sup>, *E. Le guern*<sup>1</sup>. 1) INSERM U289-NEB, Hopital de la Salpetriere, Paris, France; 2) Dulbecco Telethon Institute, Laboratories of Molecular Genetics, Gaslini Institute, and Department of Paediatrics and Center of Excellence for Biomedical Research, University of Genova, Genova, Italy; 3) INSERM U106, Hopital de la Salpetriere, Paris, France; 4) Hopital des quize-vingt, sevice 3, Paris, France.

CMT is a pathological and genetic heterogeneous group of hereditary motor and sensory neuropathies characterized by slowly progressive weakness and atrophy, primarily in peroneal and distal leg muscles. Two major types have been distinguished on anatomopathological and electrophysiological grounds: demyelinating and axonal CMT. The genetic heterogeneity is highlighted by the various modes of inheritance (autosomal dominant, X linked and autosomal recessive forms and the expanding number of different assigned loci (n=30). In some families from Japan and Brazil, a demyelinating CMT, mainly characterized by the presence of myelin outfoldings on nerve biopsies, co-segregated as an autosomal recessive trait with EOG. We first mapped this syndrome to chromosome 11p15.3 in a 4.6 cM region overlapping the locus for an isolated demyelinating ARCMT (CMT4B2) in two large consanguineous North African families. More recently, we identified in these two families two different nonsense mutations in the Myotubularin-related 13 gene, MTMR13. The MTMR family includes proteins with a phosphoinositide phosphatase activity, and proteins in which key catalytic residues are missing, and that are thus called pseudo-phosphatases. MTMR13 may be important for the development of both the peripheral nerve and the trabeculum meshwork, which permits the outflow of the aqueous humor. Both of these tissues have the same embryonic origin. Expression studies of MTMR13 during myelination, trabecular meshwork and retina development in rat, mouse and human is in progress using quantitative real time PCR assay, Northern blots and in situ hybridisation. The finalized results will be presented during the meeting.

**Does Tyrosinase modify the Congenital Glaucoma phenotype in Saudi Arabia?** *N. Hernandez*<sup>1,2</sup>, *A. Al-Rajhi*<sup>3</sup>, *D.W. Stockton*<sup>4</sup>, *R.A. Lewis*<sup>4</sup>, *J.R. Lupski*<sup>4</sup>, *B.A. Bejjani*<sup>1,2</sup>. 1) Wash State Univ, Spokane; 2) Sacred Heart Med Ctr, Spokane; 3) King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia; 4) Baylor Col Medicine, Houston, TX.

Primary Congenital Glaucoma (PCG) is an autosomal recessive disorder for which we showed decreased penetrance in the Saudi Arabian population. Approximately 94% of individuals with PCG in Saudi Arabia have homozygous or compound heterozygous mutations in cytochrome P4501B1 (*CYP1B1*). Investigation of families with multiple affected individuals with PCG showed that penetrance is about 50%. Recently, Tyrosinase (*Tyr*) was found to be a modifier of the drainage structure phenotype in *Cyp1b1*<sup>-/-</sup> mice, with *Tyr* deficiency increasing the magnitude of dysgenesis. The severe dysgenesis in newborn mice lacking both *CYP1B1* and *TYR* was alleviated by administration of the tyrosinase product dihydroxyphenylalanine (L-dopa) to the pregnant mothers (Libby et al. *Science*:299;1578-1581). To evaluate a possible role for *TYR* in the modification of the clinical PCG phenotype in the Saudi population, we sequenced all five *TYR*-coding exons in 60 individuals with homozygous and compound heterozygous *CYP1B1* mutations. Thirty-five of those individuals were nonpenetrant and 25 had full expression of the disease. Initial analysis of our data shows that there is a heterozygous mutation in exon 4 of each of three fully penetrant individuals and six nonpenetrants. Evaluation of this mutation in 100 control Saudi chromosomes is in progress. Analysis of linkage data of markers that map to chromosome 11q14-21 does not support this locus as a potential modifier for PCG in the Saudi population.

**Germ cell selection of an FGFR2 point mutation explains the paternal age effect in Apert syndrome.** A. Goriely<sup>1</sup>, G.A.T. McVean<sup>3</sup>, M. Röjmyr<sup>4</sup>, B. Ingemarsson<sup>4</sup>, A.O.M. Wilkie<sup>1, 2</sup>. 1) Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, UK; 2) Nuffield Dpt of Clinical Laboratory Sciences, University of Oxford, UK; 3) Dpt of Statistics, University of Oxford, UK; 4) Pyrosequencing AB, Uppsala, Sweden.

Observed mutation rates in humans appear higher in male than in female gametes and often increase with paternal age. This bias, usually attributed to the accumulation of replication errors or inefficient repair mechanisms during spermatogenesis, has been difficult to study directly. Apert syndrome, a dominantly inherited congenital malformation (birth prevalence ~1 in 70,000) characterised by craniosynostosis and syndactyly, is caused in ~98% of cases, by *de novo* nucleotide transversions (755C>G or 758C>G) in Fibroblast Growth Factor Receptor 2 (FGFR2). These mutations, which encode FGFR2 proteins with enhanced ligand binding, occur at a rate elevated ~500-fold over background, arise exclusively from the unaffected father and show a paternal age effect.

Using Pyrosequencing technology, we have developed a robust method to quantify the levels of the 755C>G mutation (responsible for ~2/3 of Apert syndrome cases) in the sperm of healthy male donors. We show that this mutation is present at significant levels (maximum of 1 in 6,000) in the sperm of many men, but is not substantially higher in the fathers of Apert syndrome children (n=6). Although the mutation levels increase with donor age, explaining the observed paternal age effect, we show, surprisingly, that the original mutational events occur infrequently. Instead of originating from repeated replication errors that accumulate with age, we propose that these infrequent FGFR2 mutations are enriched because they confer a selective advantage to the spermatogonial stem cells in which they arise, leading to clonal expansion of the mutant germ cell population. This work has implications for diverse fields, including clinical genetics, reproductive biology, stem cells, cancer and evolution.

Program Nr: 2330 from 2003 ASHG Annual Meeting

**Identification of transcripts regulated by PITX2 in the human ocular anterior segment.** *M.A. Lines, O. Vicaruddin, M.A. Walter.* Departments of Medical Genetics and Ophthalmology, University of Alberta, Edmonton, AB, Canada.

Mutations of the paired-bicoid homeodomain transcription factor *PITX2* cause Axenfeld-Rieger (AR) malformations of the ocular anterior chamber, as well as abnormalities of the teeth, umbilicus, and heart. In approximately fifty percent of cases, patients with AR develop secondary glaucoma due to impaired uveal aqueous drainage. While several genes governed by *PITX2* have been identified in the heart and dental primordia, ocular *PITX2* target genes remain to be discovered. We are employing two complementary methods to study *PITX2*-driven gene expression in cell lines derived from the human trabecular meshwork and nonpigmented ciliary epithelium, tissues that drain and secrete aqueous humor respectively. RNA interference was used to abrogate *PITX2* activity and effect changes in target gene expression, which will be measured via cDNA microarray. Additionally, chromatin immunoprecipitation will be used to isolate *PITX2*-responsive regulatory elements upstream of target genes. Delineating the ocular regulon governed by *PITX2* will improve our understanding of the normal development and function of these tissues, while indicating genes potentially involved in the etiology and/or pathogenesis of AR.

**Structure and expression analysis of Interferon Regulatory Factor 6 (IRF6).** A.S. Knight<sup>1</sup>, N.K. Rorick<sup>2</sup>, M.I. Malik<sup>2</sup>, J.C. Murray<sup>2</sup>, M.J. Dixon<sup>1</sup>, B.C. Schutte<sup>2</sup>. 1) Dental Medicine and Surgery, Univ Manchester, UK; 2) Dept Pediatrics, Univ Iowa.

We recently discovered that mutations in IRF6 underlie two related orofacial clefting disorders, Van der Woude and popliteal pterygium syndromes. IRF6 belongs to the IRF family of transcription factors that share a highly conserved DNA binding domain and a less well conserved protein binding domain. Several members of this family use alternative splicing to produce transcripts that encode protein isoforms that negatively regulate the full-length molecule. Northern analysis of embryonic tissues showed transcripts of approximately 2.1, 4.1 (predicted) and 20 kb. Using PCR of human and mouse cDNA panels and alignment of ESTs, we did not detect any transcripts that lack exons encoding IRF6. Based on northern and EST analysis, the 2.1 and 4.1 kb transcripts are consistent with alternative polyadenylation in exon 9, and the 20 kb transcript is consistent with an unspliced transcript. Subsequently, we performed in situ hybridization and immunohistochemical experiments on a developmental series of morphologically-staged mouse embryos. We found that *Irf6* is expressed in the leading edges of the developing facial processes at E10/E11 and in the medial edge epithelia of the palatal shelves immediately prior to and during their fusion on E14.5. Immunohistochemical analysis supports the observation that *Irf6* expression is restricted to the medial edge epithelium and suggests a common function for *Irf6* in the fusion events driving development of the primary and secondary palate. *Irf6* expression was also observed in the apical ectodermal ridge of the developing limbs at E10/E11, the molar and incisor tooth germs from E12-E15, the fusion zone on the ventral aspect of the developing genitalia from E11 onwards, and in the skin, hair and vibrissae follicles from E12. These regions of expression correlate strongly with the VWS and PPS phenotypes. *Irf6* expression was also observed in the lymph nodes. As no aspect of the VWS and PPS phenotype corresponds with this expression pattern, the function of IRF6 in these tissues is likely to be compensated by other members of the IRF family.

**A giant gene encoding a developmentally regulated novel member of the M28 peptidase family is severed by a Cornelia de Lange-associated translocation breakpoint at 3q26.3.** *E. Tonkin<sup>1</sup>, M. Smith<sup>1</sup>, P. Eichhorn<sup>1</sup>, S. Jones<sup>1</sup>, B. Imamwerdi<sup>1</sup>, M. Jackson<sup>1</sup>, S. Lindsay<sup>1</sup>, N. Carter<sup>2</sup>, T.-J. Wang<sup>1</sup>, M. Ireland<sup>1</sup>, J. Burn<sup>1</sup>, I. Krantz<sup>3</sup>, T. Strachan<sup>1</sup>.* 1) Inst Human Genetics, Univ Newcastle, Newcastle, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 3) Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia and The University of Pennsylvania School of Medicine, Philadelphia, PA.

Cornelia de Lange (CdLs) syndrome is a developmental malformation syndrome characterised by mental handicap, growth retardation, distinctive facial features, limb reduction defects and various other features including gastrointestinal and respiratory system abnormalities. A CdLs gene at 3q26.3 has been postulated on the basis of phenotypic overlap with trisomy 3q cases who have in common an extra copy of the 3q26-q27 region, and the occurrence in a classical CdLs patient of a de novo balanced translocation with a breakpoint at 3q26.3. We have identified the two breakpoints in this individual and show that the 3q26.3 breakpoint severs a novel giant gene containing at least 27 exons spanning 1.4 Mb. Northern blot analysis identified up to six different transcripts ranging from 1.3 kb to 10 kb in length with strongest expression in kidney and placenta. In situ hybridization studies show embryonic expression in various locations including the mesonephros and the duodenum. Transcript analysis has identified extensive alternative splicing in the 5' UTR plus variable use of coding sequences. Predicted protein isoforms fall within the 337-795 amino acid range and are defined by the use of alternative initiating methionine codons separated by 17 amino acids, and additionally by alternative C-terminal sequences generated by alternative splicing/polyadenylation. Sequence analysis of the predicted protein has identified a large C-terminal domain that is shared with the M28 family of zinc peptidases. Preliminary mutation screening of a panel of CdLs patient samples failed to identify patient-specific mutations.

**An innovative protocol combining multiplex QF-PCR and fluorescent conformation sensitive capillary electrophoresis (FCSCCE) for unified dosage analysis and point mutation screening.** *E.J. Ashton, S.C. Yau, Z. Hatton, S.J. Abbs.* Genetics Centre, Guy's Hospital, London, England.

Large multi-exon genes such as dystrophin, exhibiting heterogeneous mutation spectrums have, until now, required independent tests and sometimes different samples to screen for (1) gross deletions and duplications and (2) point mutations. This multi-method approach is cumbersome and inefficient for even medium throughput testing. Therefore we have developed a streamlined, comprehensive mutation screening protocol for DNA to detect deletions, duplications and point mutations in the dystrophin gene of both males and females. This unified method is applicable to any gene.

All 79 dystrophin exons are amplified in 12 multiplex QF-PCR assays and the products analysed on a multicapillary fluorescent analyser to detect exon copy number. The same PCR products are then subjected to FCSCCE to screen for point mutations using a multicapillary analyser with modified polymer. In a control study CSCE detected 98% of point mutations.

A blind trial of 50 male and 50 female samples is currently in progress to evaluate the sensitivity of the assay for detecting all mutation types. We have completed the analysis of the 50 male samples and have obtained 100% specificity and sensitivity. 28 large deletions/duplications were correctly identified, in 9 of these cases the end points were defined where they had not been previously. 8 substitutions were detected (including 1 which was not previously known about) and in 7 samples no mutation was detected. 6 of the 7 samples were from normal control males and the remaining sample was known to contain a deeply intronic mutation in a region not covered by this assay.

We have demonstrated the power of this method by applying it for a DMD family in which no samples were available from affected males and an intragenic recombination had left a pregnant female with up to a 50% carrier risk. A nonsense mutation was quickly identified in an obligate carrier, which was not present in the pregnant relative.

**Joubert Syndrome: a patient with a de novo t(2;22)(q13;q11.1).** *E. Hatchwell*<sup>1</sup>, *N. Tommerup*<sup>2</sup>, *U. Kristoffersson*<sup>3</sup>, *R. Stanyon*<sup>4</sup>, *S. KANTARCI*<sup>1</sup>. 1) Cold Spring Harbor Lab, Cold Spg Harbor, NY; 2) Dpt. of Medical Genetics, IMBG, The Panum Institute, University of Copenhagen, Copenhagen, Denmark; 3) Dpt. of Clinical Genetics, The University Hospital of Lund, Lund, Sweden; 4) Comparative Molecular Cytogenetics Core, NCI, Frederick, MD.

Joubert Syndrome (JS) is a rare autosomal-recessive condition involving agenesis or dysgenesis of the cerebellar vermis with accompanying brainstem malformations. JS is further characterized by hypotonia, developmental delay, intermittent hyperpnea, and abnormal eye movements. The biochemical and molecular basis of JS remains unknown. To map the translocation breakpoint in a patient with Joubert syndrome associated with a de novo, apparently balanced translocation t(2;22)(q13;q11.1), we have used flow sorted derivative chromosomes. In order to delineate the t(2;22)breakpoint, we initially generated a microarray containing BAC sets that span chromosomes 2 and 22 at roughly 1 MB intervals. We amplified the flow sorted chromosomes using degenerate oligonucleotide primer PCR (DOP-PCR) with a primer distinct in sequence to those used to generate BAC DNA for the array, in order to avoid cross-hybridization. We also used a recently developed method, known as Multiple Displacement Amplification (MDA) on our flow sorted material. In MDA, an isothermal reaction is performed at 300C, using f29 DNA polymerase, which synthesizes strands in excess of 70 kb. The major advantage of this method is the relative uniformity of locus representation. Amplified products generated from each of the flow sorts was differentially labeled using Cy3 and Cy5 and hybridized to our microarray. We narrowed the translocation breakpoint to a region between two BACs that are separated by 4MB. STS-PCR was performed at higher density levels and the breakpoint localized to within a 324 bp region. The breakpoint on chromosome 2 interrupts a predicted gene and we are currently engaged in analysis of this candidate gene in cases of JS.

**Functional analysis of dystrophin sequence variants: biological/clinical relevance.** *C.S. Richards<sup>1</sup>, L.H. Chin<sup>1</sup>, O. Lichtharge<sup>2</sup>, T. Schwede<sup>3</sup>, J. Kopp<sup>3</sup>, P.A. Ward<sup>1</sup>, G. Miller<sup>4</sup>, D.R. Love<sup>5</sup>, M.R. Hegde<sup>1</sup>.* 1) Diagnostic Sequencing Laboratory; 2) Computational Biology Laboratory, Department of Molecular and Human Genetics, Baylor College Medicine, Houston, TX; 3) Division of Bioinformatics, University of Basel, Switzerland; 4) Texas Childrens Hospital, Houston, TX, USA; 5) School of Biological Sciences, University of Auckland, Auckland, New Zealand.

Duchenne/Becker muscular dystrophy (DMD/BMD) is an X-linked recessive neuromuscular disorder affecting approximately 1 in 3500 males with one-third of isolated cases resulting from a new mutation in the dystrophin gene. We have developed strategy to interpret dystrophin variants using multiple approaches based on mutation-type to determine biological relevance. A comprehensive mutation analysis has been developed for the analysis entire dystrophin gene to identify whole exon deletion/duplication mutations, point mutations, small deletions and small insertions using denaturing high performance liquid chromatography (dHPLC). We have extended our studies utilizing a variety of approaches to understanding the biology of how dystrophin variants affect the structure and function of dystrophin protein in muscle and influence the expression of other genes in multiple pathways. These approaches include Evolutionary Trace to identify highly conserved and functionally important residues, protein modeling using SwissModel server and Deepview, microarray analysis to assess effects of variants on differential gene expression, and confirmation by biological studies including transcript and immunohistochemical analyses of presumptive relevant muscle proteins. Dystrophin sequence variants currently reported as unclassified variants will now be interpreted in a clinically relevant manner based on further analysis of dystrophin protein structure and function, and will provide useful information about genotype and phenotype relationships. We present here data on a single patient with a mutation in splicing mutation in intron 3 (exon3+1G>C), previously not documented. We plan to extend our efforts in future collaborative work to develop therapeutic approaches, for patients in whom we have characterized clinically relevant non-classical-type mutations.

**Genotype-Phenotype Correlation of Recessive Hereditary Inclusion Body Myopathy (IBM2).** *D. Darvish, S. Naiem, Y. Huo.* H.I.B.M. Research Group, Inc., Encino, CA.

Recessive hereditary Inclusion Body Myopathy (IBM2-MIM:600737) and Distal Myopathy with Rimmed Vacuoles (DMRV-MIM:605820) are adult onset muscle wasting disorders that are clinically and genetically indistinguishable, and often result in Quadriceps Sparing Myopathy (QSM). We refer to this phenotype collectively as IBM2/DMRV. Over the past two years, IBM2/DMRV has been associated with mutations in GNE; this gene encodes for the bifunctional enzyme GNE/MNK (EC 5.1.3.14/EC 2.7.1.60), which is the rate limiting enzyme for sialic acid biosynthesis. To date, over 30 mutations on GNE are associated with IBM2/DMRV. However, the penetrance of the mutations, and the exact relationship of the mutations to IBM2/DMRV phenotype are still ambiguous. Here we present both published and unpublished mutations, and we describe how the GNE mutations maybe related to IBM2/DMRV phenotype. We have tested 574 individuals, which include 147 patients and their immediate families. In our cohort, we identified 143 patients of Iranian heritage, and 4 patients of non-Iranian heritage. For genetic analysis, genomic samples were tested using bilateral PCR amplification of specific alleles, restriction enzyme analysis, and direct automated sequencing. Medical records were reviewed and patients interviewed. The penetrance of the GNE-M712T mutation is at most 97%. All other mutations are too rare to allow for reasonable penetrance estimation. The M712T homozygous mutation results in surprisingly diverse IBM2 phenotype with variations in sparing of specific muscle groups, age at onset of symptoms, and rate of progression. Even within a single family, the age of onset and progression can vary significantly. Based on retrospective data, pregnancy and emotional distress seem to significantly affect the rate of disease progression. Additionally, all patients with QSM screened to date have mutations on GNE, however not all GNE mutations lead to QSM. In conclusion, IBM2 phenotype is not mutation specific. It is likely that decrease in sialic acid biosynthetic flux results in increased myofiber sensitivity to degeneration. Yet unknown factors may play a significant role in IBM2/DMRV phenotype.

**A genotype-phenotype correlation for *GJB2* (connexin 26) deafness.** *K. Cryns*<sup>1</sup>, *E. Orzan*<sup>2</sup>, *A. Murgia*<sup>3</sup>, *P.L.M. Huygen*<sup>4</sup>, *F. Moreno*<sup>5</sup>, *I. del Castillo*<sup>5</sup>, *P. Chamberlin*<sup>6</sup>, *H. Azaiez*<sup>6</sup>, *S. Prasad*<sup>6</sup>, *R.A. Cucci*<sup>6</sup>, *E. Leonardi*<sup>3</sup>, *P.J. Govaerts*<sup>7</sup>, *P.H. Van de Heyning*<sup>8</sup>, *C.M. Van de Heyning*<sup>1</sup>, *R.J.H. Smith*<sup>6</sup>, *G. Van Camp*<sup>1</sup>. 1) Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Otorrhinology Unit, University Hospital of Padua, Padua, Italy; 3) Pediatrics, University of Padua, Padua, Italy; 4) Otorrhinology, University Medical Centre St Radboud, Nijmegen, The Netherlands; 5) Unidad de Genética Molecular, Hospital Ramon y Cajal, Madrid, Spain; 6) Molecular Otorrhinology Research Laboratories, Otorrhinology, University of Iowa, Iowa City, USA; 7) The Ear Group, Deurne, Belgium; 8) Otorrhinology, University of Antwerp, Antwerp, Belgium.

Mutations in *GJB2* are the most common cause of nonsyndromic autosomal recessive hearing impairment (HI), and mutation analysis of this gene is widely available as a genetic diagnostic test. HI associated with *GJB2* mutations ranges from mild to profound. To assess a possible genotype-phenotype correlation for *GJB2*, audiometric data from 277 unrelated hearing-impaired persons segregating two *GJB2* mutations were analyzed. We found that 35delG homozygotes have significantly more HI when compared to 35delG/non-35delG compound heterozygotes. Persons with two non-35delG mutations have even less HI. We observed a similar gradient of HI when we categorized mutations as inactivating (i.e. stop mutations, frame shifts) or non-inactivating (i.e. missense mutations). We could demonstrate that the *GJB2* genotype has an important impact on the degree of HI. Certain mutation combinations (including the combination of 35delG with the missense mutations L90P, V37I, or the splice-site mutation IVS1+1G>A, and the V37I/V37I genotype) are associated with significantly less HI compared to 35delG homozygous genotypes. This study is the first large and systematic analysis indicating that the *GJB2* genotype has a major impact on the degree of HI, and identifying mild genotypes. Furthermore, this study shows that it will be possible to refine this correlation and to extend it to additional genotypes. These data will be useful in evaluating habilitation options for persons with *GJB2*-related deafne.

**NOVEL MUTATIONS AND GENOTYPE:PHENOTYPE CORRELATION IN CHARCOT-MARIE-TOOTH TYPE 1B (CMT1B).** *K.T. Abe<sup>1</sup>, M.T. Magrin<sup>1</sup>, R.C.M. Pavanello<sup>1</sup>, P.E. Marchiori<sup>2</sup>, M. Zatz<sup>1</sup>*. 1) Dept. of Biology, Biosciences Institute, University of Sao Paulo, Brazil; 2) Dept.of Neurology, Faculty of Medicine, University of Sao Paulo, Brazil.

Charcot-Marie-Tooth (CMT) disease, the most frequent hereditary neuropathy, represents a group of clinically and genetically heterogeneous disorders. The most common form is CMT type 1A, caused by a duplication of 1.5Mb at 17p11.2-p12, where lies the peripheral myelin protein-22 (PMP22) gene. The second most common form, CMT1B, with an estimated prevalence of 5-10%, is caused by mutations in the myelin protein zero (MPZ) gene, at chromosome 1q21-q23. In a study of 57 patients referred to our center with a diagnosis of CMT1, we have confirmed the diagnosis of CMT1A in 58% of the cases. We are currently screening the remaining patients for mutations in the MPZ gene. The aim of this study is to estimate the frequency of CMT1B in the Brazilian population and establish genotype:phenotype correlations in affected patients. The six exons of the MPZ gene are being analyzed by SSCP and dHPLC followed by sequencing of abnormal fragments in MegaBACE automatic sequencer. Until now, we have found three novel mutations among 24 patients who were analyzed. Two are missense mutations, S54P in exon 2 and G123V in exon 3 which were not found in 340 normal chromosomes. The third one is an out-of-frame deletion of 16 pb (c.519\_535del) found in a three-year-old boy and his 39-yr-old mother. The affected mother, who has normal intelligence has a severe weakness and atrophy of lower limbs as well as reduced NCV. She can walk only short distances with support. However, her affected son presents besides difficulty in walking, a syndromic face with low ears implantation and mental retardation. These findings apparently have not been reported previously for CMT1B mutations. They give further support to the importance of genotype-phenotype correlation studies in an attempt to better understand the role of different gene domains for protein function. In addition, these preliminary findings suggest that mutations in MPZ gene (CMT1B) in Brazilian patients account for ~10% of non-CMT1A cases. Supported by: FAPESP-CEPID, PRONEX, CNPq.

**Genotype/phenotype correlations in familial tuberous sclerosis cases.** *K. Au<sup>1</sup>, C.M. Wilson<sup>1</sup>, A.T. Williams<sup>1</sup>, D.A. Johnson<sup>2</sup>, M.A. Assel<sup>1</sup>, H. Northrup<sup>1</sup>.* 1) Dept Pediatrics, The Univ Texas Medical School, Houston, TX; 2) Dept Biomathematics, The Univ Texas MD Anderson Cancer Center, Houston, TX.

Tuberous sclerosis complex (TSC) is a genetic disorder characterized by formation of benign tumors in affected organ systems. The most significant involvement resulting in morbidity and mortality occurs in the brain and kidneys. Mutations in two genes, TSC1 and TSC2, result in the TSC phenotype. Published genotype/phenotype correlations have focused on sporadic TSC cases. Further, TSC2 mutations are more frequent than TSC1 mutation(6:1)in sporadic cases. We gathered data from 32 families (123 affected individuals) with 2 affected individuals. TSC2 gene mutations were identified in 16 families (66 affecteds) and TSC1 in 11 families (41 affecteds) with 5 families (16 affecteds) having no mutation identified. Overall, our study population reported much less severe neurologic findings than studies focused on sporadic patients. We found no significant difference in TSC1 v. TSC2 mutation patients who reported seizures but we did find a statistically significant higher incidence of MR and behavioral abnormalities in TSC2 mutation patients. No TSC1 mutation patients reported renal cysts while approximately half of our TSC2 mutation patients did. Interestingly, even though the majority of findings were either the same or more severe in TSC2 mutation patients, for certain specific skin findings (ungual fibromas and shagreen patches) the TSC1 mutation patients had a more severe phenotype. Additionally, we compared mutation type between TSC2 missense mutations v. all truncating mutations (TSC2 and TSC1). TSC2 missense mutations conferred the highest risk for neurologic symptoms and TSC2 truncating mutations are associated with highest risk for disfiguring skin lesions. Further, we hypothesize that TSC2 missense mutations confer a more severe neurologic phenotype than truncating mutations possibly due to residual abnormal tuberin activity. This finding is consistent with the observation that brain tumors in TSC patients rarely exhibit loss of heterozygosity (5-10% v. 80-90% in renal tumors) suggesting that tuberin with a missense mutation may function in a dominant-negative manner.

**A novel ganglioside-induced differentiation-associated protein 1 (GDAP1) mutation associated with Charcot-Marie-Tooth disease: evidence for a founder effect in Italy.** *E. Bellone<sup>1</sup>, E. Di Maria<sup>1</sup>, R. Gulli<sup>1</sup>, P. Balestra<sup>1</sup>, D. Cassandrini<sup>1</sup>, M. Bado<sup>2</sup>, L. Doria-Lamba<sup>3</sup>, A. Schenone<sup>1</sup>, F. Ajmar<sup>1</sup>, P. Mandich<sup>1</sup>.* 1) Dept Neurosci Ophthalmol Genet, Univ Genova, Genova, Italy; 2) Unit for Neuromusc Diseases, Inst G. Gaslini, Italy; 3) Divisione e Cattedra di Neuropsichiatria Infantile, Inst G. Gaslini, Univ Genova, Italy.

Mutations in a gene encoding a novel protein of unknown function, the ganglioside-induced differentiation-associated protein 1 gene (GDAP1), are associated with one of the autosomal recessive forms of Charcot-Marie-Tooth disease (CMT4A). The function of GDAP1 in the peripheral nervous system is still unknown. A series of 76 Italian patients with severe early onset polyneuropathy and possible autosomal recessive inheritance was screened for mutations in the GDAP1 gene. All patients were negative for the 17p11.2 duplication and for mutations in the MPZ, GJB1, PMP22 and EGR2 genes. The entire coding region, including exon-intron boundaries, was examined by single strand conformation polymorphism (SSCP) and direct sequencing. An altered SSCP pattern and subsequent direct sequencing detected, in three unrelated patients, a T>G transversion (c.347 TG) which causes an aminoacidic change from methionine to arginine at codon 116 (M116R). The M116R mutation showed cosegregation with the disease in all three pedigrees and was not present in 314 control chromosomes. All patients showed early onset of the disease with pronounced foot deformities and impaired deambulation. The neurophysiological study demonstrated primary axonal damage and primary or secondary demyelination. The sural nerve biopsies revealed different abnormalities ranging from axonal de- and regeneration to demyelination and remyelination, the most prominent feature being a severe loss of larger fibers. Detailed clinical, electrophysiological and neuropathological features of the three patients will be presented. Haplotype analysis of the GDAP1 locus with three short tandem repeat markers and an intragenic single nucleotide polymorphism showed a common disease haplotype, suggesting that these families, coming from the same Italian region (Campania), may have a common ancestor.

**Molecular analysis of 4q35 rearrangements: sensitivity and specificity of EcoRI/BlnI test for FSHD. G.**

*Galluzzi<sup>1,2</sup>, M. Rossi<sup>1</sup>, L. Colantoni<sup>1,2</sup>, B. Merico<sup>1</sup>, P. Tonali<sup>1</sup>, L. Felicetti<sup>1,2</sup>, E. Ricci<sup>1,2</sup>.* 1) Department of Neurosciences, Catholic University, Rome, Italy; 2) Center for Neuromuscular Diseases, UILDM-Rome, Italy.

FSHD is one of the most common forms of muscular dystrophy, with a prevalence of about 1:20,000. While FSHD still remains a gene-orphan disease, considerable progress has been made in developing a reliable molecular test since a DNA rearrangement at 4q35 locus has been unequivocally associated with the disease. The test consists in the detection, after hybridization with probe p13E-11, of a shortened EcoRI, BlnI-resistant fragment (10 to 40 kb in FSHD patients, > than 40 kb in normal individuals). While the sensitivity of this molecular approach is very high (over 96%), its specificity has never been adequately considered. In our work we studied 151 families by PFGE. In 120 families (group A) a diagnosis of FSHD had been performed on the base of clinical features, according to ENMC Consortium criteria. The remaining 31 (group B) did not fulfill the diagnostic criteria for FSHD. 210 affected and 142 unaffected individuals from the 120 FSHD families belonging to group A and 87 individuals from the 31 belonging to group B were analyzed. In addition, we studied 71 unrelated normal individuals. Group A: an EcoRI BlnI-resistant fragment, 13 to 41 kb in size, was detected in 115 out of 120 families. Unexpectedly, in 40 individuals belonging to 17 families we found 23 BlnI-resistant, EcoRI fragments sized 23 to 41 kb in addition to those causally associated with the disease. It is worth noting that 21 out of 40 individuals carried exclusively a 23-41 kb fragment different from that associated with the disease and none was affected by FSHD. Group B: eight EcoRI, BlnI-resistant fragments in the range 22 to 41 kb were found in individuals belonging to 7 of the 31 families examined. An EcoRI,BlnI-resistant fragment sized 30 to 41 kb was detected in 5 out of 71 normal individuals. Due to the existence of overlap of 4q35 EcoRI fragments between patients and normal individuals, a diagnosis of FSHD should not be based on molecular grounds alone in families not fulfilling the diagnostic criteria for FSHD.

**Molecular characterization of p63 mutations found in six different human disorders involving limb, ectodermal, and lip/palate abnormalities.** *P.H.G. Duijf<sup>1</sup>, V. Doetsch<sup>2</sup>, J.A. McGrath<sup>3</sup>, T. Rinne<sup>1,4</sup>, J. Celli<sup>1</sup>, A. Yang<sup>5</sup>, F. McKeon<sup>5</sup>, E. van Beusekom<sup>1</sup>, J. Schalkwijk<sup>6</sup>, P. Propping<sup>7</sup>, F. Gurrieri<sup>8</sup>, B.C.J. Hamel<sup>1</sup>, H.G. Brunner<sup>1</sup>, H. van Bokhoven<sup>1</sup>.* 1) Dept Human Genetics 417, University Medical Centre Nijmegen, Nijmegen, The Netherlands; 2) Pharmaceutical Chemistry, San Francisco, CA, USA; 3) Dermatology, London, UK; 4) Medical Genetics, Turku, Finland; 5) Cell Biology, Boston, MA, USA; 6) Dermatology, Nijmegen, The Netherlands; 7) Human Genetics, Bonn, Germany; 8) Medical Genetics, Rome, Italy.

The p63 gene is a homologue of the p53 tumor suppressor gene. In contrast to p53, p63 plays an important role in development, particularly in the development of the limbs, skin, sweat and sebaceous glands, hair, and lip/palate. We have previously shown that Ectrodactyly, Ectodermal dysplasia, Cleft lip/palate (EEC) syndrome is caused by mutations in the p63 gene. Subsequently, p63 mutations were identified in five related disorders, including Hay-Wells/AEC syndrome, ADULT syndrome, Limb-Mammary Syndrome (LMS), Rapp-Hodgkin Syndrome (RHS), and Split Hand/Foot Malformation (SHFM). Clear genotype-phenotype correlations can be recognized for these mutations. EEC syndrome is caused by missense mutations in the DNA binding domain resulting in a loss of DNA binding activity, while ADULT syndrome is caused by a gain-of-function mutation in the DNA binding domain. In addition, AEC syndrome and RHS are predominantly caused by missense mutations in the SAM protein-protein interaction domain of p63. Also, most of the SHFM and LMS mutations are unique for these disorders. Moreover, the considerable clinical overlap between LMS and ADULT syndrome is paralleled by the comparable positions of the mutations in these two syndromes. Currently, we are investigating the functional consequences of p63 mutations in more detail. We have performed a yeast-two-hybrid screen to identify proteins that interact with the C-terminus of the p63 splice variant. Additionally, functional assays are being performed to investigate the relationship between LMS mutations and the gain-of-function mutation that causes ADULT syndrome. These studies will gain more insight into the normal and disrupted pathways involving p63.

**Quantitative analysis of allelic unbalance by Primer Extension and DHPLC suggests a high incidence of somatic mosaicism in tuberous sclerosis.** A. Allavena<sup>1</sup>, S. Lanzardo<sup>1</sup>, S. Padovan<sup>1,2</sup>, M. Barberis<sup>1</sup>, L. Longa<sup>1</sup>, C. Michielotto<sup>1</sup>, A. Brusco<sup>1</sup>, B. Ferrando<sup>1</sup>, N. Migone<sup>1</sup>. 1) Dept Genetics, Biol & Biochem, Univ Torino, Torino, Italy; 2) CNR, Torino.

The footprint of somatic mosaicism is the unbalance of copy number between the wild type and mutated alleles. In order to assess the incidence of somatic mosaicism in tuberous sclerosis we compared the sensitivity of two methods: DHPLC, run at 2 temperatures, and Primer Extension (PE), using forward and reverse primers adjacent to the mutation. Three pairs of wild type and mutated alleles from mosaic parents of TSC probands, representative of 2 types of DHPLC profiles, difficult and easy to read - showing either a distorted single pick, or 2 to 4, well separated picks, respectively - were cloned and mixed at decreasing ratios of mut : wt alleles. Each mix was tested by DHPLC and PE, and the results compared with those obtained from peripheral blood DNA of the mosaic parents, the probands and controls homozygous for the wt allele. The window sensitivity of PE appeared consistently wider (90% to 10% of the mut cell fraction) than that of DHPLC, whose range of detectable mosaicism in presence of difficult profiles was reduced to 40% - 20% of the mut cells. These data suggest that, a) mut-pos or mut-neg cell fractions 10% are easily missed by standard DHPLC analysis, b) the ascertainment of allelic unbalance largely depends on the availability of a balanced heterozygote for the same mutation to be used as heteroduplex profile of reference. Since most TSC mutations are unique, mosaics have a higher chance to be recognized in multiplex families than in a sporadic patient. Indeed, we found a higher prevalence of somatic mosaicism in multiplex TSC2 families (9/36; 25%) than among de novo TSC2 probands (10/153; 6,5%). It is reasonable to assume that sporadic mosaics tend to have minor signs, so that most of them are identified after the birth of a baby with a classical phenotype. In conclusion, somatic mosaicism in TSC is likely underestimated and the multiplex family data suggest that 1 of 4 TSC2 patients might originate through a post-zygotic mutation.

***HAMP* candidate as modifier gene in adult-onset form of hereditary hemochromatosis.** S. Jacolot, G. Le Gac, I. Quéré, C. Mura, C. Férec. INSERM 0115, Université de Bretagne Occidentale, Etablissement Français du Sang, Centre Hospitalier Universitaire, Brest, France.

Background: Hereditary Hemochromatosis is a genetically heterogeneous disease of iron metabolism. The most common form of the disorder, called hereditary hemochromatosis type I, is an adult-onset form which has mainly been associated with the C282Y *HFE* gene mutation. The non-*HFE*-related forms include a juvenile-onset form associated with mutations in the *HAMP* gene. The goal of this study was to evaluate the role of the *HAMP* gene in adult-onset forms of primary iron overload. Methods: We studied the *HAMP* gene in 392 C282Y homozygous patients and in 300 control subjects. We designed a D-HPLC assay to scan the *HAMP* coding sequence and sequenced DNA displaying an altered profile. Results: We found 5 patients out of 392 carrying one mutation in the *HAMP* gene. Among the three *HAMP* gene mutations, two were novel (R59G and G71D) and one was previously described (R56X); they were not detected in the control population. Discussion: Our result revealed that, the *HAMP* gene might act as a modifier gene in phenotypes related to Hereditary Hemochromatosis type I. We further highlighted that, based on the digenic model of inheritance already described in other human genetic disorders, the association of mutations in the *HFE* and *HAMP* genes may lead to an adult-onset form of primary iron overload.

**Evidence of a dominant negative effect of delta lamin A reflects the pathogenic mechanism underlying Hutchinson-Gilford progeria syndrome (HGPS).** *W. Ju, W.T. Brown, N. Zhong.* Department of Human Genetics, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY10314.

HGPS is a very rare premature aging syndrome with autosomal dominant inheritance. Recently, HGPS has been found to result from genetic defects of the LMNA gene, which encodes nuclear envelope proteins lamin A/C. A silent mutation, c2063C>T that results in G608G, generates a cryptic splicing site in exon 11 of LMNA, and consequently truncates 50 amino acids near the C-terminus of lamin A, was identified in ~80% of HGPS alleles. We have undertaken a study to demonstrate the dominant negative effect of this mutation. We transfected either the mutant LMNA construct that expresses a delta lamin A derived from the mutation c2063C>T, or a normal LMNA construct into a normal human fibroblast culture. Immunostaining was performed to study the architecture of nuclear envelopes. Bleb formations of the nuclear envelope, identical to that seen in cells derived from HGPS patients, were shown in the normal cells transfected by mutant LMNA but not in those transfected by normal LMNA. After 48-72 hours of transfection, co-immunoprecipitation studies were carried out with transfected cell extracts and antibodies to the various lamina proteins: lamin A/C, lamin B1, SREBP1, LAP2a, and Emerin, and to control proteins LAMP1 and BI1. No differences were identified, perhaps reflecting the abundance of the normal allele in HGPS cells. The finding of abnormal nuclear architecture following transfection of the mutant allele provides evidence that the mutant LMNA has a dominant negative effect in HGPS.

**Locus and allelic influences on clinical severity of Autosomal Dominant Polycystic Kidney Disease (ADPKD).** *N. Lamb*<sup>1</sup>, *W. Paxton*<sup>2</sup>, *D. Rizk*<sup>2</sup>, *J. Du*<sup>2</sup>, *J. Ladson*<sup>2</sup>, *S. Langley*<sup>2</sup>, *A. Amin*<sup>1</sup>, *E. Boerwinkle*<sup>3</sup>, *A. Chapman*<sup>2</sup>. 1) Human Genetics, Emory Univ, Atlanta, GA; 2) Medicine, Emory Univ, Atlanta, GA; 3) University of Texas Health Science Center, Houston, TX.

ADPKD is characterized by renal cyst formation and growth that leads to massive renal enlargement and end stage renal disease (ESRD). Renal volume (RV) is a significant marker for disease progression in ADPKD. ADPKD is genetically heterogeneous, with mutations in PKD1 and PKD2 occurring in 85% and 15% respectively, of cases. Mutations in PKD2 are believed to result in milder disease with regard to age of ESRD. Recent studies indicate mutation type but not position influences age of ESRD outcome in PKD2 individuals. However, time to ESRD is a relatively late clinical event in ADPKD. Therefore, we examined locus and allelic heterogeneity using renal volume, measured by magnetic resonance imaging as an early predictor of disease severity. 272 ADPKD individuals from 185 families were clinically evaluated, including measurements for RV and renal function. The PKD2 promoter, coding regions, and intron/exon boundaries were sequenced for all individuals. Thirty-one individuals, from 20 families (11%) were identified with mutations in PKD2, consistent with previous gene linkage analysis. Remaining individuals were assumed to have PKD1 mutations. PKD1 and PKD2 patients demonstrated significant and similar volume-function interaction (PKD1:  $r = -0.68$ ,  $p < 0.0001$ ; PKD2:  $r = -0.82$ ,  $p < 0.0001$ ), indicating a similar structure-function relationship. We examined the effect of mutation type and location by comparing RV in PKD2 individuals according to missense, truncating, or splice-site mutations. Significantly smaller median RV was found in individuals with splice site mutations (649mls) compared to missense (1694mls) and truncating (1111mls), suggesting that mutations that alter splicing are associated with milder disease. Missense and truncating mutations located nearer the 3' end of PKD2 also demonstrated higher RV, suggestive of a more severe outcome ( $r = 0.16$ ,  $p < 0.004$ ). Taken as a whole, these data suggests mutation type and location can provide useful prognostic indicators for individuals affected with PKD2.

**Molecular characteristics of the *OPA1* gene in the Korean patients with autosomal dominant optic atrophy.** *M.W. Seong*<sup>1</sup>, *J.Y. Kim*<sup>1,3</sup>, *J.M. Hwang*<sup>2</sup>, *H.S. Ko*<sup>1</sup>, *S.S. Park*<sup>1</sup>. 1) Laboratory Medicine, Seoul National University Hospital Clinical Research Institute, Seoul, Korea; 2) Ophthalmology, Seoul National University Bundang Hospital, Sungnam, Korea; 3) Blood Transfusion Research Institute, Korean Red Cross, Seoul, Korea.

Autosomal dominant optic atrophy (ADOA) is the commonest form of inherited optic neuropathy that features low visual acuity leading in many cases to legal blindness. A major locus mapped to chromosome 3q28 and the gene responsible, *OPA1* gene (MIM 165000), was recently identified. To identify the molecular characteristics of the *OPA1* gene, we investigate spectrum and genotype-phenotype correlation in Korean patients with ADOA. A total of 16 ADOA families were analyzed. Nine of them were from pedigrees with affected in at least two subsequent generations, two were from families with an affected sibling and four patients were sporadic. Family history was unavailable in one case. We also analyzed 14 patients with Leber's hereditary optic neuropathy (LHON) who had not harbor the primary LHON mitochondrial DNA mutations. All 28 coding exons and the flanking regions of the *OPA1* gene were amplified. Mutations were screened by SSCP and identified by direct sequencing. We identified eight different mutations among 16 patients: three splicing, three missense, one nonsense, and one frameshift mutation. All of them were novel except one (87.5%). A majority of these mutations were truncative (50%) and located throughout the gene (exons 2-25). Two of three missense mutations were found in the GTPase domain of the *OPA1* protein (exon 8-12). None of them was detected 100 normal control chromosomes. There is no remarkable genotype-phenotype correlation. Eighteen polymorphisms were found, nine of which were novel. No mutations were found in any LHON patient. *OPA1* mutations and polymorphisms in Koreans reveal a different spectrum from that in Caucasians reported and do not show a founder effect, suggesting a random mutational event occurring recently. A majority of these are truncative mutations and support that the haploinsufficiency may represent a major pathomechanism for ADOA.

**B-CAM/LU modifies Sickle Cell Disease severity.** *L.M. De Castro<sup>1</sup>, J. Jonassaint<sup>1</sup>, S. Rainey<sup>3</sup>, R. Motley<sup>2</sup>, S. Jones<sup>2</sup>, J. Galloway<sup>1</sup>, L. Zhang<sup>1</sup>, T. Uchiyama<sup>1</sup>, J.R. Eckman<sup>3</sup>, E.P. Orringer<sup>2</sup>, A.E. Ashley-Koch<sup>1</sup>, J.M. Vance<sup>1</sup>, M.J. Telen<sup>1</sup>.* 1) Duke University Medical Center, Durham, NC; 2) University of North Carolina, Chapel Hill, NC; 3) Emory University, Atlanta, GA.

B-CAM/LU mediates sickle red blood cell (RBC) adhesion to subendothelial laminin and is a candidate for modifying sickle cell disease (SCD) severity. We examined two polymorphisms in B-CAM/LU, the Lutheran blood group antigen ( $\text{Lu}^a / \text{Lu}^b$ ) and the Auberger polymorphism ( $\text{Au}^a / \text{Au}^b$ ), in 179 patients with Hb SS or Hb S<sup>0</sup>-thalassemia for associations with cerebrovascular events, acute chest syndrome, hand-foot syndrome, priapism, leg ulcers, and aseptic necrosis. For  $\text{Lu}^a / \text{Lu}^b$ , there is evidence for association with cerebrovascular events (stroke, transient ischemic attack or seizure, primarily due to an association with stroke ( $p=0.01$  genotype)) and with priapism ( $p=0.01$ ). However, the association with priapism was due to the opposite allele from stroke ( $\text{Lu}^a$  vs  $\text{Lu}^b$ , respectively). For  $\text{Au}^a / \text{Au}^b$ , preliminary results also suggested an association with priapism ( $p=0.004$  genotype). To further examine these data, we measured RBC adhesion to immobilized laminin (in a flow chamber assay) in steady state samples of 23 patients at a shear stress of 1 dyne/cm<sup>2</sup>. The mean laminin binding of  $\text{Lu}^b / \text{Lu}^b$  patients (385.6 cells/cm<sup>2</sup>) was not significantly different from  $\text{Lu}^a / \text{Lu}^b$  patients (467.3 cells/cm<sup>2</sup>). No  $\text{Lu}^a / \text{Lu}^a$  patients were observed. Examination of mean laminin binding as a function of Au genotype was also not statistically significant but there was a trend of increased mean laminin binding with increasing number of  $\text{Au}^a$  alleles ( $\text{Au}^b / \text{Au}^b$ : 285 cells/cm<sup>2</sup>;  $\text{Au}^a / \text{Au}^b$ : 437.4 cells/cm<sup>2</sup>;  $\text{Au}^a / \text{Au}^a$ : 523 cells/cm<sup>2</sup>). These data suggest that the  $\text{Lu}^a / \text{Lu}^b$  and  $\text{Au}^a / \text{Au}^b$  polymorphisms in B-CAM/LU may be important modifiers of the clinical outcomes of patients with SCD and that different clinical sequelae may have different underlying etiologic mechanisms. Further, although not statistically supported by the functional data in the small sample examined here, the genotypic associations that we have observed are most likely due to variations in RBC adhesion to laminin.

**Examination of VCAM1 as a modulator of stroke risk in sickle cell disease.** *M.J. Telen<sup>1</sup>, A.E. Ashley-Koch<sup>1</sup>, L. Zhang<sup>1</sup>, J. Jonassaint<sup>1</sup>, S. Rainey<sup>3</sup>, R. Motley<sup>2</sup>, S. Jones<sup>2</sup>, J. Galloway<sup>1</sup>, T. Uchiyama<sup>1</sup>, J.R. Eckman<sup>3</sup>, E.P. Orringer<sup>2</sup>, J.M. Vance<sup>1</sup>.* 1) Duke University Medical Center, Durham, NC; 2) University of North Carolina, Chapel Hill, NC; 3) Emory University, Atlanta, GA.

Sickle cell disease (SCD) results from a single gene mutation, yet there is remarkable variation in the clinical course of patients with this disease. Stroke occurs in only 10-20% of patients but is a significant cause of morbidity and mortality starting in childhood. Identifying molecular predictors of such clinical outcomes will have important implications for the treatment of patients with SCD. Taylor et al (2002) previously reported an association between stroke and a non-synonymous SNP (G1238C) in the VCAM1 cell adhesion molecule in 102 patients with Hb SS. We have examined this SNP in our own dataset of 179 patients with Hb SS or Hb S $\beta$ 0-thalassemia. Uncorrected chi-square or fisher-exact p-values are reported as appropriate. Preliminary analysis did not detect significant association between G1238C and the outcome of stroke alone (p=0.06 genotype). However, when broadening the analysis to include any type of cerebrovascular event (CVA; defined as stroke, transient ischemic attack or seizure), there was evidence for an association at the genotype level (p=0.02). Interestingly, we also observed evidence for association with occurrence of hand-foot syndrome (p=0.007 genotype). However, the C allele was associated with CVA in our dataset and that of Taylor et al (2002), but the G allele was associated with hand-foot syndrome. We did not detect associations with G1238C and aseptic necrosis of the hip or shoulder, acute chest syndrome, leg ulcers, or priapism. These results suggest that differing biological mechanisms may underlie the etiology of these sickle complications. Thus, we conclude that VCAM1, and potentially other cell adhesion molecules, are likely to play an important role in some but maybe not all complications of SCD. Further examination in larger datasets will be needed to confirm this hypothesis.

**Identifying dosage-sensitive genes in the Smith-Magenis Syndrome region.** *P. Fonseca, K. Walz, J. Lupski.* Dept Human Molecular Genetics, Baylor Col Medicine, Houston, TX.

The Smith-Magenis Syndrome (SMS) is thought to be a contiguous gene syndrome associated with a 4Mb deletion in chromosome 17p11.2. Haploinsufficiency of one or more genes in the region seems to be responsible for the etiology of the disease. The 1Mb critical region is syntenic to a region of murine chromosome 11 and the number and order of the genes are highly conserved. A deletion and its reciprocal duplication were engineered in the mouse spanning the genomic interval commonly deleted in SMS patients to model the disease and to study dosage effects of the genes in the region. Heterozygous deleted (Df(11)/+) mice present craniofacial abnormalities, seizures, obesity and a shorter period length when compared to wild-type littermates. Duplicated (Dp(11)/+) animals are underweight and show hyperactivity and learning disabilities. Analysis of Df(11)/Dp(11) animals suggests that most of the observed phenotypic features result from gene dosage effects. The three strongest candidates for dosage effects genes are Rai1 (Retinoic Acid Induced), Drg2 (Developmentally Regulated G protein) and Rasd1 (Dexamethasone-induced RAS-related protein). The RASD1 protein is hormonally regulated and is involved in the Erk-MAP kinase pathway. DRG2 is a GTP-binding protein with a potential role in early neurogenesis. Rai1 is retinoic acid induced and is specifically expressed in the mouse brain during development. Retinoic acid is known to be involved in the development of craniofacial abnormalities. Recently, dominant frameshift mutations leading to protein truncation in the RAI1 gene were identified in patients with many features observed in SMS. We used BACs containing the three candidate genes to generate overexpressing mice and to perform in vivo complementation, by crossing transgenic animals with the engineered heterozygous deleted mice. The F1 generation is being analyzed for the phenotypic features found in Df(11)/+ and Dp(11)/+ mice. The use of transgenic technology will provide a powerful means to assess gene dosage effects in the mouse, as well as identifying the gene responsible for the phenotype in the SMS mouse model through complementation analysis.

**A CLUSTER OF MUTATIONS IN THE UMOD GENE CAUSES FAMILIAL JUVENILE HYPERURICEMIC NEPHROPATHY WITH ABNORMAL EXPRESSION OF UROMODULIN.** *K. Dahan<sup>1</sup>, O. Devuyst<sup>2</sup>, M. Smaers<sup>1</sup>, G. Loute<sup>3</sup>, J.M. Poux<sup>4</sup>, M.F. Gagnadoux<sup>5</sup>, D. Chauveau<sup>6</sup>, J.P. Cosyns<sup>7</sup>, C. Antignac<sup>8</sup>, Ch. Verellen-Dumoulin<sup>1</sup>, Y. Pirson<sup>2</sup>.* 1) Dept Genetics, UCL Saint-Luc Hosp, Brussels, Belgium; 2) Division of Nephrology, UCL Saint-Luc Hosp, Brussels, Belgium; 3) Dept of Nephrology, Princesse Paola Hospital, Aye, Belgium; 4) Dept of Nephrology, Frejus, France; 5) Dept of Pediatric Nephrology, Hopital Necker, Paris, France; 6) Division of Nephrology and INSERM U507, Hopital Necker, Paris, France; 7) Dept of Pathology, UCL Saint-Luc Hospital, Brussels, Belgium; 8) Universite Paris V, Necker Hospital, INSERM U574 and Department of Genetics, Paris, France.

Familial juvenile hyperuricemic nephropathy (FJHN [MIM 162000]) is an autosomal-dominant disorder characterized by abnormal tubular handling of urate and late development of chronic interstitial nephritis leading to progressive renal failure. We and others previously identified a locus for FJHN on chromosome 16p12 close to the *MCKD2* locus, which is responsible for a variety of autosomal dominant medullary cystic kidney disease (MCKD2). *UMOD*, the gene encoding the Tamm-Horsfall/uromodulin protein maps within the FJHN/MCKD2 critical region. Mutations in *UMOD* were recently reported in 4 families with FJHN/MCKD2 disease. We have identified 8 novel mutations in *UMOD* (7 missense and one in-frame deletion) among FJHN families, clustering in the highly conserved exon 4. The consequences of *UMOD* mutations on uromodulin expression were investigated by immunohistochemistry in 3 renal biopsies from 2 families. There was a markedly increased expression of uromodulin in a cluster of tubule profiles, suggesting an accumulation of the protein in tubular cells. Consistent with this observation, urinary excretion of uromodulin was significantly decreased. In conclusion, our study points out to a mutation clustering in the exon 4 of *UMOD* as a major genetic defect in FJHN. Identification of *UMOD* mutations thus allows an accurate diagnosis and genetic counselling in a significant subset of FJHN/MCKD2 disease. These data give new insights on the function of uromodulin and the renal handling of urate.

**Neonatal Onset Multisystem Inflammatory Disease (NOMID): further evidence for genetic heterogeneity and search for novel additional NOMID causing genes.** *I. Aksentijevich<sup>1</sup>, F. Austin<sup>1</sup>, J.J. Chae<sup>1</sup>, R. Goldbach Mansky<sup>2</sup>, D.L. Kastner<sup>1</sup>.* 1) Genetics & Genomics Branch, NIH/NIAMS, Bethesda, MD; 2) Office of the Clinical Director NIH/NIAMS, Bethesda, MD.

Neonatal Onset Multisystem Inflammatory Disease (NOMID/CINCA syndrome) is a rare autoinflammatory disease characterized by fever, meningitis, uveitis, sensorineural hearing loss, urticarial rash, and a characteristic deforming arthropathy. NOMID is caused by missense mutations in *CIAS1* (*NALP3*, *PYPAF1*), which encodes cryopyrin. NOMID is allelic with Muckle-Wells (MWS) and familial cold autoinflammatory syndrome (FCAS). More than 30 mutations causing MWS/FCAS/NOMID have been reported to date, all in the NACHT domain of the protein. We previously reported 6 mutations in 13 NOMID cases, 5 of which were novel. Consistent with the recently discovered role of *CIAS1* in IL-1 regulation, we found evidence for increased IL-1, as well as TNF, IL-3, IL-5, and IL-6, in monocytes from a patient with the D303N mutation. Subsequently, we have analyzed 8 more NOMID patients and found mutations in only 4. Two of the mutations are novel (F523C and G326E). Monocytes from these patients showed increased levels of IL-1 precursor by Western blot analysis regardless of whether a *CIAS1* mutation was present. Overall, only 50% (10/21) of our NOMID patients are *CIAS1* mutation positive, which further strengthens evidence for genetic heterogeneity. Cryopyrin is a member of the recently identified family of genes known as PYPAFs or NALPs, with more than 14 members identified so far. We screened our *CIAS1* mutation negative patients for mutations in the NACHT domains of several of the NALP molecules that are highly homologous to cryopyrin or that have similar tissue expression profiles as possible NOMID candidate genes, including NALP1/DEFKAP, NALP2/PYPAF2, NALP4/PAYPAF4, NALP6/PYPAF5, NALP12/PAYPAF7, as well as apoptosis-associated speck-like protein with a CARD (ASC), which interacts with cryopyrin to regulate apoptosis and proinflammatory caspases. We have identified several missense substitutions in these molecules, and we are currently screening controls and evaluating the functional consequences of these variants.

**Genetic Testing for Hereditary Hyperferritinemia Cataract Syndrome: a Common Mutation and Coincident Hemochromatosis Genotype.** *D.G. Brooks*<sup>1</sup>, *D. Stambolian*<sup>2</sup>. 1) Medical Genetics; 2) Ophthalmology & Genetics, Univ Pennsylvania, Philadelphia, PA.

Hereditary Hyperferritinemia Cataract Syndrome (HHCS) is defined by dominant inheritance of cataracts, elevated serum ferritin and specific mutations of the L-ferritin gene, HFERL. Mutation of the iron responsive element in the 5' UTR of the HFERL mRNA causes disinhibition of L-ferritin translation. Serum ferritin reaches up to 2,300 mg/dL in HHCS, often resulting in misdiagnosis as hemochromatosis. Four observations have been made in the largest series of patients undergoing genetic testing for HHCS in the U.S.: Of 11 referrals accepted with the combination of elevated ferritin and cataract 9 had mutations in HFERL. A novel variant, C33T, has subsequently been confirmed in another HHCS family. Four of 9 kindreds carry the G32A mutation and all of these families have German and/or English ancestry; G32A is also the most common HFERL mutation in French and Italian HHCS families. Of note, 3 of the 7 G32A-linked HHCS families are also segregating the 2 common hemochromatosis (HFE) mutations. Each family includes at least one HHCS patient with the compound heterozygous HFE genotype C282Y/H63D. Two of these individuals have the highest ferritin levels ever reported in HHCS (2,750-4,700). Phlebotomy treatment of possible iron overload achieved only 10-25 percent reductions of ferritin in 2 such patients indicating mild iron loading. Requiring that cases have both cataract and hyperferritinemia produces high sensitivity for HHCS mutation testing. Haplotype analysis is planned to differentiate a founder effect of the common G32A variant from recurring mutation. We have identified 3 individuals with genotypes predisposing to 2 genetic diseases that both increase ferritin: HHCS and hemochromatosis. Such individuals are at very high risk of being misdiagnosed as hemochromatosis and inappropriately treated by phlebotomy therapy. While this case series is too small to draw conclusions, it is possible that a selective advantage is conferred by high ferritin levels in HHCS that may buffer high free iron concentrations in individuals with concurrent hemochromatosis mutation(s).

**A genome wide scan for Familial Idiopathic basal Ganglia Calcification (Fahr's disease) identifies new candidate regions and confirms genetic heterogeneity.** *J.R.M. Oliveira<sup>1</sup>, S. Hopfer<sup>1</sup>, J. Papp<sup>2</sup>, E. Spiteri<sup>1</sup>, J. Klepper<sup>3</sup>, J.*

*Gilbert<sup>4</sup>, Z.K. Wszolek<sup>4</sup>, M. Hutton<sup>4</sup>, F. Boller<sup>4</sup>, M.J. Sobrido<sup>1</sup>, D.H. Geschwind<sup>1</sup>.* 1) David Geffen Medical School Neurology Dept, University of California, Los Angeles, CA; 2) Department of Human Genetics, UCLA, Los Angeles, CA; 3) Department of Pediatric Neurology, University of Essen, Essen, Germany; 4) Department of Neurology, Mayo Clinic, Jacksonville, FL.

Fahr's disease, or Idiopathic Basal Ganglia Calcification (IBGC), is a neurological condition characterized by calcifications in the basal ganglia nucleus, cerebellum and occasionally the cerebral subcortical white matter. Clinical manifestations include dystonia, parkinsonism, and neurobehavioral symptoms such as psychosis. The first locus associated with IBGC resides on the long arm of the chromosome 14 (IBGC1 - Geschwind et al 1999). Considering a family of Spanish origin, with probable linkage to the same region, the critical region may be narrowed to 10.9 cM (Sobrido et al 2003). **PURPOSE:** To assess genetic heterogeneity in IBGC and to define new candidate regions we performed linkage analysis in several families with IBGC. **METHODS:** A 10cM genome wide scan was performed in 4 families with a total of 47 subjects using a ABI MD 10 marker panel. An additional family with 14 more subjects is still under analysis. Using LINKAGE and SIMWALK2 we performed multipoint and two point analysis. **RESULTS:** The largest single-point lod score was observed on chromosome 7 with a LOD score of 3.023 at marker D7S519 in the FB2 family (10 affected). The minimal interval defined by haplotype analysis is between the markers D7S484 and D7S506, spanning about 20cM. Three smaller families, with a total of 16 affected, had a maximum multipoint LOD score of 3.487 on chromosome 9, at a position roughly midway between D9S157 and D9S171. Haplotype analysis shows that these families share a common region around 16 cM between the markers D9S171 and D9S1817. These results reinforce preliminary studies demonstrating genetic heterogeneity in Fahr's disease and report two potential new candidate regions, one of them shared by three families.

**DNA sequence variants in AGTR2 are not associated with X-linked mental retardation.** *S. Huang*<sup>1</sup>, *M. Peng*<sup>2</sup>, *M.X. Zoleikhaeian*<sup>1</sup>, *W. Sun*<sup>1</sup>, *C.M. Strom*<sup>1</sup>. 1) Dept Molecular Genetics, Quest Diagnostics, San Juan Capistrano, CA; 2) Harvard Partners Center for Genetics and Genomics, Harvard Medical School, Cambridge, MA.

Angiotensin II is a potent regulator for many of the well-known stimulatory physiological activities including secretion of aldosterone, vasoconstriction, and renal sodium reabsorption. These actions are primarily mediated by Angiotensin Receptor I (AGTR1), the receptor function of a second receptor AGTR2 was largely unknown. Recent studies have suggested that one frame shift and three missense mutations of AGTR2 may be associated with X-linked mental retardation (Vervoort et al., 2002). To assess the effect of AGTR2 on brain development and cognitive function, we screened DNA from a cohort of 500 male patients submitted for Fragile X testing that were negative for FMR1 expansion. As controls, we also screened DNA from presumably nonretarded 500 males and normal females. Single nucleotide primer extension methodology was utilized to screen the previously described sequence variants in the AGTR2 gene (Vervoort et al., 2002). We detected hemizygotes for the frame shift mutation, 402delT, and hemizygotes of the missense mutation, G62T, in male patients both with or without mental retardation and in similar frequencies. DNA from 1000 normal female controls showed the G62T mutation in about 10%. Nishimura et al. (1999) also showed that in human a large fraction of the general population (42%) carry another functionally significant mutation (A-1332G) in AGTR2 gene. Collectively these results argued that mutations in AGTR2 gene are not associated with X-link mental retardation. The possible role of AGTR2 in the central nervous system still need to be clarified.

**Mutations in the human *LARGE* gene cause a form of congenital muscular dystrophy with severe mental retardation and abnormal glycosylation of -dystroglycan (MDC1D).** C.A. Longman<sup>1</sup>, M. Brockington<sup>1</sup>, C. Kennedy<sup>2</sup>, C. Jimenez<sup>1</sup>, S. Torelli<sup>1</sup>, C. Sewry<sup>1</sup>, S. Brown<sup>1</sup>, F. Muntoni<sup>1</sup>. 1) Dubowitz Neuromuscular Centre, Imperial College, London, UK; 2) Pediatric Neurology Department, Southampton, UK.

The congenital muscular dystrophies (CMD) are a heterogeneous group of autosomal recessive disorders, four of which are due to defects in genes encoding known or putative glycosyltransferases. Fukuyama CMD, Muscle-Eye-Brain disease and Walker-Warburg syndrome, severe forms with eye abnormalities and neuronal migration defect, are due to mutations in *fukutin*, *POMGnT1* and *POMT1* respectively. Mutations in the fukutin-related protein (*FKRP*) gene cause congenital muscular dystrophy 1C and limb girdle muscular dystrophy 2I, forms not typically associated with brain involvement. The expression of -dystroglycan is altered in these disorders and evidence indicates this is due to its abnormal glycosylation.

The Large<sup>myd</sup> mouse has a homozygous deletion in the gene encoding a putative glycosyltransferase, Large. Large<sup>myd</sup> mice have a progressive myopathy, neuronal migration defect and abnormal glycosylation of -dystroglycan. Thus, the human *LARGE* gene was a strong candidate for involvement in human muscular dystrophies with abnormal glycosylation of -dystroglycan.

We have identified *LARGE* mutations in a patient with congenital muscular dystrophy. She is a 17 year old girl of non-consanguineous British parents with profound mental retardation and extensive white matter changes on brain MRI but apparently normal brain structure. She is a compound heterozygote for a non-conservative missense mutation, G1525A (Glu>Lys), and G2000insT (which causes a frameshift and premature termination), both within the putative second catalytic domain of Large. Immunolabelling of glycosylated -dystroglycan is reduced in skeletal muscle and immunoblotting demonstrates a reduction in its molecular weight. Overlay assays show that -dystroglycan still has some residual laminin -2 binding. This is the first description of mutations in the human *LARGE* gene; we propose to name this novel form of congenital muscular dystrophy MDC1D.

**Identification of a locus for type I punctate palmoplantar keratoderma on chromosome 15q22-24.** A. Martinez-Mir<sup>1</sup>, A. Zlotogorski<sup>2</sup>, D. Londono<sup>3</sup>, D. Gordon<sup>3</sup>, A. Grunn<sup>4</sup>, E. Uribe<sup>5</sup>, L. Horev<sup>2</sup>, I.M. Ruiz<sup>5</sup>, N.O. Davalos<sup>5</sup>, O. Alayan<sup>2</sup>, J. Liu<sup>4</sup>, T.C. Gilliam<sup>4</sup>, J.C. Salas-Alanis<sup>6</sup>, A.M. Christiano<sup>1,7</sup>. 1) Department of Dermatology, Columbia University, New York, NY; 2) Department of Dermatology, Hadassah Medical Center, Jerusalem, Israel; 3) Laboratory of Statistical Genetics, Rockefeller University, New York, NY; 4) Columbia Genome Center, Columbia University, New York, NY; 5) Hospital General de Occidente Zapopan, Jalisco, Mexico; 6) Departamento de Dermatología, Servicio Médico Universidad Autónoma de Nuevo León, Monterrey N.L., Mexico; 7) Department of Genetics and Development, Columbia University, New York, NY.

The identification of the molecular basis of disorders of keratinization has significantly contributed to our understanding of skin biology, revealing new information on key structures in the skin such as the intermediate filaments, desmosomes and gap junctions. Among these disorders, there is an extraordinarily heterogeneous group known as palmoplantar keratodermas (PPK), for which only a few molecular defects have been described. Here we report the identification of the first locus for type I punctate PPK. A genomewide scan was performed on an extended autosomal dominant pedigree and linkage to chromosome 15q22-24 was identified. With the addition of two new families with the same phenotype, we confirmed the mapping of the locus for punctate PPK to a 9.98-cM interval, flanked by markers D15S534 and D15S818 (maximum two-point LOD score of 4.23 at  $\alpha=0.01$  for marker D15S988). According to the physical maps at NCBI (build #30), UCSC (April 2003 release), and deCODE Genetics, the critical linkage interval identified here corresponds to a region of 7.7 Mb, syntenic to mouse chromosome 9. These findings will facilitate the identification of a new gene involved in skin integrity that could also contribute to the understanding of the multiple organ involvement in the syndromic forms of PPK.

**Identification and characterization of a causal gene responsible for severe developmental delay and a pharyngeal anomaly from a patient with *de novo* translocation [46, XY, t(6;12)(q16;p12)].** K. Yamada<sup>1</sup>, T. Ono<sup>1</sup>, Y. Yamada<sup>1</sup>, N. Ishihara<sup>1,2</sup>, T. Ohki<sup>3</sup>, K. Miura<sup>3</sup>, T. Kumagai<sup>3</sup>, S. Sonta<sup>1</sup>, N. Wakamatsu<sup>1</sup>. 1) Dept Genet, Inst Developmental Res, Aichi Human Serv Ctr, Aichi; 2) Dept Pediatr, Nagoya Univ, Sch Med, Nagoya,; 3) Dept Pediatr Neurol, Central Hosp, Aichi Human Serv,Ctr, Aichi, Japan.

We report the identification and characterization of a gene located at a *de novo* balanced reciprocal translocation 46,XY,t(6;12)(q16;p12) in a patient with severe developmental delay and a pharyngeal anomaly. Fluorescent *in situ* hybridization (FISH) analysis demonstrated that a breakpoint in chromosome 6q16 to be located within a single BAC clone of 98I9 and that of chromosome 12p12 between 684O24 and 841C19. Southern blot analysis using cDNAs or genomic DNA fragments within these BAC clones as a probe as well as direct sequencing analysis of the PCR products between the two chromosomes demonstrated that a breakpoint at 6q16 is 9-kb upstream of *DKFZp564B0769* and that of 12p12 is intron 16 of *PEPP2* encoding phosphoinositol 3-phosphate-binding protein-2, respectively. The *PEPP2* consists of 26 exons containing multifunctional domain of Pleckstrin homologous domain which bind inositol phosphate and various proteins, and is expressed ubiquitously. These results suggest that *PEPP2* is important for normal brain development, and haploinsufficiency of the *PEPP2* likely resulting in severe developmental delay.

***RECQL4* mutation saving the helicase domain results in the RAPADILINO syndrome.** H.A. Siitonen<sup>1</sup>, O. Kopra<sup>1</sup>, H. Kääriäinen<sup>2</sup>, H. Haravuori<sup>1</sup>, R.M. Winter<sup>3</sup>, A-M. Säämänen<sup>4</sup>, L. Peltonen<sup>1,5</sup>, M. Kestilä<sup>1</sup>. 1) National Public Health Institute, Helsinki, Finland; 2) The Family Federation of Finland, Helsinki, Finland; 3) Institute of Child Health, London, UK; 4) University of Turku, Finland; 5) University of Helsinki, Finland.

RAPADILINO syndrome is a rare recessive syndrome with multiple dysmorphic features. Patients have a proportionate small stature, absent or hypoplastic thumbs, radius and patellae. They have characteristic face, normal intelligence and juvenile diarrhea that subsides later in life. RAPADILINO and Rothmund-Thomson syndromes (RTS) show some overlapping features such as radial ray defects but the hallmark symptom of RTS, poikiloderma is never seen in RAPADILINO patients. In contrast to dramatic dermatological changes leading to poikiloderma in RTS, the only dermatological sign in some RAPADILINO patients are patches of skin resembling caf-au-lait spots. Because mutations in *RECQL4* have been found in RTS, *RECQL4* was seen as an excellent candidate gene for RAPADILINO syndrome.

Linkage analysis was performed using markers D8S1836, D8S373 and D8S1925 flanking *RECQL4*, and significant lod scores were observed supporting this hypothesis. We identified four novel mutations in the *RECQL4* and the location of the consequent changes in the protein seems to determine either RAPADILINO or RTS phenotype. Mutations in genes of *RECQL* family are so far associated with Rothmund-Thomson, Werner and Bloom syndromes, all characterized by high predisposition to malignancies, RTS being especially associated with osteosarcoma. However, the most common RAPADILINO mutation, saving the helicase domain of the *RECQL4* protein, results in a non-cancerous phenotype. In situ hybridizations of mouse tissues revealed the most intense signal of *Recql4* in chondrocytes and enterocytes well reflecting the tissue symptoms of RAPADILINO. The high expression in chondrocytes will give a new insight to the normal bone development and growth disturbances in RAPADILINO as well as to the molecular mechanisms behind osteosarcoma, characteristic to RTS.

**Charcot-Marie-Tooth type 2D in a large Australian family of English origin is associated with a novel (H418A) mutation in the glycyl tRNA synthetase gene.** *N. Sambuughin<sup>1</sup>, K. Christodoulou<sup>2</sup>, H. Holley<sup>1</sup>, M. Tsingis<sup>2</sup>, K. Sivakumar<sup>1</sup>, L. Goldfarb<sup>3</sup>, G. Nicholson<sup>4</sup>.* 1) Neurology Research, Barrow Neurological Inst, Phoenix, AZ, US; 2) The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 3) National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, US; 4) ANZAC Medical Research Institute, Concord Hospital, New South Wales, Australia.

Charcot-Marie-Tooth (CMT) disease is a heterogeneous group of hereditary peripheral neuropathies. On the basis of electrophysiological and histopathological studies CMT had been divided into demyelinating (CMT1) and axonal (CMT2) types. Teenage-onset hereditary axonopathy with atrophy of thenar and interossei muscles, mild weakness of foot dorsiflexion developing later in the course of illness, and minimal subjective loss of sharp and vibration sense in the feet was observed in eight members of a four-generation Australian family of English origin. EMG revealed chronic partial denervation; nerve conduction studies showed mild slowing of motor conduction velocity (median motor range 44-50 m/sec, peroneal motor 43 m/sec to not obtainable). The condition in this family is linked to 7p14 chromosomal region, and the affected individuals share a 7-marker disease-associated haplotype. Two syndromes, an axonal type of CMT (CMT2D) and a distal form of spinal muscular atrophy (dSMA-V) recently reported to be linked to the 7p14 region, are caused by mutations in the glycyl tRNA synthetase (GARS) gene (*Am J Hum Genet* 72:1293-99, 2003). Analysis of GARS gene sequences in patients from the Australian family identified a novel heterozygous mutation changing His to Arg at a highly conserved residue 418 located between the core catalytic and the anti-codon binding domains of the GARS protein. The H418A mutation co-segregates with the disease in the family and is absent in 100 unrelated Caucasian controls. These findings further support the association between the CMT2D/dSMA type V syndrome and mutations in GARS. The mechanisms by which mutations in the ubiquitously expressed housekeeping glycyl tRNA synthetase cause these highly specific phenotypes remain to be elucidated.

**Characterization of the PSTPIP1-mediated Inflammatory Pathway Involved in PAPA Syndrome, an Autoinflammatory Disease.** *C.A. Wise<sup>1</sup>, E.J. Smith<sup>1</sup>, L.B. Bennett<sup>2</sup>, D. Zhang<sup>1</sup>, G. Wood<sup>3</sup>, D.L. Kastner<sup>3</sup>, V.M. Pascual<sup>2</sup>.* 1) Seay Research Center, Texas Scottish Rite Hosp, Dallas, TX; 2) UT Southwestern Medical School and Baylor Institute for Immunology Research, Dallas, TX; 3) Genetics and Genomics, NIAMS, NIH, Bethesda, Maryland.

PAPA (pyogenic arthritis, pyoderma gangrenosum, and acne, MIM 604416) syndrome, a new member of the heritable autoinflammatory disorders, is characterized by invasion of polymorphonuclear leukocytes into joints and skin, producing early-onset, destructive arthritis with variable skin involvement. We have shown that this disease is caused by missense mutations in the adaptor protein proline serine threonine phosphatase-interacting protein 1 (PSTPIP1, also known as CD2BP1), and that these mutations result in altered binding to PEST type protein tyrosine phosphatase (PTP PEST) and pyrin. Mutations in pyrin cause Familial Mediterranean Fever (FMF), an autoinflammatory disorder also marked by episodic influx of polymorphonuclear leukocytes into affected areas. We have hypothesized that PAPA syndrome is the result of an alteration in innate immunity in which affected individuals exist in a constitutive pro-inflammatory state, and that inflammation results from activation of a pyrin-mediated pathway downstream of PSTPIP1. To investigate this we have used expression profiling to characterize leukocytes of PAPA syndrome patients. Total cellular RNA from peripheral blood mononuclear cells of 9 affected individuals was compared to the same from 14 healthy controls using oligonucleotide microarrays. Parametric statistical group comparisons revealed 7 of transcripts differentially expressed between the two groups ( $p < 0.05$ ). These included PTP PEST and caspase 1, members of the pyrin pathway. Hierarchical clustering spontaneously differentiated PAPA affected individuals, with a range of clinical severity, from controls. Eleven transcripts remained significantly upregulated after stringent Bonferroni multiple testing correction, including genes implicated in apoptosis and monocyte activation. Further analyses of these data are in progress, as are experiments to identify members of the autoinflammatory pathway upstream of PSTPIP1.

**Genetic heterogeneity for Pyridoxine Dependent Seizures.** *C. Bennett*<sup>1</sup>, *H. Huynh*<sup>1</sup>, *I. Glass*<sup>1</sup>, *S. Gospe*<sup>2</sup>. 1) Division of Genetics & Development, RR-249, University of Washington School of Medicine, Seattle, WA; 2) Division of Pediatric Neurology, CHRMC 5D-4, Seattle, WA.

Pyridoxine-Dependent Seizures (PD) is a rare autosomal-recessive disorder where patients are dependent on high daily supplements of Vitamin B6 (Pyridoxine) to prevent seizures that are otherwise refractory to standard medication. Pyridoxine is a cofactor for glutamic acid decarboxylase (GAD), which converts glutamate to GABA. Examination of a PD patient brain sample, who died during seizure, revealed high levels of glutamate and low levels of GABA. High levels of glutamate and low levels of GABA were subsequently observed in the CSF of a PD patient prior to treatment, normalizing after administration of Pyridoxine. These clinical observations have led to the hypothesis that mutations within GAD cause PD. Several genetic studies have focused on the two isoforms of GAD, GAD65 and GAD67. One study examined three non-consanguineous North American families and excluded linkage to GAD65 by haplotype segregation analysis. These results were confirmed in similar genetic studies in Japanese PD patients where haplotype segregation analysis and mutational analysis excluded GAD65 and GAD67. In 2000, a genomewide linkage scan utilizing five families of North African descent (four of which were consanguineous) mapped a locus for PD at chromosome 5q31. A combined LOD score of 8.43 was obtained, and recombinant haplotype analysis defined a candidate interval of 5cM. Using DNA from 3 non-consanguineous North American PD families, we performed linkage analysis with markers within this 5q31 PD interval. Two families were consistent with linkage to this locus. However, recombination between PD and 5q31 markers was present in the third family, establishing genetic heterogeneity for PD. We hypothesize that mutations of an as yet undiscovered pyridoxine transporter gene may be the cause of PD. *GAD65GAD67*.

**Experience of a French network focused on the delineation of ceroid lipofuscinoses variants.** *C. Caillaud, and the French network on NCL (INSERM/AFM rare disorders).* Department of Genetics, Cochin Institute, Paris, France.

Neuronal ceroid lipofuscinoses (NCL) are neurodegenerative disorders, transmitted as an autosomal recessive trait, characterized by the accumulation of autofluorescent lipopigments, particularly in neurons. The clinical heterogeneity of these diseases (four main clinical forms and numerous variants) is clearly linked to the genetic diversity. Indeed, at least seven different loci have been described to date, among which six have been cloned : two encode an enzymatic protein and four a transmembrane protein of unknown function. An interactive network including neuropaediatricians, anatomopathologists, geneticists and researchers in France and United Kingdom was created in order to delineate the different forms of ceroid lipofuscinoses among French patients. The first step was the recruitment and clinical analysis of NCL patients. This work was performed by physicians who have an extensive experience of these pathologies, with the aim to define the various clinical presentations. Patients were first tested for the common CLN1, CLN2 and CLN3 genes at the enzymatic and/or molecular level and then for alternative genes (CLN6,...). Patients which do not map to any of the known NCL loci and may represent specific variants were collected. They will be used for the characterization of novel loci after morphological confirmation (presence of characteristic lipopigments) and distribution among homogeneous groups according to clinical, ultrastructural and geographic criteria. Our work demonstrated that the diversity of NCL clinical forms was linked not only to the presence of different mutations in the same gene, but also to the high number of genes involved in the pathogenesis of these diseases. Delineation of the clinical variants facilitates the genetic counselling of at-risk couples. Thus, since the beginning of the project, around twenty prenatal diagnoses have been performed in NCL families. This work will also permit to obtain informations on the pathophysiology, epidemiology and genetics of NCL and to open the way to the future development of specific therapies, including gene therapy.

**Molecular modeling of novel mutations in Fabry disease.** *K. Azibi<sup>1,2</sup>, C. Caillaud<sup>1,2</sup>, M.F. Szajnert<sup>2</sup>, J. Dussau<sup>1</sup>, J.P. Puech<sup>1</sup>, L. Poenaru<sup>1,2</sup>.* 1) Laboratoire de Genetique, Faculte de Medecine Cochin, Universite Paris 5, Paris, France; 2) Institut Cochin, Unite 567 INSERM, CNRS, Paris, France.

Fabry disease is an X-linked glycosphingolipid storage disease resulting from deficient activity of the lysosomal alpha-galactosidase A. This enzyme defect leads to the accumulation of globotriaosylceramide in the lysosomes of vascular endothelial and smooth muscle cells, but also in plasma. Therefore, clinical manifestations in the classical form are due to pathology of small vessels resulting in angiokeratoma, renal failure and heart and brain ischemia. Death occurs from renal or cardiac complications. The alpha-galactosidase gene (GLA) was amplified and completely sequenced in 50 patients and 28 potential carriers from 67 families. 36 mutations (17 novel and 19 previously described) were identified. The novel mutations were : four nonsense mutations (Q212X, W245X, W349X and W262X), seven missense mutations (A156N, S297C, P265R, I354K, G361A, D264A and Q279H), a 1-bp insertion (InsG10680) and five deletions (1236del15, 5113delA, 10594delAT, 7317delA, 7338delG). These results confirm the previously reported heterogeneity of mutations causing Fabry disease and have also permitted to clarify the carrier status of females and to offer them reliable genetic counselling. To understand the structural basis of Fabry disease, we mapped the mutations described above onto a three-dimensional model of human alpha-galactosidase A (alpha-GAL). This model was based on the X-ray structure and the similarity of the chicken alpha-N-acetylgalactosaminidase, an enzyme which is closely related to alpha-GAL. Different programs were used to generate representations of protein topography (schematic topogram, alpha-helices and beta-strands, electronic density representations). They permitted to reveal the positions where mutations were located and the effects of these mutations on the active site of the enzyme and on the stability of the folded protein. This study allowed to define the severity of the mutations leading to Fabry disease and therefore to improve the phenotype prediction. Reference : S.C. Garman, D.N. Garboczi. Structural basis of Fabry disease. *Mol. Genet. Metab.* 2002, 77, 3-11.

**Molecular analysis of the glomulin gene in glomuvenous malformation families.** *M.T. Kloos<sup>1</sup>, E. Crocker<sup>1</sup>, C. Haisley-Royster<sup>2</sup>, C.L. Hunter<sup>3</sup>, T.P. Leedom<sup>1</sup>, N.C. Nevin<sup>4</sup>, S.J. Orlow<sup>5</sup>, N. Prose<sup>2</sup>, S.A. Simpson<sup>6</sup>, G.H. Vance<sup>3</sup>, D.F. Murrell<sup>7</sup>, D.A. Marchuk<sup>1</sup>.* 1) Dept. of Mol. Genet. and Microbiol; 2) Dept. of Dermatology, Duke University Medical Center, Durham, NC; 3) Dept. of Med. and Mol. Genet., Indiana University, Indianapolis, IN; 4) Northern Ireland Regional Genetics Centre, Belfast, Northern Ireland; 5) Dept. of Dermatology, NYU School of Medicine, New York, NY; 6) Dept. of Med. Genet., Aberdeen Royal Hospitals, Aberdeen, Scotland; 7) St. George Hospital, Sydney, Australia.

Mutations in the gene encoding glomulin (also termed FAP68) have recently been reported in patients with autosomal dominant glomuvenous malformations (GVMs). GVMs are characterized by vascular abnormalities involving smooth-muscle-like glomus cells, which present as cutaneous bluish-purple lesions. We ascertained and collected DNA for seven GVM families/patients from the U.S., U.K., and Australia. Five were large enough to either establish linkage or a common disease haplotype near the glomulin locus on chromosome 1p22. Mutations were identified in glomulin in all seven families, two of which are novel. All are predicted to be truncating mutations. In 4 of the 7 families/patients a 157delAAGAA was identified. This mutation has been previously described and with this report, identified in 11 of 27 families described to date. This common mutation was previously attributed to a founder effect in families collected from diverse geographical areas. We also find that our 4 families with this mutation show some evidence of a common disease haplotype with each other, and possibly with those previously reported. If this is due to a common ancestral founder, it suggests a relatively ancient origin for this mutation, as it has now been identified in families from 8 countries on 3 continents. Using existence sequence databases, we identified a novel coding exon which was not previously recognized in the original report. This exon was shown to be an authentic part of the glomulin transcript by RT-PCR analysis from a panel of adult human tissues. No mutations were found to date in this novel exon, but it should be included in subsequent mutation screening to ensure complete coverage of the gene.

**Homozygosity Mapping of a Gene for Arterial Tortuosity Syndrome.** *P. Coucke<sup>1</sup>, M.W. Wessels<sup>2</sup>, P. Van Acker<sup>1</sup>, R. Gardella<sup>3</sup>, S. Barlati<sup>3</sup>, P.J. Willems<sup>4</sup>, M. Colombi<sup>3</sup>, A. De Paepe<sup>1</sup>.* 1) Dept Medical Genetics, University Hospital Ghent, Ghent, Belgium; 2) Dept Clinical Genetics, Obstetrics and Gynecology, Erasmus University, Rotterdam, The Netherlands; 3) Dept of Biomedical Sciences and Biotechnology, University of Brescia, Italy; 4) Synergene, Belgium.

Arterial tortuosity syndrome (ATS, MIM 208 050) is a rare connective tissue disorder characterized by generalized tortuosity, elongation, stenosis and aneurysms of the major arteries. Skin and joint abnormalities including hyperextensibility or hyperlaxity of the skin, joint laxity or contractures and inguinal hernias, reminiscent of other connective tissue diseases, can also be observed. Other phenotypic abnormalities include micrognathia, elongated face, high palate, beaked nose, sliding hernia and ventricular hypertrophy. Histopathologic studies show abnormalities of the elastin network in the large arteries. The mode of inheritance of ATS is autosomal recessive, but the disease gene has not yet been identified. Until now, a very limited number of ATS patients have been described and few multiplex families have been published. However, some inbred multiplex families originating from Morocco and Italy have recently been reported and create the opportunity to localize the ATS gene. We have performed a total genomesearch by homozygosity mapping in three consanguineous multiplex families, and mapped the ATS gene to chromosome 20q13. Recombinations within an extended haplotype of 11 microsatellite markers localized the ATS gene between markers D20S836 and D20S109, an interval of 9.5 cM which represents 4.1 Mb on the physical map. Based on the different databases, the candidate region for ATS contains 31 predicted transcripts. Genes or homologues of structural genes involved in the extracellular matrix, more in particular those involved in the elastogenesis pathway, will be considered as strong candidates. Until now, no obvious candidate gene has been identified.

**DHPLC screening of ATP8B1 in Finnish women suffering from Intrahepatic Cholestasis of Pregnancy.** *J.N.*

*Painter<sup>1</sup>, M. Savander<sup>1</sup>, A-E. Lehesjoki<sup>1</sup>, A. Ropponen<sup>2</sup>, K. Aittomki<sup>1</sup>.* 1) Folkhlsan Institute of Genetics, Biomedicum P.O. Box 63, Department of Medical Genetics, University of Helsinki 00014 Finland; 2) Department of Gynaecology and Obstetrics, Helsinki University Hospital, 00029 Helsinki, Finland.

Intrahepatic Cholestasis of Pregnancy (ICP, also known as obstetric cholestasis) is a disease occurring usually in the third trimester of pregnancy, characterised by generalised (and possibly intense) itching and increased levels of total bile acids in maternal blood. Whilst the condition can be particularly uncomfortable for the mother, the symptoms resolve spontaneously after delivery. The outcome for the foetus is less certain, as ICP is associated with increased rates of premature birth, intrauterine distress and/or sudden death. Whilst the aetiology of the disease is still largely unclear, and likely to be genetically heterogenous, ICP has been reported in mothers of children affected with progressive familial intrahepatic cholestasis (PFIC) types 1, 2 and 3. One of the cholestasis genes, ATP8B1, causing both PFIC1 and benign recurrent intrahepatic cholestasis (BRIC), has often been implicated as a possible cause of ICP. The risk for women heterozygous for mutations in ATP8B1 may be increased, as mothers of children suffering from both diseases, relatives of BRIC patients as well as BRIC sufferers themselves, may experience ICP. In addition, BRIC is at least superficially similar to ICP, as cholestatic episodes are periodic, of variable intensity, apparently 'benign' with no permanent liver damage, and resolve after some time. To investigate whether ATP8B1 could be a cause of ICP in Finland we are using denaturing high-performance liquid chromatography (DHPLC) to screen affected women for mutations in the 27 exons of ATP8B1. At the time of writing we have screened 144 sporadic and 19 familial patients. Despite finding a number of intronic and exonic SNPs, some apparently unique to the Finnish population, no disease causing mutations have as yet been discovered. At present, it appears that ATP8B1 is not responsible for ICP in Finland.

**Unexpected 11p15 anomalies in Sotos syndrome and NSD1 mutations in Beckwith-Wiedemann syndrome.** G. BAUJAT<sup>1</sup>, M. RIO<sup>1</sup>, D. SANLAVILLE<sup>1</sup>, A. MUNNICH<sup>1</sup>, C. GICQUEL<sup>2</sup>, V. CORMIER-DAIRE<sup>1</sup>, L. COLLEAUX<sup>1</sup>. 1) INSERM U393, Hopital Necker-Enfants Malades, Paris, FRANCE; 2) Laboratoire d'Explorations Fonctionnelles Endocriniennes et Inserm U515, Hpital Armand Trousseau, Paris, France.

Sotos syndrome is an overgrowth syndrome characterized by pre- and postnatal overgrowth, macrocephaly, advanced bone age, variable degree of mental retardation and typical facial features. Deletions and point mutations of the NSD1 gene account for largely 80% of Sotos syndrome, while the disease mechanism of other cases remains unknown.

On the other hand, Beckwith-Wiedemann syndrome (BWS) is a distinct overgrowth condition characterized by macroglossia, omphalocele, visceromegaly, hypoglycemia and an elevated risk of developing embryonal tumors. BWS is a genetically heterogeneous disorder caused by dysregulation of imprinted growth regulatory genes within the 11p15 region. CDKN1C mutation and 11p15 uniparental disomy account for 30% of patients but in many cases the disorder is due to epigenetic defects i.e. isolated hypermethylation of H19 or demethylation of KCNQ1OT. The molecular defect underlying a significant proportion of sporadic BWS cases remains unknown.

Although Sotos and BWS are clinically distinct conditions, they share common features such as macrosomia, neonatal hypoglycemia, seizure or cardiac anomalies. Based on this phenotypic overlap, we tested whether unexplained Sotos cases could be related to 11p15 anomalies and whether unexplained BWS could be related to NSD1 deletions or mutations. Indeed, one UPD and one imprinting mutation of the 11p15 region were identified in a series of 19 Sotos patients carrying no NSD1 anomaly. On the other hand, 51 BWS children with no 11p15 anomaly were tested for NSD1 mutation. No deletion was found but most interestingly, we identified 2 mutations in 11 children. These results suggest that, despite clinical differences, the two disorders may have more similarities than previously thought, based on molecular genetic findings and we propose that NSD1 protein could be involved in imprinting of the chromosome 11p15 region.

**Evaluation of the Multiplex Ligation-Dependent Probe Amplification (MLPA) technology in the diagnosis of Rett syndrome.** *S. Boulanger, L. Mariage, L. Van Maldergem, Y. Gillerot, P. Hilbert.* Human Genetics Center, Institute of pathology and Genetics, Loverval, Belgium.

Rett Syndrome (RTT) is an X-linked progressive neurodevelopmental disorder and one of the most common causes of mental retardation in females, with an incidence of 1 in 10.000-15.000. Sequencing of the coding and splicing regions of the methyl-CpG binding protein (MECP2) gene is thought to yield a 50 to 80 % range of disease-causing mutations considering patients fulfilling clinical criteria. Recently, gross rearrangements of the MECP2 gene, which were not evidenced by classical sequencing, were detected by Southern blot analysis. It could represent a significant proportion of cases lacking mutations. On a total of 116 girls selected with a panel of signs and symptoms compatible with RTT, we have identified 22 classical mutations. In order to evaluate the importance of possible gross rearrangements in the mutation-negative cases, we used Multiplex Ligation-Dependent Probe Amplification (MLPA) technology. Up to now, 53 of the negative cases were tested by MLPA and 4 showed a deletion of one or more exons. Two of them have deletion of exons 3 and 4, one a deletion of the first exon and the last one a deletion of exon 4. For two patients (one with deletion of exon 4 and one with deletion of exons 3 and 4), we confirmed the rearrangement by Southern blot analysis. These preliminary results confirm that a search for MECP2 deletions is important for the diagnosis of Rett Syndrome and that MLPA is a simple and fast technology to reveal these alterations.

**Animal models for Gdi1 non-specific mental retardation.** P. D'Adamo<sup>1</sup>, H. Welzl<sup>1</sup>, D. Wolfer<sup>1</sup>, H.P. Lipp<sup>1</sup>, L. Rinaldi<sup>2</sup>, D. Toniolo<sup>2</sup>. 1) Anatomy, University of Zurich, Zurich, Switzerland; 2) DIBIT, San Raffaele Scientific Institute, Milano, Italy.

MR is a common and highly heterogeneous human disorder characterized by childhood onset and mental handicap as the only clinical symptom. Many studies have been undertaken to determine the causes of MR and all have demonstrated high heterogeneity due to both genetics and environmental factors. In recent years a small number of X linked genes for MR (MRX) were identified and they confirmed the heterogeneity of the disorder and demonstrated that the newly identified genes are important tools for understanding the molecular basis of MR. One of the genes identified was GDI1, which encodes one of the proteins controlling the activity of the small GTPases of the Rab family, in vesicle fusion and intracellular trafficking. To gain insights into the role of the genes identified in MR we have produced a mouse mutant of Gdi1. The Gdi1 deficient mice were viable and fertile. They were normal in many tasks to assess learning capacity and emotional behavior, but they were impaired in tasks requiring formation of temporal associations suggesting defects in short term memory. They also show lowered aggression and altered social behavior. Our results show that in mice, as in humans, lack of Gdi1 spares most CNS functions and affects a hippocampus function related to short term memory formation, suggesting evolutionary conservation of basic cognitive function(s) and tentatively confirming that simple animal models can be of great value in the study of human MR. Moreover, lack of Gdi1 was not responsible for alterations of parameters of SV exocytosis and neurotransmitter release. Electrophysiological analysis of the Gdi1 KO mice demonstrated that lack of Gdi1 is responsible for specific deficits in short and long term synaptic plasticity, suggesting that the mice could present depletion of the reserve synaptic vesicle pool. This phenotype was confirmed using electron microscopic studies of the Gdi1 KO hippocampus showing that the number and the distribution of SV is altered in the KO.c.

**Comparison of phenotypes, neuronal electrophysiology, and gene expression patterns between Fmr2 and Af5q31 KO mice.** *Y. Gu*<sup>1</sup>, *B. Antalffy*<sup>2</sup>, *E. Weeber*<sup>3</sup>, *D. Armstrong*<sup>2</sup>, *D.L. Nelson*<sup>1</sup>. 1) Molec & Human Genetics, Baylor College Med, Houston, TX; 2) Department of Pathology, Baylor College of Medicine, Houston, Texas 7703; 3) Division of Neuroscience, Baylor College of Medicine, Houston, Texas 7703.

Fmr2 and AF5q31 belong to the AF4/FMR2 gene family sharing several highly homologous domains with two other members of this family: AF4 and LAF4. In humans, loss of function of FMR2 is associated with mild mental retardation; expansion and methylation of a CCG triplet repeat at FRAXE is the most common mutation. No phenotypes associated with loss of function of other members in this family have been described in humans. Available evidence from vertebrate and fruit fly studies suggest that this family is involved in gene expression regulation, cell expansion, and embryonic development as well as adult organ function. We are interested in studying these functions through development of mouse models. We have created both Fmr2 and AF5q31 knockout models and studied these two models through analysis of phenotypes, electrophysiological responses in neurons of the hippocampus, targeted gene expression patterns and neuronal expansion. The results showed that absence of either gene affected electrophysiological responses in neurons of hippocampus and target gene expression in a distinct way. For example, Af5q31 knockout mice exhibited abnormality in paired pulse facilitation, but normal long term potentiation of hippocampal neurons while the Fmr2 knockout displayed normal paired pulse facilitation, with abnormal long term potentiation. In AF5q31 knockout mice, we found at least 50% embryonic lethality of offspring. Embryonic death can occur as early as day 12.5 post coitus (PC). Other knockout embryos appeared developmentally delayed compared with normal control embryos at the same stage. In Fmr2 knockout mice, GABA neurons were reduced in the cerebrum, especially in the hippocampus. Expression of members of the Sp family was affected in both models and the results demonstrated different members of the Sp family were regulated by FMR2 and AF5q31.

**Novel *MECP2* mutations identified from Japanese patients with classical and variant Rett syndromes. Y.**

*Yamada*<sup>1</sup>, *K. Miura*<sup>2</sup>, *T. Kumagai*<sup>2</sup>, *T. Fujii*<sup>3</sup>, *T. Ishikawa*<sup>4</sup>, *T. Tandou*<sup>5</sup>, *N. Nomura*<sup>1</sup>, *K. Yamada*<sup>1</sup>, *S. Sonta*<sup>1</sup>, *N. Wakamatsu*<sup>1</sup>. 1) Dept Genetics, Inst Dev Res, Aichi Human Service Ctr, Kasugai Aichi, Japan; 2) Dept Pediatr Neurol, Centl Hosp, Aichi Human Service Ctr, Kasugai Aichi, Japan; 3) Dept Pediatr, Shiga Med Ctr Child, Moriyama, Shiga, Japan; 4) Dept Pediatr, Med Sch, Nagoya City Univ, Nagoya, Aichi, Japan; 5) Dept Pediatr, Kanoiwa Hosp, Koufu, Yamanashi, Japan.

The Rett syndrome (RTT, MIM 312750), a progressive neurodevelopmental disorder, is caused by mutations in the methyl-CpG-binding protein 2 gene (*MECP2*) located at Xq28, as X-linked dominant trait. We have been analyzing the gene in Japanese patients divided into classical RTT, variant RTT, and mentally retarded patients with Rett-like features. Mutations in *MECP2* have been identified in most of the patients with classical and variant RTT, and 70 % of all the mutation were common mutations and other 30 % were rare mutations (Yamada et al, Hum Mut, 2001, 18: 253). By the additional studies to confirm the diagnosis of RTT using the PCR method coupled with direct sequencing, we report here four novel *MECP2* mutations responsible for classical and variant RTT. In a variant RTT patient, two single base substitutions, a novel C to G transversion resulting in amino acid change of F157L and a C to T transition generating A201V reported as a non-pathogenic variant, were found. The missense mutation F157L is consider to be associated with the clinical phenotype, since that was located at the methyl-binding domain and some other causal mutations were detected around the site. A nonsense mutation (E137X) generated from a nucleotide substitution of G to T, and two deletion mutations, 119delAG and 855delA resulting in amino acid frame-shift, 40fs48X and 285fs288X, respectively, are also new to the data base of *MECP2* mutations. The patient with 855delA had also the A201V in the same allele. Furthermore, in a patient with the most common mutation (T158M), a new missense mutation G232A raised from a G to C substitution was also detected. However, the G232A seems to be a new non-pathogenic variant, since the substitution was also found in the father's X chromosome.

Program Nr: 2373 from 2003 ASHG Annual Meeting

**Studies of FMRP-binding RNAs with a yeast tri-hybrid system.** *A. Wronska, W. Ju, W.T. Brown, N. Zhong.*  
Department of Human Genetics, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Fragile X syndrome is the most common inherited mental retardation resulted from lack of the fragile X gene FMR1-encoded protein FMRP, which function has been suggested to regulate cellular translations through binding to 4-5% of RNA molecules. In this study, we have employed an in vivo approach to test FMRP binding to a certain number of RNA molecules that have been determined to be differentially transcribed in fragile X cells and to identify FMRP-binding RNAs. A human FMR1 coding sequence was cloned to a yeast tri-hybrid system to express FMRP as a bait protein, for interacting with prey RNAs. Eight target RNA molecules, four G-quartet regions and four non-G-quartet regions were selected from the MAP1B, NAP22, TMEM1, UNC13, and were tested for the FMRP-RNA binding. Our results showed that all RNA sequences with G-quartet structure bind to FMRP, but all sequences with non-G-quartet did not bind to FMRP. In addition, four novel RNA molecules, the protein tyrosine kinase (NTRK2), toll/interleukin-1 receptor-like (TLL3), G-protein-coupled receptor 45 (GPR45), and a hypothetical transmembrane protein (SBB154), were identified from library screening to bind to FMRP when a human brain cDNA library was screened by FMRP.

**Mutations in ZNF41 are associated with cognitive deficits.** *S. Shoichet<sup>1</sup>, K. Hoffmann<sup>1</sup>, C. Menzel<sup>1</sup>, U. Trautmann<sup>2</sup>, B. Moser<sup>1</sup>, M. Hoeltzenbein<sup>1</sup>, B. Echenne<sup>3</sup>, H. vanBokhoven<sup>4</sup>, C. Moraine<sup>5</sup>, J.P. Fryns<sup>6</sup>, J. Chelly<sup>7</sup>, H.D. Rott<sup>2</sup>, H.H. Ropers<sup>1</sup>, V.M. Kalscheuer<sup>1</sup>.* 1) Max-Planck Institute for Molecular Genetics, Berlin, Germany; 2) Institute of Human Genetics, University of Erlangen-Nuremberg, Germany; 3) Centre Hospitalier Universitaire de Montpellier, Hopital Saint-Eloi, 34295 Montpellier Cedex 5, France; 4) Department of Human Genetics, University Medical Centre, Nijmegen, The Netherlands; 5) Services de Génétique -INSERM U316, CHU Bretonneau, Tours, France; 6) Center for Human Genetics, Clinical Genetics Unit, Leuven, Belgium; 7) Institut Cochin de Génétique Moléculaire, CNRS/INSERM, CHU Cochin 75014 Paris, France.

Non-syndromic X-linked mental retardation (MRX) is defined by an X-linked inheritance pattern of low IQ and problems with adaptive behaviour, and the absence of additional specific clinical features. The MRX genes identified to date account for less than one third of all MRX, suggesting that numerous other gene defects cause the disorder in other families. In a patient with severe non-specific mental retardation and a de novo balanced translocation t(X;7) (p11.3;q11.21), we have cloned the DNA fragment containing the X-chromosomal and the autosomal breakpoint. In silico analysis provided no indication for a causative role for the chromosome 7 breakpoint in MR, whereas on the X-chromosome the ZNF41 gene was found to be disrupted. Expression studies indicated that ZNF41 transcripts are absent in a cell line of the patient, suggesting that the mental disorder in this patient results from loss of functional ZNF41. Screening of a panel of MRX patients led to the identification of two potentially disease-causing ZNF41 mutations. A proline to leucine amino acid exchange is present in affected members of one MRX family. A second family harbours a mutation that results in loss of transcription of specific ZNF41 splice variants. Wild type ZNF41 contains a highly conserved transcriptional repressor domain that is linked to mechanisms of chromatin remodelling. Our results suggest that ZNF41 is critical for cognitive development; further studies aim to elucidate the specific mechanisms by which ZNF41 alterations lead to mental retardation.

**Enhanced exon skipping causing mild Börjeson-Forssman-Lehmann Syndrome results from a novel PHF6 mutation.** *D.J. Picketts<sup>1</sup>, D. Vallée<sup>1</sup>, M.A. Lazzaro<sup>1</sup>, A.G. Hunter<sup>2</sup>, G.E. Graham<sup>2</sup>.* 1) Molecular Medicine Program, Ottawa Health Research Inst, Ottawa, ON, Canada; 2) Childrens Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

Börjeson-Forssman-Lehmann (BFL) syndrome is an X-linked recessive disorder characterized by moderate to severe mental retardation, obesity, epilepsy, hypogonadism, gynaecomastia, and minor facial anomalies including large ears and excessive facial fat. The disease was recently shown to result from mutations in the PHF6 gene located in Xq26. Here, we present mutational analyses for two Canadian BFL syndrome families. One family with classical features of BFL syndrome had a missense mutation in exon 8 (Arg257Gly) that has been previously reported. Affected individuals from the second family displayed a less severe phenotype including mild developmental delay. Analysis of the PHF6 gene in this family identified a T to A substitution in intron 2, creating a novel acceptor splice site 7 base pairs upstream of the consensus sequence. Inclusion of the seven nucleotides causes a frameshift and protein truncation. As such, we postulated that the mild phenotype might result from incomplete use of the aberrant splice acceptor site thereby creating some normally spliced PHF6 transcript. However, RT-PCR analysis demonstrated two aberrantly spliced products, a larger transcript (+7 bp) in which the novel acceptor splice site was used, and a smaller transcript in which exon 3 was skipped. Skipping of exon 3 maintains the ORF producing a protein that is reduced in size by 34 residues yet retains both the nucleolar localization signal and the two PHD zinc finger domains. To confirm that these transcripts are translated, in the absence of an antibody to the PHF6 protein, we used cell fractionation to isolate polysomes from patient lymphoblasts and demonstrated by RT-PCR that both altered transcripts are associated with ribosomes. In light of these results, we predict that the smaller PHF6 protein can functionally compensate for the loss of full-length PHF6 and that the mild disease is likely due to haploinsufficiency or reduced protein function due to the loss of a functional domain encoded by exon 3.

**Analysis of polymorphic sites within ornithine transcarbamylase (OTC) gene improves mutation analysis in females with OTC deficiency.** *L. Dvorakova*<sup>1</sup>, *L. Stolnaja*<sup>1</sup>, *E. Tietzeova*<sup>1</sup>, *L. Azevedo*<sup>2,3</sup>, *L. Vilarinho*<sup>4</sup>, *A. Amorim*<sup>2,3</sup>, *E. Hrubá*<sup>1</sup>, *M. Hrebicek*<sup>1</sup>. 1) Inst Inherit Metabol Disorders, Prague, Czech Republic; 2) Inst. Pathol. Immunol. of Univ. Porto, Porto, Portugal; 3) Faculty of Sciences, Univ. Porto, Porto, Portugal; 4) IGMJM, Porto, Portugal.

Ornithine transcarbamylase (OTC) deficiency is the most common urea cycle disorder. In spite of its X-linked inheritance increasing number of female patients manifesting this disorder is diagnosed. Four out of 16 Czech and Slovak probands, in whom the diagnosis was proved by mutation analysis, were females. Direct sequencing of PCR products from peripheral lymphocyte DNA revealed heterozygosity for missense (K210Q, G195R), nonsense (Q285X) and splicing (IVS7+1G>T) mutations. In other four patients (two males, two females) who had clinical and biochemical signs of OTC deficiency we were unable to find any mutation. One of these patients was a female with typical clinical and biochemical symptoms of OTC deficiency. As sequencing failed to identify any mutation, we analyzed six frequent intragenic polymorphisms that form 7 haplotypes in Czech population. Comparison of these polymorphisms and haplotypes in the patient and her parents suggests that the patient lacks a part of her father's OTC gene encompassing exon 10. X-inactivation analysis performed in DNA isolated from patient's peripheral leukocytes, salivary cells and urinary sediment cells using a method assaying differential methylation of HUMARA gene shows only slight preferential inactivation of maternal allele (70:30, 70:30 and 67:33, respectively). This case shows that the intragenic polymorphism and haplotype studies may significantly contribute to proper diagnosis in females heterozygous for X-linked disorders. Supported by grants NE 6557-3-01 from Ministry of Health and VZ 111100003 from Ministry of Education of the Czech Republic and by Portugal grants PRAXIS XXI/BD/21780/99 and POCTI/1999/MGI/35809.

**Identification of Novel Mutations in Filipino Maple Syrup Urine Disease Cases.** *C.L.T. Silao<sup>1,2</sup>, C.D. Padilla<sup>1,2</sup>, H. Nakamura<sup>3</sup>, M. Matsuo<sup>3</sup>*. 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines, Manila; 2) Department of Pediatrics, University of the Philippines College of Medicine-Philippine General Hospital, Manila, Philippines; 3) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan.

Maple Syrup Urine Disease (MSUD) is a rare autosomal recessive inborn error of metabolism caused by deficient activity of the branched chain ketoacid dehydrogenase (BCKAD) complex. This multienzyme complex catalyzes the oxidative decarboxylation of 3 branched chain ketoacids (BCKA) derived from the essential branched chain amino acids (BCAA) leucine, isoleucine, and valine. The eventual accumulation of these BCKAs and BCAAs produces the distinct burnt sugar smell noted in these patients and may eventually cause severe neurodegenerative or rapidly fatal consequences if left untreated. Several causal mutations have been identified in the 3 catalytic components comprising this enzyme complex. A study to determine the molecular basis of MSUD was carried out on two subjects belonging to unrelated families from the Philippines. Mutation analyses, consisting of polymerase chain reactions and direct sequencing of the entire dihydrolipoyl transacylase (E2) and the alpha subunit of the branched chain alpha-ketoacid decarboxylase (E1 alpha) gene of the BCKAD complex, yielded a novel missense mutation and a novel nonsense mutation respectively. These two novel mutations presented, one of which occurring homozygously, caused classical Maple Syrup Urine Disease. To our knowledge the compound heterozygous patient is the second known case, so far, having simultaneously two different mutations in 2 different genes of the BCKAD proteins. Molecular characterization of MSUD is essential to better understand this metabolic disorder. Our results also provides further evidence of genetic heterogeneity in Filipino MSUD patients.

**Cytochrome c oxidase deficiency due to mutations in SCO2 gene.** *K. Vesela<sup>1</sup>, H. Hansikova<sup>1</sup>, M. Tesarova<sup>1</sup>, P. Martasek<sup>1</sup>, J. Houstek<sup>2</sup>, J. Zeman<sup>1</sup>.* 1) Charles University, Prague, Czech Republic; 2) Academy of sciences, Prague, Czech Republic.

Cytochrome c oxidase (COX), terminal protein complex of mitochondrial respiration chain, plays an important role in the energy utilization of OXPHOS. Several proteins involved in cytochrome c oxidase (COX) assembly processes were described. One of them, Sco2 protein, encoded by SCO2 gene, transports Cu into COX subunits and enables COX to accept electrons from cytochrom bc. So far less than 15 children were described with mutations in SCO2 gene. Here we present the results of molecular analyses in six new children with mutations in SCO2 gene. **Material and Methods:** The DNA from tissue or fibroblasts of 30 children with isolated COX deficiency was examined. The coding region of SCO2 gene was sequenced and results were confirmed by RFLP. **Results:** Mutations in SCO2 gene were found in 6 children from 4 unrelated families. One child was compound heterozygote for the mutation C1280T (Q53X) and G1541A (E140K), five others were homozygotes for G1541A mutation. The course of the disease was fatal in all children, but the clinical symptoms differed significantly. Clinical symptoms in patients with homozygous G1541A mutations developed between the third and sixth month of age and included inspiratory stridor, hypotonia, encephalopathy and progressive respiratory insufficiency. On the contrary, fatal neonatal encephalopathy with severe hypertrophic cardiomyopathy was observed in the compound heterozygote. **Discussion:** COX deficiencies represent one of the most common mitochondrial diseases in childhood. Two distinct clinical phenotypes were recognised in our group of patients with COX deficiency and mutations in SCO2 gene. *Supported by GAUK 3/2002/c; VZ 111100003..*

Program Nr: 2379 from 2003 ASHG Annual Meeting

**Development of an ALSIN gene-targeted mouse model.** *H. Deng, R. Fu, H. Zhai, A. Azim, T. Siddique.* Neurology Dept, Northwestern Univ, Chicago, IL.

Amyotrophic lateral sclerosis (ALS) is a progressive paralytic disorder caused by degeneration of the upper motor neurons in the motor cortex and lower motor neurons in the brainstem and the spinal cord. We previously linked the recessive form of juvenile ALS type 3 (ALS2) to chromosome 2q3335, and subsequently we reported that a differentially spliced gene encoding short and long forms of a protein, which we named alsin, is mutated in both juvenile ALS and juvenile primary lateral sclerosis (JPLS). This gene has two transcriptional forms with two distinct poly(A) signals. The short form has 4 exons and the long form has 34 exons, respectively, with the first 4 exons shared by both forms. The gene products, which we called alsin, are two distinct proteins with the short one being 396 amino acids and long one being 1657 amino acids in size, and the short form shares 371 amino acids with the long form at the N-terminus (Yang et al, 2001). To investigate the physiological function of alsin and the pathogenic mechanism by which loss of alsin leads to ALS or PLS, we constructed a targeting vector that was designed to replace exon 4 and a part of exon 3 with neo- cassette. We identified two positive ES cells with right targeting events and alsin gene-targeted mice were developed from these ES cells. The homozygous mice are fertile and phenotypically normal by 4 months. The additional updated data will be presented.

**Screening to Develop a Zebrafish Model of Spinal Muscular Atrophy.** *A.Q. Hejmanowski<sup>1</sup>, M.L. McWhorter<sup>2</sup>, C.E. Beattie<sup>2</sup>, A.H.M. Burghes<sup>3</sup>, T.W. Prior<sup>1</sup>*. 1) Department of Pathology, Ohio State University, Columbus, OH; 2) Department of Neuroscience, Ohio State University, Columbus, OH; 3) Department of Molecular and Cellular Biochemistry, Ohio State University, Columbus, OH.

Spinal Muscular Atrophy (SMA) is a recessive disease that causes deterioration of anterior horn cells in the spinal column, leading to a loss of muscle innervation and muscle atrophy. It is the leading genetic cause of death among children under the age of two. SMA is caused by mutations in the Survival of Motor Neuron (SMN) gene. There are two copies of SMN located on chromosome 5: SMN1 (telomeric) and SMN2 (centromeric). Mutations in SMN1 cause disease. Several animals have genes homologous to SMN, including *Rattus norvegicus*, *Mus musculus*, *Danio rerio*, *Sus scrofa*, and *Bos taurus*. Given the size restraints of most labs, studies to find a disease model have focused on the first three animals. Zebrafish (*Danio rerio*) have only one copy of SMN, which means the event that caused humans to have two copies took place later in evolution. The small size, fast reproductive rate and SMN similarities have made the zebrafish a good model candidate. In addition, the developing zebrafish embryo is transparent, allowing close observation during critical developmental periods. Our work has focused on screening mutagenized zebrafish to locate a fish with disease causing mutations in SMN. We have worked with DNA from fish exposed to gamma irradiation and fish exposed to ENU. Gamma irradiation tends to cause large deletions or rearrangements. These fish are screened using fluorescent dosage on an ABI 377. 134 individual zebrafish have been screened using the 3' end of -actin and SMN exon 7. In our next round of gamma fish, we will be adding SMN exon 1. ENU tends to cause single base changes or single base deletions. These fish are screened using denaturing high performance liquid chromatography (DHPLC) on a Transgenomic WAVE system. 260 zebrafish have been DHPLC screened for all SMN exons except 5.

**Investigation of TGF- plasma levels as a modifier of the phenotype of Hereditary Hemorrhagic Telangiectasia.**

*T.L. Squire*<sup>1,4</sup>, *S. Srinivasan*<sup>1,4</sup>, *R.J. Akhurst*<sup>2</sup>, *H.M. Arthur*<sup>3</sup>, *D.A. Marchuk*<sup>1</sup>. 1) Dept. of Molecular Genetics & Microbiology, Duke University Medical Center, Durham, NC, USA; 2) University of California at San Francisco, San Francisco, CA, USA; 3) Institute of Human Genetics, University of Newcastle, Newcastle upon Tyne, NE1 3BZ, UK; 4) Both individuals contributed equally to this work.

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disorder characterized by multisystemic vascular dysplasia. Mutations in either of two genes, *ENDOGLIN* (*ENG*) or *ACTIVIN RECEPTOR-LIKE KINASE 1* (*ACVRL1* or *ALK1*), endothelial receptors for transforming growth factor beta (TGF-), are known to cause the disease. In humans, the expression of the clinical symptoms is highly variable, even among individuals carrying the same mutation, suggesting that additional genetic and/or environmental factors act as modifiers in the progression of this disease. One such modifier has been suggested for a mouse model of HHT type 1 (*Eng*<sup>+/-</sup> mice), where a higher frequency of vascular lesions was observed in the 129/Ola background than in C57BL/6 background. Since the 129/Ola strain contains low latent TGF-1 levels in plasma (median levels approximately 60% of that for C57BL/6), genes regulating TGF-1 levels were suggested as potential modifiers of the disease phenotype. To test this hypothesis, we crossed *Acvr11*<sup>+/-</sup> and *Eng*<sup>+/-</sup> mice separately with *Tgfb1*<sup>+/-</sup> mice, in a predominantly C57BL/6 genetic background. The single (*Acvr11*<sup>+/-</sup>) and double heterozygous offspring (*Acvr11*<sup>+/-</sup> *Tgfb1*<sup>+/-</sup>) were phenotyped at age 11 months by gross anatomical examination at necropsy. Greater than 50% of all *Acvr11* heterozygotes displayed a noticeable HHT phenotype, the strongest indicator of which was dilated sinusoidal vessels in liver. The incidence of the HHT phenotype was not substantially different between the *Acvr11* single and double heterozygotes. Additionally, preliminary investigation of 10 *Eng*<sup>+/-</sup> mice revealed no difference in the disease prevalence as a result of *Tgfb1* genotype. These results suggest that plasma TGF-1 concentration may not be an important modifier of the phenotype in HHT.

**Fgd1, the Cdc42GEF responsible for Faciogenital Dysplasia, directly interacts with cortactin and mAbp1 to alter osteoblast cell shape.** *J. Gorski, P. Hou, L. Estrada.* Dept Pediatrics & Human Genetics, Univ Michigan, Ann Arbor, MI.

FGD1 mutations result in Faciogenital Dysplasia (FGDY), an X-linked disease that affects skeletal formation and embryonic morphogenesis. FGD1 and Fgd1, the mouse FGD1 ortholog, encode guanine nucleotide exchange factors (GEF) that specifically activate Cdc42, a Rho GTPase that controls actin cytoskeletal organization. To further understand FGD1/Fgd1 signaling and begin to elucidate the molecular pathophysiology of FGDY, we demonstrate that Fgd1 directly interacts with cortactin and mouse actin-binding protein 1 (mAbp1), actin-binding proteins that regulate actin polymerization. In yeast two-hybrid studies, cortactin and mAbp1 Src homology 3 (SH3) domains interact with a single Fgd1 SH3-binding domain (SH3-BD). Biochemical far-western studies show that the Fgd1 SH3-BD directly binds to cortactin and mAbp1 *in vitro*; immunoprecipitation studies show that Fgd1 interacts with cortactin and mAbp1 *in vivo*. These analyses also show that Fgd1 SH3-BD mutations disrupt binding. Immunocytochemical analyses show that Fgd1 colocalizes with cortactin and mAbp1 in the subcortical actin cytoskeleton in cell ruffles, and that Fgd1 subcellular targeting is dynamic. Immunocytochemical studies also show that the cortactin SH3 domain targets Fgd1 protein to the subcortical actin cytoskeleton, and that abnormal Fgd1 targeting results in actin cytoskeletal abnormalities and marked changes in cell shape and viability. Furthermore, immunocytochemical analyses show that altered Fgd1/Cdc42 signaling alters osteoblast cell morphology. These data demonstrate that Fgd1 specifically and directly interacts with cortactin and mAbp1, and that these interactions play an important role in regulating cell shape. These data also indicate that Fgd1 plays a key role in regulating the actin cytoskeleton: by binding cortactin and mAbp1, Fgd1 is targeted to the dynamic cortical actin cytoskeleton; by activating Cdc42, Fgd1 activates NWASP to stimulate Arp2/3-directed actin polymerization. Thus, these data demonstrate that Fgd1/Cdc42 signaling plays a role in regulating the osteoblast actin cytoskeleton, and that Faciogenital Dysplasia is a disorder of FGD1/Cdc42 signaling.

**Gene expression profile of spinal muscular atrophy using microarrays.** *R. Olasso<sup>1</sup>, V. Joshi<sup>1</sup>, N. Roblot<sup>1</sup>, G.M. Lathrop<sup>2</sup>, M. Mayer<sup>3</sup>, J. Melki<sup>1</sup>.* 1) Molecular Neurogenetics Laboratory, INSERM, E.223, 2 rue Gaston Crmieux, 91057. Evry, France; 2) CNG, Evry; 3) Hopital Saint-Vincent de Paul, Paris.

Spinal Muscular Atrophy (SMA) is a common autosomal recessive neuromuscular disorder characterized by degeneration of motor neurons leading to progressive paralysis with muscular atrophy. SMA is caused by mutations of the Survival of Motor Neuron gene (SMN1). In addition, the molecular pathway linking SMN defect to SMA phenotype remains to be elucidated. The Cre-loxP recombination system has been used to direct deletion of the murine *Smn* to either neuronal or skeletal muscle cells. Both neuronal and muscular mutant mice display severe muscle paralysis leading to early death through motor neuron or skeletal muscle degeneration respectively. To characterize the degenerative process in SMA and identify the targets of SMN1 gene defect, comparative analysis of gene expression profiles have been performed using cDNA microarrays. Targeted tissues (skeletal muscle or spinal cord) of mutant mice (muscular or neuronal, respectively) were analyzed and compared to those of control mice at different stages of the disease course. Real time PCR of reverse transcripts was used to validate microarray results. Among the genes regulated, several protein families were shown to be involved including components of cytoskeleton, transcription factors and proteins implicated in proliferation/differentiation and metabolic pathways. A gene highly up-regulated in early stage of SMA disease progression in both types of mouse models has been selected for further investigation. Mice knock out for this candidate gene have been crossed to SMA mouse models to evaluate its role in SMA pathogenesis or disease progression. In addition, a first set of candidate genes has been selected to determine whether they are regulated in a similar manner in human SMA. To this end, real time PCR of reverse transcripts extracted from SMA tissue samples (skeletal muscle or spinal cord) or lymphocytes was performed. This study should help in designing biological markers for disease progression and in clarifying the SMA pathophysiology. Finally, they could also represent new potential targets for therapeutics in SMA.

**Functional absence of the tubulin-folding protein TBCE in the syndrome of hypoparathyroidism, mental and growth retardation, and facial dysmorphism.** *M.C. Huang<sup>1</sup>, M. Rubinstein<sup>2</sup>, B. Loeys<sup>3</sup>, R. Parvari<sup>2</sup>, G.A. Diaz<sup>1</sup>.* 1) Department of Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Ben Gurion University of the Negev, Beer Sheva, Israel; 3) Institute of Genetic Medicine, Johns Hopkins Hospital, Baltimore, MD.

Mutations in *TBCE* (tubulin-binding cofactor E) cause the syndrome of hypoparathyroidism, mental retardation, facial dysmorphism and growth failure (HRD or Sanjad-Sakati syndrome (SSS), MIM 241410; AR-KCS, MIM 244460). *TBCE* is a chaperone protein required for the proper folding of tubulin. Disruption of microtubule (MT) organization and organelle distribution has been described in disease cells homozygous for a deletion in a MT-binding domain (del52-55). We report studies in fibroblast cells from a compound heterozygous patient predicted to effectively express only a truncated protein, C371X. MT density was decreased in C371X cells relative to wildtype and del52-55 cells. However, MT-organizing centers had a more normal appearance than those in del52-55 cells. The distribution of the MT-dependent Golgi apparatus (GA) also showed mutation-specific differences. Staining in del52-55 mutant cells was diffuse and encircled the nucleus, while C371X cells displayed a more normal distribution. Differences between the mutants were also observed when tagged constructs were expressed in cultured cells. Despite disruption of the  $\alpha$ -tubulin binding domain, del52-55 sequestered  $\alpha$ -tubulin from MTs and tubulin monomers, leading to loss of cellular tubulin. In contrast, the C371X mutant did not destroy MTs despite accumulating to high levels in transfected cells, implicating the C-terminal end of the protein in  $\alpha$ -tubulin regulation. Immunoblotting with antibody to *TBCE* revealed that protein levels were greatly decreased in the mutant cell lines, suggesting that the mutants were unstable. These findings suggest that the disease phenotype results from near absence of cellular *TBCE*, with differences in the functional capacity of residual protein accounting for the divergent cellular phenotype. *TBCE* may be involved in MT dynamics or organization *in vivo*, rather than protein folding.

**Evidence for a DNA double-strand break-dependent activation of the Fanconi Anemia/BRCA pathway during the repair of DNA-interstrand crosslinks.** *A. Rothfuss, M. Grompe.* Molecular and Medical Genetics, Oregon Health&Sciences University, Portland, OR.

The detailed role of the FA/BRCA complex in the repair of DNA interstrand crosslinks (ICL) in human cells is not known. We therefore systematically investigated the involvement of the FA/BRCA complex in the initial steps of ICL repair in primary human fibroblasts. ICL repair in human cells consists of several steps, starting with a replication-independent recognition and incision of the lesion. The incised ICL are then processed further and DNA-double strand breaks (DSB) form as repair intermediates exclusively in S-phase, possibly when a replication fork becomes arrested at an incised ICL. We can show that Fanconi Anemia (FA) primary fibroblasts are fully proficient in these initial steps of ICL repair. The sensing and incision of ICL as well as the subsequent formation of DSB appeared normally in FA cells, suggesting a role of the FA/BRCA pathway downstream in ICL repair, after DSB have formed. Interestingly, analysis of the formation of monoubiquitinated FANCD2 indicates a slow activation of the FA/BRCA complex during ICL repair, which parallels the occurrence of DSB. In contrast, FANCD2 monoubiquitination occurs rapidly after ionizing radiation, consistent with the idea that the FA/BRCA complex is specifically activated upon DSB-formation. Using immunocytochemistry for the detection of FANCD2 foci, we can further show that this activation is restricted to a subpopulation of cells, which are also BrdU-positive. We therefore conclude that, while being dispensable for the early events in ICL repair, the FA/BRCA pathway is specifically activated in S-phase cells after DSB have formed as repair-intermediates. Most likely, this S-phase specific activation reflects a function of the FA/BRCA complex in the homologous recombination of DSB.

**Connexin 43 (Cx43) Mutations in Oculodentodigital Dysplasia (ODDD) Result in Gap Junction Dysfunction.**

*W.A. Paznekas<sup>1</sup>, A. Seki<sup>2</sup>, W. Coombs<sup>2</sup>, S.M. Taffet<sup>2</sup>, M. Delmar<sup>2</sup>, E.W. Jabs<sup>1</sup>.* 1) Johns Hopkins Univ, Balto, MD; 2) SUNY Upstate Medical Univ, Syracuse, NY.

ODDD, an autosomal dominant syndrome with high penetrance and phenotypic variability, has craniofacial and limb dysmorphisms. A thin nose with hypoplastic alae nasi and microphthalmia contribute to the distinctive facial appearance. Oral features include enamel hypoplasia, microdontia, and partial adontia, and digital anomalies consist of syndactyly in the feet and hands, involving digits 4 and 5 (Type III), camptodactyly, and clinodactyly. Spastic gait and progressive leukodystrophy are common. Conductive hearing loss, cataracts, glaucoma, keratoderma, and cardiac abnormalities can be observed. We found Cx43 gene mutations segregating in 49 affected members of 21 families. Cx43 codes for a protein that assembles into intercellular channels that regulate a variety of physiological and developmental processes through the exchange of small ions and signaling molecules. Mutations include: 18 amino acid substitutions (Y17S, S18P, G21R, G22E, K23T, A40V, Q49K, Q49P, R76S, L90V, V96A, Y98C, K102N, I130T, K134E, G138R, R202H, V216L) and two duplications (Q49dup, F52dup). The alterations occur throughout the protein except for the carboxyl terminus and third transmembrane region. Mutant and wildtype Cx43-GFP (Cx43 concatenated to GFP) were transiently transfected into N2A cells. Formation of gap junction plaques was assessed by fluorescence microscopy and the ability to form functional channels was evaluated by dual patch clamp. Three ODDD mutations localized in the 2nd half of the cytoplasmic loop of the Cx43 protein were found to affect channel electrical properties. Gap junction plaques were found on transfected cell pairs for all 3 mutants. I130T and K134E drastically diminished and mutation G138R eliminated formation of functional channels. Single channel analysis revealed a decrease in unitary conductance of K134E (54 pS) but no change for I130T (110 pS) when compared to wildtype (102 pS). These data suggest that the mutations significantly diminish the contribution of the affected allele in the formation of Cx43 channels in affected individuals.

**Identification of additional transcripts in the facioscapulohumeral muscular dystrophy region on human chromosome 4q35.** *J. Clapp, D.J. Bolland, A. Jenkinson, J.E. Hewitt.* Institute of Genetics, University of Nottingham, Nottingham, UK.

Facioscapulohumeral muscular dystrophy (FSHD) is caused by a unique genetic rearrangement close to the telomere of human chromosome 4q. The disease is causally associated with deletions within a tandem DNA repeat (D4Z4). A position effect mechanism has been proposed whereby loss of D4Z4 subunits leads to upregulation of genes in the 4q35 region. A recent study has indicated that mRNA levels of three genes (*FRG1*, *FRG2* and *ANTI*) may be increased in FSHD patient muscle. However, the physical distance encompassing these genes is almost 5Mb and is poorly characterized at the genomic level, thus there may be other genes whose expression is perturbed by the FSHD mutation. We have used a combination of bioinformatics, Northern blotting and RT-PCR to produce a detailed analysis of the gene complement and expression profiles for the distal 5.5Mb of 4q. Thus far, 29 transcripts have been identified, many of which are expressed in fetal or adult skeletal muscle and are currently being examined as candidates for a role in FSHD. The majority of the genes are clustered in the proximal 2.5Mb of 4q35. We have examined in detail the 3Mb interval between the cadherin gene *FAT* and *FRG1* at the distal end of this region as this has been especially poorly characterized. Interestingly, we have found at least two transcripts in this interval that appear to represent spliced, non-coding RNAs. To investigate the evolutionary history of the FSHD region and to help gene identification strategies, we have carried out comparative mapping studies in mouse and puffer fish. In the homologous region on mouse chromosome 8, gene content, distribution and density are similar to human. However, *FRG2* and D4Z4 are not conserved and the *Fat-Frg1* interval is some 0.5Mb larger than the human equivalent region. Although homology of synteny is less extensive in *Takifugu* and *Tetraodon*, the *FAT-FRG1* linkage group is conserved in both these genomes with the two genes separated by 100-120kb in both puffer fish, suggesting there may be important sequences in this interval.

**Dominant lamin A/C gene mutations can be associated to neuropathy.** *S. Benedetti<sup>1</sup>, S. Previtali<sup>1</sup>, D. Toniolo<sup>1</sup>, S. Iannaccone<sup>1</sup>, A. Quattrini<sup>1</sup>, P. Carrera<sup>1</sup>, M. Ferrari<sup>1</sup>, E. Bertini<sup>2</sup>.* 1) D.R. San Raffaele, IRCCS, Milano, Italy; 2) Bambino Gesù, IRCCS, Roma, Italy.

The coexistence of neurogenic and myogenic etiology in scapuloperoneal syndrome was not previously ascribed to a single gene. Defects in the nuclear envelope protein lamin A/C, initially described in Emery-Dreifuss muscular dystrophy, have been associated to a variety of pathologies, affecting mainly muscular and adipose tissues. Recently, mutations in the lamin A/C encoding gene (LMNA) have been reported in families affected by autosomal recessive Charcot-Marie-Tooth type 2 neuropathy. We describe here two patients associating features of myopathy and neuropathy linked to dominant LMNA mutations. Patient 1 presented with tip walking, lower limb weakness and moderately elevated serum CK. Neurophysiological studies revealed a sensory-motor axonal neuropathy, whereas muscle biopsy showed signs of both neurogenic and myogenic features. Molecular analysis of LMNA gene revealed a heterozygous R571C substitution in a conserved region of the lamin C specific C-terminal domain. Interestingly, another mutation affecting the same codon (R571S) has been previously described and associated to a completely different phenotype, characterized by atrial fibrillation and dilated cardiomyopathy with no signs of skeletal muscle involvement. Patient 2 presented mild proximal weakness and fatigability. She was carrying a pacemaker for cardiac arrhythmia and had a familiar history of sudden death. Needle electromyography showed mild myopathic changes. A biopsy specimen from the quadriceps revealed chronic myogenic and neurogenic features including atrophic angular fibers and type grouping. Analysis of the LMNA gene showed a heterozygous four nucleotides deletion in exon 5 (864del4), leading to premature protein truncation. The same mutation was found in the asymptomatic younger brother. This report describes for the first time dominantly-inherited alterations of the nuclear lamins affecting both muscle and peripheral nerve. It also underlines the intra- and inter-familial clinical heterogeneity of LMNA mutations, suggesting the involvement of modifier genes in determining the phenotype.

**A West European cluster of severe cardiac and skeletal myopathy associated with a de novo R406W mutation in desmin.** A. Dagnadorj<sup>1</sup>, M. Olivé<sup>2</sup>, J-A. Urtizberea<sup>3</sup>, M. Halle<sup>4</sup>, A. Shatunov<sup>1</sup>, C. Bönnemann<sup>5</sup>, K-Y. Park<sup>1</sup>, H. Goebel<sup>6</sup>, I. Ferrer<sup>2</sup>, P. Vicart<sup>7</sup>, M. Dalakas<sup>1</sup>, L. Goldfarb<sup>1</sup>. 1) National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, US; 2) Institut de Neuropatologia, Ciutat Sanitària i Universitària de Bellvitge, Hospitalet de Llobregat, Barcelona, Spain; 3) Hopital Raymond Poincaré, Garches, France; 4) Medizinische Klinik, Georg-August-Universität, Goettingen, Germany; 5) Division of Neurology, The Children's Hospital of Philadelphia, Philadelphia, PA, US; 6) Department of Neuropathology, Johannes Gutenberg-University Medical Center, Mainz, Germany; 7) Laboratoire Cytosquelette et Développement, Faculté de Médecine Pitié-Salpêtrière, Paris, France.

This study has identified four patients originating from Greece, Spain and Germany who suffered from progressive cardiac arrhythmia and conduction blocks followed by muscle weakness and atrophy in the lower extremities subsequently spreading to the upper limbs, trunk and neck muscles. Each patient needed a permanent pacemaker or an ICD, all four became severely incapacitated in their twenties-early thirties, and one died of cardiac complications at the age of 28 years. Skeletal muscle biopsies showed intracytoplasmic aggregates strongly reacting with anti-desmin antibodies. A R406W mutation was identified in each patient. The pathogenic potential of the desmin R406W mutation was documented by its deleterious effects in the SW13 (vim-) cells. The mutation was not present in patients parents, although paternity check did not identify alleles coming from a different source but the parents. The mutation-carrying chromosomes showed no similarity, clearly indicating that the R406W substitution is a recurrent de novo mutation. Structural analysis of mutant desmin protein performed by ESyPred3D automated homology modeling indicates that the high pathogenic potential of this mutation results from disabling of the highly conserved YRKLLEGEE motif at the C-terminal end of the 2B helix that has a critical role in desmin filament assembly.

**Phenotypic and molecular characterization of the *myd* mouse, a model of glycosylation-deficient muscular dystrophies.** C.J. Moore<sup>1</sup>, P.K. Grewal<sup>1</sup>, R. Herbst<sup>2</sup>, T. Dechat<sup>3</sup>, R. Bittner<sup>3</sup>, J.E. Hewitt<sup>1</sup>. 1) Institute of Genetics, University of Nottingham, Nottingham, UK; 2) Brain Research Institute, University of Vienna Medical School, Austria; 3) Neuromuscular Research Department, Institute of Anatomy, University of Vienna, Austria.

Within the last two years mutations in four genes encoding glycosylation enzymes have been shown to cause muscular dystrophy; *POMGnT1* (Muscle Eye Brain disease), *POMT1* (Walker Warburg syndrome), *Fukutin* (Fukuyama congenital muscular dystrophy) and *FKRP* (congenital muscular dystrophy type 1C and Limb girdle muscular dystrophy 2I). *POMT1* and *POMGnT1* are both involved in *O*-mannosyl glycosylation, the activities of the other two proteins are not known. Abnormal glycosylation is thus implicated as an important mechanism underlying a subset of muscular dystrophies. Aberrant glycosylation of the dystrophin-associated protein -dystroglycan (-DG) is present in all these diseases, suggesting these genes act in a common pathway. Recently, we showed that the causative mutation in the myodystrophy (*myd*) mouse is also in a putative glycosyltransferase gene, *Large*. The *myd* mouse has progressive muscular dystrophy, neuronal migration defects and a mild cardiomyopathy, associated with hypoglycosylation of -DG in brain and muscle. Now, we show that the neuromuscular junctions in *myd* mice are irregularly distributed. Staining for synaptophysin shows aberrant and irregular sprouting of nerve terminals at the synaptic region. To investigate specific glycosylation changes in *myd* muscle we have used lectin overlay and pull-down assays. Several lectins that display differential binding to -DG from *myd* and wild type muscle have been identified. An unusual feature of the *Large* protein is the presence of a coiled-coil region, which may be involved in protein-protein interactions. Therefore, we have used a Sos recruitment based, yeast-two-hybrid screen using *Large* as bait and identified six potential interactors. Our study of the *myd* mouse may help us to dissect the molecular pathways underling glycosylation-deficient muscular dystrophies.

**Allelic heterogeneity of SMARD1 at the IGHMBP2 locus : identification of nine novel mutations.** *I. Maystadt*<sup>1,2,3</sup>, *M. Zarhrate*<sup>1</sup>, *C. Verellen*<sup>2</sup>, *A. Munnich*<sup>1</sup>, *L. Viollet*<sup>1</sup>. 1) INSERM U393, Necker Hospital, Paris, France; 2) Department of Human Genetics, Catholic University of Louvain, Brussel, Belgium; 3) FNRS, Brussel, Belgium.

Spinal Muscular Atrophy with Respiratory Distress (SMARD), also known as Diaphragmatic Spinal Muscular Atrophy or Distal Hereditary Motor Neuropathy type VI (dHMNVI), is an autosomal recessive disorder characterized by neurogenic muscular atrophy due to progressive anterior horn cell degeneration, and by early life-threatening respiratory failure due to diaphragmatic dysfunction. Spinal muscular atrophy with respiratory distress is clinically and genetically heterogeneous. SMARD type 1, characterized by the onset of respiratory failure within the first weeks of life, has been ascribed to chromosome 11q13-q21 (Grohmann et al, 1999). In six SMARD1 families, seven mutations were identified in the IGHMBP2 gene, encoding the immunoglobulin mu-binding protein 2 (Grohmann et al, 2001). This gene is homologous to the mouse IGHMBP2 gene, which accounts for spinal muscular atrophy in the neuromuscular degeneration mouse (nmd). The cellular function of IGHMBP2 is still unknown. We report here the identification of nine novel IGHMBP2 mutations, in five patients with a typical SMARD1 phenotype, beginning at the age of one to six months. Eight of these mutations were detected by DHPLC analysis of the IGHMBP2 coding sequence and all were confirmed by direct double strand DNA sequencing. Seven mutations were missense (Q196R, P216L, L251P, D565B, L577P, R603C, R637C), and two were nonsense mutations (C496X, R790X). None of them were found in at least 100 control chromosomes from a group of healthy individuals. Except for the nonsense mutation R790X in exon 13, all these novel mutations occurred in the putative DNA helicase domain of the gene, as for mutations previously reported. The mutations occurred at highly conserved residues, strongly supporting their pathogenic nature. The identification of novel IGHMBP2 variants will help to diagnosing SMARD1 and may contribute to the functional characterization of IGHMBP2 gene product.

**Muscleblind is Associated with Splicing Alterations in Myotonic Dystrophy.** *L.E. Machuca-Tzili, M. Fardaei, H. Thorpe, J.D. Brook.* Institute of Genetics, University of Nottingham, Nottingham, United Kingdom.

Myotonic dystrophy (DM1) is the most frequent autosomal dominant myopathy in adults. The cardinal features of DM are myotonia, muscle wasting and weakness, cataract, hypogonadism, frontal balding and ECG changes. The mutation underlying DM1 is an unstable triple repeat (CTG) located in the 3-UTR of the DMPK gene. Recently a second form of the disease (DM2) has been identified which is caused by an expansion of the CCTG tetranucleotide repeat in a different gene, ZNF9.

Several models have been proposed to explain the molecular basis of myotonic dystrophy. The RNA dominant hypothesis proposes that an expanded CUG or CCUG-containing transcript could sequester specific RNA binding proteins leading to aberrant alternative splicing. One of these proteins is Muscleblind, which is encoded for three different genes (MBNL1, MBNL2, MBNL3). The expanded transcripts accumulate as RNA nuclear foci in DM1 and DM2 cells and co-localise with MBNL proteins. There is evidence of dysregulation of splicing of different genes in DM1 patients.

In order to test if the Z-band disruption in DM is related to alterations in the alternative splicing of Z-band transcripts, RT-PCR studies were carried out in muscle biopsies from DM patients looking at the alternative isoforms of the sarcomeric gene ZASP. At the same time gene knockdown studies were performed in mouse myoblasts (C2C12) to elucidate the role of MBNL proteins in these events. Specifically RNAi was used to knock-down the three Mbnl genes. There is significant difference in the splicing pattern of ZASP transcripts between normal and DM human samples, and in the mouse homolog between normal and knock-down cells. Our results suggest that ZASP represents a novel target for abnormal mRNA splicing in Myotonic Dystrophy.

**Gene expression profiling of Fukuyama-type congenital muscular dystrophy -Neurogenic terminal maturational delay in muscle fibers.** *M. Taniguchi<sup>1</sup>, H. Kurahashi<sup>1,2</sup>, S. Noguchi<sup>3</sup>, J. Sese<sup>4</sup>, T. Tsukahara<sup>3</sup>, I. Nishino<sup>3</sup>, S.*

*Morishita<sup>4</sup>, T. Toda<sup>1</sup>.* 1) Div Functional Genomics, Osaka Univ Grad Sch Med, Osaka; 2) Div Mol Genetics, Fujita Health Univ, Aichi; 3) Dept Neuromuscul Res, NCNP, Tokyo; 4) Dept Computational Biol, Tokyo Univ Grad Sch Frontier Sci, Tokyo, Japan.

Fukuyama-type congenital muscular dystrophy (FCMD), Walker-Warburg syndrome, and muscle-eye-brain (MEB) disease are similar autosomal recessive disorders characterized by CMD, lissencephaly due to a defect during neuronal migration, and eye anomalies. We have identified the genes for FCMD and MEB, which encode the fukutin protein and the POMGnT1 glycosyltransferase. These are thought to modulate the glycosylation of  $\alpha$ -dystroglycan, and mutations in such glycosyltransferases are known to result in posttranslational disruption of dystroglycan-ligand interactions in skeletal muscle and brain in these congenital muscular dystrophies. To investigate the pathophysiology of this  $\alpha$ -dystroglycanopathy, we analyzed gene expression profiling of skeletal muscle in FCMD by using cDNA microarray. In FCMD muscle, extracellular components were highly expressed through all stages of the disease irrelevant to the severity of fibrosis. Gene expression of muscle components were not highly upregulated compared to other types of muscular dystrophy. Slow type myosin heavy chain was dramatically downregulated. Histochemical analysis showed the increased rate of type 2C fibers in FCMD. These imply that FCMD muscle is in active fibrotic phase whereas the muscle fibers are in immature state. Real-time quantitative PCR confirmed that agrin, a key protein in postsynaptic muscle differentiation through neuromuscular junction, was highly upregulated in FCMD muscle; the downstream genes such as Musk and synaptophysin were in low expression. These suggest that the main pathophysiology of FCMD might be the disorder of terminal muscle fiber differentiation induced by the disruption of neuromuscular signal transmission. Though severe necrotic degeneration or wasting of muscle fibers has been thought as the main result of the fibrotic change in CMD, differentiatinal change of immature muscle fibers may lie in the pathophysiologic change of FCMD.

**Detection of thirty novel mutations in the *FBNI* gene in patients with Marfan syndrome or related fibrillinopathy. The Australian perspective.** L.C. Ades<sup>1,2,3</sup>, K.J. Holman<sup>1,4</sup>, M. Brett<sup>1,4</sup>, B. Bennetts<sup>4</sup>, A. Biggin<sup>1</sup>. 1) Marfan Research Group; 2) Department of Clinical Genetics; 3) Discipline of Paediatrics and Child Health; 4) Department of Molecular Genetics. The Children's Hospital at Westmead, Westmead, NSW, Australia.

Marfan syndrome (MFS) is a disorder of the extracellular matrix caused by mutations in the gene encoding fibrillin-1 (*FBNI*). Recent studies have illustrated the variability in disease severity and clinical manifestations of MFS. Clear evidence for useful genotype-phenotype correlations has been slow to emerge.

We have screened 57 unrelated patients with MFS or a Marfan-like phenotype using a combination of single strand conformation polymorphism (SSCP) and/or denaturing high performance liquid chromatography (DHPLC). We were able to detect 49 different *FBNI* mutations, 30 (62%) of which were novel. The mutations comprised 37 substitutions (76%), 10 deletions (20%), 1 duplication (2%) and 1 insertion-deletion (2%). There were 29 missense (59%), 9 frameshift (18%), 8 splice site (16%) and 3 nonsense mutations (6%).

A custom database containing detailed clinical information and results from *FBNI* mutation screening was developed in order to analyse possible genotype-phenotype correlations. Patients with an identified *FBNI* mutation were more likely to have ectopia lentis (EL) and cardiovascular complications compared to those without an identifiable mutation (p0.05, relative risks of 4.7 and 2.0, respectively). EL was also found to be more prevalent in patients whose mutations involved cysteine residues (p0.05, relative risk 1.6). The data presented here demonstrate an overall mutation detection of 86%. This increased to a detection of 93% when considering only DHPLC analysis of patients meeting the Ghent criteria.

DHPLC is a reliable and robust technique for *FBNI* mutation detection. We plan to continue to collate detailed clinical information and mutation screening data with the aim of elucidating further genotype-phenotype correlations.

**Factor IX mutations in Korean hemophilia B patients.** *Y.H. Cho, H.K. Seo, J.H. Kyhm, E.S. Shin, C.H. Lee.*  
Department of Medical Genetics, College of Medicine, Hanyang Univ, Seoul 133-791, Korea.

Hemophilia B or Christmas disease is an X-linked recessive bleeding disorder due to mutations of the coagulation factor IX gene. Hemophilia B is known to be caused by a variety of mutations, which can be found in the whole coding regions. The purpose of this study was to find out molecular defects of factor IX gene in Korean hemophilia B patients, and to establish a method for prenatal and carrier diagnosis. The promoter region, eight exons and their intron boundaries were amplified using PCR in 26 DNA samples. The PCR products were subcloned into pGEM-T easy plasmid vector and transformed into JM109 high efficiency competent cells. DNA sequencing of each PCR product was performed by cycle sequencing with ABI PRISM BigDye Terminator Cycle Sequencing Ready Reaction Kits(Ver. 2.0) and ABI PRISM 310 automated sequencer. With direct sequencing analysis, mutations were detected in 23 cases. Ten cases were found to harbor point mutations in exon H, 3 cases each in exon B and G, 2 cases in exon E, and one case each in exon C, D, and E respectively. Two cases of splice site mutations were found at intron 4 and 7. In the sequence analysis, 13 cases were transition, and 9 cases were transversion. Thirteen cases were missense mutations, 7 cases were nonsense mutations, one case was frameshift mutation due to single base deletion, and 2 cases were splice site mutations. Fifteen mutations were known by previous studies, and 8 cases were novel mutations found in this study. This study revealed that the mutation pattern in factor IX gene of Korean hemophilia B patients is extremely heterogeneous and wide spread over whole coding regions, although majority of mutations were found at exon H. And the direct mutation analysis will be very useful for the prenatal and carrier diagnosis as complementary to indirect linkage analysis.

**Eight novel mutations revealed by DHPLC analysis of the neurofibromatosis type 1 (NF1) gene in southern Italian NF1 patients.** *A. Gabriele<sup>1</sup>, M. Ruggieri<sup>2,3</sup>, G. Peluso<sup>1</sup>, T. Sprovieri<sup>1</sup>, A. Patitucci<sup>1</sup>, A. Magariello<sup>1</sup>, R. Mazzei<sup>1</sup>, F.L. Conforti<sup>1</sup>, S. Genovese<sup>2</sup>, E. Ciancio<sup>2</sup>, A. Gambardella<sup>4</sup>, M. Muglia<sup>1</sup>, Molecular genetics.* 1) ISN, CNR, Cosenza, Italy; 2) ISN, CNR, Catania, Italy; 3) DEPARTMENT OF PAEDIATRICS, UNIVERSITY Catania, Italy; 4) INSTITUTE OF NEUROLOGY, UNIVERSITY OF MAGNA GRAECIA, Catanzaro, Italy.

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder with a prevalence of 1 in 3500 individuals in the general population and is characterized by pigmentary changes, neurofibromas and systemic complications. We performed, by means of denaturing high performance liquid chromatography (DHPLC) and DNA sequencing, molecular analysis in 27 exons of the NF1 gene in a panel of 85 consecutive NF1 patients from southern Italy. DHPLC is largely automated heteroduplex-based technique optimised, in this study, for the rapid screening of mutations in exons 4a, 4b, 4c, 5, 10a, 10b, 10c, 14, 15, 16, 19a, 19b, 20, 21, 22, 23.1, 23.2, 23a, 24, 25, 26, 27a, 27b, 29, 34, 37 and 41 of the NF1 gene. Mutational screening of the NF1 gene revealed the presence of sixteen different mutations. In particular, eight represented known mutations: 165 del TGTT, R440X, Y489C, H781P, 1152 del ACTC, R1276X, K1423E, 2162 ins.A and eight were novel mutations. Of the eight novel mutations two created a stop codon (E1192X, Q1360X), two were nucleotide substitutions (L1109F, N1394D), two were small insertions (1504 insA, 2265 insC), one was a small deletion (1503delG), and another was a splice site mutation (IVS24+1GA). None of the novel mutations was detected in 100 control chromosomes. In conclusion, we have confirmed the possibility for routine molecular diagnosis in NF1 by direct mutation detection using DHPLC that appears to be a simple, rapid and efficient methodology. The identification of these eight novel mutations contributes to the definition of the NF1 gene germ-line mutational spectrum.

**Novel single base pair deletion of the CYP1B1 gene in a family with primary congenital glaucoma.** *S. Cuevas Sr<sup>1</sup>, C. Chima<sup>1</sup>, L.M. Gonzalez<sup>1</sup>, M.R. Rivera<sup>1</sup>, O. Messina<sup>2</sup>, I. Babayan<sup>2</sup>.* 1) Genetica, Hospital General de Mexico, Mexico DF, Mexico; 2) Oftalmologia, Hospital General de Mexico, Mexico DF, Mexico.

Primary congenital glaucoma (PCG) is an uncommon disease with an incidence that ranges from 1 in 1,1250 to 1 in 22,000 births in several populations. Although some PCG patients are sporadic cases, PCG appears to harbor autosomal recessive mode of inheritance. PCG has been linked to homozygous mutations in the CYP1B1 gene that is located on chromosome 2p22-p21. The CYP1B1 gene contains 3 exons with an ORF of 1,629 bp starting in the second exon, and harbors nine TCDD-responsive (dioxin-responsive) enhancer core binding motifs. The CYP1B1 gene codifies for cytochrome P4501B1, a member of a subfamily of cytochrome P450. Mutations and polymorphisms have been identified in the CYP1B1 gene. Mutations affecting the conserved core structures of cytochrome P4501B1 result in PCG while mutations in other regions hold the potential to define differences in the estrogen metabolism. In the present study, we describe a family with PCG due to a novel single base pair deletion within codon 370 (C1453del) of the CYP1B1 gene. This family also harbored a novel polymorphic variant of the cytochrome P4501B1 with six single nucleotide polymorphisms (SNPs) not previously reported.

**Mutation screening in patients with hereditary haemorrhagic telangiectasia.** *P. Bayrak Toydemir, J. McDonald, K. Ward, R. Mao.* DNA Diagnostic Lab, University of Utah, Salt Lake City, UT.

Hereditary Haemorrhagic Telangiectasia (HHT) is an autosomal dominant disorder characterized by vascular dysplasia leading to telangiectases and recurrent hemorrhage. The disease exhibits variability in clinical expression and age of onset. Mutations in at least two genes, endoglin (*ENG*) on chromosome 9 region q34 and activin A receptor type II-like 1 (*ALK1* or *ACVRL1*) on chromosome 12 region q13 have been shown to be associated with the disease.

We developed a cascade mutation screening assay for *ENG* and *ALK1* genes and analyzed a total of 22 unrelated families diagnosed by HHT. Conformation sensitive gel electrophoresis (CSGE) was used to screen mutations in the coding regions of both genes. The variants seen in CSGE were confirmed by a follow up sequencing analysis in both directions. Subsequently, the samples negative in the CSGE will be sequenced to completion for the whole coding regions of *ENG* and *ALK1*.

By using linkage data, when available, and our screening assay we have found *ENG* mutations in 6 families and *ALK1* mutations in 4 families. In 2 families disease causing mutations were not detected by CSGE or sequencing although linkage was shown to *ENG* locus in one family and to *ALK1* locus in the other. In these cases, presence of large deletions could not be excluded with our method. One family did not show linkage to either *ENG* or *ALK1* loci, suggesting a third locus.

To date we have found mutations in 10 of 22 HHT patients. We are continuing to analyze the remaining patients. The identification of the mutations in HHT patients is helpful for surveillance of the affected individuals and family members in risk.

**Screening for Sequence Variations in the von Willebrand Factor Gene using DHPLC.** *D.B. Bellissimo<sup>1</sup>, J.K. Kakela<sup>1</sup>, K.D. Friedman<sup>1</sup>, J.C. Gill<sup>2</sup>, R.R. Montgomery<sup>2</sup>.* 1) Blood Center of Southeastern WI, Milwaukee, WI; 2) Medical College of Wisconsin, Milwaukee, WI.

Von Willebrand disease (vWD) is a common inherited bleeding disorder caused by quantitative (types 1 and 3) and qualitative (type 2) defects in von Willebrand Factor (vWF). Many of the type 2 mutations are localized to exons 18-20 (type 2N) and exon 28 (types 2A, 2B and 2M) making them amenable to DNA sequence analysis. However, the analysis of vWF mutations outside these localized exons is complicated by the large size of the vWF gene that is ~180 kb, containing 52 exons and whose mRNA is 8.7 kb. A simple and sensitive method to scan genes for potential mutations would be useful for vWD and other genetic disorders. The goal of this study was to determine the sensitivity and feasibility of the denaturing high performance liquid chromatography (DHPLC) system for detection of mutations and polymorphisms in the vWF gene. Primers were designed to amplify each exon while avoiding amplification of the vWF pseudogene. Exon-specific primers were tagged with sequencing primers, allowing direct sequencing of each vWF exon. The primers were designed with GC-clamps in order to optimize the melt profile of each vWF amplicon. All sequence variations in 33 previously characterized vWD samples were detected using DHPLC, making the technique one hundred percent sensitive in comparison to DNA sequencing. The sequence variations were distributed among various vWF exons including exons 4, 12, 17, 18, 19, 20, 28, 37 and 52 as well as representing vWD types 1, 2A, 2B, 2M and 2N. In addition, we identified 16 novel potential mutations or polymorphisms in 15 vWD patients. Four of the mutations have clear functional consequences. Two nonsense mutations were identified in exons 3 (R34X) and 28 (R1566X). A deletion in exon 5 (~124 bp) and a deletion in exon 23 (~8 bp) were also found. The functional aspects of the remaining 12 sequence variations need to be assessed. Six of the eight variations within exons changed the amino acid. Four variations in introns were also identified. We conclude that DHPLC is a useful tool for scanning the vWF gene and identifying sequence variations.

**Use of Temperature Gradient Capillary Electrophoresis (TGCE) for Complete Scanning of Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) Gene.** *L. Chou*<sup>1</sup>, *E. Lyon*<sup>1,2</sup>. 1) Research and Development, ARUP Laboratories, Salt Lake City, UT; 2) Pathology Department, University of Utah.

Mutation analysis reveals DNA variation associated with complex inherited diseases. Many of these diseases involve large genes with many different mutations. Direct sequencing identifies these mutations but is laborious and time consuming in both set-up and analysis. Emerging technologies to scan large genes for any heterozygous alteration include denaturing high performance liquid chromatography (D-HPLC) and temperature gradient capillary electrophoresis (TGCE). These technologies detect heteroduplexes that form from re-annealed heterozygous samples. Any alteration detected is confirmed by sequence analysis for the specific region of the gene. This study focused on scanning for mutations in the cystic fibrosis transmembrane regulator (CFTR) gene using TGCE. We designed exon-specific primers to amplify the entire coding region of the CFTR gene using standard PCR conditions. An initial sample set that included 20 mutations covering 8 exons and 4 introns were identified by oligo ligation assay (OLA). TGCE scanning showed 100% agreement with OLA for heterozygous samples. Since homozygous mutants do not form heteroduplexes, these samples require mixing with a known wild type allele to form artificial heteroduplexes. De-identified clinical samples with no mutation detected by OLA were subsequently scanned for mutations in all 27 exons. Results were confirmed by bi-directional sequence analysis, showing 100% concordance. Among 12 randomly chosen samples with no identified mutations by OLA, only 2 samples (17%) were found to be true wild types in all 27 exons scanned. Ten samples had known polymorphisms. One sample had a previously reported mutation in intron 14b (2789+2insA), a possible mRNA splicing defect. We also found a mutation at exon 20 (3991 G/A), which changed the amino acid from glycine to arginine (G1287R) and is not reported in the current database. In conclusion, TGCE has a great potential for use in a high throughput clinical environment for mutation scanning, thus reducing sequencing cost and effort.

**Germline fumarate hydratase mutations and evidence for a founder mutation underlying multiple cutaneous and uterine leiomyomata.** *G.S. Chuang<sup>1</sup>, A. Martinez-Mir<sup>1</sup>, L. Horev<sup>2</sup>, B. Glaser<sup>2</sup>, A. Geyer<sup>1</sup>, M. Landau<sup>3</sup>, A. Waldman<sup>3</sup>, D. Gordon<sup>1</sup>, L.J. Spelman<sup>4</sup>, I. Hatzibougias<sup>5</sup>, D.E. Engler<sup>1</sup>, P.B. Cserhalmi-Friedman<sup>1</sup>, J. Green<sup>6</sup>, M.P. Garcia Muret<sup>7</sup>, M. Prieto Cid<sup>7</sup>, S. Brenner<sup>8</sup>, E. Sprecher<sup>9</sup>, A.M. Christiano<sup>1</sup>, A. Zlotogorski<sup>2</sup>.* 1) Departments of Dermatology and Genetics & Development, Columbia University, New York, NY; 2) Department of Dermatology, Hadassah Medical Center, Jerusalem, Israel; 3) Departments of Dermatology, Wolfson Medical Center, Holon, and Haemek Medical Center, Afula, Israel; 4) South East Dermatology, Brisbane, Queensland, Australia; 5) Institute of Pathology, Thessaloniki, Greece; 6) Department of Dermatology, St. Vincent's Hospital, Melbourne, Australia; 7) Servicio de Dermatología, Hospital de Sant Pau, Barcelona, Spain; 8) Department of Dermatology, Sourasky Medical Center, Tel-Aviv, Israel; 9) Department of Dermatology, Rambam Medical Center, Haifa, Israel.

Multiple cutaneous and uterine leiomyomata syndrome (MCL) is an autosomal dominant disease characterized by the presence of benign tumors of smooth muscle origin (leiomyoma) in skin and uterus in female, and skin leiomyoma in male patients. MCL can also be associated with type II papillary renal cell cancer (HLRCC). The locus for MCL and HLRCC was recently mapped to chromosome 1q42.3-q43 and subsequently, dominantly inherited mutations in the fumarate hydratase gene (FH) were identified. Here we report the clinical and genetic analysis of 16 families with MCL. Mutational analysis of the FH gene revealed a total of 13 different mutations accounting for the disease in all families. We have identified missense, nonsense, splicing, in-frame deletions and frameshift mutations. All of them are unique to single families, with the exception of the splicing mutation 905-1G>A, identified in four families of Iranian origin. The analysis of highly polymorphic microsatellite markers in the vicinity of the FH gene showed a shared haplotype in these four families, suggesting that 905-1G>A represents a founder mutation. Collectively, we have identified 10 novel and three previously described FH mutations that further support the role of FH in the pathogenesis of MCL.

**Two novel mutations in the *PRX* gene in patients with demyelinating Charcot-Marie-Tooth disease: evidence for intrafamilial phenotypic variability.** *M. Cesani, M. Milani, S. Baratta, C. Caccia, D. Pareyson, F. Taroni.* Div. Biochemistry & Genetics, Ist. Naz. Neurologico "C. Besta", Milan, Italy.

Hereditary peripheral neuropathies are a clinically and genetically heterogeneous group of disorders that can be inherited as autosomal dominant (AD), autosomal recessive (AR) or X-linked traits. The sensory and motor demyelinating forms represent the most common inherited peripheral nerve diseases and constitute a wide phenotypic spectrum which includes Charcot-Marie-Tooth disease type 1 (CMT1), Dejerine-Sottas disease (DSD), congenital hypomyelinating neuropathy, and hereditary neuropathy with liability to pressure palsies. At least 20 genetic loci and twelve genes have been associated with the demyelinating form of CMT and related disorders. A limited number of loci have been linked to the rare autosomal recessive forms of CMT1. Mutations in the gene coding for periaxin (*PRX*), a cytoskeleton-associated protein expressed in the noncompact peripheral myelin, have been shown to cause both AR-CMT (CMT4F) and DSD in a small number of patients. Using DHPLC and sequence analysis, we have screened for *PRX* mutations a group of 30 patients with severe demyelinating neuropathy, negative for the common 17p11 duplication and mutations in the *MPZ*, *PMP22* and *GJB1* genes. In one family, two siblings with a severe form of demyelinating neuropathy were found to be compound heterozygotes for two novel *PRX* mutations, one frameshift mutation (2688delC) and one nonsense mutation (1908C->T). Both mutations were located in exon 7, affecting only the long variant of the protein (L-periaxin). Interestingly, the two patients exhibited a different phenotype. One sib had an early-onset very severe DSD phenotype characterized by motor delay and profound reduction in motor conduction velocities (<6 m/sec) while the other had a milder phenotype with later onset and motor conduction velocities of 10-15 m/sec. Nerve biopsy was performed in the first patient showing severe fiber loss and onion-bulb formation. (Partially supported by a grant Ricerca Finalizzata Ministero della Sanità to F.T.).

**Screening candidate genes for mutations using genome custom resequencing microarrays.** *P. Chudgar*<sup>1</sup>, *N. Xu*<sup>1</sup>, *L.P. Chorich*<sup>1</sup>, *C. Liu*<sup>2</sup>, *J.A. Warrington*<sup>2</sup>, *L.C. Layman*<sup>1,3</sup>. 1) Dept. OB/GYN, Medical Coll GA, Augusta, GA; 2) Affymetrix, Inc., Santa Clara, CA; 3) Neurodevelopmental Biology Program, Inst Mol Med Genet, Med Coll GA, Augusta, GA.

Patients with idiopathic hypogonadotropic hypogonadism (IHH) present with absent puberty, infertility, and low gonadotropins. To date, mutation analysis of these genes has been performed utilizing traditional PCR-based techniques, such as SSCP or DGGE, followed by DNA sequencing. The use of genome custom resequencing microarrays allows a high throughput technology to detect gene mutations, whereby 30kb of sequence from multiple genes can be screened per patient per chip. However, because this is a relatively new application of this technology there exists some uncertainty about its efficacy for mutation detection in research laboratories. In this pilot study we screened 8 IHH patients for mutations in six different genes using microarrays. Long range PCR was performed and PCR products for each patient sample were pooled, purified, and fragmented. PCR products were then labeled with biotin, hybridized individually to a microarray, washed, stained with streptavidin, scanned, and analyzed by the ABACUS program. For six chips, 92-93% of bases were called with high confidence scores, while for two patients only 67% of bases were called. A total of 38 single nucleotide polymorphisms (SNPs) were identified from 30kb in these eight patients, including 12 in exons, 9 in the promoter/5 untranslated region, 5 in 3 untranslated region, 9 in introns, and 3 that are being determined. To date, 18 of 19 (94.7%) SNPs have been confirmed by DNA sequencing, while the others are currently being sequenced. Since only 67% of bases were called correctly on two chips, the presence of genomic rearrangement is currently being evaluated. Twenty-four additional arrays are currently being completed. The use of custom resequencing microarrays has already permitted the identification of new gene mutations in IHH patients. The results of these studies will determine the feasibility of using custom resequencing microarrays for mutation detection in disease studies carried out in individual research laboratories.

**Genomic structure and novel mutations in the *TRIM37* gene in Mulibrey nanism.** *R. Hämäläinen<sup>1</sup>, K. Avela<sup>1</sup>, J. Kallijärvi<sup>1</sup>, M. Lipsanen-Nyman<sup>2</sup>, A.-E. Lehesjoki<sup>1</sup>.* 1) Folkhälsan Institute of Genetics and Department of Medical Genetics, Biomedicum Helsinki, University of Helsinki, Finland; 2) The Hospital for Children and Adolescents, and Helsinki University Central Hospital, University of Helsinki, Finland.

Mulibrey nanism is an autosomal recessive growth disorder of unknown pathogenesis. It belongs to the diseases of the Finnish disease heritage and 80 % of the approximately 100 patients diagnosed worldwide are Finnish. Mulibrey nanism is characterized by prenatal-onset growth failure, typical facial features and pericardial constriction with hepatomegaly. The patients have an increased incidence of ovarian tumors and Wilms tumor. The intellectual capacity of Mulibrey nanism patients is normal.

Mutations in the *TRIM37* gene, encoding a peroxisomal protein, underlie Mulibrey nanism. *TRIM37* contains a RING-B-box-Coiled-coil domain (denominated TRIM for TRIPartite Motif) and an additional TRAF (Tumor necrosis factor Receptor Associated Factor) domain. Five truncating mutations with no evidence for genotype-phenotype correlation have previously been reported in Mulibrey nanism patients.

By using publicly available sequences and by sequencing the remaining gaps, we determined the genomic organization of the 24 exon *TRIM37* cDNA. Knowing the exon-intron junctions and using intronic primers, we then performed mutation screening in Mulibrey nanism patients and identified six novel disease-associated mutations. These mutations were absent in 190 control chromosomes studied. Five of the new mutations are truncating while the sixth is the first missense mutation reported so far in Mulibrey nanism patients. This missense mutation was shown to result in altered subcellular localization of the mutated *TRIM37* protein, further suggesting that it is pathogenic. The eleven Mulibrey nanism associated mutations identified to date are evenly distributed in the *TRIM37* gene. Initial analysis indicates no genotype-phenotype correlation in Mulibrey nanism.

**Point-of-care genetic testing: rapid detection of single nucleotide polymorphism (SNP) by competitive allele-specific short oligonucleotide hybridization (CASSOH) with immunochromatographic strip.** *Y. Matsubara<sup>1</sup>, S. Kure<sup>1</sup>, M. Hiratsuka<sup>2</sup>, M. Mizugaki<sup>2</sup>.* 1) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 2) Department of Clinical Pharmaceutics, Tohoku Pharmaceutical University, Sendai, Japan.

The clinical application of genetic information to individual healthcare requires simple and rapid identification of nucleotide changes in clinical settings. To date, numerous methods to detect single nucleotide substitutions (SNPs and mutations) have been reported. However, currently available SNP detection methods require either cumbersome laboratory procedures, such as electrophoresis, or expensive instrumentation which has been primarily developed for high-throughput analysis in human genome research. None of these procedures are readily performed in local clinical laboratories. Recently, we have devised a novel low-tech method for detecting SNPs using competitive allele-specific short oligonucleotide hybridization (CASSOH) with immunochromatographic strip (Matsubara & Kure, *Human Mutation*, in press). The method detects a SNP within 10 min after the completion of PCR by forming a visible gold-particle line on a chromatographic test strip. The procedure does not demand either sophisticated equipment or technical expertise. We further modified the method to allow direct analysis of whole blood without DNA extraction. The CASSOH method has been successfully applied to the detection of clinically important SNPs in drug metabolism (CYP2C19\*2, TPMT\*3C, ALDH2\*2, NAT2\*5, NAT2\*6, NAT2\*7, UGT1A1\*6 and mitochondrial 1555A>G) and Factor V Leiden. Also we were able to detect disease-causing mutations in medium-chain acyl-CoA dehydrogenase deficiency (ACADM/985A>G), non-ketotic hyperglycinemia (GLDC/1691G>T), glycogen storage disease type Ia (G6PC/727G>T), cystic fibrosis (CFTR/delF508), Tay-Sachs disease (HEXA/1277insTATC) and breast cancer (BRCA1/5382insC and BRCA2/6174delT). Our method would facilitate point-of-care genetic testing in local hospitals and out-patient clinics, promising potentially diverse clinical applications.

**Homozygosity-based screening with multiple locus-specific microsatellite markers toward the diagnosis of autosomal recessive retinitis pigmentosa.** *H. Kondo*<sup>1</sup>, *T. Tahira*<sup>2</sup>, *A. Mizota*<sup>3</sup>, *M. Kondo*<sup>4</sup>, *H. Hayashi*<sup>1</sup>, *K. Hayashi*<sup>5</sup>, *Y. Miyake*<sup>4</sup>, *K. Oshima*<sup>1</sup>, *K. Hayashi*<sup>2</sup>. 1) Ophthalmology, Fukuoka University, Fukuoka, Fukuoka, Japan; 2) Div. Genome Analysis, Res. Center for Genet. Inf., Med. Inst. of Bioregulation, Kyushu University, Fukuoka, Japan; 3) Ophthalmology, Chiba University, Chiba, Japan; 4) Ophthalmology, Nagoya University, Nagoya, Japan; 5) Hayashi Eye Hospital, Fukuoka, Japan.

Retinitis pigmentosa (RP) is a group of progressive hereditary disorders of the retina. Despite the importance of identifying the causative gene of RP, diagnosis of the recessive form (arRP) is often non-definitive due to extensive gene heterogeneity. Mutations in each of the arRP genes (16 genes identified so far) are very rare. Therefore, considerable cases of arRP may be the result of the homozygosity of single ancestral founder mutations. Compared to European countries and the United States, higher frequency of consanguineous marriage is found among the older individuals in Japanese. Thus, higher rate of mutations that are homozygous by descent is expected for the responsible genes among arRP patients of this population. Taking this into advantage, we describe a systematic method to efficiently diagnose the genetics of arRP patients. Sixty-two di-, tri-, or tetra-nucleotide repeats within or near the 16 genes known to be responsible for arRP were used as markers in multiplex amplification and genotyping. Heterozygosity of locus-specific markers excluded the majority of the examined genes as candidates, and mutation screening for the genes with homozygous alleles was considered. Thirty-eight Japanese patients with isolated RP or arRP (six with consanguineous marriage) were tested. Twenty-one patients (55%) revealed one or more heterozygous alleles of all 16 genes and were excluded in the initial screen. Of the rest of 17 patients, one, two and three genes remained as candidates in six, eight and three patients, respectively. Mutations are being searched for seven candidate genes (*CNGB1*, *NR2E3*, *PDE6A*, *PDE6B*, *RHO*, *RLBP1* and *TULP1*) in nine patients. This systematic approach should facilitate detection of homozygous alleles for molecular diagnosis of arRP.

**Frequency of Connexin 26 35delG Mutation Among Kurdish Patients With Non-syndromic Sensorineural Hearing Loss in Kermanshah, the West of Iran.** *N. Mahdieh<sup>1</sup>, K. Ali-Madadi<sup>2</sup>, H. Yazdan<sup>2</sup>, A.K. Dehghan<sup>2</sup>, S. Arzhangi<sup>1</sup>, A. Ebrahimi<sup>1</sup>, S. Kazemi<sup>2</sup>, Y. Riazalhosseini<sup>1</sup>, H. Najmabadi<sup>1</sup>.* 1) Genetics Research Center, USWR University, Tehran, Tehran, Iran; 2) Genetic Counselling Center, Welfare & Rehabilitation Organization of Kermanshah-Iran.

Hearing loss is the most prevalent form of sensory impairment in humans, with approximately 1 in 1000 live births. Mutations in connexin 26 gene are the most common cause of autosomal recessive non-syndromic hearing loss (ARNHL) throughout the world. This gene is believed relevant to half of all cases of hereditary deafness. Cx26 shows diverse mutations, that one mutation occurs very frequently in Europe- the 35delG mutation. In previous study the prevalence of GJB2 mutation has been demonstrated to be around 20%. In this study our goal is to assess the frequency of 35delG in province of Kermanshah, Kurdish population. We studied 35 patients with ARNHL by ARMS-PCR. Six of them had 35delG mutation in connexin 26 gene that 2 were homozygous, 4 were heterozygous and 27 were normal for 35delG (77%). These results suggest that frequency of 35delG is lower than around 11% compared to the other Iranian populations.

**A novel missense mutation in the Presenilin-1 (PSEN1) gene associated with sporadic Early Onset Alzheimer Disease (EOAD).** *M. Liguori<sup>1</sup>, R. Cittadella<sup>1</sup>, I. Manna<sup>1</sup>, A. La Russa<sup>1</sup>, V. La Bella<sup>2</sup>, F. Piccoli<sup>2</sup>, A. Quattrone<sup>1,3</sup>.* 1) Inst Neurological Sciences, National Research Council, Cosenza, Italy; 2) Inst Neuropsychiatry, University of Palermo, Italy; 3) Inst Neurology, University of Catanzaro, Italy.

AD is the most common cause of dementia in which genetic factors play a substantial role. The majority of EOAD has been associated to mutations in the PSEN1 gene (18 up to 50 percent), in familial and in sporadic cases. We report a novel mutation in an Italian 48-year-old woman from Sicily with a negative family history for dementia. She was a teacher but she had lost her working ability because of a progressive short-term memory impairment started 3 years before. At the time of the clinical evaluation, she had a severe cognitive decline with a temporal-spatial disorientation; she had mostly lost the ability to take care to herself. The blood laboratory parameters were normal as the analysis of her cerebrospinal fluid; MRI scan showed a diffuse cerebral atrophy. Amplifications of PSEN1 exons from 3 to 12 were performed on genomic DNA by standardised laboratory protocols. PCR products were then screened by Denaturing High-Performance Liquid Chromatography (DHPLC) technology, an automated method for detecting DNA sequence variants (Transgenomics). The eventually aberrant exons were sequenced on an ABI Prism 377 automated sequencer applying the dideoxy-dye terminator technique. Results: The DHPLC analysis showed an aberrant exon 5; the sequencing evaluation revealed a single nucleotide substitution at codon 116 (nucleotide 595: C->T, in heterozygous state) that changed the correspondent amino acid (Thr to Ile). In order to confirm this novel mutation, we analysed 50 healthy controls from the same geographic area (north-western Sicily) and 50 from another southern Italy region (Calabria) by DHPLC procedure but we did not find abnormal results in all the examined exon 5. Conclusions: These results confirm the detection of a novel T116I missense mutation in an extremely interesting region of PSEN1 gene (TM1-TM2 loop); we also confirm the feasibility of DHPLC as screening procedure for genetic point mutations.

**Notch3 mutations in families with Cadasil from southern Italy.** *R. Mazzei<sup>1</sup>, F.L. Conforti<sup>1</sup>, T. Sprovieri<sup>1</sup>, M. Zappia<sup>2</sup>, F. Bono<sup>2</sup>, A. Magariello<sup>1</sup>, A. Toscano<sup>3</sup>, A. Patitucci<sup>1</sup>, M.G. Arena<sup>3</sup>, P. Valentino<sup>2</sup>, A.L. Gabriele<sup>1</sup>, P.L. Lanza<sup>4</sup>, M. Muglia<sup>1</sup>.* 1) ISN, CNR, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) Department of Neuroscience, Psychiatry and Anesthesiology Science, University of Messina, Italy; 4) Neuroradiology Unit, Ospedale Annunziata, Cosenza, Italy.

CADASIL (Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy) is an increasingly recognized adult-onset autosomal dominant vascular dementia, caused by highly stereotyped mutations in Notch3 gene on chromosome 19. Previous studies aimed at determining the distributions of mutations in the Notch3 gene found that the mutations were located in the epidermal growth factor (EGF) repeats, which are encoded for the first 23 exons but exon 1. It has been reported that 60 to 70% of mutations cluster in exons 3 and 4 and therefore a limited screen can be achieved by examining these exons alone. The aim of the present study was to screen for the exons 2-23 of Notch3 gene in 25 subjects from 7 unrelated families with CADASIL from southern Italy. All the patients were clinically examined and underwent neuroimaging studies. Molecular investigation was performed by DHPLC analysis and subsequently direct sequencing. We found 7 pathogenic mutations: two of these mutations were in exon 3, two in exon 6, three in exon 8. One mutation in exon 3 and three mutations in exon 8 are novel mutations. An optimal approach toward mutational screening in a given population is possible if the spectrum of mutations in that population is known. To date, no molecular study has been carried out for CADASIL in geographically defined populations, with the exception of Finland. Our results demonstrate that exon 4 is not the hot spot for mutations in Notch3 gene in families with CADASIL from southern Italy, and suggest that in our population can be appropriate to start molecular analysis of patients with possible CADASIL by investigating exon 8, and if this is negative to proceed to exons 3 and 6, and then to screen the remaining exons of the Notch3 gene.

**PTPN11 mutations in Noonan syndrome and hydrops fetalis.** *J.R. Jones<sup>1</sup>, T.C. Wood<sup>1</sup>, M.A. Whalen<sup>2</sup>, C. Haddock-Bolt<sup>1</sup>, L.H. Seaver<sup>1</sup>, R.J. Schroer<sup>1</sup>, R.C. Rogers<sup>1</sup>, D.E. Everman<sup>1</sup>, M.J. Friez<sup>1</sup>.* 1) Greenwood Genetic Center Greenwood, SC; 2) Boston University School of Medicine, Center for Human Genetics, Boston MA.

Noonan Syndrome (NS) is an autosomal dominant condition characterized by short stature, webbing of the neck, pectus excavatum/carinatum, cryptorchidism, characteristic facies, and cardiac defects including pulmonic stenosis and hypertrophic cardiomyopathy. NS has also been associated with hydrops fetalis. It has recently been reported that approximately 50% of NS cases may be due to mutations in the PTPN11 gene that encodes the nonreceptor protein tyrosine phosphatase SHP-2. As many as 80% of these changes have been found to cluster in specific regions of exons 3, 8, and 13. In order to identify potential PTPN11 mutations in 15 individuals with suspected NS and 12 fetuses with hydrops fetalis, we sequenced these three exons (3,8,13). Our analyses revealed mutations in 3 of the 15 patients believed to have NS. Of these three patients, two bore the diagnosis of NS based on their clinical presentation. One carried a novel A1517C transversion (Q506P) while the other possessed a previously described mutation, A1510G (M504V). The third patient presented with short stature and pulmonic stenosis; however, the case was complicated by the occurrence of congenital syphilis and hydrops. A G1507C transversion (G503R) was detected in this patient. This mutation was recently described in an individual with growth retardation, pulmonic stenosis and juvenile myelomonocytic leukemia (JMML). Our analyses also detected a G214A transition (A72T) in one female stillborn fetus described as hydropic based on the presence of subcutaneous edema and a cystic hygroma. The fetus was also noted to have a Dandy-Walker malformation, a left sided diaphragmatic hernia, an interrupted aortic arch, ventriculoseptal defect and persistent left superior vena cava. The A72T substitution has been found previously in 2 patients with JMML but without NS. Our study has identified a novel PTPN11 mutation in an individual with NS and, to our knowledge, is the first report of a PTPN11 mutation in a fetus with hydrops fetalis.

**Sodium channel -1 subunit mutations in severe myoclonic epilepsy of infancy and infantile spasms.** *J. Mulley<sup>1</sup>, R. Wallace<sup>1</sup>, B. Hodgson<sup>1</sup>, B. Grinton<sup>2</sup>, R. Gardiner<sup>3</sup>, R. Robinson<sup>3</sup>, V. Rodriguez-Casero<sup>7</sup>, L. Sadleir<sup>4</sup>, J. Morgan<sup>5</sup>, L. Harkin<sup>1</sup>, L. Dibbens<sup>1</sup>, T. Yamamoto<sup>1</sup>, E. Andermann<sup>6</sup>, S. Berkovic<sup>2</sup>, I. Scheffer<sup>2</sup>.* 1) Cytogenetics & Molec Genetics, Women's & Children's Hosp, Adelaide, Australia; 2) Medicine (Neurology), University of Melbourne, Austin & Repatriation Medical Centre, Melbourne, Australia; 3) Pediatrics & Child Health, Royal Free & University College, London, England; 4) Pediatrics, Wellington School of Medicine, University of Otago, Wellington, New Zealand; 5) Royal Children's Hospital, Llantrisant, Wales; 6) Neurogenetics, Montreal Neurological Institute and Hospital, Montreal, Canada; 7) Neurology, Royal Children's Hospital, Melbourne, Australia.

Mutations in SCN1A, the gene encoding the -1 subunit of the sodium channel, have been found in Severe Myoclonic Epilepsy of Infancy (SMEI) and Generalized Epilepsy with Febrile Seizures Plus (GEFS+). Mutations in SMEI include missense, nonsense and frameshift mutations more commonly arising *de novo* in affected patients. This finding is difficult to reconcile with the family history of GEFS+ in a significant proportion of patients with SMEI. Infantile spasms (IS) or West syndrome is a severe epileptic encephalopathy which is usually symptomatic. In some cases no etiology is found and there is a family history of epilepsy.

We screened SCN1A in 24 patients with SMEI and 23 with IS. Mutations were found in 8 of 24 (33%) SMEI patients, a frequency much lower than initial reports from Europe and Japan. One mutation near the carboxy terminus was identified in an IS patient. A family history of seizures was found in 17 of 24 patients with SMEI. The rate of SCN1A mutations in this cohort of SMEI patients suggests that other factors may be important in SMEI. Less severe mutations associated with GEFS+ could interact with other loci to cause SMEI in cases with a family history of GEFS+. This study extends the phenotypic heterogeneity of mutations in SCN1A to include infantile spasms.

**Identification of a novel WISP3 mutation in an inbred Israeli Arab kindred with progressive pseudorheumatoid dysplasia.** *Y. Hujeirat<sup>1</sup>, S. A. Shalev<sup>1</sup>, J. A. Martignetti<sup>2</sup>, R. J. Desnick<sup>2</sup>, A. Shalata<sup>2</sup>.* 1) Genetic Inst, HaEmeck Medical Ctr, Afula, Israel; 2) Human Genetic Department, Mount Sinai School of medicine, USA.

Progressive pseudorheumatoid dysplasia (PPD) (MIM# 208230) is an autosomal recessive disorder that may be initially misdiagnosed as juvenile rheumatoid arthritis. PPD is a progressive hereditary arthropathy, leading to restricted mobility of multiple peripheral joints and osseous swelling of the interphalangeal and other joints, platyspondyly and irregularities of the vertebral bodies. Symptoms appear in early childhood, and consist of limited motion, stiffness, painless swelling of several small and large joints, muscular weakness, and consequently progressive difficulty in ambulation. PPD is a rare disorder, which has been reported with increased frequency among Arab and Mediterranean populations. Mutations in the WISP3 gene, which is a member of the CCN family encoding putative growth regulators, have been found in PPD -affected individuals. We report in a newly identified large Muslim Israeli-Arab family with 8 affected individuals. Sequencing all 5 coding exons of the WISP3 gene revealed a mutation in exon 3, codon 179 which resulted in a dinucleotide deletion (del TG) leading to early protein truncation, missing the third and fourth domains, the throbospondin and c-terminal cystine knot- like domain, respectively. This homoallelic mutation was found in all affected individuals and segregated appropriately within other family members. Of the particular interest, screening of 69 unrelated healthy individuals from this village revealed an overall carrier frequency of 5.7%.

**Update on the spectrum of *TRPS1* mutations in the tricho-rhino-phalangeal syndrome types I and III. H.-J. Lüdecke, S. Gross, M. Trommler, P. Brega.** Humangenetik, Universitätsklinikum, Essen, Germany.

Mutations in the *TRPS1* gene, which codes for a zinc finger transcription factor, lead to the development of the tricho-rhino-phalangeal syndrome (TRPS) types I and III. They are characterized by craniofacial dysmorphism, brachydactyly and short stature. The latter signs are more severe in TRPS type III. Previously, we described 35 different mutations in the *TRPS1* gene (Lüdecke *et al.*, 2001, AJHG 68:81-91). Nonsense mutations were associated with TRPS I and missense mutations, exclusively found in the GATA-type zinc finger (GATA-zf, amino acids 896 to 920), caused TRPS III. Here we report the identification of 26 novel *TRPS1* mutations. Together with 7 mutations reported by others, 68 different mutations have now been found in 95 unrelated patients. Twenty of the 35 base substitutions as well as the 12 insertions and the 21 deletions lead to premature translation stop codons. Three base substitutions affect splice signals. The remaining 12 base substitutions cause missense mutations. Worth noting is that 28 of the 95 patients (29.5 %) have mutations in the 123 bp exon 6, which encodes the GATA-zf, or the adjacent intron 6 splice donor site. We found 9 novel mutations in exon 6. Two insertions, 1 deletion and 3 base substitutions cause premature stop codons. The other 3 base substitutions cause missense mutations. As expected, the W907R causes TRPS III. However, the novel A919V mutation causes TRPS I, whereas exchange of the same amino acid to threonine (A919T) resulted in a TRPS III phenotype. Interestingly, the Y923H mutation, adjacent to the GATA-zf, was found in a patient with an atypical face and normal height, but apparently small hands. Radiologic examination of the hands is pending. Surprisingly, one nonsense mutation in exon 6 (Y915X) is associated with a TRPS III phenotype. Only 4 missense mutations are not located in exon 6. Two of them (R952C and R952H) affect the nuclear localization signal and prevent nuclear entrance of TRPS1. The other two (C1217R and C1217Y) alter the first cysteine of the first IKAROS-like zinc finger. All 6 patients in whom we identified the last 4 missense mutations present with a TRPS I phenotype.

**A novel MID1 mutation in siblings with X-linked Opitz G/BBB syndrome.** *S.E. Harris<sup>1</sup>, E.V. Bawle<sup>2</sup>, E.F. Rappaport<sup>1</sup>, B.S. Emanuel<sup>1</sup>, S.C. Saitta<sup>1</sup>.* 1) Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Genetics and Metabolic Disorders, Children's Hospital of Michigan, Detroit, MI.

Opitz G/BBB syndrome involves midline structural defects of the craniofacies, trachea, heart and urinary tract. The phenotype is variable, but often includes hypertelorism, cleft lip and palate, tracheal and pharyngeal malformations, cardiac structural defects, and hypospadias. Both X-linked and autosomal dominant inheritance have been described. Additionally, there is significant clinical overlap with the 22q11.2 deletion syndrome. We report a family with 3 siblings (2 males and one female) with varying features of Opitz G/BBB, mildest in the affected sister. FISH analysis for a deletion of chromosome 22q11.2 was normal. Thus, despite the presence of an affected female, we examined the MID1 gene on Xp22. MID1 protein interacts with microtubules and its loss of function is associated with the X-linked form of Opitz syndrome. Using DHPLC (WAVE) analysis and confirmatory sequencing of PCR products, we detected a novel nonsense mutation in codon 575 (TGG to TGA; W575X) resulting in the loss of the last 92 amino acids of the carboxy-terminal domain. This mutation is predicted to significantly impair MID1 function, and was not found in 100 control X chromosome alleles tested. This finding underscores the importance of mutation analysis for accurate recurrence risk counseling in disorders that are genetically heterogeneous, particularly in X-linked disorders in which female heterozygotes manifest symptoms.

**A novel mutation within ECM1 gene in Korean patient with lipoproteinosis.** *J.S. Lee<sup>1, 2</sup>, C.H. Lee<sup>2</sup>, H.W. Lee<sup>2</sup>, E.S. Park<sup>2</sup>*. 1) Dept Clinical Genetics, Yonsei Univ Col Medicine, Seoul, Korea; 2) Brain Korea 21 Project for Medical Science, Yonsei University.

Lipoproteinosis(LP. OMIM 247100), also known as hyalinosis cutis et mucosae is a rare autosomal recessive disorder characterized by early hoarseness, unusual skin eruption and itchy eyes. It occurs throughout the world and more frequent in Northern Cape Province in South Africa. Genome-wide linkage analysis had recently been performed to identify a responsible gene and the gene was mapped to chromosome 1q21.2. Finally, extracellular matrix protein 1(ECM1) gene was noted as a candidate gene for the disease and different mutations were identified in patients families with different ethnic origins. ECM1 has been thought to have a role as a negative regulator of endochondral bone formation, inhibiting alkaline phosphatase activity and bone mineralization. Until today, only some mutations have been known as causes of the disease and this is the first report on a Korean patients family. We have screened exon 6 and 7 of the ECM1 gene as previously described (Hamada et al.,2002) that is known to be a hot spot for mutations in lipoproteinosis patient. Compound heterozygote mutations, ACG130ATG/892delC were identified in Korean patient. An A to T substitution changes arginine codon for methionine and 892delC mutation was previously described in a Japanese patient. Since the disease itself is very rare and only a small number of mutations were so far identified in different ethnic groups, there should be more study on the characterization of different mutations of the ECM1 gene in patients with different ethnic origins.

***OPAI* mutations in Finnish families with dominant optic atrophy (DOA).** A. Puomila<sup>1</sup>, R. Paananen<sup>1</sup>, M. Mäntyjärvi<sup>2</sup>, E.M. Sankila<sup>3</sup>, M. Somer<sup>4</sup>, M.L. Savontaus<sup>1</sup>, E. Nikoskelainen<sup>2</sup>, K. Huoponen<sup>1</sup>. 1) Department of Medical Genetics, University of Turku, Turku, Finland; 2) Department of Ophthalmology, University of Turku, Turku, Finland; 3) Helsinki University Eye Hospital, Helsinki, Finland; 4) Family Federation of Finland, Helsinki, Finland.

Several linkage studies localise dominant optic atrophy (DOA) to chromosome 3 (3q28) and mutations in the *OPAI* gene encoding a large dynamin-related GTPase protein have been detected in DOA patients. We are in the process of identifying Finnish DOA families and screening the *OPAI* gene in order to find the pathogenic mutations. At the moment, our 15 index cases include patients from large families showing linkage to the *OPAI* gene locus, as well as sporadic cases. We have used intronic primers to amplify and sequence 28 coding exons of the *OPAI* gene. Thus far, five novel pathogenic mutations have been identified in seven families. Three families share the same mutation (970delCGTTCTCCA) suggesting that they most probably have a common ancestor. The other mutations are restricted to one family only, as seen in other populations. Different types of mutations were found (703CT ArgSTOP, 1065+2tc, 1212delTgtaa, 1768CT ArgTrp). Mutation screening of the other cases is still going on. As there seems to be no clear mutational hot-spot in the *OPAI* gene, simple rapid DNA testing can be offered only to those families where the mutation is known.

**The recurrent Basque mutation in Brazilian calpainopathy patients.** *F. Paula<sup>1</sup>, A. Sáenz<sup>2</sup>, A.M. Cobo<sup>2</sup>, A. Lopez de Munain<sup>2</sup>, A. Urtizberea<sup>3</sup>, M. Zatz<sup>1</sup>.* 1) Human Genome Research Center, Sao Paulo University, Sao Paulo, Brazil; 2) Hospital Donostia, San Sebastián, Basque Country, Spain; 3) Service de Medecine Physique et Readaptation de l'Enfant, Hospital Raymond Poincare, Garches, France.

Limb-girdle muscular dystrophy (LGMD) is a heterogeneous group of genetic disorders characterized by progressive weakness predominantly in the pelvic and shoulder-girdle musculature. LGMD2A, one of the most prevalent forms of LGMD in many populations, is caused by mutations in the calpain-3 gene (CAPN3). More than 120 CAPN3 mutations have been identified. Most represent private changes found in specific families but, particular pathogenic changes have been reported more frequently in some genetic isolates. One of this, the recurrent 2362AG>TCATCT mutation (exon 22), was found in more than 90% of the calpainopathy patients from Basque country, most of them associated with a founder haplotype. We have recently identified pathogenic mutations in the CAPN3 gene in patients from 44 unrelated Brazilian genealogies. Eleven families (25%) were found to carry the 2362AG>TCATCT change: 6 are homozygotes and 5 are compound heterozygotes. In order to verify the origin of this mutation in Brazilian patients we are studying the haplotype flanking the CAPN3 gene as compared to one Basque patient using 4 microsatellites with 1cM interval: cen-D15S779-D15S782-D15S778-D15S783-ter. All 2362AG>TCATCT Brazilian chromosomes have the same haplotype (1, 1, 4, 3) suggesting a single origin for this mutation. We are currently comparing these results with Basque patients carrying the same mutation. The preliminary results showed in one Basque patient the same haplotype suggesting a common origin for the 2362AG>TCATCT mutation in Brazilian and Basque patients. Since immigrants from several European countries, including Portugal and Spain, colonized Brazil it is likely that the origin of this mutation is Basque. Supported by FAPESP-CEPID, PRONEX, CNPq.

**Mutation analysis of the L1CAM gene in 200 patients.** *Y.J. Vos<sup>1</sup>, E. Verlind<sup>1</sup>, A. Kooistra<sup>1</sup>, I. Stolte-Dijkstra<sup>1</sup>, W.S. Kerstjens-Frederikse<sup>1</sup>, C.H.C.M. Buys<sup>1</sup>, R.M.W. Hofstra<sup>2</sup>.* 1) Clinical Genetics, University Hospital, Groningen, The Netherlands; 2) Medical Genetics, University of Groningen, The Netherlands.

Mutations in the L1CAM gene, which encodes an immunoglobulin-like neural cell adhesion molecule, cause several neurological syndromes: HSAS (Hydrocephalus due to Stenosis of the Aqueduct of Sylvius); MASA syndrome (Mental Retardation, Aphasia, Shuffling gait, adducted thumbs); SP1 (Spastic Paraparesis type 1); ACC (Agenesis of Corpus Callosum). The L1 gene is located at Xq28, consists of 28 exons and encodes a protein of 1256 amino acids. The L1-protein is a transmembrane glycoprotein. It includes an extracellular part with six immunoglobulin like domains and five fibronectin type III like domains, a transmembrane domain and a short cytoplasmic C-terminal tail. Up to now 142 different pathogenic mutations, in 153 families, spread over all regions of the gene, have been identified and published (<http://dnalab-www.uia.ac.be/dnalab/11/>). The clinical diagnosis of a male patient is based on the finding of two or more characteristics such as hydrocephalus and adducted thumbs, or spasticity and mental retardation. In the majority of cases there is a positive family history. Confirmation of the clinical diagnosis by molecular analysis is essential to identify carriers in the families and to make it possible to offer reliable prenatal diagnosis. Since the molecular analysis of the L1CAM gene is very laborious, because of the rather large size of the coding region, we developed an efficient pre-screening method, based on denaturing gradient gel electrophoresis (DGGE), followed by direct sequencing of the amplicon with an aberrant banding pattern. To date DNA of 200 patients has been analysed, patients with a positive family history as well as sporadic cases. In 39 patients, 36 different mutations have been found: 13 missense mutations, 7 nonsense mutations, 6 deletions/insertions, 9 splice site mutations and in one case the deletion of the whole gene. Of those mutations 24 had not been published before. Most missense mutations are considered pathogenic as they affect the structural integrity of one of the above mentioned domains.

**Mutations in the *SIMPLE* gene are a relative common cause of dominant Charcot-Marie-Tooth disease (CMT1C) and related peripheral neuropathies.** *G.M. Saifi*<sup>1</sup>, *K. Szigeti*<sup>1</sup>, *W. Wiszniewski*<sup>1</sup>, *J.R. Lupski*<sup>1,2</sup>. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Room 604B, Houston, TX 77030, USA; 2) Department of Pediatrics, Baylor College of Medicine, One Baylor Plaza, Room 604B, Houston, TX 77030, USA.

Charcot-Marie-Tooth disease is a clinically and genetically heterogeneous group of inherited peripheral neuropathies characterized by progressive weakness and atrophy of distal limb muscles. It has an estimated prevalence of 1 in 2500. Mutations have been reported in twenty genes and an additional ten loci are associated with CMT. We report here the results of our studies on one of the recently identified CMT genes, *SIMPLE*. We screened this gene for mutations in 192 CMT cases. In these 192 cases, a molecular etiology has not been established despite examining for many potential causes in several CMT genes including the CMT1A duplication, *PMP22*, *Cx32*, *MPZ*, *EGR2*, *PRX*, *NEFL*, *MTMR2*, *GDAP1*, *TDPI*, *SOX10* and *LMNA*. We have so far identified four different missense mutations in *SIMPLE* in nine families. In addition, we identified two silent changes in another nine CMT families. The missense mutations and the silent changes were not found in 188 control chromosomes. It thus appears that mutations in *SIMPLE* could be the most frequent cause of CMT after the CMT1A duplication and *Cx32* mutations. Segregation analysis has confirmed that one of the mutations is associated with the disease phenotype. Out of these 18 families, there are 3 families in whom we had previously identified mutations in other CMT genes and the mutation had not segregated with the disease phenotype. We are currently screening these families for simultaneous segregation of one of the silent changes in *SIMPLE* and the mutation identified in one of the other CMT genes. Further, preliminary studies indicate that the phenotypes of patients fall in a wide spectrum, similar to what has been observed in *MPZ* mutations. This indicates that mutations in *SIMPLE* in conjugation with a mutation in another CMT gene may be central to the pathogenesis of the disease and modulate the variability of the phenotype.

**Sequence alterations in the RP1 and RHO genes in Chinese patients with retinitis pigmentosa.** *C.P. Pang, D.Y. Wang, P.O.S. Tam, L. Baum, K.W. Choy, D.S.C. Lam, W.M. Chan.* Ophthalmology & Visual Sci, Chinese Univ Hong Kong, Hong Kong, China.

Retinitis pigmentosa (RP) is among the most common inherited forms of blindness, affecting about 1 in 4,000 people in most ethnic groups. Mutations in many genes cause RP. We screened for sequence alterations in the coding exons and splice regions of the RHO and RP1 genes in 173 unrelated Chinese patients, some of their family members, and 190 control subjects. Among 10 sequence changes found in RHO, M309I, P347L and 5211delC caused RP. 5211delC leads to the negatively-charged final 22 amino acids containing 6 phosphorylation sites being replaced by a 32 amino acid positively-charged nonsense sequence. In RP1 we identified 2 nonsense and 11 missense sequence alterations: R677X and D984G caused RP and R1933X did not. In this Chinese RP population 6 RHO and 10 RP1 novel sequence variations were found. In contrast to the other C-terminal truncation, Y1053, R1933X of RP1 appears benign. Therefore the RP1 polypeptide sequence between amino acids 1052 and 1933, which contains a transmembrane domain (1120-1142) and leucine-zipper motif (1396-1417), must be present at undiminished levels to maintain photoreceptor function. In RHO, the C-terminal nonsense mutation 5211delC may lead to mis-sorting of rhodopsin protein. The expected frequency of RP1 and RHO mutations combined among this Chinese RP population is low, less than 10% ( $5/173=3.0\%$ , 95% confidence interval: 0.4%-10.0%).

**Development of a molecular diagnostic screening for the autosomal recessive polycystic kidney disease gene,**

***PKHD1***. S. Rossetti<sup>1</sup>, R. Torra<sup>2</sup>, E. Coto<sup>3</sup>, M. Consugar<sup>1</sup>, V. Kubly<sup>1</sup>, M. El-Youssef<sup>1</sup>, V.E. Torres<sup>1</sup>, P.C. Harris<sup>1</sup>. 1) Div Nephrology and Gastroenterology, Mayo Clinic & Foundation, Rochester, MN; 2) Fundacio' Puigvert, Barcelona, Spain; 3) Hospital Central de Asturias, Oviedo, Spain.

Autosomal Recessive Polycystic Kidney Disease (ARPKD) is a severe form of childhood nephropathy affecting about 1:20,000 live births. The disease is characterized by fusiform dilatation of the collecting ducts in the kidney and congenital hepatic fibrosis (CHF) and Caroli's disease, (CD) in the liver. The ARPKD gene, *PKHD1*, has been recently cloned and contains 66 coding exons that encode a ~450 Kda protein, fibrocystin. We have used denaturing high-performance liquid chromatography for mutation analysis of this large multi-exon gene in a large cohort of 89 pedigrees, 64 with a primary diagnosis of ARPKD and 25 with CHF and/or CD. This phenotypically heterogeneous cohort has allowed us to better define the phenotypic range associated with *PKHD1* mutations. A total of 47 different mutations were found on 78 disease alleles. The detection rate was highest in severely affected ARPKD patients (perinatal death)(85%), 42% in other ARPKD cases and lowest (32%) but still important in CHF/CD. These mutations were truncating, missense and potential splicing changes, and both mutations were identified in 27 pedigrees, plus one mutation in additional 24 families. Some frequent mutations (9689delA, 5895InsA, T2869K, T36M and I222V) were proven to be ancestral changes by haplotype analysis with existing and newly developed intragenic and closely flanking microsatellite markers. Preliminary genotype-phenotype correlations show that probands with a double-truncating genotype have the severe form of ARPKD. The modest detection rate in ARPKD cases without the most severe disease indicates that an accurate description of the phenotype may be important. Genotyping analysis using a haplotype generated with the new highly informative and closely linked markers could complement the mutation screening in a diagnostic setting, in particular in families in which one diagnostic *PKHD1* mutation has been identified. Overall, the prospect for molecular genetic testing in this devastating disorder looks good.

**L1 retrotransposition during embryogenesis in the mother of a patient with choroideremia.** *J.A.J.M. van den Hurk<sup>1</sup>, I.C. Meij<sup>1</sup>, L.H. Hoefsloot<sup>1</sup>, I.J. de Wijs<sup>1</sup>, T.J.R. van de Pol<sup>1</sup>, A.S. Plomp<sup>2</sup>, H.G. Brunner<sup>1</sup>, F.P.M. Cremers<sup>1</sup>.* 1) Department of Human Genetics, University Medical Center Nijmegen, Nijmegen, The Netherlands; 2) The Netherlands Ophthalmic Research Institute, Amsterdam, The Netherlands.

Choroideremia (CHM) is a progressive chorioretinal degeneration caused by mutations in the widely expressed *CHM* gene on chromosome Xq21. The product of this gene, Rab escort protein (REP)-1, is involved in the posttranslational lipid modification and subsequent membrane targeting of Rab proteins, small GTPases that play a key role in intracellular trafficking.

In the course of a comprehensive mutation screen of the *CHM* gene, an insertion of a full-length L1 retrotransposon into *CHM* exon 6 was identified in a patient with choroideremia. The L1 insertion causes the deletion of exon 6 from the *CHM* mRNA. As the reading frame is maintained, this results in a protein product lacking amino acids 235 through 273. Interestingly, analyses of the patients family indicated germline and somatic mosaicism for the L1 element in the *CHM* gene in the mother. These findings provide the first evidence consistent with an L1 retrotransposition event during embryogenesis.

**Mutations of the PKD1 gene among Japanese patients with autosomal dominant polycystic kidney disease. T.**

*Tamura*<sup>1</sup>, *A. Yamaki*<sup>1</sup>, *S. Hashimoto*<sup>1</sup>, *E. Higashihara*<sup>2</sup>, *Y. Shimizu*<sup>1</sup>. 1) Dept Medical Genetics, Kyorin Univ Sch Health Sci, Hachioji, Tokyo, Japan; 2) Dept Urology, Kyorin Univ Sch Medicine, Mitaka, Tokyo.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common hereditary disorders. The prevalence of ADPKD in the Japanese population has been estimated as approximately 1 in 4000. We performed the linkage analysis using six polymorphic microsatellite markers flanking to PKD1 or PKD2. Among 21 Japanese ADPKD families, 16 families linked to PKD1 and 2 families linked to PKD2 whereas 3 families (K68, K71, K123) linked to neither PKD1 nor PKD2. However, two different nonsense mutations were detected in two of three affected members of families K68 and K123. Mutation detection of PKD1 has been complicated because several PKD1-like genes locate on chromosome 16p13.1 and 2.5 kb polypyrimidine tract is present in intron 21 of PKD1 gene. Although more than 100 mutations such as various amino acids alterations and abnormal splicing have been reported for entire PKD1 gene, hot spots were not yet found. We performed simple PCR for the unique region (exon 34 ~ 46) and long range PCR followed by short range PCR for the homologous region (exon 22 ~ 33). We analyzed PCR products by WAVE (DHPLC method). We found eight mutations in the unique region: one splicing mutation caused by 20 bp deletion in intron 43, C>A at 48566 (Cys3693Ter) in exon 38, C>T at 51237 (Gln4124Ter) and C>T at 51042 (Glu4059Ter) in exon 45, G deletion at 48012 in exon 37, GGTC insertion at 50868 in exon 44, CC deletion at 51114 and GCACCTG insertion at 51110 in exon 45. In the homologous region seven missense mutations were detected and these mutations were not found in 50 unrelated normal individuals. 26 SNPs including 3 cSNPs. were found during the course of PKD1 mutant detection.

**Identification of a novel SCA14 mutation in Dutch autosomal dominant cerebellar ataxia families.** *R.J. Sinke<sup>1</sup>, D.S. Verbeek<sup>1</sup>, B.P.C. van de Warrenburg<sup>2</sup>, S.J. Piersma<sup>1</sup>, F.A.M. Hennekam<sup>1</sup>, P.F. Ippel<sup>1</sup>, P.L. Pearson<sup>1</sup>, N.V.A.M. Knoers<sup>3</sup>, H.P.H. Kremer<sup>2</sup>.* 1) Dept. of Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands; 2) Dept. of Neurology, University Medical Center Nijmegen, Nijmegen, The Netherlands; 3) Dept. of Human Genetics, University Medical Center Nijmegen, Nijmegen, The Netherlands.

Autosomal dominant cerebellar ataxias (ADCAs) comprise a group of neurodegenerative disorders, characterized by an adult age of onset, gait and limb ataxia, disturbances of speech and oculomotor control, and additional variable features. To date, 22 different SCA (spinocerebellar ataxia) loci have been identified in ADCA. The corresponding gene has been cloned for ten of these loci. Screening of the SCA1,2,3,6 and 7 genes has yielded a diagnosis for about 70% of the Dutch ADCA families. Mutations in the SCA10,12 and 15 genes have not been detected in the remaining families. Interestingly, the CAG repeat expansions, especially in the SCA3 and SCA6 genes, display strong founder effects in the Dutch ADCA population. Because this might also be the case for other, unknown SCA genes, we searched for shared haplotypes in 28 small Dutch ADCA families to try to identify novel SCA genes. We initially set out to analyze all reported SCA-loci for which the corresponding genes had not yet been identified. In addition, we performed genealogical investigations to link any distantly related families. By doing so, we identified 3 small families that appeared to be related and that could be linked to the SCA14 locus on chromosome 19 (max. lod score 4,62). At this stage, the PRKCG gene was identified as the SCA14 disease gene. Accordingly, we sequenced this gene in the affected family members and identified a novel missense mutation, Gly118Asp, in exon 4. Currently, we are screening the entire Dutch SCA negative panel for additional SCA14 mutations. While the mutation mechanism in most SCA genes is identified as repeat expansions, in the two most recent SCA genes (SCA14 and FGF14) missense mutations appear to be pathogenic. This opens up a new perspective in the further unraveling of the intriguing disease mechanism of these neurodegenerative disorders.

**Two novel mutations in the PTPN11 gene associated with Noonan and LEOPARD syndromes.** *S. Ylonen<sup>1</sup>, J. Körkkö<sup>1</sup>, M. Somer<sup>2</sup>, J. Ignatius<sup>1</sup>.* 1) Dept of Clinical Genetics, University Hospital of Oulu, OULU, FINLAND; 2) Dept of Clinical Genetics, Väestöliitto, The Finnish Family Federation, HELSINKI, FINLAND.

Recently, missense mutations in PTPN11, the gene encoding protein-tyrosine phosphatase, nonreceptor type,11, has been described in several patients with Noonan syndrome (NS) or Multiple Lentigines /LEOPARD syndrome (LS). Some of these mutations have been described in more than one family. Codon 308 in exon 8 appears to be a significant mutation hotspot for NS, Asn308Asp being the most common mutation found in several studies. That codon 308 is a hotspot for NS has been further indicated by the finding of an Asn308Ser missense mutation in some additional families. In LS, hotspots have been found in exons 7 and 12. We have investigated PTPN11 gene mutations with PCR-CSGE-sequencing and gene sequencing in 4 Finnish NS patients and in one two generation family with prominent lentigines and the diagnosis consistent with LS. In one patient with typical NS we found an Asn308Thr mutation which has not been described before. This finding further indicates that codon 308 in exon 8 is a significant mutation hotspot in NS. In the LS family we found a novel mutation Gln510Glu in exon 13. This finding indicates that mutations causing Multiple Lentigines/LEOPARD syndrome phenotype are not restricted to exons 7 and 12.

**The C1490Y mutation in *ABCA4* ; a possible founder mutation in the South African Stargardt population.** A.V. September, R. Ramesar, L.J. Greenberg. Human Genetics, University of Cape Town, Cape Town, South Africa.

Mutations in *ABCA4* are associated with autosomal recessive Stargardt disease (STGD). This study aimed to assess the mutation spectrum of *ABCA4* underlying STGD in South Africa (SA).

Sixty one affected, unrelated STGD individuals and 120 unrelated, unaffected, ethnically matched control individuals were selected. Single strand conformation polymorphism analysis (SSCP) and Heteroduplex (HD) analysis in conjunction with polymerase chain reaction amplification was used as the mutation detection technique to screen the entire coding region of the gene, followed by direct sequencing. Haplotypes were constructed for 11 of the 61 families using the mutation and the markers D1S188, D1S406 and D1S236.

A total of 53 sequence variants were identified that were potential disease-causing mutations in 37 of the 61 STGD families. The majority of these individuals were heterozygous for single mutations with 16 of the 61 individuals found to be compound heterozygotes for 2 different mutations. These variations included single base substitutions resulting in 10 missense, 2 truncation and 2 splice site mutations. In addition, 1 deletion resulting in a frameshift mutation was also identified. Two of the 15 different sequence variants identified were novel. The C1490Y variant was the most common mutation identified (19/61) and was absent in the 120 controls. This variant has only ever been identified in 3/150 patients from North and Central Europe. A single haplotype was identified for the 4 most common sequence variants and 2 haplotypes were identified for R602W.

In summary, at least one mutation has been identified in 61% of the STGD individuals investigated of whom 26% are compound heterozygotes. The mutation analysis together with the haplotype analysis, have demonstrated that there are several origins of mutations of the *ABCA4* gene, within the SA STGD population. The observed high prevalence of the C1490Y variant together with the haplotype analysis suggests a possible founder effect in SA.

**Mutation analysis of the *NSDI* gene - genetic testing for Sotos syndrome.,** *G. Raca*<sup>1</sup>, *D.J. Waggoner*<sup>1</sup>, *J. Kamimura*<sup>2</sup>, *N. Matsumoto*<sup>2</sup>, *G.B. Schaefer*<sup>3</sup>, *K.O. Welch*<sup>1</sup>, *C.L. Martin*<sup>1</sup>, *S. Das*<sup>1</sup>. 1) Human Genetics, University of Chicago, Chicago, IL; 2) Human Genetics, Nagasaki University School of Medicine, Sakamoto, Japan; 3) Nebraska Medical Center, Omaha, NEX.

Sotos syndrome is characterized by pre and postnatal accelerated somatic growth, characteristic facies, advanced bone age and developmental delay. Deletions and mutations of the *NSDI* gene have recently been demonstrated in patients with Sotos syndrome and account for approximately 77% of patients. We have developed mutation analysis of the *NSDI* gene using a denaturing high performance liquid chromatography (DHPLC) and sequencing-based assay for clinical testing purposes. The *NSDI* gene has 23 exons that are amplified with flanking intron sequence in 47 PCRs. Amplified products are subject to DHPLC analysis using optimized temperature conditions predicted using the Navigator software program (Transgenomic Inc.). We have validated our DHPLC/sequencing-based mutation assay in the *NSDI* gene and have accurately identified all 29 sequence changes tested, including a number performed in a blinded fashion. To date we have performed deletion analysis of the *NSDI* gene by FISH testing in 118 patients referred to our laboratory for Sotos syndrome and found deletions in 7, i.e. 6%. Patients with *NSDI* deletions tended to have the typical features of Sotos syndrome. Mutations have been identified in 7 of 13 (54%) non-deleted Sotos syndrome patients as well as seven polymorphisms were identified. Two patients with Weaver syndrome were analyzed and no mutations were found. While the majority of patients with mutations had typical features of Sotos syndrome, there was clinical variability within the group. Two patients did not have advanced growth while two patients did not have dysmorphic features. We are currently in the process of analyzing further patients for mutations in the *NSDI* gene and genotype-phenotype results of these patients will be presented.

**Mutations of UMOD in the tubulo-interstitial diseases MCKD and FJHN associate with intracellular aggregates and excretion reduction of uromodulin.** *L. Rampoldi<sup>1</sup>, G. Caridi<sup>2</sup>, F. Boaretto<sup>3</sup>, I. Bernascone<sup>1</sup>, D. Santon<sup>3</sup>, G. Lamorte<sup>1</sup>, R. Tardanico<sup>4</sup>, G. Colussi<sup>5</sup>, F. Scolari<sup>4</sup>, A. Amoroso<sup>3</sup>, G. Ghiggeri<sup>2</sup>, G. Casari<sup>1</sup>.* 1) DIBIT, S.Raffaele Scientific Institute, Milan, MI, Italy; 2) Laboratory of Nephrology, G. Gaslini Institute, Genoa, Italy; 3) Genetics Service, Istituto per l'Infanzia Burlo Garofolo, Trieste, Italy; 4) Spedali Civili and University of Brescia, Brescia, Italy; 5) Ospedale di Circolo, Varese, Italy.

Medullary cystic kidney disease is a typical tubulo-interstitial disorder characterized by alteration of urinary concentration, hyperuricemia, tubulo-interstitial fibrosis, frequent cysts at the cortico-medullary junction and renal failure. It is a genetic and clinical heterogeneous disorder with two known loci, i.e. MCKD1 (OMIM 174000) on chromosome 1q21 and MCKD2 (OMIM 603860) on chromosome 16p12. Familial juvenile hyperuricemic nephropathy (OMIM 162000) features are very similar to those seen in MCKD, i.e. hyperuricemia, gout, progressive renal failure and autosomal-dominant inheritance. A locus for FJHN was mapped to a chromosome 16p region that overlapped with the MCKD2 locus in two Czech and one Japanese families. Very recently, mutations in the gene encoding uromodulin have been reported in MCKD and FJHN families, demonstrating that FJHN and MCKD are allelic disorders. In two unrelated MCKD and one FJHN Italian families linked or compatible with linkage to the chromosome 16 MCKD2/FJHN locus we performed mutational analysis of UMOD gene and identified three novel uromodulin gene mutations that segregated with the disease phenotype. These results provide the first independent confirmation that UMOD mutations are responsible for MCKD2. Immunohistochemistry and electron microscopy on MCKD/FJHN kidney biopsies reveal pathologic evidence of dense intracellular accumulation of uromodulin in tubular epithelia of the thick ascending limb of Henle's loop. Western blot analysis of patient urine shows a severe reduction of excreted uromodulin. Preliminary transfection experiments with the mutant isoforms in HEK293 and HeLa cell lines that do not express uromodulin reveal a maturation impairment of mutant protein that is consistent with clinical findings.

Program Nr: 2429 from 2003 ASHG Annual Meeting

**Characterization of novel mutations in the Tudor domain and in the promoter region of the SMN1 gene in Spanish SMA patients.** *E. Tizzano, I. Cusco, M.J. Barcelo, E. del Rio, M. Baiget.* Dept Genetics, Hosp Sant Pau, Barcelona, Spain.

Spinal muscular atrophy( is an autosomal recessive neuromuscular disorder characterized by the degeneration and loss of motor neurones of the anterior horn of the spinal cord. The absence or mutations in the survival motor neurone (SMN1) gene causes SMA resulting in a reduced production of functional SMN protein. Approximately 90% of the SMA patients present homozygous deletions of the SMN1 gene and in the remaining patients, subtle mutations have been described. We present a thorough molecular analysis of four type I SMA patients who retained one copy of the SMN1 gene. Long-range genomic PCR analysis and RNA studies led to the identification of four previously unreported changes. Two of them were intragenic mutations (I116F and Q136E)affecting a very conserved region containing the Tudor domain of the exon 3. Alteration of this highly conserved domain should be critical for SMN function in spinal cord given that both patients suffered from type I SMA and died before the first year of life. In the remaining two patients no changes were found in the coding region or exon-intron boundaries but in one a promoter point mutation was identified that led to the absence of SMN1 transcript. The last patient showed a partial deletion of the 5' end of the gene that includes the C212 and C272 markers and ends before exon 2a. Our results highlight the importance of the Tudor domain region for SMN function and indicate that SMA patients without homozygous deletion of exon 7-8 or subtle mutations in the coding sequences may have transcription defects as a result of point mutation or deletions in the promoter region. Supported by FIS 02-1275.

**Novel disease-causing mutations in DNAI1 gene in Primary Ciliary Dyskinesia (PCD).** M. Zariwala<sup>1</sup>, P.G. Noone<sup>1</sup>, M.W. Leigh<sup>1</sup>, R.U. De Iongh<sup>2</sup>, L.M. Morgan<sup>2</sup>, J. Horvath<sup>3</sup>, H. Omran<sup>3</sup>, H. Mitchison<sup>4</sup>, M.R. Knowles<sup>1</sup>. 1) UNC-Chapel Hill, NC; 2) Concord Hospital, Sydney; 3) the Universitats-Kinderklinik, Freiburg; 4) Royal Free and University College Medical School, London.

Primary ciliary dyskinesia (PCD), usually inherited as an autosomal recessive trait, is characterized by sino-pulmonary disease and half the patients have situs inversus. The PCD phenotype results from axonemal abnormalities; 80% have dynein arm defects in cilia. It is a heterogeneous disorder and disease causing mutations have been reported in *DNAH5* (n=6 families) [Olbrich et al., Nat. Genet. 30: 143, 2002] and *DNAI1* (n=6 families) [Pennarun et al., AJHG 65: 1508, 1999; Guichard et al., AJHG 68: 1030, 2001; Zariwala et al., AJRCMB 25: 577, 2001]. The 219+3insT mutation in *DNAI1* represents 6 of the 12 reported mutant alleles and 3 other mutant alleles are in exon 17 of *DNAI1*. We studied 81 unrelated PCD patients to test for 219+3insT and exon 17 mutations in *DNAI1* (41 with situs inversus). Of the 76 patients with ultrastructural analysis of cilia, 70% had defective outer dynein arm. The 219+3insT mutation was screened by mutation-induced *HpaI* restriction site; 3 of 81 patients harbored 219+3insT mutation (2 were homozygous and 1 was heterozygous). Due to allelic heterogeneity, we used sequence analyses to screen exon 17. No previously reported mutations in exon 17 were detected, but 2 patients had novel mutations at codons 538 and 548. One mutation (G1783A; A538T) was found on one allele of a patient, who had 219+3insT on the other allele. Another patient had the A538T mutation on one allele (inherited from the mother) and a nonsense mutation (G1815; W548X) on the second allele (inherited from the father). Each of these mutations resides in a conserved WD-repeat region and would be predicted to lead to abnormal folding of the protein. None of the 160 alleles analysed from non-PCD controls had the 2 novel mutations. In conclusion, we detected mutations in *DNAI1* in 4 unrelated PCD patients. This abstract is funded by GCRC #00046, M01 RR00046-42 and NIH HL04225.

**Spontaneous multiple mutations in mouse show proximal spacing consistent with temporally coordinate events and alterations with p53-deficiency.** *J. Wang, K. Hill, K. Farwell, W. Scaringe, S. Sommer.* Dept Molecular Genetics, City of Hope/Beckman Res Inst, Duarte, CA.

Analysis of spontaneous multiple mutations in normal and tumor cells may constrain hypotheses about the mechanisms responsible for multiple mutations and provide insight into the mutator phenotype. Previously, it was estimated that spontaneous multiple mutations in Big Blue mice are about 660-fold more frequent than expected by chance in both normal and tumor tissues [Buettner et al., 2000 *Mutat Res*, 252:219]. The spacing between multiple mutations was generally close; the distribution of mutation spacing fit an exponential distribution, albeit with substantial scatter. Herein, the frequency, pattern and spectrum of spontaneous multiple mutations are examined as a function of age, tissue type, p53 deficiency and neoplasia in a sample augmented by 2,658 additional, sequenced mutants. Previous findings are confirmed and several additional observations are made: i) spacing between mutations in doublets in this larger sample now fit an exponential distribution more precisely ( $R^2=0.98$ ), consistent with temporally coordinate events. The half life of mutation spacing is 120 nucleotides; ii) doublet frequencies are similar among somatic tissues and reduced in the germline; iii) singlets and doublets show similar overall increases in frequency with age; iv) doublet frequencies are elevated in somatic tissues of p53-deficient mice (Li Fraumini cancer syndrome model;  $p=0.005$ ) and v) doublets and singlets in tumors have a significantly different mutation pattern ( $p=0.007$ ). The observations are consistent with the temporally coordinated occurrence of spontaneous multiple mutations by a transient error-prone condition and do not suggest a major role for the recently discovered Y family of error-prone polymerases.

**Comprehensive Sequence Analysis Ruled out Disease Association with the CFTR Gene in a Family with Atypical CF Presentations.** *W. Sun<sup>1</sup>, J. Redman<sup>1</sup>, R. Wallerstein<sup>2</sup>, J. McCarrier<sup>2</sup>, D. Lee<sup>2</sup>, A. Buller<sup>1</sup>, M. McGinniss<sup>1</sup>, F. Quan<sup>1</sup>, C. Strom<sup>1</sup>.* 1) Molec Gen Dept, Nichols Inst, Quest Diagnostics Inc, San Juan Capistrano, CA; 2) Department of Pediatrics, Hackensack University Medical Center, Hackensack, NJ 07601.

Cystic fibrosis (CF) is the most common life-limiting recessive genetic disease in Caucasians. Mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene are responsible for the disease in almost all patients. In addition to causing the classical CF phenotype, CFTR mutations have been associated with congenital bilateral absence of the vas deferens (CBAVD), chronic pancreatitis, allergic bronchopulmonary aspergillosis and chronic rhinosinusitis. Nevertheless, factors other than mutations in the CFTR gene can produce phenotypes clinically indistinguishable from nonclassic cystic fibrosis caused by CFTR dysfunction (N Engl J Med. 347:401-7). We report that comprehensive sequence analyses of the entire coding region as well as the splice junction sites of the CFTR gene have been performed on a family with atypical CF presentations, including both parents and four symptomatic children with chronic sinusitis and chronic cough. One sibling, the most seriously affected, had pan-sinusitis, bronchiectasis, and recurrent otitis. Her genotype showed homozygosity for the M470V polymorphism only. We detected two previously reported rare gene variants, G576A and R668C, in two of the affected children. However, our study indicated that these variants are in cis in this family. In addition, other polymorphic markers in the CFTR gene allowed us to track the segregation of parental CFTR alleles to each of the children. Since the affected children have inherited different CFTR alleles, our data rules out CFTR as the sole causative agent. G576A and R668C, did not cosegregate with disease phenotype and thus are not pathogenic in this family. Our study also showed that comprehensive sequence analysis of the CFTR gene not only detected rare disease-causing mutations and variants, it also served as a powerful tool for linkage study to establish/rule out disease association with the CFTR gene locus in affected families.

**Identification and characterization of novel mutations in patients with Enhanced S Cone syndrome.** *N. Udar<sup>1</sup>, M. Marmor<sup>2</sup>, M. Chalukya<sup>1</sup>, S. Yelchits<sup>1</sup>, R. Silva-Garcia<sup>1</sup>, K. Small<sup>1</sup>.* 1) Jules Stein Eye Institute, The David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Department of Ophthalmology, Stanford University Medical Center, Stanford, California.

Enhanced S Cone syndrome (ESCS) is a rare autosomal recessive retinal disorder characterized by absence of rod function and by large amplitude S cone mediated signal to short wavelength stimuli with an increased sensitivity to blue light. Unlike other inherited retinal degenerations where photoreceptors are lost due to apoptosis, ESCS manifests a gain in function of photoreceptors. The causative gene NR2E3, is a nuclear receptor located on chromosome 15q23. NR2E3 is a retinal expressed ligand-dependent transcription factor with a 2.2 kb transcript. Although there are very few reports of mutation screening for this disorder, the majority of reported mutations involve R311Q at the 3 end of the gene. In contrast, our mutations were at the 5 end of the gene. Using a direct sequencing approach, we screened the entire gene in 2 patients (1 from Brazil) belonging to independent families and identified the mutations. The first patients is a compound heterozygote for IVS1-2AC and del 190-198. The other patient was homozygous for del 196-201. Only the intronic mutation has previously been reported, the other two are novel. Interestingly the only other 9 base deletion reported previously overlaps with the mutations we have identified and is likely to occur due to a simple repeat within the exon. The identification of these mutations implies that the amino acid 64-69 are critically necessary for the proper functioning of the protein. Our results identify the second hot-spot for mutation within this gene. This is also the first report of the mutation in a Brazilian family with ESCS.

**Myogenesis in Facioscapulohumeral Dystrophy (FSHD) and Control Myoblasts.** *D.A. Figlewicz<sup>1,2</sup>, I. Coltas<sup>1</sup>, Y. Hong<sup>1</sup>, J.E. Sowden<sup>2</sup>, R. Tawil<sup>2</sup>.* 1) Neurology, University of Michigan, Ann Arbor, MI; 2) Neurology, University of Rochester, Rochester, NY.

Facioscapulohumeral dystrophy (FSHD) is an autosomal dominant disorder resulting from deletion of 3.3kb repeats on chromosome 4q35. We have observed phenotypic differences in myoblasts cultured from FSHD skeletal muscle biopsies, including morphologic changes and loss of replicative capacity. Our data to date support the hypothesis that FSHD myoblasts leave the cell cycle earlier, fuse more readily, and upregulate some genes associated with myogenesis. In order to further investigate this phenomenon we are studying the relationship between several cell cycle and transcription regulators in myoblasts (including p53, p21, MyoD, and myostatin) using real-time PCR, immunocytochemistry and Western blotting. Myostatin is a member of the TGF-beta family of growth factors and a negative regulator of myogenesis; inhibition of myostatin or myostatin signalling pathways is currently of great interest as a therapeutic treatment for muscular dystrophies. It has been proposed by others that the myostatin gene is a downstream target gene of MyoD and may be involved in myoblast withdrawal from the cell cycle. Because we have previously shown that MyoD is upregulated in FSHD muscle, we wished to determine whether myostatin is also upregulated. Levels of myostatin mRNA are proportional to MyoD levels in myoblasts. At the protein level, myostatin is expressed in myoblasts preparing to fuse, and most robustly in multinucleate cells (myotubes) undergoing nuclear fusion. As might be expected, levels of myostatin, MyoD, and p21 are much lower in myoblasts at low confluence. Thus far we have not observed differences in relative proportions of these factors between FSHD and control myoblasts; however absolute differences secondary to increased MyoD upregulation may contribute significantly to the overall pathogenesis of FSHD. This work was supported by funds from NIAMS R21 and MDA (USA).

**The CAG-repeat polymorphism of the *POLG1* gene is not associated with male oligozoospermia.** C. Michielotto<sup>1,2</sup>, L. Stuppia<sup>3,4</sup>, C. Foresta<sup>5</sup>, M. Zeviani<sup>6</sup>, F. Ferrari<sup>6</sup>, E. Dragone<sup>1</sup>, V. Gatta<sup>3</sup>, S. Pintor<sup>3</sup>, M. Rossato<sup>5</sup>, G. Matullo<sup>2,7</sup>, N. Migone<sup>1,2</sup>, A. Brusco<sup>1,2</sup>. 1) S.C. Genetica Medica, Azienda Osp. San Giovanni Battista, Torino, Italy; 2) Dept. Genetica Biol. Bioch.-Univ. Torino, Italy; 3) Dept. Scienze Biomediche, Univ. Chieti, Italy; 4) ITOI-CNR, Bologna, Italy; 5) Dept. Scienze Mediche e Chirurgiche, Univ. Padova, Italy; 6) Ist. Naz.le Neurologico C.Besta-IRCCS, Milano, Italy; 7) I.S.I, Villa Gualino, Torino.

*POLG1* is a nuclear gene encoding for the catalytic subunit of human mitochondrial DNA polymerase. Absence of the common 10-CAG-repeat allele in *POLG1* has recently been reported in association with a reduced number of spermatozoa (oligozoospermia). To verify these data we studied three case/control cohorts from three different Italian geographical areas. Criteria for inclusion of patients were: (1) moderate oligozoospermia (number of spermatozoa 5-20x10<sup>6</sup>/ml); (2) normal karyotype; (3) absence of Y chromosome deletions in the AZF-a, -b and -c regions. 105 probands from Piedmont (North-Western Italy), 95 from Veneto (North-Eastern Italy), and 77 from Abruzzo (Central Italy), and three sets of controls from each geographical area were selected (Piedmont, N=131; Veneto, N=96; Abruzzo, N=121). Analysis of the *POLG1* gene CAG-repeats was performed through a fluorescent PCR. Within each area, frequencies of the 10/10, 10/X and X/X genotypes did not significantly differ in infertiles vs. controls (P=0.38, 0.19, and 0.32 in Piedmont, Veneto and Abruzzo respectively). The data from the three areas were then pooled, and again the distribution of the three genotypes between infertiles and controls did not show any statistically significant difference (P=0.11). Indeed, the oligozoospermics from all three areas showed a lower frequency of the X/X genotype than in controls (1.9 vs. 5.3%, 1.1 vs. 2.1%, 1.3 vs. 5.0%, and 1.4 vs.4.0% in Piedmont, Veneto, Abruzzo, and in the pool). Our findings suggest that, at least in Italy, the *POLG1* CAG-repeat polymorphisms do not contribute to male oligozoospermia.

**SLUG (SNAI2) is not a common cause of Waardenburg syndrome type 2 (WS2).** *T.A. Maher<sup>1</sup>, C.T. Baldwin<sup>1,2</sup>, G. Zhao<sup>1</sup>, A. Milunsky<sup>1,2</sup>, J.M. Milunsky<sup>1,2,3</sup>.* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Department of Genetics and Genomics; Boston University School of Medicine, Boston, MA.

Waardenburg syndrome (MIM193500) has an incidence of at least 1 in 40,000 and is one of the most common autosomal dominant syndromes associated with hearing loss. WS is characterized by sensorineural hearing loss, pigmentary abnormalities of the iris, hair, and skin, and is responsible for about 3% of congenital hearing loss. WS is a variably penetrant autosomal dominant disorder that is characterized as a neurocristopathy. Several different types of WS exist, each with different associations. Dystopia canthorum is lacking in WS2, differentiating it from WS1. Using the W-index to distinguish types 1 and 2, our cohort of patients were characterized as WS2. WS2 is a heterogeneous disorder showing linkage to different genomic regions. Approximately 10-20% of WS2 families have mutations in the *MITF* gene. Sequencing of the *MITF* coding sequence revealed 2 mutations (Ex 6 89670 CT ; W241X) in our cohort of 36 unrelated WS2 patients. Recently, 2 unrelated families were reported with a homozygous gene deletion of SLUG (SNAI2 on chromosome 8q11). We examined our cohort of WS2 patients for SLUG gene mutations by sequencing of the coding exons and by southern blot to detect partial or whole gene deletions. No homozygous deletions were found. Sequencing of the coding regions did not detect any mutations. Hence, we conclude that SLUG mutations are not a common cause of WS2.

**Locus CFM1: a potential modifier of pancreatic disease in children with cystic fibrosis.** *M.K. Sontag<sup>1,2</sup>, J.E. Hokanson<sup>2</sup>, J.A. Marshall<sup>2</sup>, M. Corey<sup>3</sup>, G.O. Zerbe<sup>2</sup>, L-C. Tsui<sup>3,4</sup>, J. Zielenski<sup>3</sup>, F.J. Accurso<sup>1</sup>.* 1) Pediatrics, University of Colorado Health Sciences Center, Denver, CO; 2) Preventive Medicine & Biometrics, University of Colorado Health Sciences Center, Denver, CO; 3) Hospital for Sick Children, Toronto, ON, CAN; 4) University of Hong Kong, Hong Kong.

Cystic fibrosis (CF) is a common mendelian disease, with variable phenotype. Immunoreactive trypsinogen (IRT), a pancreatic enzyme precursor, is a marker of pancreatic injury, a significant source of morbidity in CF. IRT is elevated in young children with CF and declines with age, corresponding to pancreatic damage and destruction. Infants with CF who present with Meconium Ileus (MI) have lower IRT levels than infants without MI, suggesting a relationship between pancreatic damage and MI. The CFM1 region on 19q13 is associated with MI in children with CF. To determine if the CFM1 locus is associated with IRT levels we studied serial IRT levels in 288 infants with CF. Rapid, moderate, and slow decliners were identified using a mixed effects model analysis. Genotyping in the CFM1 region is complete on 37 children with CF and both parents. Each trio was genotyped for 6 markers in the CFM1 region. Each of the markers is multi-allelic, and we tested for linkage distortion at each allele. The most significant allele for each marker is presented. Transmission disequilibrium testing (TDT) was performed on rapid decliners (n=9).

Mrkr/allele	D19S408/5	D19S217/4	LOC284248/7	APOC/1	D19S219/1	D19S112/3
<sup>2</sup> (p)	2.0(0.16)	3.6(0.05)	1.0(0.32)	2.0(0.16)	1.3(0.26)	3.0(0.08)

The markers in order (q13.2)(centel),<sup>2</sup>, and p value are shown. The positive association found with allele 4 at marker D19S217 supports other findings that this allele is associated with MI. More families will be screened in order to verify this trend and to look for candidate gene(s) in the CFM1 locus. We conclude that CFM1 is a potential modifier of early pancreatic injury in CF.

**Testing the Position-Effect Variegation Hypothesis for Facioscapulohumeral Muscular Dystrophy By Analysis of Histone Modification and Gene Expression in Subtelomeric 4q.** *M. Ehrlich<sup>1</sup>, G. Jiang<sup>1</sup>, F. Yang<sup>1</sup>, V.*

*Vedanarayanan<sup>2</sup>, P.G. van Overveld<sup>3</sup>, S. van der Maarel<sup>3</sup>.* 1) Human Genetics, Tulane Med. Sch., New Orleans, LA; 2) Dept. of Neurology, Univ. of Mississippi Med. Sch., Jackson, MS; 3) Dept. of Human Genetics, Univ. Leiden, Leiden, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is a unique dominant disorder involving shortening an array of tandem repeats. This copy-number polymorphic 3.3-kb repeat, D4Z4, is on 4q35 and 10q26 but only 4q35 arrays with <11 copies are linked to FSHD. The most popular model for how the array-shortening causes FSHD is that it leads to D4Z4 heterochromatinization, which spreads proximally along 4q35, causing overexpression of FSHD genes in cis, similar to a loss of position-effect variegation. To test for heterochromatinization in 4q35 subregions, we did chromatin immunoprecipitation (ChIP) analysis of histone H4 acetylation using real-time PCR. First, we showed that there was an average of 2.5-fold less immunoprecipitation (SD, 0.5; N, 14) of constitutive heterochromatin standards than of unexpressed euchromatin standards. Then, in contradiction to the above model for FSHD, we found that H4 acetylation of a non-repeated DNA region adjacent to 4q35 and 10q26 D4Z4 arrays was in the range of unexpressed euchromatin and not of constitutive heterochromatin in both normal and FSHD lymphoid cells. Although ChIP could not be done on muscle, another prediction of the above model was tested by quantitating transcripts from FSHD candidate genes FRG1 and ANT1 on 4q35. Contrary to a recent report, there was no increase in their transcript levels in FSHD skeletal muscle vs. controls. Also, no difference was seen between normal and FSHD lymphoid cells in H4 acetylation at FRG1 5' and ANT1 promoter regions; all were hyperacetylated like expressed gene standards. Therefore, our results favor a different model for the molecular genetic etiology of FSHD, such as, differential long-distance cis looping that depends upon the presence of a 4q35 D4Z4 array with less than a threshold number of copies of the 3.3-kb repeat. Supported in part by FSH Society Grant FSHS-MB-06 and NIH Grant R21 AR48315.

**Mutation of *SFTPC* in infantile pulmonary alveolar proteinosis with or without fibrosing lung disease. M.**

*Bahuau*<sup>1</sup>, *M. Griese*<sup>2</sup>, *S. Marque*<sup>1</sup>, *F. Brasch*<sup>3</sup>, *S. Schumacher*<sup>2</sup>, *J. de Blic*<sup>1</sup>, *C. Houdayer*<sup>1</sup>, *J. Elion*<sup>1</sup>, *R. Couderc*<sup>1</sup>, *M. Tredano*<sup>1</sup>. 1) Biochimie Biologie Molculaire, Hpital Trousseau (MB, SM, CH, RC, MT), Pneumologie, Allergologie Pdiatriques, Hpital des Enfants-Malades (JB), Fdration de Gntique, INSERM U458, Hpital Robert-Debr (JE), AP-HP, Paris, France; 2) Kinderklinik und Kinderpoliklinik, Dr. von Haunerschen Kinderspital, Ludwig-Maximilians Universitt, Mnchen, FRG; 3) Dept. of Pathology, Bergmannsheil, University of Bochum, FRG.

Pulmonary surfactant protein C (SP-C) is a highly hydrophobic peptide produced by type-II alveolar cells by processing of a precursor protein (pro-SP-C), that enhances surface tension and, possibly, facilitates the recycling of pulmonary surfactant. Recently, two dominant-negative mutations of the pro-SP-C-encoding gene (*SFTPC*, MIM 178620), were reported in families with vertically-inherited interstitial lung disease. We have examined the SP-C protein and precursor as well as their encoding gene in 34 sporadic or familial, neonatal and juvenile, cases with unexplained respiratory distress (URD) (SP-B deficiency related to *SFTPB* ruled out). One patient with complete SP-C deficiency had no detectable mutation of *SFTPC*. Of the 10 patients with abnormal pro-SP-C processing, from analysis of broncho-alveolar lavage fluid, two distinct heterozygous *SFTPC* mis-sense mutations were evidenced. The first, g.1286T>C (I73T), inherited de novo, resulted in progressive respiratory failure with intra-alveolar storage of a protein-rich, PAS-positive, material (PAP), and interstitial lung disease. The second, g.2125G>A (R167Q), was found in two PAP patients from the endogamic White settler population of Runion Island in which URD has an unexpectedly high prevalence. Since this mutation was diagnosed in subjects from this subpopulation but without evidence for lung disease, interference of exposures or modifier genes may be proposed. These observations extend the phenotypic spectrum related to *SFTPC* mutation from interstitial lung disease to PAP. Notably, the reported mutations do not appear to be dominant negatives. In-vitro studies are pending to monitor the biosynthesis of the two mutant proteins.

**Primary Ciliary Dyskinesia / Kartagener syndrome: Searching for genes in a highly heterogeneous disorder.** *J.L. Blouin<sup>1</sup>, C. Albrecht<sup>1</sup>, C. Gehrig<sup>1</sup>, G. Duriaux Sail<sup>1</sup>, J.F. Strauss III<sup>2</sup>, L. Bartoloni<sup>1</sup>, C.D. DeLozier Blanchet<sup>1</sup>, S.E. Antonarakis<sup>1</sup>.* 1) Medical Genetics, University Hospitals and School of Medicine, Geneva, Switzerland; 2) University of Pennsylvania, Philadelphia, PA.

Primary Ciliary Dyskinesia (PCD) is an autosomal-recessive disorder with an incidence of 1/20000, characterized by dysmotility of cilium and sperm tail. When respiratory infections and bronchiectasis are associated with situs inversus (50%) the disease is referred to as Kartagener Syndrome (KS). We had shown earlier by linkage analysis an extensive locus heterogeneity in concordance with wide spectrum of axonemal ultrastructural defects. In addition to the loci colocalizing with genes coding for proteins of the dynein arms, defective in 50% of cases, we proposed additional loci (on chromosomes 4q, 19q, 10p, 13q, 15q), which may anchor other PCD genes. To date the genetic causes of PCD/KS have been identified in 10-24% of patients; pathogenic mutations were found in the genes coding for dyneins DNAI1, DNAH5, and DNAH11. In our effort to determine the full spectrum of PCD genes we had screened patients for mutations of other genes DNAH9, HFH4, DNAI2, DNAH3, HP28, DNAL4, DNAL1. In DNAH3, a heterozygous missense substitution (P1197L) was observed in a conserved protein residue, not found in a control population supporting for a pathogenic role of this mutation in PCD. The pathological roles of other missense variants in DNAH9 (P333L), and DNAH3 (A3529D) confirmed as rare polymorphisms remain to be elucidated. We report here a mutation scan in unrelated patients with PCD for three additional reasonable candidate genes. The Sperm Associated Antigen 6 (chr.10p12.2), the human homolog of chlamydomonas PF16 associated with flagellar paralysis, and the Polymerase Lambda (chr.10q24) disrupted in a KO mouse with hydrocephalus, situs inversus and infertility were analysed in a cohort of 54 unrelated patients. The gene for outer arm Beta Heavy Chain DNAH17 was screened in 4 families linked to chr.17q25 where this gene maps. To date, no pathogenic mutations have been found, excluding these genes as major factors of PCD. (Supported by the Swiss National Foundation and the Carvajal foundation of Geneva).

**Analysis of a Fibrillin 1 Pseudoexon and Its Effects on Nonsense Mediated Degradation.** *P.A. Gupta, D.D. Wallis, D. Guo, T. Guidry, V. Tran-Fadulu, D.M. Milewicz.* Dept Internal Medicine, Univ Texas Houston Med Sch, Houston, TX.

Marfan Syndrome (MFS) is an autosomal dominant disorder of the connective tissue. MFS results from mutations in the fibrillin-1 (FBN1) gene. Most mutations are missense mutations, however, there is a significant percentage of mutations that lead to splicing errors. Researchers have predicted that splicing errors might account for ~15% of disease causing mutations. An overwhelming number of these mutations found that lead to alternative splicing result from mutations in the donor or acceptor splice sites, or the branch point, all part of the cis elements that mediate RNA splicing. Conversely, very few reports of pseudoexons have been described. This is the first report to describe the presence of a pseudoexon in FBN1, leading to a milder case of MFS. The pseudoexon results from a creation of a donor splice site in intron 64, leading to the in frame inclusion of a 93 bp fragment of intronic sequence in between exons 63 and 64. The first codon of the pseudoexon is a stop codon. We performed studies that would determine if the pseudoexon with the stop codon initiates nonsense mediated degradation (NMD), a pathway that degrades mRNAs with a premature stop codon (PTC). We believe that NMD reduces the number of mutant alleles, thus reducing the severity of MFS in this family.

**The introduction of exonic splice enhancer elements improves exon inclusion in familial dysautonomia.** *M.M Hims*<sup>1, 2</sup>, *M. Leyne*<sup>1, 2</sup>, *E. Ibrahim*<sup>2</sup>, *J. Mull*<sup>1, 2</sup>, *S.P. Gill*<sup>1, 2</sup>, *R. Reed*<sup>2</sup>, *S.A. Slaugenhaupt*<sup>1, 2</sup>. 1) Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA.

Familial Dysautonomia (FD) is a progressive degenerative disorder of the sensory and autonomic nervous system with a remarkably high carrier frequency of 1 in 30 in the Ashkenazi Jewish (AJ) population. The major FD mutation is a single-base change at base pair 6 of intron 20 (IVS20+6 T>C) in the *IKBKAP* gene. This mutation results in an apparent decrease in splicing efficiency that leads to variable, tissue-specific skipping of exon 20. We have successfully developed an in vivo splicing minigene system that accurately models the aberrant splicing seen in FD. We have generated mammalian expression vector constructs containing *IKBKAP* exon19-ivs19-exon20-ivs20-exon21 for both the wild-type and FD pre-mRNA sequences. These constructs were transfected into HEK 293T cells, RNA extracted and RT-PCR was carried out to determine which spliced species were produced from the minigenes. Sequence analysis of these RT-PCR products reveals that the majority of spliced transcripts from the FD construct are missing exon 20, while the major spliced transcript from the wild-type construct includes exon 20. These results demonstrate that, in vivo, the FD mutation is sufficient to cause increased skipping of exon 20. Examination of the sequence of *IKBKAP* exons shows that exon 20 has weak splice sites and that exon 20 contains few predicted exonic splice enhancer (ESE) elements. We postulate that the low ESE content and weak splice sites of exon 20 are exacerbated by the IVS20+6 T>C mutation which then leads to deleterious exon skipping. Furthermore, we have shown that the introduction of known ESE sequences into exon 20 of the *IKBKAP* minigenes by site directed mutagenesis, can improve the efficiency of exon 20 inclusion and can compensate for the negative effects of the IVS20+6 T>C mutation. These results suggest that the tissue specific exon skipping seen in FD patients may be related to the role of ESEs in enhancing exon 20 inclusion in specific tissues, and that our studies will yield valuable insight into the mechanism of tissue-specific splicing.

**The myotonic dystrophy type 2 (DM2) CCTG expansion does not prevent allele specific *ZNF9* expression.** *J.M. Malikowski<sup>1</sup>, M.L. Moseley<sup>1</sup>, A.K. Mosemiller<sup>1</sup>, D. Jin<sup>1</sup>, B. Schooser<sup>2</sup>, W. Kress<sup>3</sup>, K. Ricker<sup>3</sup>, J.W. Day<sup>1</sup>, L.P.W. Ranum<sup>1</sup>.*  
1) Institute of Human Genetics, University of Minnesota, Minneapolis, MN; 2) Ludwig-Maximilians-University, Germany; 3) University of Wurzburg, Germany.

We recently demonstrated that myotonic dystrophy type 2 is caused by a CCTG expansion in intron 1 of the *zinc finger protein 9 (ZNF9)* gene. Similar to DM1, RNA foci containing the repeat accumulate in nuclei of affected DM2 tissue. DM2 expansions (75-11,000 CCTGs, mean ~20kb) are often much larger than for other expansion disorders. To understand the molecular consequences of the DM2 expansion we performed a series of experiments with haploid and homozygous cell lines to determine the effects of the DM2 expansion on *ZNF9* expression. RT-PCR on chromosome separated mouse-human hybrid cell lines containing a single copy of the normal or expanded (1,000 CCTGs) human DM2 allele indicates that the CCTG expansion does not prevent allele specific splicing. Consistent with normal splicing, RNA in situ hybridization in control and expansion carriers indicates that exon 1 and exon 5 (5' and 3' of the CCTG, respectively) localize primarily to the cytoplasm but not to the CCUG-containing nuclear foci. The identification of a rare patient homozygous for the DM2 expansion has provided an opportunity to examine the effects of very large CCTG expansions (>5000 CCTGs) on *ZNF9* expression without the complications introduced by the expression of the murine homolog or the normal human allele. Northern analysis demonstrates that *ZNF9* is expressed at comparable levels in myoblasts generated from control as well as DM2 patients heterozygous or homozygous for the CCTG expansion. Western analyses of myoblast cell lines using polyclonal antibodies generated against *ZNF9* show comparable levels of *ZNF9* protein in myoblast cell lines from control, heterozygous and homozygous expansion carriers. In summary, even very large DM2 expansions (>5000 CCTGs) do not prevent transcription or splicing of *ZNF9* and do not appear to affect overall *ZNF9* protein levels in homozygous myoblasts. These results are consistent with a model in which CCUG expansions themselves alter cellular function causing DM2.

**Mutations at the RMRP (Cartilage-Hair Hypoplasia) Gene: Haplotyping and Comparative Genomics.** *L. Bonafe*<sup>1</sup>, *E.T. Dermitzakis*<sup>2</sup>, *S.E. Antonarakis*<sup>2</sup>, *A. Superti-Furga*<sup>1</sup>, *A. Reymond*<sup>2</sup>. 1) Division of Molecular Pediatrics, University of Lausanne, Switzerland; 2) Division of Medical Genetics, University of Geneva, Switzerland.

The RMRP gene on chromosome 9 has several unusual features. It is small, with a promoter region of approx. 300 bp and a transcribed intronless region of 267 bp; and its transcript remains untranslated as it associates as an RNA component to the RNase MRP complex. In spite of its small size, we have identified no less than eight SNPs (four within its promoter, three in the transcribed region, one immediately 3'), and we and others have identified over forty different putative pathogenic mutations in individuals with Cartilage-Hair Hypoplasia variants. The putative pathogenic mutations can be divided into two classes: small insertions (6 to 30 bp) around the 5' of the transcribed region; and substitutions, insertions and deletions of single or adjacent nucleotides within the transcribed region. Because no functional assay for RMRP activity is available, and there seem not to be clear genotype-phenotype correlations, assessment of the sequence changes as pathogenic or neutral polymorphisms relies only on segregation within affected families and/or presence in randomly chosen control individuals. To address the significance of sequence changes identified in humans, we compared the sequence of human RMRP against a set of orthologous sequences covering the entire Eutherian tree and an outgroup from the Metatheria (human, monkey, lemur, mouse, porcupine, rabbit, pig, cat, shrew, armadillo, elephant and wallaby). Most putative pathogenic mutations in the transcribed region (27 positions out of 31), but not the polymorphisms (0 position out of 3), affect nucleotides that are strongly conserved. The eight SNPs show linkage disequilibrium and define two main groups that differ by 4 SNPs. No obvious ethnic association could be identified. Both the frequency and the spectrum of sequence changes identified at the RMRP gene are unusual; it is unclear whether this is caused by specific mutational mechanisms and/or by a different selective pressure.

**Functional significance of the carboxy-terminus of the Wilson disease copper-transporting ATPase.** *G. Hsi, L.M. Cullen, D.M. Glerum, D.W. Cox.* Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

Wilson disease (WND) is a disorder of copper transport in which copper accumulates in the liver, brain and kidneys. The defective gene, *ATP7B*, encodes a copper-transporting ATPase, ATP7B. We investigated the significance of the carboxy (C)-terminus of ATP7B with respect to its biosynthetic role in copper delivery to the ferroxidase ceruloplasmin. The C-terminal region has not been extensively analyzed. Its importance for function is unclear as there is not a high prevalence of disease-causing mutations in the C-terminus of ATP7B, with only two missense mutations and one deletion reported in patients. This suggests that either there are only a few critical amino acids in the region necessary for function or sequence changes cause mild disease that remain undiagnosed. We used an assay that exploits the similarities between the yeast and human copper transport systems to assess the functional capabilities of ATP7B variants. The yeast ferroxidase, Fet3p, requires copper from the yeast homologue of ATP7B, Ccc2p, and cannot function in the presence of a nonfunctional Ccc2p; expression of wild-type human *ATP7B* in *ccc2* mutant yeast complements the iron-deficient phenotype. We demonstrated that the C-terminus of ATP7B appears to be necessary for protein stability, as removal of the entire non-membrane terminus leads to reduced protein production and cessation of growth in iron-limited media. However, growth is partially restored when an additional three amino acids are present, and is near wild-type levels when two-thirds of the C-terminus is removed. Measurement of ferroxidase activity is a more sensitive indicator of copper transport function: a deletion of two-thirds of the C-terminus of ATP7B resulted in slight impairment in the ability to deliver copper to Fet3p. Two patient missense mutations exhibited full complementation of the yeast *ccc2* phenotype and thus are not impaired in their ability to transport copper to Fet3p. However, these mutations may still affect ATP7B function as the protein has an additional role within the hepatocyte involving copper trafficking prior to biliary excretion. This aspect can be assessed further in a mammalian cell assay.

**Characterisation of two novel splicing enhancer sequences in the dystrophin gene, located within a LINE1**

**element and involved in XLDC.** *P. Rimessi<sup>1</sup>, F. Gualandi<sup>1</sup>, T. Patarnello<sup>2</sup>, F. Muntoni<sup>3</sup>, E. Calzolari<sup>1</sup>, G.*

*D'Agostaro<sup>1</sup>, A. Ferlini<sup>1</sup>.* 1) Section of Medical Genetics, University of Ferrara, Ferrara, Italy; 2) Dipartimento di Biologia, University of Padova (Italy); 3) Department of Paediatrics, Hammersmith Hospital Campus, Imperial College, London (UK).

Splicing mutations are responsible for the 15% of human genetic diseases and are often regulated in a tissue/cell-specific manner. A relevant category of sequences required for both constitutive and alternative splicing are splicing enhancers. These RNA motifs are located within exons or introns and participate to the exon definition process. SR proteins, a family of essential splicing factors, are recruited directly to the RNA by the enhancer elements or indirectly by interactions with other general splicing factors. Mobile elements, accounting for at least 40% of the human introns, include LINE and Alu sequences which are known to generate protein diversity by using different mechanisms as 3 transduction and exon shuffling. We identified and functionally characterised two purine-rich regions located within dystrophin intron 11 and involved in splicing regulation. The role of these motifs was highlighted by an intronic dystrophin mutation causing X-linked dilated cardiomyopathy (XLDC) and determining the tissue-specific incorporation of an aberrant exon into the dystrophin transcript. These two motifs, as well as the 5 cryptic splice site used by the aberrant exon in the XLDC family, are contained within an atypical L1 5 region. The first splicing sequence occurs within the aberrant XLDC exon while the second one is localised within its 3 intron. These sequences behave in vitro as splicing enhancers because their deletion strongly interferes with the aberrant dystrophin exon inclusion. Our results suggest that these motifs might be involved in the pathogenesis of the XLDC in this family. RNA electrophoresis mobility shift assays (REMSA) demonstrate that the enhancer sequences interact with proteins in HeLa nuclear extracts. We are currently identifying the specific SR protein(s) binding the splicing motifs identified. Acknowledgement The EU FINGER and the Telethon-Italy grants are acknowledged.

**Spinocerebellar ataxia type 10 ATTCT pentanucleotide repeat expansions in multiple Brazilian families.** *P.*

*Fang<sup>1</sup>, H.A.G. Teive<sup>2</sup>, I. Alonso<sup>3</sup>, L. Jardim<sup>4</sup>, J. Sequeiros<sup>3</sup>, I. Silveira<sup>3</sup>, S. Raskin<sup>5</sup>, E. Schmitt<sup>1</sup>, P.A. Ward<sup>1</sup>, T. Matsuura<sup>1</sup>, T. Ashizawa<sup>6</sup>, B.B. Roa<sup>1</sup>.* 1) Dept Molec Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Medicine, Federal Univ Parana, Brazil; 3) UnIGENE, IBMC, Univ of Porto, Portugal; 4) Dept Medical Genetics, Hospital de Clinicas, Porto Alegre, Brazil; 5) Laboratorio Genetika, Brazil; 6) Dept Neurology, The University of Texas Medical Branch, Galveston, TX.

Spinocerebellar ataxia type 10 (SCA10) is an autosomal dominant neurogenetic disorder characterized by cerebellar ataxia and seizures. SCA10 is associated with a non-coding ATTCT pentanucleotide repeat expansion in the SCA10 gene, with a normal range of 10-22 repeats, and expansion mutations ranging in the hundreds to thousands of repeats. SCA10 was previously reported primarily in ataxia patients of Mexican ancestry. Our molecular studies have identified SCA10 expansions in a total of eight unrelated families of Brazilian ancestry. Affected individuals from six unrelated Brazilian kindreds were referred for clinical testing at the Baylor DNA Diagnostic laboratory. SCA10 expansion mutations were identified in these SCA10 patients, ranging from ~1600 to ~2300 repeats determined by Southern analysis. The clinical findings in these patients include progressive gait ataxia, abnormal cerebellar signs and nystagmus. Seizures were not observed in these Brazilian patients, in contrast to previous reports on Mexican SCA10 patients. One Brazilian family was documented to exhibit anticipation through maternal transmission, wherein the mother had an expanded allele of ~1600 repeats and a reported age of onset ~40 years, while her affected child had ~1900 repeats and an earlier onset at ~30 years of age. In addition, two other Brazilian families tested positive for SCA10 expansions using modified PCR-based methods. Patients from these families also showed symptoms of progressive cerebellar ataxia without seizures. Our collective molecular studies on hundreds of ataxia patients in North America and Portugal indicate that SCA10 is a rare form of hereditary ataxia, with a significant incidence that appears to be limited to the Mexican and Brazilian populations.

**Mosaicism for *FMR1* gene full mutation and deletion in a fragile X female.** *H. Fan*<sup>1</sup>, *J.K. Booker*<sup>1</sup>, *S.E. McCandless*<sup>1</sup>, *V. Shashi*<sup>2</sup>, *R.A. Farber*<sup>1</sup>. 1) University of North Carolina, Chapel Hill, NC; 2) Wake Forest University School of Medicine, Winston-Salem, NC.

Most cases of fragile X syndrome result from expansion of CGG repeats in the *FMR1* gene; deletions and point mutations of *FMR1* are much less common. Mosaicism of an *FMR1* full mutation with a deletion or with a normal allele has been reported in fragile X males. Here we report on a fragile X female who is mosaic for an *FMR1* full mutation and an intragenic deletion. The patient is a 3-year-old girl with developmental delay, autistic-like behaviors and significant speech and language abnormalities. The *FMR1* trinucleotide repeat mutation was analyzed by Southern blotting of peripheral blood DNA digested with EcoR I and Eag I, using a <sup>32</sup>P-labeled StB 12.3 probe. The autoradiograph demonstrated the presence of a methylated full mutation at 6.4 kb (expansion to about 440 repeats), a normal female allele in methylated (5.2 kb) and unmethylated (2.8 kb) forms, and an additional fragment at 5.0 kb. This result indicates that the patient is mosaic for a full mutation and a deletion, in the presence of a normal allele. The extent of the deletion was determined by PCR amplification and sequencing of the DNA flanking the breakpoint. As expected, the normal allele and deletion allele amplified, but the expanded allele did not. We mapped the 5' breakpoint 63/65 bp upstream from the CGG repeat region and the 3' breakpoint 86/88 bp downstream of the CGG repeats within the *FMR1* gene. (The exact breakpoints cannot be determined because of the presence of a GG sequence at both ends of the deletion.) The deletion removed 210 bp, including the entire CGG repeat region. The full mutation was presumably inherited from a premutation or full mutation in the patient's mother (studies pending). The deletion, which remained methylated at the Eag I site, was probably derived from the full mutation allele. Mosaicism of this type is rare in females with a fragile X mutation, but should be kept in mind in interpretation of Southern blots. In this case, the deletion does not appear to affect the phenotype of the patient.

**Polyglutamine expansions induce irreversible chromatin remodelling and alteration of photoreceptors maintenance in SCA7 and HD transgenic mice.** *D. Devys<sup>1</sup>, D. Helmlinger<sup>1</sup>, G. Abou-Sleymane<sup>1</sup>, G. Yvert<sup>1</sup>, Y. Trottier<sup>1</sup>, S. Picaud<sup>2</sup>, J.L. Mandel<sup>1</sup>.* 1) Molecular Pathology, IGBMC, Illkirch, France; 2) INSERM EMI-99-18, Paris, France.

Spinocerebellar ataxia type 7 (SCA7) and Huntingtons disease (HD) belong to a group of nine inherited progressive neurodegenerative diseases caused by a CAG/polyglutamine (polyQ) expansion and characterized by continuous accumulation of mutant protein. Although retinal degeneration is only observed in SCA7, we described a retinal phenotype in an HD mouse model comparable to that found in our SCA7 transgenic mice. In SCA7 mice, mutant ataxin-7 is expressed exclusively in photoreceptors and induces a progressive and long-lasting retinal dysfunction but a delayed and limited cell loss, even in 2.5 years old mice. We also observed that rod photoreceptor chromatin structure was dramatically altered leading to a strong downregulation of rhodopsin and other genes coding for proteins of the phototransduction pathway. Mutant ataxin-7 transgene which expression is driven by rhodopsin promoter was also early and dramatically downregulated. Surprisingly, mutant ataxin-7 extinction contrasted with a constant worsening of the retinal phenotype leading to a complete loss of photoreceptor activity. A previous study reported that abolishing mutant huntingtin expression reversed neurological phenotype in an inducible HD mouse model. We demonstrate here that retinopathy progression in SCA7 mice is not dependent upon continuous expression of mutant ataxin-7, raising the possibility that polyQ induced neuronal dysfunction may be irreversible.

**Polyglutamine aggregation impairs nuclear export of huntingtin.** *J.C. Cornett<sup>1, 2</sup>, S.H. Li<sup>1</sup>, X.J. Li<sup>1</sup>*. 1) Dept Human Genetics, Emory University, Atlanta, GA; 2) Graduate Program in Genetics and Molecular Biology.

Huntingtons disease (HD) is one of at least nine distinct neurological diseases caused by expanded polyglutamine repeats in the disease proteins. Nuclear accumulation and aggregation of polyglutamine proteins are common features of these diseases, suggesting a close link between nuclear localization and toxicity. In HD, N-terminal huntingtin fragments accumulate in the nucleus and form inclusions whereas full-length huntingtin is predominantly localized in the cytoplasm. Lack of conserved nuclear import or export sequences in N-terminal htt suggests that small N-terminal huntingtin may passively shuttle into and out of the nucleus. We treated huntingtin exon 1 stably-transfected HEK293 and PC12 cells with Leptomycin B (LMB), a nuclear export inhibitor. In both cell lines LMB treatment led to an increase in nuclear huntingtin. LMB had no effect on the distribution of full-length huntingtin in stably-transfected HEK293 cells. This suggests that N-terminal huntingtin shuttles into and out of the nucleus such that inhibition of nuclear export can increase its concentration in the nucleus. To investigate whether the nuclear accumulation of N-terminal huntingtin is dependent on Ran GTPase, which is found to be critical for the nuclear export of certain types of RNAs and molecules, we transfected huntingtin exon 1 containing 23Q or 120Q into tsBN2 cells. These cells have a temperature sensitive mutation resulting in the suppression of Ran-dependent nuclear transport at the non-permissive temperature. The nuclear distribution of transfected huntingtin was not altered from the permissive temperature to the non-permissive temperature. Thus, huntingtin's nuclear accumulation is unlikely dependent on Ran. Transfected NLS-tagged huntingtin exon 1 with 120Q was present as soluble and aggregated proteins in the nucleus. When shifted to the non-permissive temperature, the soluble pool of mutant huntingtin became diffuse in the cytoplasm while aggregated huntingtin remained in the nucleus. This result suggests that soluble huntingtin may be exported from the nucleus via an unknown mechanism but polyglutamine aggregation impairs the nuclear export of huntingtin.

**Genetic study of Portuguese patients with a Huntington disease-like phenotype.** *M.C. Costa<sup>1,2</sup>, M. Constante Pereira<sup>1</sup>, P. Magalhães<sup>1</sup>, M.T. Matamá<sup>1</sup>, F. Ferreirinha<sup>1</sup>, J. Cerqueira<sup>1</sup>, M.M. Santos<sup>1,3</sup>, J. Sequeiros<sup>1,4</sup>, P. Maciel<sup>1,2,4</sup>.*  
1) UnIGENE, IBMC, Univ. Porto, Portugal; 2) Life and Health Sciences Research Institute, School of Health Sciences, Univ. Minho, Portugal; 3) Department of Medicine, CHUM, Hôpital Notre-Dame, Univ. Montréal, Canada; 4) Department of Populations Studies, ICBAS, Univ. Porto, Portugal.

Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder characterised by involuntary choreiform movements, cognitive impairment, dementia and personality changes. A few patients are known with a similar clinical presentation but no expansion of the CAG repeat on the *HD* gene (Huntington disease-like, or HD-L). We now report a group of 95 Portuguese patients with a HD-L phenotype, including 47 with typical and 48 with unusual HD symptoms (36 presented only the movement disorder, while 12 had only psychiatric symptoms). Overall mean age at onset was 46.2±9.9 years (range, 3-83). Given that SCA17 and DRPLA share some of the clinical features with HD, their causative genes, encoding for TATA-binding protein (*TBP*) and atrophin-1 (*DRPLA*), were also screened for repeat expansions. These HD-L patients were then screened for repeat expansions on the genes *HDL1* and *HDL2* genes encoding, respectively, for junctophilin-3 and prion protein. In addition, because of some clinical overlap, namely of the movement disorder, between HD and neuroferritinopathy, the adenine insertion (460-461InsA) on the *FTL* gene, which encodes for ferritin light polypeptide, was also screened in all HD-L patients; the entire *FTL* gene was sequenced for those patients presenting only movement incoordination (n=30). Expansions on the repetitive tracts of the *HDL1*, *HDL2*, *TBP* and *DRPLA* genes, as well as the 460-461InsA on the *FTL* gene, were excluded in all patients; also, no other mutations were found on the *FTL* gene for the patients studied. None of the genes that should be included in the differential diagnosis of HD was responsible for the disease on our series. Further investigation on the genetic heterogeneity of HD-L is still needed.

**Intranuclear neuronal inclusions in two female carriers of the fragile X premutation.** *C.M. Greco<sup>1</sup>, F. Tassone<sup>2</sup>, S. Jaquemont<sup>3</sup>, R.J. Hagerman<sup>3</sup>, P.K. Sahota<sup>2</sup>, A. Delacourte<sup>4</sup>, C.A. Maurage<sup>4</sup>, P.J. Hagerman<sup>2</sup>.* 1) Department of Pathology, University of California at Davis, Sacramento, CA; 2) Department of Biological Chemistry, UC Davis, Davis, CA; 3) MIND Institute, University of California Davis Medical Center, Sacramento, CA; 4) Service d'Anatomie et Cytologie Pathologique, CHU, Lille.

Premutation alleles of the fragile X mental retardation 1 (FMR1) gene (55 to 200 CGG repeats) have been found to cause a neurodegenerative disorder, fragile X-associated tremor/ataxia syndrome (FXTAS), in some males over 50 yr. The major clinical features of FXTAS are progressive intention tremor and/or cerebellar gait ataxia, dementia, parkinsonism, autonomic dysfunction, and peripheral neuropathy. Here, we report the first cases of female carriers of the fragile X premutation presenting with neurological symptoms and neuronal intranuclear inclusions. Case 1 (80 CGG repeats, AR 0.3) experienced her first symptoms at the age of 56 years with expressive and receptive aphasia. She subsequently developed hyperphagia, incontinence, progressive frontotemporal symptoms, hallucinations, and swallowing difficulties. She expired at 66 years. Neurohistological analysis showed ubiquitin positive intraneuronal and astrocytic inclusions, similar to those previously described in male carriers of the fragile X premutation. Additionally, histologic features diagnostic of Alzheimers disease were present. Case 2 (87 CGG repeats, AR 0.6) had mild tremor for the last 3 years and ataxia for the last year prior to her death. She did not have any significant cognitive deficit (FSIQ was 100). Preliminary results of histologic examination of the brain show intranuclear inclusions in neurons and astrocytes without other significant pathology. We also analyzed brain tissue from an asymptomatic female premutation carrier who died at the age of 76 of uterine cancer. Brain gross examination and neurohistological analysis did not show any abnormalities. Her CGG repeats were 30, 70 with an AR of 0.8. These findings suggest that FXTAS is a neurodegenerative syndrome that can be observed not only in premutation males but also rarely in female premutation carriers.

**Expanded Ataxin-3 Enhances Staurosporine-Induced Neuronal Cell Death and Decreases bcl-2 Expression.** *M. Hsieh*<sup>1,2</sup>, *H.-F. Tsai*<sup>3,4</sup>, *S.-Y. Li*<sup>5</sup>. 1) Dept Life Sci, TungHai Univ, Taichung, Taiwan; 2) Life Science Research Center, TungHai Univ, Taichung, Taiwan; 3) Institute of Medicine, Chung Shan Med Univ, Taichung, Taiwan; 4) School of Medical Technology, Chung Shan Med Univ, Taichung, Taiwan; 5) Dept Life Sci, Chung Shan Med Univ, Taichung, Taiwan.

Machado-Joseph disease (MJD) is an autosomal dominant spinocerebellar degeneration characterized by a wide range of clinical manifestations. Unstable CAG trinucleotide repeat expansion in MJD gene on long arm of chromosome 14 has been identified as the pathologic mutation of MJD. Apoptosis was previously shown to lead to neural cell death of the disease. In this study, we utilized human neuroblastoma SK-N-SH cells stably transfected with HA-tagged full-length MJD with 78 polyglutamine repeats to examine the effects of polyglutamine expansion on neuronal cell survival under different apoptotic stress. Various pro-apoptotic agents were used to assess the tolerance of the mutant cells and to compare the differences between cells with and without mutant ataxin-3. Concentration and time course experiments showed that the increase in staurosporine-induced cell death was more pronounced and accelerated in cells containing expanded ataxin-3 via MTS assays. Microscopic observations also demonstrated that cells expressing expanded ataxin-3 were more sensitive to staurosporine-induced apoptosis. Interestingly, under basal conditions, Western blot and immunocytochemical analysis showed a significant decrease of Bcl-2 protein expression in cells containing expanded ataxin-3 when compared with that of the parental cells. However, the protein levels of Bax and Bcl-xL were not significantly altered. These results indicated that expanded ataxin-3 that leads to neurodegenerative disorder significantly impaired the expression of Bcl-2 protein, which may be responsible, at least in part, for the weak tolerance to apoptotic stress and ultimately resulted in an increase stress-induced cell death upon stress.

**Consequences of polyglutamine and polyalanine expansions in the context of the protein Ataxin7.** *M. Latouche<sup>1</sup>, P. Fragner<sup>1</sup>, K.H. El Hachimi<sup>2</sup>, E. Martin<sup>1</sup>, A. Sittler<sup>1</sup>, A. Brice<sup>1</sup>, G. Stevanin<sup>1</sup>.* 1) INSERM-U289-NEB, Paris, France; 2) INSERM U106, Paris, France.

Spinocerebellar ataxia type 7 (SCA7) is caused by polyglutamine (polyQ) expansions in Ataxin7. PolyQ diseases are characterized by the presence of intranuclear inclusions (NIIs) due to the inherent ability of polyQ-mutated proteins to aggregate. To determine the role of the nature of the repeated amino acid vs the protein context and the role of aggregation in the pathological process, we produced and compared cellular models with polyalanine (Ataxin7-90A) and polyQ expansions (Ataxin7-100Q). Ataxin7-90A and Ataxin7-100Q were transiently expressed in HEK293 cells and in primary cultures of rat embryonic mesencephalic neurons. In both cases (Ataxin7-90A and -100Q) the formation of nuclear and perinuclear aggregates was observed. In addition, the presence of chaperones and components of the Ubiquitin-Proteasome system in these NIIs points to an abnormal folding of the expanded proteins. However, the aggregates formed by Ataxin7-90A, as visualized using optic microscopy, are morphologically distinct from the Ataxin7-100Q NIIs. Furthermore, at the ultrastructural level, amorphous deposits of Ataxin7-90A, but no fibrillar inclusions as observed with Ataxin7-100Q, were detected. Finally, Ataxin7-90A was more toxic than Ataxin7-100Q in primary cultures of mesencephalic neurons.

**Expression of expanded polyglutamine protein induces behavioral changes in *Drosophila*.** *S.M. Shin*<sup>1,2</sup>, *Y.T. Kim*<sup>2</sup>, *W.Y. Lee*<sup>3</sup>, *G.M. Kim*<sup>3</sup>, *D.K. Spinocerebellar ataxia type-3 or Machado-Joseph disease (SCA3/MJD) is an autosomal dominant neurodegenerative disease caused by triplet nucleotide expansion. The expansion of the polyglutamine tract near the C-terminus of the *MJD1* gene product, ataxin-3, above a threshold of 40 glutamine repeats causes neuronal loss and degeneration. The expanded ataxin-3 forms aggregates, and nuclear inclusions (NIs), within neurons, possibly due to the misfolding of mutant proteins.

Here we report upon the behavioral test changes related to truncated and expanded forms of MJD protein (MJDtr) in *Drosophila*, and show that expanded MJDtr, when expressed in the nervous system causes characteristic locomotor dysfunction and anosmia. This phenomenon has not been previously reported in transgenic *Drosophila* models. In addition, *in vivo* expression of anti-apoptotic gene *bcl-2* showed no evidence of ameliorating the deleterious effect of MJDtr-Q78s, either in the eye or the in the nervous system. The study shows that such transgenic *Drosophila* models express ataxic behavior as observed in human patients.

Program Nr: 2456 from 2003 ASHG Annual Meeting

**The FMR1 premutation and spinocerebellar ataxia.** *K. Storm, F. Kooy, N. Peeters, M. Van den Bergh, L. Vits.*  
Medical Genetics, University of Antwerp, Antwerp, Belgium.

**Background:** Recent studies report the clinical involvement of the fragile X (FMR1) premutation in male carriers affected by a characteristic late-onset syndrome involving progressive action tremor with ataxia, cognitive decline and generalized brain atrophy, also called fragile X-associated tremor/ataxia syndrome or FXTAS. The symptoms of FXTAS may be confused with those of spinocerebellar ataxia. **Objective:** To explore the relative frequency of FMR1 premutations among familial and sporadic spinocerebellar ataxias, a cohort of 97 male patients with neurodegenerative disorders referred for genetic analysis of the spinocerebellar ataxia genes and found to be negative for the SCA1, 2, 3, 6 and 7 mutations were analyzed by PCR amplification / Southern blot to determine the CGG-repeat size in the FMR1 gene. **Results:** FMR1 premutations were not detected in any of the cases investigated so far. The largest allele found contains 48 repeats, a finding within the non-pathogenic range (< 200 CGG-repeats). **Conclusion:** These preliminary results indicate that the FMR1 premutation may only be a rare cause of spinocerebellar degeneration. Additional studies of larger cohorts of SCA-negative patients are required to ascertain the relative frequency of FMR1 premutations and also to determine the boundaries of the CGG-repeat expansion associated with this disorder. Studies may be extended to patients with parkinsonian signs.

Program Nr: 2457 from 2003 ASHG Annual Meeting

**Probable mechanism of trinucleotide repeat expansion in a patient with SCA17.** *A. Shatunov, F. Pagan, E. Fridman, J. Leib, M. Hallett, L. Goldfarb.* National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, US.

Expansion of glutamine coding repeats in at least nine genes causes well defined neurodegenerative disorders, including Huntingtons disease and Spinocerebellar ataxias. Polyglutamine expansion in the TATA-box-binding protein (TBP) has recently been associated with SCA17. We observed a sporadic case of prominent ataxia and progressive intellectual decline in a young American woman with disease onset at age 19. The patient showed 55 triplet repeats in the TBP gene and was diagnosed with SCA17. The patients unaffected parents have normal length alleles. The expansion in the TBP gene differs from other genes by the presence of multiple CAG and CAA triplets organized in recognizable blocks and therefore allowing structural analysis. The patients expanded repeat area is composed of the paternal full-length repeat region in tandem with a downstream part of the paternal second repeat allele. The patients normal allele has a distinct sequence coming from the mother. Our data based on haplotype and sequence analyses of the TBP gene region in the patient and her parents suggest that the patients father is germ-line mosaic, and unequal crossover is a likely mechanism by which the pathogenic allele was generated.

**Intranuclear inclusions in fragile X-associated tremor/ataxia syndrome neuronal cells from five premutation carriers.** *F. Tassone*<sup>1</sup>, *R.J. Hagerman*<sup>2,3</sup>, *D. Garcia*<sup>1</sup>, *P.K. Sahota*<sup>1</sup>, *E.W. Khandjian*<sup>4</sup>, *C.M. Greco*<sup>5</sup>, *P.J. Hagerman*<sup>1</sup>. 1) Dept Biological Chemistry, Univ California, Davis, Davis, CA. Department of Biological chemistry, School of Medicine, UC Davis, Davis, CA; 2) MIND Institute, University of California Davis Medical center, Sacramento, CA; 3) Department of Pediatrics, University of California Davis Medical Center, Sacramento, CA; 4) Department of Medical Biology, Laval University, Quebec, Canada; 5) Department of Pathology, University of California Medical Center, Sacramento, CA.

A neurodegenerative disorder, fragile X-associated tremor/ataxia syndrome (FXTAS) has recently been described in a subgroup of adult male carriers of the fragile X mental retardation 1 (FMR1) premutation (55 to 200 CGG repeats). Clinical involvement is associated with the presence of eosinophilic intranuclear inclusions in neuronal and astroglial cells throughout the brain. To investigate the possibility that larger (full mutation) expansions may be present in the cells that harbor the inclusions in brain (neural mosaicism) we have performed detailed post-mortem neuropathological and molecular analysis of multiple regions throughout the brain of five male carriers of premutation alleles, who had presented with neurological symptoms consistent with FXTAS prior to death. DNA genotype analysis revealed a lack of any inter-region allelic size heterogeneity; premutation alleles of the same CGG repeat number were present in all brain regions examined and were also identical to the allele size present in peripheral blood. Neuropathology studies revealed the presence of intranuclear inclusions in both neurons and astrocytes, and cerebellar neurodegeneration that included Purkinje cell loss and axonal swelling in all five premutation carriers. This study establishes that brain tissues with premutation alleles are subject to a specific, fragile X-associated neuropathology that includes neuronal intranuclear inclusion formation, and excludes the possibility that cryptic, full mutation alleles are responsible for either inclusion formation or FXTAS.

**Small-pool PCR analysis of premutation alleles at the *FRDA* (frataxin) locus.** *R. Sharma*<sup>1</sup>, *M. Gomez*<sup>1</sup>, *S. Shah*<sup>1</sup>, *M. Delatycki*<sup>2</sup>, *L. Pianese*<sup>3</sup>, *A. Monticelli*<sup>4</sup>, *B. Keats*<sup>5</sup>, *S.I. Bidichandani*<sup>1</sup>. 1) Dept Biochem & Molec Biol, Oklahoma Univ Health Sci, Oklahoma City, OK; 2) Murdoch Institute, Australia; 3) BIOGEM, Italy; 4) IEOS CNR-DBPCM, Naples, Italy; 5) Genetics, LSU Medical Center, LA.

Friedreich ataxia is caused by abnormal expansions of a GAA triplet-repeat sequence in intron 1 of the *FRDA* gene. This repeat is highly polymorphic; normal alleles contain 5-30 triplets and disease-causing alleles contain 100-1700 triplet-repeats. Rare alleles with 30-100 triplet-repeats, termed premutations, do not normally cause disease, but may expand into the pathogenic range when transmitted from parent to child. It is not known at what stage hyperexpansion of premutation alleles occurs, i.e., does it occur in mitotic division of pre-germ cells, during meiosis, or in post-fertilization mitotic division? We decided to analyze premutation alleles by SP-PCR of peripheral blood leukocytes in order to investigate if expansion occurs during mitotic division. We analyzed a total of 4581 individual DNA molecules from carriers of seven alleles ranging in size from 30-105 triplet-repeats. While the GAA-30 and GAA-39 alleles were stable, alleles containing 66-105 were somatically unstable. The average mutation load was 12.1% with 8.5% contractions and 3.6% expansions. Our previous demonstration of instability in an allele with 44 triplet-repeats means that the threshold length for the initiation of somatic instability at the *FRDA* locus is between 40 and 44 triplets, which is approximately the size of a eukaryotic Okazaki fragment. Contrary to the expansions seen in parental transmissions, these alleles showed only small slippage type events, with a paradoxical bias towards contractions. In fact, the GAA-39 allele, which was stable in our SP-PCR assay, underwent hyperexpansion in two parent-to-child transmissions. These data demonstrate that the process of hyperexpansion is unlikely to occur during mitotic division of somatic cells. Furthermore, the fact that the threshold length for the initiation of instability corresponds to the size of a eukaryotic Okazaki fragment suggests that somatic instability may stem from errors in lagging strand synthesis.

**Nuclear localization of polyglutamine-expanded Androgen Receptor is not required for Transglutaminase-potentiated proteasome dysfunction.** *T.C. Scanlon<sup>1,2</sup>, L.K. Beitel<sup>1,3</sup>, B. Gottlieb<sup>1</sup>, M.A. Trifiro<sup>1,2,3</sup>.* 1) Lady Davis Institute, Montreal, Quebec, H3T 1E2, Canada; 2) Department of Human Genetics, McGill University, Montreal, Quebec H3A 1B1, Canada; 3) Department of Medicine, McGill University, Montreal, Quebec H3A 1B1, Canada.

The polyglutamine (polyQ) expansion in the Androgen Receptor (AR) has been shown to be the molecular insult responsible for Spinal Bulbar Muscular Atrophy (SBMA). PolyQ-expanded tracts could act as good glutamyl donors in reactions catalyzed by Transglutaminase(TG). TG-mediated isopeptide bonds are proteolytically resistant, and may thus cause malfunction of the ubiquitin-proteasome protein degradation pathway.

To test this hypothesis, we have utilized HEK 293 cells stably transfected with a GFPu plasmid: Green Fluorescent Protein fused to an amino acid sequence known to target a protein to the proteasome. Proteasomal malfunction results in accumulation of GFP, and can be monitored by fluorescence detection. We have previously shown that proteasomal dysfunction caused by transient-co-transfection of polyQ-expanded AR and TG occurs androgen-dependently. It has been hypothesized that androgen-induced nuclear localization of the AR is responsible for the observed androgen-dependence of SBMA animal models. Transfection studies are underway to test this hypothesis, employing ARs in which the nuclear localization sequence has been deleted by removing amino acids 628-640 (NLS). These constructs do not enter the nucleus upon androgen introduction. Preliminary results may indicate transfection of polyQ-expanded NLS mutants, but not normal tract-length receptors cause proteasomal dysfunction. In addition, formation of protein aggregates is observed in cells which do not exhibit proteasomal dysfunction. Therefore nuclear localization is not critical, and androgens may induce a conformational change rendering the polyQ-expanded AR a better substrate for TG isopeptide bond formation, resulting in proteasomal dysfunction. In addition, formation of cytoplasmic protein aggregates does not contribute to proteasomal dysfunction.

**A dominant form of congenital stationary night blindness (adCSNB) in a large Chinese family: Exclusion of five known point mutations in three genes as the cause of the disorder.** *S.-H. Chen<sup>1</sup>, S. Zhuang<sup>2</sup>, S. Hu<sup>2</sup>, X. Liu<sup>3</sup>, B. Lin<sup>3</sup>, W. Wu<sup>3</sup>.* 1) Department of Pediatrics, University of Washington and Molecular Diagnostic Lab, Children's Hosp/Reg Med Ctr, Seattle, WA; 2) Hangzhou Hua-Da Genomic Center, Hangzhou, Zhejiang, P.R. China; 3) The School of Optometry and Ophthalmology, Wenzhou Medical College, Wenzhou, Zhejiang, P.R. China.

Congenital stationary night blindness (CSNB) is a group of eye disorders characterized by absence, or severe deficiency of night vision under dim illumination and is non-progressive in nature. Affected patients have been identified with autosomal dominant, autosomal recessive and X-linked forms of the disease. We have studied a large Chinese family with CSNB. The disorder has been continuously transmitted through at least 12 generations with over 40 known affected individuals. Based on the pattern of inheritance, the mode of inheritance is an autosomal dominant form (ad) of CSNB. We have obtained electroretinograms (ERG) from three patients and two normal individuals in this family. The ERG data revealed that the patients had diminished rod isolated responses in b-wave (10-20% of normal amplitude) to dim scotopic light (<1 cd/m<sup>2</sup>/s) under dark adaptation, and a decrease (~50% of normal amplitude) of a-wave and b-wave responses to bright light (24 cd/m<sup>2</sup>/s) stimulation following dark adaptation. Cone responses to single bright flash under light adaptation were normal. Cone responses to 30-Hz flicker had normal amplitude in the patients. The ERG data are consistent with the diagnosis of adCSNB. Five known point mutations in three different genes (rhodopsin, beta-cGMP phosphodiesterase and alpha-transducin) have been identified to be responsible for adCSNB in other (Caucasian) populations. We have amplified and sequenced exons containing the five known mutation sites of 16 affected and 14 unaffected individuals in this family. No mutation was found in any affected individuals. We conclude that the mutation causing the defect in this family must reside in another site or gene and thus is different from the ones found in Caucasian population.

**A Novel Compound Heterozygous Mutation in the Cellular Retinaldehyde-Binding Protein Gene (*RLBPI*) in a Patient With Retinitis Punctata Albescens.** *F.Y. Demirci*<sup>1</sup>, *B.W. Rigatti*<sup>1</sup>, *T.S. Mah*<sup>1, 2</sup>, *M.B. Gorin*<sup>1, 2</sup>. 1) Dept. of Ophthalmology, SOM, Univ. of Pittsburgh, Pgh, PA; 2) Dept. of Human Genetics, GSPH, Univ. of Pittsburgh, Pgh, PA.

Mutations in the gene (*RLBPI*) encoding the cellular retinaldehyde-binding protein (CRALBP) cause retinal dystrophy, variously termed as autosomal recessive retinitis pigmentosa, retinitis punctata albescens (RPA), Bothnia dystrophy, and Newfoundland rod-cone dystrophy. Recessive mutations in *RLBPI* (chr 15q26) seem to be an uncommon cause of retinal degeneration and only six CRALBP disease-causing mutations have been reported to date. The human CRALBP contains 316 amino acid residues (the initial Met is not present in the final protein) and functional studies suggest that ligand interactions are localized to C-terminal residues (120-313). A male patient presented with a clinical phenotype suggestive of RPA, characterized by numerous fine yellow-white dots in the retina. Using direct PCR sequencing, we screened the coding exons of *RLBPI* (exons 2-8) for mutations in genomic DNA sample obtained from this patient. We identified a novel compound heterozygous missense mutation of Gly145Asp (exon 5) and Ile200Thr (exon 6) in the *RLBPI* gene. Subsequent analysis of DNA samples obtained from his parents demonstrated that the two sequence alterations observed in proband's DNA were located on different alleles (each parent transmitted one alteration) and therefore both copies of the gene were altered (consistent with recessive disease). Analysis of 100 control chromosomes from normal subjects revealed no individuals with these sequence alterations. The *RLBPI* mutations identified in this study are likely to be pathogenic, based upon the prediction that these changes would have major effects on the protein by affecting the C-terminal domain, the variants were not found among normal controls, and they alter the evolutionary conserved residues among human, bovine, and mouse CRALBP orthologues. Identification of these novel mutations add to our understanding of the functional properties of CRALBP and the molecular basis of the retinal pathology associated with *RLBPI* defects.

**Evidence of autosomal dominant Leber congenital amaurosis (LCA) underlain by a CRX heterozygote null allele.**

*I. Perrault<sup>1</sup>, S. Hanein<sup>1</sup>, S. Gerber<sup>1</sup>, F. Barbet<sup>1</sup>, J.-L. Dufier<sup>2</sup>, A. Munnich<sup>1</sup>, J.-M. Rozet<sup>1</sup>, J. Kaplan<sup>1</sup>.* 1) Unité de recherches sur les Handicaps Génétiques de l'Enfant, INSERM U393, Hôpital des Enfants malades, Paris, France; 2) Service d'Ophtalmologie, Hôpital des Enfants Malades, Paris, France.

Leber congenital amaurosis (LCA) is characterized by a congenital blindness or greatly impaired vision in the first months of life. Hitherto, LCA was considered as an autosomal recessive genetically heterogeneous condition. Yet, the identification of de novo mutations in one LCA gene, CRX, opened the debate of a possible dominant inheritance in some LCA cases. Here, we report the transmission through two generations of an unambiguous LCA phenotype, accounted for by a heterozygote 1 bp deletion of the CRX gene, suggesting dominant inheritance of LCA in this pedigree. Considering the parental consanguinity of the index case in this family, the hypotheses of digenism or modifying effect of an other gene were very unlikely, supporting the view that in rare cases, LCA could be inherited as an autosomal dominant trait.

Program Nr: 2464 from 2003 ASHG Annual Meeting

**A *CRYGD* mutation associated with autosomal dominant cataract linked to chromosome 2q.** A. Shiels, D. Mackay. Ophthalmology/Visual Sciences, Washington Univ Sch Medicine, St Louis, MO.

Non-syndromic Mendelian cataract is a clinically and genetically heterogeneous lens disorder that most frequently presents as a sight-threatening autosomal dominant trait in childhood. Here we have mapped a locus for a dominant form of coral-like cataract to the gamma-crystallin gene (*CRYG*) cluster on chromosome 2q32-q36. Linkage analysis gave significantly positive two-point LOD scores ( $Z$ ) at markers D2S371 ( $Z = 3.81$ , recombination fraction [ $\theta$ ] = 0) and D2S369 ( $Z = 3.64$ ,  $\theta = 0$ ). Haplotype analysis indicated that the disease gene lay in the ~15 cM genetic interval between D2S1384 and D2S2248. Sequencing analysis of the *CRYG* cluster in an affected member of the pedigree failed to detect any significant nucleotide changes in the coding exons of *CRYGA*, *CRYGB* or *CRYGC*, however, we identified a heterozygous CA transversion in exon 2 of *CRYGD* that was predicted to result in the non-conservative, missense substitution of threonine for proline. Allele-specific PCR analysis confirmed that the mutant A allele co-segregated with affected but not unaffected members of the pedigree and excluded the CA transversion as a single nucleotide polymorphism in a panel of 170 normal unrelated individuals. This study suggests that a mutation in *CRYGD* underlies a historically important type of coralliform cataract first reported in 1895.

**NDP gene mutations in French Norrie families.** *G. ROYER*<sup>1</sup>, *S. HANEIN*<sup>2</sup>, *V. RACLIN*<sup>1</sup>, *N. GIGAREL*<sup>1</sup>, *J.-M. ROZET*<sup>2</sup>, *A. MUNNICH*<sup>1, 2</sup>, *J. STEFFANN*<sup>1</sup>, *J.-L. DUFFIER*<sup>3</sup>, *J. KAPLAN*<sup>1, 2</sup>, *J.-P. BONNEFONT*<sup>1, 2</sup>. 1) Genetics Department; 2) INSERM Unit U393; 3) Ophthalmology Unit, Hopital Necker-Enfants Malades, Paris, France.

Norrie disease is a rare and severe X-linked condition characterized by congenital blindness, and occasionally deafness and mental retardation in males. This disease has been ascribed to mutations in the Norrie disease protein gene (NDP) on chromosome Xp11.1. The function of the gene product remains unknown. Previous investigations of the two coding exons of NDP have identified largely sixty mutations so far. We analysed by direct sequencing the NDP gene in a series of twenty-one French families, eight of them being multiplex families. Thirteen mutations were detected in fourteen of the twenty-one families, including five intragenic deletions and eight point mutations. Six of them - namely, R38C, H43Q, V45M, IVS2-1G>C, R90C, and C128R - are hitherto unreported. Only one mutation was found to have arisen de novo. No NDP mutation was found in the seven remaining families. This observation raises the issues of misdiagnosis, phenocopies, or existence of other X-linked or autosomal genes, the mutations of which would mimic the Norrie disease phenotype.

**An exploration of Leber congenital amaurosis locus, allelic, and inheritance complexity.** *D.W. Stockton<sup>1</sup>, R. Quijano<sup>1</sup>, D. Nguyen<sup>1</sup>, M. Leppert<sup>2</sup>, R.A. Lewis<sup>1</sup>, J.R. Lupski<sup>1</sup>.* 1) Dept Molec & Human Genet, Baylor College Medicine, Houston, TX; 2) Eccles Institute of Human Genetics, University of Utah, Salt Lake City, UT.

Leber congenital amaurosis (LCA) is a clinically and genetically heterogeneous retinal dystrophy. Its causes have been partially unraveled at three mapped loci and at the molecular level through the discovery of six genes that, when mutated, result in LCA. Our data from sequencing every exon of all six testable genes in a cohort of LCA patients has revealed novel mutations that, like other published series, can explain the disease in a minority of cases. In many published reports, only a single heterozygous mutation is identified in genes associated with recessively inherited disease and attributed to cause the disease. Our comprehensive examination of each of these six genes for every individual raises doubt on this interpretation since, for nearly one third of families in which homozygous or compound heterozygous mutations were identified in one of the six genes, a heterozygous alteration was identified in one of the other genes. These third mutations do not appear to be necessary to cause disease and are being evaluated further for both segregation and modification of the phenotype. These mutations could alter significantly the interpretation of DNA analysis for diagnostic purposes.

**Optineurin and Juvenile Open Angle Glaucoma.** C.E. Willoughby<sup>1,2</sup>, L. Chan<sup>1</sup>, S. Herd<sup>1</sup>, G. Billingsley<sup>1</sup>, N. Noordeh<sup>1</sup>, A. Levin<sup>1</sup>, Y. Buys<sup>3</sup>, G. Trope<sup>3</sup>, E. Héon<sup>1</sup>. 1) Dept Ophthalmology and Vision Sciences, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept of Medicine, University of Liverpool, Liverpool, UK; 3) Department of Ophthalmology, Toronto Western Hospital, Toronto, ON, Canada.

Sequence changes in *OPTN* (chr10p14-p15) at the GLC1E locus, were reported to cause or increase susceptibility to primary open angle glaucoma (POAG) and normal tension glaucoma (NTG). We assessed the role of *OPTN* in patients with juvenile open angle glaucoma (JOAG), in which the elevated intra-ocular pressures are associated with severe visual morbidity. Inclusion criteria: age of onset < 40 years, IOP > 22mmHg with optic nerve damage and visual field loss. Mutational analysis of *OPTN* used a combination of SSCP and direct sequencing. Sixty-six unrelated mixed ethnicity probands with JOAG were screened. Patients with *OPTN* sequence changes were further screened for *MYOC* sequence changes. A total of 10 sequence alterations were identified in subjects with glaucoma (JOAG and POAG) and control individuals. All sequence changes, except for H486R and A134A, were previously reported in POAG or controls. The c1767A>G nucleotide change (H486R) in exon 14 of *OPTN*, occurs in a highly conserved residue, and was seen in one patient with JOAG (1/66) and was not present in 101 control individuals nor in 107 POAG patients. A R545Q sequence change in exon 16 of *OPTN* was detected in one Chinese individual with familial JOAG and was not detected in 170 ethnically mixed control individuals but was present in 3/16 Chinese controls, suggesting R545Q may be an ethnic specific polymorphism. M98K was seen in 7/132 (5.3%) chromosomes of individuals with JOAG, in 8/96 (8.3%) chromosomes of patients with POAG and in 5/202 (2.4%) control chromosomes. The prevalence of the M98K polymorphism may confer a susceptibility risk to POAG ( $p>0.05$ ) but does not appear to predispose to JOAG. This is the first report of a potentially disease causing sequence alteration in *OPTN* in juvenile open angle glaucoma. Interestingly, the segregation of *OPTN* and *MYOC* mutations in one family, with both JOAG and POAG, is suggestive of an interaction between *MYOC* and *OPTN*.

**The (CGG)<sub>n</sub> repeat element within the 5'untranslated region of the *FMRI* message provides both positive and negative *cis* effects on *in vivo* translation of a downstream reporter.** L.-S. Chen, F. Tassone, P. Sahota, P.J. Hagerman. Biological Chemistry, University of California Davis, Davis, CA.

The human fragile X mental retardation 1 (*FMRI*) gene contains a polymorphic (CGG) trinucleotide repeat element in its 5'untranslated region (UTR). Expansion of the (CGG)<sub>n</sub> element beyond 200 repeats (full mutation range) generally leads to transcriptional silencing; consequent loss of the *FMRI* protein (FMRP) results in fragile X syndrome, the most frequent form of inherited mental retardation. For carriers of smaller expansions (54n200; premutation range), FMRP levels are gradually reduced with increasing repeat number, despite elevated *FMRI* mRNA levels, suggesting that translation is impeded within the premutation range. To examine in more detail the influence of the CGG repeat on translation, CMV immediate-early promoter constructs, containing the *FMRI* 5'UTR with various (CGG)<sub>n</sub> repeat lengths (0 n 99) and a downstream (luciferase) reporter, were transfected into two human lines, a neural cell-derived line (SK) and a fetal kidney cell-derived line (293). For both cell types, the CGG element exerts distinct effects on reporter expression, depending on the length of the repeat. For n 30, luciferase expression decreases with increasing repeat length, consistent with earlier observations of decreased FMRP expression in peripheral blood leukocytes over the same repeat range, despite a slight increase in mRNA level for the larger repeats. Surprisingly, for smaller alleles in the normal range (0 n 30), reporter expression actually increases by nearly two-fold with increasing repeat length in the absence of any change in mRNA level. These results suggest that the CGG repeat element can exert both positive (n 30) and negative (n 30) effects on translation. Interestingly, optimal translation appears to occur near the modal repeat number within the general human population.

Rett syndrome is an X-linked severe neurodevelopmental disorder predominantly affecting females. Genetic analysis of classical patients has shown that in approximately 80% of these cases the syndrome is caused by different mutations in the gene encoding methyl-CpG-binding protein-2 (MECP2). The routine DNA-diagnostic screening protocol mostly involves DHPLC, DGGE, SSCP or direct sequence analysis of the coding exons and immediate flanking intronic regions of the gene. These approaches however do not allow detection of gross rearrangements in the MECP2 gene. For this purpose we have analyzed 12 mutation-negative cases using a multiplex ligation-dependent probe amplification (MLPA, MRC-Holland) technique to allow the detection of deletions and/or duplications in the MECP2 gene. The tested cases involved 4 classical and 2 atypical Rett syndrome patients and a further 6 patients displaying some Rett-like suggestive symptoms. By means of this approach we identified gross rearrangements in 2 of the 4 analyzed classical Rett cases. In one case we observed a deletion of exon 3 and most of the coding region of exon 4. In the second case a duplication of exon 3 and the coding region of exon 4 was detected. Both rearrangement were subsequently verified and confirmed by Southern blot analysis. No aberrations were observed in any of the other cases. Our findings warrant further (MLPA) studies to establish the prevalence of large rearrangements in the MECP2 gene in mutation negative classical Rett syndrome cases. The MPLA technique could subsequently easily be implemented in the routine molecular screening protocol.

**Mutation analysis of MECP2 gene: Detection of three novel mutations and two novel polymorphisms. D.**

Zahorakova<sup>1</sup>, R. Rosipal<sup>1</sup>, J. Hadac<sup>2</sup>, N. Misovicova<sup>3</sup>, S. Nevsimalova<sup>4</sup>, J. Zeman<sup>1</sup>, P. Martasek<sup>1</sup>. 1) Department of Pediatrics, 1st Faculty of Medicine, Charles University, Prague, Czech Republic; 2) Department of Child Neurology, Thomayer University Hospital, Prague, Czech Republic; 3) Department of Clinical Genetics, University Hospital, Martin, Slovak Republic; 4) Department of Neurology, 1st Faculty of Medicine, Charles University and General University Hospital, Prague, Czech Republic.

**Background:** Rett syndrome (RTT) is an X-linked dominant severe neurodevelopmental disorder caused by mutations in the methyl-CpG-binding protein 2 gene (MECP2). MeCP2 protein was identified by its ability to bind specifically to CpG-methylated DNA and is thought to act as a global transcriptional repressor. It contains two main functional domains, an N-terminal methyl-CpG-binding domain (MBD) followed by a transcriptional repression domain (TRD). There are 5 prevalent mutations known in the MECP2 that cause RTT. Four of them are detectable by restriction analysis. We report mutation analysis of 46 patients with clinical diagnosis of RTT from Czech and Slovak republics.

**Methods:** The whole coding sequence of MECP2 was amplified by PCR. Products were examined by restriction analysis and automatic direct sequencing. **Results:** The analysis revealed 15 different disease-causing mutations in 33 sporadic patients (72%). Three of them have not been previously published: a missense mutation - P302S, a small deletion of 3 bp - 1069delAGC, and the deletion of 172 bp along the insertion of 41 bp - 1063del172bp+ins41bp. Fifteen patients had missense mutations (R133C, K135E, T158M, R306C), fourteen patients carried nonsense mutations (Y141X, R168X, S204X, R255X, R270X, R294X), and one had a frameshift mutation (1157del41bp). Two novel polymorphisms, 587 C>G (T196S), and 815 C>T (P272L) were detected in patients carrying mutations R133C, respectively R255X. **Conclusions:** Our results facilitate the diagnosis of RTT at the molecular level in the Slavonic population, and provide insight into the molecular pathology of Rett syndrome. *Supported by GAUK 301/01/P068..*

**Reduced expression of proteolipid protein 2 in XLMR patients with mild mental retardation.** *T. Wang<sup>1</sup>, L. Zhang<sup>1</sup>, C. Obie<sup>1</sup>, P. Boytner<sup>2</sup>, C. Schwartz<sup>2</sup>, A. Wright<sup>3</sup>, J. Trent<sup>4</sup>, D. Valle<sup>1</sup>.* 1) Inst. of Genet. Med., Johns Hopkins Univ., Baltimore, MD; 2) Greenwood Genetic Center and Clemson Univ., SC; 3) MRC Hum. Genet. Unit, Western General Hosp., Edinburgh, UK; 4) NHGRI, Bethesda, MD.

X-linked Mental retardation (XLMR) occurs in 1 in 600 males and is genetically heterogeneous. Approximately 40 genes have been cloned among the estimated 150-200 responsible loci on the X chromosome. Using a human X chromosome-specific cDNA microarray, we screened lymphoblast cell lines from 32 XLMR males and identified a candidate gene that encodes proteolipid protein 2 (PLP2). Significant reduction (~6-8 fold) of PLP2 mRNA was confirmed by Northern blot in lymphoblasts in three patients and PLP2 protein was not detectable by Western blot. DNA sequencing revealed a C>A mutation in the proximal promoter of PLP2 that alters the core binding site for Ets-domain transcription factors. The same mutation was detected in another young XLMR male with mild mental retardation with an overall IQ of 69. Moreover we found this mutation co-segregates with mild mental retardation in a four-generation X-linked pedigree with MR and RP. Linkage analysis in this family mapped the responsible gene to Xp11.23, the location of PLP2. We are screening a large collection of control males to determine if this mutation is associated with MR phenotype. PLP2 is a 17 kD membrane protein with 4 trans-membrane domains and shares similar physical properties but not sequence homology with PLP1, the gene responsible for Pelizaeus-Merzbacher disease. In a related work we found that a mis-sense mutation in PLP2 may be associated with retinal degeneration. RT-PCR study showed that PLP2 is expressed in multiple tissues including brain and retina. In situ hybridization revealed PLP2 expression in cerebral cortex and especially in the hippocampus. By immunohistochemistry and con-focal microscopy, we localized PLP2 protein to the ER membrane in cultured cells. Using chimeric mutant PLP2 promoter-luciferase reporter gene constructs in HEK293 cells, we found the mutant promoter reduced the transcription by 3-4 folds. These results suggest that reduction of PLP2 expression may be associated with XLMR.

**Chromosomal abnormalities in male infertility: Screening and diagnosis. A PRELIMINARY STUDY IN THE SOUTH OF TUNISIA.** *A. Bahloul<sup>1</sup>, N.B. Abdelmoula<sup>2</sup>, A. Amouri<sup>3</sup>, A. Saad<sup>4</sup>, L. Keskes<sup>2</sup>, T. Rebai<sup>2</sup>.* 1) Service d'urologie, CHU H. Bourguiba, Sfax, Tunisia; 2) Laboratoire d'Histologie Embryologie, Facult de Mdecine de Sfax, Tunisia; 3) Laboratoire de Cytogntique, Institut pasteur Tunis, Tunisia; 4) Laboratoire de Cytogntique, Hpital F. Hached Sousse.

Chromosome investigations have shown that about 2-10% of infertile men has an abnormal karyotype. Sex chromosome abnormalities predominate and the most prevalent anomaly is 47,XXY (Klinefelter's syndrome) with a frequency of 60%. We report a cytogenetic study that was carried out in 182 patients. The aim of this preliminary prospective study was to detect chromosomal abnormalities on infertile men with sperm count less than 10 million. X chromatin investigations were carried out for screening of numerical X chromosome abnormalities, classical cytogenetic analysis was conducted mainly by R banding and FISH analysis was carried out when it was necessary. The results of this study showed an overall incidence of 10,5% chromosome abnormalities. Cytogenetic abnormalities predominantly concern the X chromosome (56%), including Klinefelter's syndrome and 46,XX males, but also rearrangements such as deletions and reciprocal translocations. Results of our preliminary study confirm the elevated impact of numerical abnormalities of X chromosome in males with azoospermia . It suggest that both sex chromatin and chromosomal analysis should be considered as a routine examination in men with severe oligospermia or azoospermia. This enables access to genetic counseling and testing, which can be facilitated by their assisted reproduction providers. Having genetic risk information allows these patients to make educated, thoughtful decisions about their reproductive options.

**Usefulness of cytogenetics in female infertility.** *F. Ben Mrad<sup>1</sup>, N.B. Abdelmoula<sup>1</sup>, A. Amouri<sup>2</sup>, M. Mnif<sup>3</sup>, W.E. Abbes<sup>3</sup>, A. Saad<sup>4</sup>, M. Abid<sup>3</sup>, T. Rebai<sup>1</sup>.* 1) laboratoire d'histologie, faculte de medecine de sfax, Sfax, Tunisia; 2) laboratoire de cytogenetique, institut pasteur de tunis, Tunisia; 3) laboratoire de cytogenetique, CHU F. Hached Sousse, Tunisia; 4) Service d'endocrinologie, CHU H. Chaker Sfax, Tunisia.

Female factor infertility are less clearly defined but women with premature ovarian failure are at increased risk for being carriers of structural or numerical sex chromosome abnormality. Women who have mosaicism for sex chromosome aneuploidy are also observed to repeated failed IVF cycles. The association of recurrent spontaneous abortion with parental chromosome abnormalities has long been established. There is approximately a 5-6% risk that either the male or the female is a carrier of a chromosome abnormality. These are frequently structural abnormalities such as robertsonian translocations, reciprocal translocations, or inversions. POF-related abnormalities range from the complete absence of one X chromosome to assorted deletions and translocations to mutations in specific genes. Potential molecular mechanisms include both dominant and recessive mutations in X-linked genes as well as nonspecific chromosome effects that impair meiosis. A list of candidate X-linked POF genes is emerging from molecular studies of X chromosome abnormalities. We report a prospective study that was carried out in all patients affected by premature ovarian failure with secondary amenorrhea and referred, since 1999, to the endocrinology service of the Hedi Chaker university hospital of Sfax. First to establish the prevalence of chromosome abnormalities we performed cytogenetic analyses. In this study cytogenetic abnormalities predominantly concern the X chromosome, including mosaic Turner syndrome, but also rearrangements such as deletions. Mutational analysis of candidate genes in these women with idiopathic POF is needed to determine which gene contribute to the cause of this disorder.

**Prolonged prenatal exposure to magnesium sulfate associated with bone abnormalities mimicking genetic bone disease.** *J.M. Kogan<sup>1</sup>, K.E. Wedig<sup>2</sup>, J.A. Whitsett<sup>2</sup>, E.K. Schorry<sup>1</sup>*. 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Division of Neonatology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Two female former 30-week premature triplets (triplets B and C) were evaluated at 3 weeks of age for multiple fractures and bone abnormalities to rule out genetic bone disorder. The infants were conceived by IVF to a 32 y.o. G2P0Ab1 mother. Pregnancy was complicated by premature rupture of membranes of triplet A at 20 weeks. Preterm labor beginning at 22 weeks was treated with brethine, sulindac, and indocin, as well as magnesium sulfate at 2.5g/hr for 8.5 weeks. The babies were delivered by C-section for suspected chorioamnionitis and polyhydramnios. The infants were intubated and treated with surfactant. Triplet A died on the first day of life with sepsis. At 3 weeks of age, x-rays of triplets B and C revealed thin, demineralized bones with multiple fractures of the ribs, humeri, and clavicle. Skull bones were demineralized, with no wormian bones noted. Triplet C also had the appearance of hemi-vertebrae on spine X-rays. Examination was significant for very wide fontanelles, and white sclera. Initial lab values included normal calcium and phosphorus, mildly elevated magnesium, and elevated alkaline phosphatase for both infants. Phosphoethanolamine levels were normal. The bone abnormalities were presumed to be related to prolonged prenatal exposure to magnesium, with genetic bone disease unlikely. The infants developed BPD and were discharged to home on oxygen as well as a high calcium/phosphorus formula, however follow-up DEXA scans at 3 months age showed persistent low bone density.

Previous reports have shown a causal relationship between prolonged magnesium tocolysis and abnormal fetal bone mineralization. The exact mechanism is unknown but has been hypothesized to be related to fetal parathyroid gland suppression. Our patients showed a more severe degree of demineralization and greater number of fractures than other reported cases. This case points out the necessity of including prolonged magnesium therapy in the differential diagnosis of the newborn infant with multiple fractures.

**Prenatal Diagnosis of Osteogenesis Imperfecta Type 3.** *C. Maxwell<sup>1,2</sup>, A. Toi<sup>3</sup>, S. Keating<sup>4</sup>, M. Thomas<sup>1</sup>, D. Chitayat<sup>1,2,5</sup>.* 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Univ. of Toronto, Toronto, Canada; 2) Dept. of Obstetrics and Gynecology, Division of Maternal Fetal Medicine, Mount Sinai Hospital, Univ. of Toronto, Toronto, Canada; 3) Dept. of Medical Imaging, Mount Sinai Hospital, Univ. of Toronto, Toronto, Canada; 4) Dept. of Laboratory Medicine and Pathobiology, Mount Sinai Hospital, Univ. of Toronto, Toronto, Canada; 5) Department of Pediatrics, Division of Clinical Genetics and Metabolism, The Hospital for Sick Children, Univ. of Toronto, Toronto, Canada.

Osteogenesis imperfecta (OI) type 3 is a non-lethal, progressively deforming skeletal dysplasia often recognized after birth due to short stature and antenatal fractures. Inheritance is usually autosomal dominant.

On fetal ultrasound, findings include demineralization and fractures resulting in shortening and angulation of long bones with absence of narrow chest and rib fractures. We report three cases of OI type 3 presenting with bowed or angulated long bones on fetal ultrasound.

Case 1: A 19 week ultrasound revealed bent femora, tibiae, fibulae and humeri measuring below the 5th percentile. The skull was indented with external pressure. Post termination X-rays showed slight demineralization, asymmetrical healing fractures of the long bones and thin ribs.

Case 2: A 19 week ultrasound revealed all long bones measuring below the 3rd percentile and bent femora. Post termination X-rays showed asymmetrical fractures of long bones more pronounced in the lower limbs.

Case 3: A woman with known OI type 3 presented at 17 weeks of gestation. Fetal ultrasound revealed short femora and humeri and absent calvarial ossification. The long bones showed marked angulation at sites of healing fractures. The chest was not deformed. DNA analysis confirmed the diagnosis.

Differentiation of OI type 3 from OI type 2 is important for genetic counseling as the former is non-lethal. Shortening and asymmetrical deformity of long bones less severe than in OI type 2 with relative sparing of chest and ribs suggest the diagnosis.

**Twins and Heart Defects: a retrospective study of 27 cases.** *P. Eydoux<sup>1</sup>, V. Cusin<sup>2</sup>, J.F. Oury<sup>3</sup>, A.L. Delezoide<sup>4</sup>, A. Azancot<sup>5</sup>.* 1) Cytogenetics, Children's and Women's Hospital, Vancouver, BC, Canada; 2) Biochimie Genetique, Hospital Robert Debre, Paris, France; 3) Obstetrics and Gynecology, Hospital Robert Debre, Paris, France; 4) Biologie du Developpement, Hospital Robert Debre, Paris, France; 5) Cardiologie Foetale, Hospital Robert Debre, Paris, France.

Congenital heart defects (HD) are among the most prevalent malformations in liveborns. Twin studies have demonstrated a strong genetic component of HD, which are more frequent in monozygotic (MZ) than dizygotic (DZ) twins. In the former, heart malformations may be discordant despite identical genotype and similar prenatal environment, resulting in a relatively low concordance rate. In reported series, results are often impaired because of insufficient data to identify the HD and to determine zygosity. In this retrospective study, we report prenatal and postnatal data on 27 sets of twins diagnosed during fetal life by echocardiography, in which zygosity was established using morphological and molecular criteria. Between 1990 and 1999, 33 HD were detected in 27 twin pregnancies. All fetuses had a karyotype and all fetuses with a cono-truncal HD were tested for microdeletion 22q11. DNA was analyzed from amniotic fluid cells or from placenta de-paraffinated specimens. Whenever intra-uterine fetal death (IUFD) or termination of pregnancy occurred, complete macroscopic examination of the fetus and placenta was performed. Out of 33 HD, 9 were type I, 16 were type II, 2 were type III, 3 were type IV and 3 type VI. Sex ratio of affected fetuses seemed close to 0.5 except for type III and VI, for which only female were affected (n=5). Our sample was skewed towards MZ pregnancies, mostly monochorionic (MC) diamniotic (DA). Sixteen IUFD occurred. Overall, MZ pregnancies were more frequent in our sample. The most frequent HD was type II (half of the cases). HDs were frequently discordant in MZ pregnancies and always discordant in DZ pregnancies. An excess of females was seen in DC pregnancies, and most IUFDs occurred in MZ pregnancies and in males. Monosomy X was a frequent finding in MZ pregnancies. The significance of these findings will be discussed.

**Polymorphisms in matrix metalloproteinase-2 are associated with increased risk of developing thoracic aortic aneurysm.** *D. Guo*<sup>1</sup>, *Z. Yin*<sup>1</sup>, *Y. Qi*<sup>1</sup>, *A. Estrera*<sup>2</sup>, *H. Safi*<sup>2</sup>, *S. Shete*<sup>3</sup>, *T. King*<sup>1</sup>, *D. Milewicz*<sup>1</sup>. 1) Dept Internal Medicine, Univ Texas/Houston Med Sch, Houston, TX; 2) Dept of Cardiovascular Surgery, Univ Texas/Houston Med Sch, Houston, TX; 3) Dept of Epidemiology, Univ of Texas M. D. Anderson Cancer Center, Houston, Texas.

Metalloproteinases (MMPs) are a family of proteinases that play a role in remodeling vascular extracellular matrix in both normal and pathological states, including aortic aneurysm. MMP2 was expressed at elevated levels in thoracic aortic aneurysm and dissection (TAAD). To understand the genetic contribution to the development of sporadic TAAD, we genotyped single nucleotide polymorphisms (SNPs) located in MMP2 and performed case-control association studies. Eight SNPs in MMP2 were selected from the Celera database along with a function SNP that had been reported. These SNPs were genotyped in 166 Caucasian controls and 297 Caucasian TAAD patients. Two of these SNPs showed to be significantly associated with TAAD. Allele G of MMP2-2 and allele C of MMP2-3 showed significant association with TAAD ( $p=0.01$ ). For MMP2-2, the odds ratio (OR) was 1.44 (95% confidence interval (C.I.) 1.08-1.92) for allele G as compared to allele A and similarly for MMP2-3, the OR was 1.44 (C.I. 1.09-1.90) for allele C as compared to allele T. Similarly, for MMP2-2, the OR was 1.88 (C.I. 1.05-3.38) for individuals who carried genotype GG compared to those carried genotype AA and for MMP2-3, the OR was 2.01 (C.I. 1.18-3.45) for individuals carried genotype CC compared to those carried genotype TT. Interestingly, in male population, individuals carried genotype CC in MMP2-3 had a significantly higher risk of developing TAADs compared to those carried genotype TT. The haplotypes of MMP2-2 and MMP2-3 were constructed. The haplotype frequencies were significantly different between TAAD and control with a  $p$ -value of 0.03. The individuals who had the homozygous GC genotype showed significantly higher risk of developing TAAD compared to individuals who had the homozygous AT genotype. The  $p$ -value is 0.02 and OR is 2.322 (C.I. 1.14 4.73). Our results suggest that MMP2 could be implicated as the susceptibility genes for development of TAADs.

**In utero methotrexate exposure resulting in long bone aplasia.** *D.J. Zand<sup>1</sup>, C. Blanco<sup>2</sup>, B. Coleman<sup>2</sup>, D. Huff<sup>3</sup>, E. Zackai<sup>1</sup>.* 1) Dept Genetics, CHOP, Philadelphia, PA; 2) Dept Radiology, Hospital of the University of Pennsylvania, Philadelphia, PA; 3) Dept Pathology, CHOP, Philadelphia, PA.

Methotrexate has been increasingly utilized to control autoimmune disease, as an anti-neoplastic agent, and as an abortifacient. Fetal exposure has been reported to result in facial and digital dysmorphology similar to that observed in fetal aminopterin syndrome, a structurally related folic acid antagonist. Megalencephaly, cranial ossification defects, hypertelorism, prenatal growth deficiency, and post-axial polydactyly are some of the most consistent fetal findings. We report two cases where methotrexate was used unsuccessfully as an abortifacient. Ultrasound and fetal MRI imaging suggested digital and facial dysmorphia consistent with methotrexate exposure. Both pregnancies were electively terminated based on prenatal radiographic findings. Ultrasound evaluation of the fetus in Case 1 showed the radius and ulna to be shortened and bowed, while the femora were notably absent. Hypertelorism and microcephaly were also present. Cardiac echo noted double outlet right ventricle (DORV) pathology. In Case 2, skeletal anomalies included bilateral absence of radii and fibulae. Frontal bones were asymmetric and a large parietal foramina was present. Post mortem evaluation noted an absent thymic isthmus, accessory spleens, and facial dysmorphia including hypertelorism, bulbous nasal tip and high arched, prominent eyebrows. There were only three post axial digits and a thumb on both hands. To our knowledge, this is the first report of long bone aplasia associated with in utero methotrexate exposure. In our two cases, either fibulae or radii were involved bilaterally. This affect may correlate with the high methotrexate dose required for abortifacient use. These two cases emphasize that prenatal ultrasonographic monitoring is vital for evaluation of pregnancies exposed to methotrexate.

**THE IMPACT OF PRENATAL DIAGNOSIS ON THE BIRTH PREVALENCE OF MALFORMED CHILDREN IN A REGION WITHOUT UPPER LIMIT FOR TERMINATION OF PREGNANCY.** *B. Dott, Y. Alembik, M.P. Roth, C. Stoll.* Medical Genetics, Hopital de Hautepierre, Strasbourg, France.

Objectives : to describe the impact of prenatal diagnosis on the birth prevalence of congenital anomalies (CA) during 22 years in a well defined population. Material : 293,923 consecutive pregnancies of known outcome. The study was divided into 3 periods 79-88, 89-94 and 95-2000. In the area under study there is no upper limit for termination of pregnancy (TOP). Results : During the 3 periods of the study the livebirth (LB) prevalence of the malformed per 10,000 decreased for some CA : central nervous system (16.3, 11.6, and 12.2), neural tube defects (5.6, 2.3, and 2.9) musculoskeletal system (51.6, 48.5, and 45.6), transposition of great arteries (5.0, 3.4, and 3.7), and Down syndrome (DS) 21 (9.8, 10.7, and 6.2) but increased for other : encephalocele (0.68, 0.86, and 1.04), urinary system (36.5, 60.7, and 63.2), congenital heart defects (67.3, 79.0, and 71.2), respectively whereas the prevalence rate of TOP increased for all categories of CA. For non chromosomal CA the prevalence rate of TOP for 1000 total births/year increased from 0.9 to 1.8 and to 2.5, respectively. For DS the ratio LB/TOP was 5.1, 1.3, and 0.4, respectively. The total number of malformed fetuses/children increased in parallel to the increase of the number of TOPs. The gestational age at TOP decreased dramatically for DS. However for non chromosomal CA it was the opposite as TOP was performed after 24 weeks of gestation in 42%, 66%, and 74% of the cases, respectively. This evolution of the prevalence rate of LB from 1979 to 2000 was the result of more efficient but late prenatal diagnosis on one hand and of the increase of maternal age, (the 35-37 years-old group involved 6% of the TOP in 1979-1988 and 17% of the cases in 1995-2000). In conclusion in a region where there is no upper limit for TOP, these last two decades, despite more efficient prenatal diagnosis and an increasing number of TOPs the LB prevalence of malformed children decreased for only some categories of CA. Except for chromosomal anomalies, the number of late TOPs, after 24 weeks of gestation, was increasing.

**Use of microarray technology to identify differential gene expression in Down syndrome placentae: validation of methodology.** *P. Dar, J.C. Ferreira, K.C. Livne, J. Segal, D. Khabele, B.L. Gross, S.J. Gross.* Dept OB/GYN, Albert Einstein Col Medicine, Bronx, NY.

Background: Detection rates for prenatal maternal screening for Down syndrome (DS) has improved over the past decade, although false positive rates remain a clinically significant issue. Genome wide gene scanning has the potential to ultimately identify more specific markers for DS. Using microarray technology, we previously identified 7 genes that were overexpressed in pooled second trimester DS placentae compared to controls. Purpose: The aim of this present study was to validate the findings from our microarray experiments using Quantitative Real Time RT-PCR (QPCR) in an independent set of placental samples. Methods: Samples of DS (n=8) and control (n=6) second trimester placentae were obtained anonymously under an IRB approved protocol. RNA was extracted and reverse transcribed to cDNA aliquots, which were amplified with QPCR as per our standard protocol. The gene expression ratios of DS vs. controls were calculated using the Student t-test. Results:

Gene/EST	N31645	KRT8	PLAC3	AA001841	ALDH7	KISS-1	PTTG1IP
DS/N Ratio	4.6	5	16.6	7.2	1.2	6.7	1.1
P value	<0.05	<0.05	<0.05	<0.05	NS	<0.05	NS

Conclusions: This study confirms our initial premise that microarray technology can be used for genome wide detection of differentially expressed genes in aneuploid placentae and that independent validation is necessary. Further study of confirmed genes and their protein products can be used to develop a more precise panel of markers and further our understanding of the underlying pathogenic mechanisms in DS.

Program Nr: 2481 from 2003 ASHG Annual Meeting

**Gene expression profiles of the TNF-related apoptotic pathway in Down Syndrome placentae.** *S.J. Gross, P. Dar, K.P. Livne, J.C. Ferreira, B.L. Gross, D. Khabele.* Div Reproductive Genetics, Dept OB/GYN, Albert Einstein Col Medicine, Bronx, NY.

**Background:**Down syndrome (DS) is the most common aneuploidy identified at birth. Apoptotic mechanisms have been implicated in the phenotypic features of this syndrome. TNF superfamily ligands and their receptors have been identified in human placentae and are thought to play a major role in both the normal and pathologic development of this organ. Characteristic clinical and pathological sequelae of DS may be related to abnormal placental development. **Purpose:**The purpose of this study was to determine if genes related to the TNF apoptotic cascade are differentially expressed in DS placentae.**Methods:**Samples of DS (n=6) and control (n=6) second trimester placentae that were matched for gestational age were obtained anonymously under an IRB approved protocol. RNA was extracted and reverse transcribed to cDNA aliquots which were amplified with QPCR, using sequence specific primers for TNF-related apoptosis-inducing ligand (TRAIL), TNF-, TRAIL death receptor DR4 and TRAIL decoy receptors DcR1 and DcR2. The association between gene expression in DS (cases vs. controls) for each gene was calculated using the Student t-test (significance at  $p < 0.05$ ).**Results:**TRAIL expression was significantly upregulated in DS placentae compared to controls (DS expression level 163.3, control expression level 52.1,  $p$  value=0.0004). The remaining four genes did not show significant differential expression. **Conclusions:**TRAIL was significantly overexpressed in DS placentae compared to controls while TNF-alpha as well as the three TRAIL receptors evaluated were not. Further studies are required to characterize the expression and determine the biological function of TRAIL and other genes whose function may modulate TRAIL activity.

**Trisomy 8 pseudomosaicism in amniocytes: difficulties in prenatal diagnosis and counseling.** *S. Carter*<sup>1</sup>, *P. Dar*<sup>1</sup>, *V. Pulijaal*<sup>1</sup>, *B. Gross*<sup>2</sup>, *C. Salafia*<sup>2</sup>, *S. Gross*<sup>1</sup>. 1) Reproductive Genetics, Montefiore Medical Ctr, Bronx, NY; 2) Bronx Lebanon Hospital, Bronx, NY.

Trisomy 8 mosaicism is a rare disorder with extreme phenotypic variability. It is characterized by mild to moderate mental retardation, dysmorphic facial features, skeletal malformations, and cardiovascular anomalies. Additionally, the literature has reports of individuals with mosaicism for trisomy 8 cells who have normal intelligence. This wide phenotypic presentation presents a challenge for genetic counseling when this chromosome complement is detected prenatally. Another confounding factor is that prenatal diagnosis of this pseudomosaicism has resulted in anomalous newborns with true mosaicism.

Here we report a case of prenatal diagnosis of trisomy 8 pseudomosaicism following a positive MSAFP3 screen for Down syndrome in a 20-year-old G3P0020 biracial female. The family and pregnancy history were unremarkable. Amniocentesis was performed without complications and the limited fetal ultrasound was normal. The amniocentesis results revealed 46, XX (35 cells)/47,XX,+8 (1 cell), type B pseudomosaicism. A detailed ultrasound performed at 21 weeks gestation demonstrated normal fetal anatomy and appropriate interval growth. After genetic counseling, the patient decided to terminate the pregnancy because of the uncertain neurodevelopmental prognosis. Fetal tissue was obtained for cytogenetic analysis and a detailed postmortem examination was performed.

We present the post termination results, summarize the literature for case management guidelines, and discuss the complexity of counseling for this rare mosaicism.

**Application of the multi-PRINS technique for simultaneous detection of chromosomes 18, X and Y in uncultured amniocytes.** *M. Gadji, K. Krabchi, M. Bronsard, R. Drouin.* Human and Molecular genetic research center, Medical biology, Laval University, Quebec, PQ, Canada.

**Objective:** Comparative evaluation of the multi-PRINS (primed in situ labeling) technique for simultaneous detection of chromosomes 18, X and Y in uncultured amniocytes for prenatal diagnosis of aneuploidy. **Methods:** The multi-PRINS technique for simultaneous detection in the same cells of three chromosome targets, 18, X and Y, was performed according to the procedure described by Yan J et al. *Chromosoma* 109:565, 2001. Oligonucleotides were annealed to their specific individual chromosome targets, followed by in situ elongation using Taq DNA polymerase to incorporate labeled dUTPs. The sites of the newly synthesized DNA sequences were revealed as fluorescent signals using immunochemical reaction. The fluorescent signals corresponding to chromosomes 18, X and Y were displayed as yellow, red and green color spots, respectively. Multi-FISH using commercial chromosome 18, X and Y probes was carried out for comparison. Two persons, one blinded, examined all slides. Fifty cases were analyzed using both multi-PRINS and multi-FISH. Between 50 and 200 nuclei were scored for each case for each technique. To compare the sensitivity and specificity of PRINS and FISH, Fisher's exact test was carried out using the observed distribution of cells showing one or more signals. **Results:** In all cases, there was no significant difference in the detection of chromosomes 18, X and Y regarding the sensitivity, the specificity and the efficiency. Both multi-PRINS and multi-FISH yield similar distribution of the number of spots per nucleus. Both techniques were able to identify aneuploid cases without ambiguity. The entire PRINS procedure, including the harvest time, could be completed in less than 5 hours vs. FISH in 24 hours. **Conclusion:** Multi-PRINS can accurately and reliably detect aneuploidies involving chromosomes 18, X and Y in uncultured amniocytes as well as can multi-FISH. In addition, multi-PRINS represents a faster and more cost-effective alternative to FISH for prenatal testing of aneuploidy in uncultured amniocytes.

**Multiple fetal anomalies including holoprosencephaly caused by 7q monosomy/5q trisomy in the offspring of a double translocation carrier.** *L. Mehta*<sup>1</sup>, *A. Yenamandra*<sup>2</sup>, *P. Koduru*<sup>2</sup>, *J. McLaughlin*<sup>1</sup>, *R. Schiff*<sup>1</sup>, *N. Vohra*<sup>3</sup>, *B. Rochelson*<sup>3</sup>. 1) Medical Genetics & Cardiology, Schneider Children's Hospital at North Shore; 2) Cell Genetics; 3) Maternal-Fetal Medicine, North Shore University Hospital, Manhasset, N.Y.

A 35 y.o. woman was found to have fetal sonogram findings consistent with alobar holoprosencephaly (HPE); a single orbit, absent nasal structures and a supraorbital proboscis were present. Echocardiogram revealed a large inlet-VSD and a small mid-muscular VSD. The couple have had a healthy child, two miscarriages and an infant with anencephaly who died at birth. Fetal karyotype on amniocentesis was initially reported as normal 46,XX. It was then determined that the father carried two apparently balanced chromosome translocations, t(1;8)(q32;q21.1) and t(5;7)(q35;q36). Given the subtle terminal breakpoints of the (5;7) translocation, FISH and high resolution studies were done on amniocytes. It was confirmed that the fetus was monosomic for 7q36-ter and trisomic for 5q35-ter. The anomalies present are consistent with this imbalance. Deletion of terminal 7q causes haploinsufficiency of the SHH gene located at 7q36 (HPE3 locus). Terminal 7q deletions are consistently reported with variable degrees of HPE and other malformations but anencephaly is not reported; there were no documented chromosome studies on the anencephalic infant. Trisomy for terminal 5q is reported with dysmorphisms, growth and developmental delays and heart defects. The presence of two translocations in one individual, as in the father, is rare. Notably chromosome 7 is involved in three reported double translocation cases; in one such case, two fetuses with HPE inherited 7q32-ter monosomy from the carrier father. Our pt. opted to continue the pregnancy (as she did the previous anencephalic pregnancy). It was of note that the father's chromosome result was not divulged, and was only ascertained through records. Without this information, the subtle fetal chromosome imbalance would have been missed. This case highlights the importance of subtelomeric FISH testing in unexplained multiple malformation syndromes, particularly with a suspicious family history.

**Down syndrome with pure partial trisomy 21q22 due to a paternal insertion (4;21) uncovered by amniotic fluid interphase FISH.** *D. Hopcus-Niccum<sup>1</sup>, J.R. Stanley<sup>2</sup>, S.A. Vaz<sup>2</sup>, J.J. Mulvihill<sup>1</sup>, S. Li<sup>1</sup>.* 1) Department of Pediatrics, OUHSC, Oklahoma City, OK; 2) Prenatal Assessment Center, Department of Obstetrics-Gynecology, OUHSC, Oklahoma City, OK.

FISH analysis to screen aneuploidies of the selected chromosomes X, Y, 13, 18 and 21 on fetal cells utilizing commercial probes (AneuVysion, Vysis, USA) is becoming a standard test despite rare false-positive or false-negative results. A 32-year-old Caucasian woman had amniocentesis at 18 weeks and 4 days gestation because of a positive screen for Down syndrome and a slightly increased nuchal fold (0.58 cm). Overnight FISH was performed and all thirty nuclei analyzed had two signals of X chromosome and three signals of chromosome 21. The diagnosis of a female fetus with Down syndrome was made. Seven days later, routine chromosome analysis showed all 15 cells had a modal number of 46 chromosomes, including two X chromosomes. Neither an extra chromosome 21 nor a Robertsonian translocation was found. A relatively larger, but subtle, light band (4q21), was noticed on one homologue; later, it was confirmed that part of 21q22 was inserted into the band of 4q21. Chromosome analysis of both parents revealed that the father carried an apparently balanced insertion (4;21). To further determine the size of the inserted chromosome 21 segment, FISH analysis utilizing a locus specific probe (AML1) and a chromosome 21 paint probe was performed. An AML1 gene signal was clearly visualized on the derivative chromosome 4. Hybridization of the chromosome 21 paint probe showed that approximately one third of the whole long arm of chromosome 21 was inserted in the band 4q21. The karyotype of the fetus was defined as 46,XX,der(4)ins(4;21)(q21;q22.13-q22.2). Genetic counseling was provided regarding the implication of the laboratory findings and the couple decided to continue the pregnancy. The baby was delivered without complication at 40 weeks gestation. As expected, the baby has typical features of Down syndrome. In this case, without knowing of the presence of three signals of 21q, this fetus could have been a missed diagnosis or a difficult determination of the origin of this white extra chromosome material.

**PGD for aneuploidy on 513 embryos from 56 initiated cycles using laser assisted embryo biopsy and FISH significantly increases implantation rates, reduces miscarriages, and decreases multiple births.** *W.G. Kearns<sup>1</sup>, J. Graham<sup>2</sup>, T. Han<sup>2</sup>, J. Carter<sup>2</sup>, A. Davis<sup>2</sup>, K.S. Richter<sup>2</sup>, E. Widra<sup>2</sup>, M.J. Levy<sup>2</sup>.* 1) Center for Preimplantation Genetics, Rockville, MD; 2) Shady Grove Fertility, Rockville, MD.

PGD was performed to increase implantation rates (IR), reduce miscarriages and reduce multiple births following in vitro fertilization (IVF). Patients underwent PGD due to 2 recurrent miscarriages or unsuccessful IVF cycles. The control group comprised couples with 2 unsuccessful IVF cycles undergoing routine IVF. PGD was performed on blastomeres from 513 cleaving embryos from 56 initiated cycles prior to 44 embryo transfers. Embryo biopsy and FISH were used to determine aneuploidy for chromosomes 13, 14, 15, 16, 17, 18, 21, 22, X and Y. One blastomere from each 4-9 cell embryo was analyzed. Twenty-four percent (125/513) of embryos were diploid and 72 embryos were transferred for 44 couples. Fifteen percent (76/513) of embryos were not diagnosed because of cell fragmentation. Aneuploidy was found in 61% (312/513) of embryos tested. No transfer occurred for 12 couples due to a chromosome abnormality in all embryos analyzed.

Age	PGD IR	Controls IR
< 38 yrs	38% (SE=9)	22% (SE=2)
38 - 40yrs	36% (SE=17)	13% (SE=2)
> 40yrs	7% (SE=4)	5% (SE=2)

Thirty-nine percent (17/44) of women achieved a clinical pregnancy with an IR of 28% (20/72). PGD significantly increased ( $p < 0.05$ ) the IR for women under 41. PGD also overall reduced the miscarriage rate from 15% (23/153) to 6% (1/17) and the percent of multiple births from 28% (40/142) to 12% (2/17) compared to controls.

**High incidence of unbalanced conceptuses from segregation of a paternal balanced translocation 7q34;9q34.1.**

*S.B. Olson<sup>1,4,5</sup>, H. Lawce<sup>4</sup>, N. Ouhibi<sup>2</sup>, C. Davis<sup>4</sup>, C. Durum<sup>4</sup>, J. Lira<sup>4</sup>, S. Kelson<sup>4</sup>, M.L. Sorensen<sup>5</sup>, P. Stenzel<sup>3,5</sup>, M. Vahdati<sup>4</sup>, Y. Akkari<sup>1,4,5</sup>.* 1) Dept Mol & Med Genet, Or Hlth & Sci Univ(OHSU), Portland, OR; 2) Dept OB/GYN, OHSU, Portland, OR; 3) Dept Path, OHSU, Portland, OR; 4) Cytogenet Lab, OHSU, Portland, OR; 5) School of Med, OHSU, Portland, OR.

Useful figures regarding risks to specific balanced translocation carriers of producing unbalanced gametes and offspring are scarce. Early data from preimplantation genetic diagnosis (PGD) studies suggest the incidence of unbalanced conceptuses in these families to be higher than previously estimated. We report the cytogenetic analysis of 4 fetuses and 11 embryos in a family with a paternal balanced rearrangement. The couple was ascertained following an abnormal maternal serum screen with abnormal ultrasound at 16 weeks gestation (increased nuchal fold of 5.2 mm; bilateral pyelectasis). Amniocyte chromosome analysis, followed by parental karyotyping, revealed a 46,XX,der(9)t(7;9)(q34;q34.1)pat karyotype. A follow-up ultrasound at 20 weeks gestation showed increased nuchal translucency (3.8 mm), bilateral club feet and a complex heart defect. The pregnancy was terminated. Autopsy further delineated the heart anomaly as double outlet right ventricle with side-by-side great vessels and subaortic VSD, hypoplastic left heart with patent mitral valve, bicuspid pulmonic valve and bicuspid aortic valve. Three subsequent pregnancies were unbalanced, including another with der(9) and two with der(7). Three of the 4 fetuses presented with increased nuchal translucencies. Autopsy was refused for the second der(9). One der(7) fetus had bilateral club feet with no other anomalies; the other had as sole findings small kidneys and adrenals with normal histology. PGD was also performed on 11 embryos; 10 of these were unbalanced reflecting at least 6 different segregation products of the translocation; one balanced embryo implanted and resulted in spontaneous loss. This study illustrates the high incidence of unbalanced conceptuses in balanced translocation families and emphasizes the importance of thorough genetic counseling in making informed reproductive decisions.

**Prenatal detection of *de novo* balanced chromosomal rearrangements: a follow-up study.** M. Shago<sup>1,6</sup>, W.S. Meschino<sup>3</sup>, S.A. Farrell<sup>4</sup>, D. Chitayat<sup>2,6</sup>, E.J.T. Winsor<sup>5,6</sup>. 1) Departments of Paediatric Laboratory Medicine and; 2) Clinical Genetics, Hospital for Sick Children; 3) Department of Genetics, North York General Hospital; 4) Department of Genetics, Credit Valley Hospital; 5) Pathology and Laboratory Medicine, Mount Sinai Hospital; 6) University of Toronto, Toronto, Canada.

Prenatal detection of *de novo* balanced chromosomal rearrangements presents a dilemma for expectant parents. Whereas familial balanced rearrangements are generally without clinical manifestations, *de novo* rearrangements are associated with an increased risk of mental retardation (MR) and/or congenital anomalies. Based on a study by Warburton (1991), risk values of 6.7% and 9.4% for *de novo* translocations and inversions respectively are frequently provided to parents. The present study is a chart review of 61 patients with prenatal diagnosis of a *de novo* apparently balanced reciprocal translocation or inversion. Our goal was to document decisions made by parents, and to provide information on long term follow-up of children identified prenatally with *de novo* balanced rearrangements. Patients were identified by searches of cytogenetic databases from 1988 to present. Outcome of pregnancies was livebirth 44%, termination 32%, intrauterine demise 4%, and unknown 20%. Postnatal outcome information was available for 39 of the pregnancies. Age at last follow-up ranged from birth to 11 years. In the translocation group two children with abnormalities were identified: one had severe expressive language disorder and one had developmental delay with intractable seizures. In the inversion group one child with multiple congenital anomalies and one child with a hydronephrotic kidney were identified. Excluding cases ascertained due to ultrasound abnormalities, the risk for phenotypic/developmental abnormality was 8% in the *de novo* translocation group (n=25) and 20% in the *de novo* inversion group (n=10). Although this study provides further evidence that there is an increased risk for abnormality associated with *de novo* apparently balanced chromosomal rearrangements, a larger case-controlled study is necessary to obtain a more accurate risk.

Program Nr: 2489 from 2003 ASHG Annual Meeting

**Tandem direct duplication of 8p22-23.1 associated with Dandy-Walker variant.** *P.Z. Reingold, P. Dar, S.M. Carter, S. Klugman, P.L. Wilmot, V.R. Puligaal, S.J. Gross.* Dept of OB/GYN. Albert Einstein College of Medicine/Montefiore Medical Center. Bronx, NY.

Background: Inverted duplication 8p is one of the most common duplications observed and ranks in frequency with the other classical deletion syndromes, such as Wolf-Hirschhorn and cri-du-chat. It is characterized by profound mental retardation commonly related to agenesis of corpus callosum and/or Dandy-Walker malformation, facial dysmorphism, and malformations of kidneys and heart. Tandem direct duplication of the 8p22-23.1 segment, however, is a rare finding. In the small number of cases thus far reported isolated mental retardation was the most prevalent finding in the absence of associated anomalies. Case report: We describe a 32 year old G2P1000 pregnant patient who was referred to our genetic counseling clinic for a positive maternal serum screening test for Down syndrome. Her medical history was unremarkable and her obstetrical history was significant for full term intrauterine fetal death thirteen years prior to current pregnancy. First trimester screening revealed a nuchal translucency in the normal range but abnormal maternal serum biochemical markers levels (betaHCG 2.16MOM and PAPP-A 0.38MOM). Second trimester maternal serum quad screen was positive for Down syndrome (Risk of 1:65). Chromosome analysis and FISH revealed a 46XX, dir dup(8) (p22p23.1) karyotype. Detailed sonographic anatomy scan performed at 22 weeks revealed an isolated absence of the inferior vermis, consistent with the diagnosis of Dandy-Walker variant. Following a thorough genetic counseling the patient opted to continue with the pregnancy. Comment: This rare case implicates a possible association between tandem direct duplication of the 8p22-23.1 and Dandy-Walker variant. Detailed sonographic evaluation of the fetal posterior fossa should be offered to patients carrying a fetus with such karyotype.

**Chromosome abnormalities among fetuses with pleural effusions detected on prenatal ultrasound examination: Comparison of aneuploidy rates between isolated pleural effusions and those with other congenital anomalies.** *K. Waller, T. Custer, A. Donnenfeld.* Genzyme Genetics, Dallas, TX, Santa Fe, NM, and Philadelphia, PA.

**Purpose:** To determine the frequency of chromosome abnormalities in fetuses with prenatally detected pleural effusions and to compare the aneuploidy rate between pregnancies with isolated pleural effusions and those with additional anomalies. **Methods:** A retrospective analysis of our database for amniotic fluid samples submitted with an indication of pleural effusion was performed. **Results:** Amniotic fluid analysis was performed on 250 samples in which pleural effusion was identified as an indication for chromosome analysis. In 95 of these samples (38%), pleural effusion was the only fetal abnormality identified as an indication for chromosome analysis. The remaining 155 fetuses had other associated anomalies identified in addition to pleural effusion (complex pleural effusions). No cell growth occurred in 2 cases among the isolated pleural effusions and in 7 cases among the complex pleural effusions. Eight significant chromosome abnormalities were identified in the isolated pleural effusions (8.6%) including five cases of trisomy 21, one case of trisomy 18, one mosaic trisomy 20, and one mosaic unbalanced translocation. Among the complex pleural effusion cases, there were 74 chromosome abnormalities (30.4%). 37 had 45,X, 26 had trisomy 21, 5 had trisomy 18, two had mosaic Turner syndrome, two had unbalanced translocations, one had trisomy 13 and one had triploidy. The difference in aneuploidy rate between the isolated pleural effusions and the complex effusions was statistically significant  $P < 0.0001$  by Wald Chi-Square test. The estimated odds ratio was 0.091 indicating that chromosome abnormalities are 11.03 times more likely among fetuses with complex pleural effusions than isolated pleural effusions. **Conclusions:** Chromosome analysis is warranted following the detection of a pleural effusion on prenatal ultrasound examination. The aneuploidy rate in fetuses with isolated pleural effusions (8.6%) is significantly less than among fetuses with complex pleural effusions (30.4%) ( $p < 0.0001$ ).

**SLAMDUNC-a very successful new community program for first trimester combined screening for Down syndrome.** *L.J Sheffield<sup>1,2,3</sup>, R. Williamson<sup>1,2,3</sup>, J.L. Halliday<sup>2,4</sup>, R.M. Forbes<sup>1</sup>, A.M. Jaques<sup>2,3</sup>, A. Cronin<sup>1,2</sup>, L. Bonacquisto<sup>1</sup>, I. Francis<sup>1,2</sup>.* 1) Genetic Health Services Victoria,; 2) Murdoch Childrens Research Institute; 3) Department of Paediatrics, University of Melbourne; 4) Victorian Birth Defects Register, Department of Human Services, Melbourne, Australia.

We describe the first community based application of first trimester combined screening for Down syndrome in 18140 pregnancies. Our program uses a Single Laboratory And Many Diagnostic Ultrasound Nuchal-translucency Centres (abbreviated SLAMDUNC). The ultrasound is done in many specialised private obstetric ultrasound practices in the community. The results are better than when the ultrasound and biochemistry are done in a single tertiary centre as in an OSCAR (One Stop Counselling Assesment and Risk) clinic. SLAMDUNC detected 60/64 (93.8%) of the cases of Down syndrome for a false positive rate of 5%. If the detection rate is fixed at 85% then the false positive rate is 2.1% which compares very favourably to the 6% false positive of the SURUSS study for the combined test and the 1.3% false positive test of the integrated test. We also show for the first time, that the accuracy of the test is significantly greater if the blood sample is collected before 13 weeks. These state of the art results were achieved by using well-trained obstetric ultrasonologists, a very experienced screening laboratory and a team of genetic counselors, clinical geneticists and clerical staff. This presentation shows how the program worked to achieve the achievements of an OSCAR clinic but taking the ultrasound test out of tertiary centre into the community.

**Invasive trophoblast antigen (ITA) as a marker of fetal aneuploidy in the first and second trimester of pregnancy.** *U. Sancken*<sup>1</sup>, *R. Schemer*<sup>2</sup>, *M.R. Pandian*<sup>3</sup>, *J.E. Lee*<sup>3</sup>. 1) Institute of Human Genetics, University of Goettingen, Goettingen, Germany; 2) Nichols Institute Diagnostics, Bad Vilbel, Germany; 3) Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

ITA is a hyperglycosylated isoform of human chorionic gonadotropin (hCG) that has been reported to be increased in trisomy 21 (Down syndrome) affected pregnancies. In order to confirm these findings, we are conducting a prospective study of pregnant women undergoing routine prenatal screening at 10 to 18 weeks of gestation. To date, ITA concentrations have been determined in 2,500 urine and 5,000 serum samples. Pregnancy outcomes are being obtained from cytogenetic analysis of amniotic fluid or phenotypic observations following birth. Here we report early results. Between the 10th and 14th weeks of gestation, ITA levels decreased sharply, after which they decreased gradually to a plateau at 16 weeks of gestation. Serum ITA levels were dependent on maternal weight at time of specimen collection ( $ITA = 5.43 - 0.0152 * \text{weight}$ ; weight in kg). Although pregnancy outcomes are still being gathered, so far we have identified 18 aneuploid cases. The table below shows the distribution of serum ITA results in these cases.

Centile	Trisomy 21	Trisomy 18	Triploid	Turner	Klinefelter
>95th	6/7	0/3	0/2	0/3	0/3
<5th	0/7	3/3	2/2	0/3	0/3

Conclusion: Our preliminary results indicate that ITA may be a useful marker for prenatal detection of fetal aneuploidy (eg, trisomies 21 and 18). Accurate assessment of gestational age, especially in early gestation, and correction for maternal weight will be required when interpreting ITA concentrations.

**Y chromosome heterochromatin of differing lengths in two cell populations of the same individual.** *H. Lawce<sup>1</sup>, Y. Akkari<sup>1,2</sup>, S. Kelson<sup>1</sup>, C. Smith<sup>1</sup>, C. Davis<sup>1</sup>, M. Vahdati<sup>1</sup>, S.B. Olson<sup>1,2</sup>.* 1) Clin. Cytogenetics Lab, Oregon Health & Science Univ, Portland, OR; 2) Dept. Mol. and Med. Genetics, Oregon Health & Science Univ, Portland, OR.

The human Y chromosome is known to contain a heterochromatic region on the distal q arm comprising two highly repetitive sequence families, DYZ1 and DYZ2. This region is variable in length in different male populations without known clinical consequence. In this report, we present an unusual case of the prenatal diagnosis of a fetus with two populations of the Y chromosome: one with a short block of heterochromatin (Yqh-) and one with a longer block of heterochromatin (Yqh+). These two populations were further studied using fluorescent in situ hybridization (FISH) and quinacrine banding (Q-banding). Both Y chromosomes appeared to be structurally normal by these analyses. The biological father, to date, has been unavailable for study. Subsequent ultrasound examination at 20 weeks gestation revealed male genitalia. Based on these findings and the present understanding of this region of the Y chromosome, the family was counseled to expect no clinical impact of the two different Y chromosome-bearing cell populations. The baby was delivered at term without complications; the phenotype appeared normal. Follow-up post-natal blood chromosome analysis confirmed the presence of the two cell populations. The child is progressing normally at 9 months of age. This mosaicism may be explained by a post-zygotic simple deletion or unequal crossover event between sister chromatids in the DYZ region.

**Prognostic Significance And Phenotype Correlation In Infertile Men With Yq Microdeletions.** *R. Dada<sup>1</sup>, N.P. Gupta<sup>2</sup>, K. Kucheria<sup>1</sup>*. 1) Anatomy, AIIMS, New Delhi, India; 2) Urology, AIIMS, New Delhi, India.

Microdeletion of the long arm of the Y chromosome, are associated with spermatogenic failure and have been used to define three regions on Yq (AZFa, AZFb and AZFc) which are critical for spermatogenesis. These 3 loci act at different stages of germ cell development and deletion of each loci result in a characteristic phenotype. Deletion of AZFa, AZFb, AZFc results in Sertoli Cell Only syndrome (SCO), maturation arrest and hypospermatogenesis respectively. One hundred and seventy five infertile males with idiopathic oligozoospermia and azoospermia were included in this study. Cytogenetic and semen analysis was done in each case. Testicular Fine Needle aspiration Cytology was collected whenever possible. Of the 175 cases, 40 cases were klinefelter or variants. In cytogenetically normal cases microdeletion analysis was done using STS-PCR approach using primers sY84, sY86 (AZFa); sY127, sY134 (AZFb); sY254, sY255 (AZFc). Eight of the 102 cases showed deletion of at least one of the AZF loci. Four cases had AZFc deletion, three cases had AZFa and AZFb deletion and one case showed AZFb deletion alone. Two cases with AZFa and AZFb had SCO Type 1 syndrome and 2 cases of AZFc deletion showed hypospermatogenesis and 1 case showed maturation arrest. The FSH and LH levels were elevated in these cases. Variation in testicular phenotype in cases with AZFc deletion is due to multiple copies of the gene and presence of autosomal genes. Thus various factors genetic, epigenetic and environmental modulate the effect of these genes. Cases with AZFc microdeletion show a progressive decline in semen quality thus these cases are counselled to go in for semen cryoconservation at the earliest age should they opt for ICSI at a later date. Deletion on Y chromosome make the Y chromosome more prone to secondary larger deletions resulting in worsening of testicular phenotype. Therefore detection of Yq microdeletions encompassing the AZF loci determines the prognosis and management of these infertile cases.

**Common Arterial Trunk in the fetus: characteristics, associations and outcome in a multicenter series of 23 cases.** *M. Gentile*<sup>1,2</sup>, *D. Paladini*<sup>3</sup>, *M. Marasini*<sup>4</sup>, *A.L. Buonadonna*<sup>1</sup>, *M.G. Russo*<sup>3</sup>, *A. Di Carlo*<sup>1</sup>, *F. Cariola*<sup>1</sup>, *M. Vassallo*<sup>3</sup>, *P. Volpe*<sup>2</sup>. 1) Dept Medical Genetics, IRCCS S de Bellis, Castellana (BA), Bari, Italy; 2) Neonatal-Maternal Health Department, ASL BA/04, Bari, Italy; 3) Dept. Obstetrics and Gynecology, University Federico II, Naples; 4) Dept. Pediatric Cardiology, IRCCS Gaslini, Genova.

Objective: To assess: A) the accuracy of prenatal diagnosis; B) the incidence of extra-cardiac and chromosomal anomalies; C) the perinatal outcome in a population of 23 fetuses diagnosed with common arterial trunk (CAT), seen at three referral centers. Design: Observational trial of 23 fetuses with a confirmed diagnosis of CAT. All of them underwent fetal echocardiography, detailed anatomic scan and karyotyping. In 19/23 cases, FISH analysis was performed to detect the 22q11 microdeletion. The following variables were retrieved from databases and evaluated: gestational age at diagnosis, anatomic variants of the CAT, the presence of extra-cardiac and chromosomal anomalies, pregnancy and fetoneonatal outcome. Results: prenatal diagnosis of CAT proved correct in 23/24 cases, the last case being a pulmonary atresia with ventricular septal defect (PAVSD). A second cardiovascular anomaly was present in 8 cases (34.8%). Extra-cardiac anomalies were found in 10 cases (43.4%). FISH analysis showed the presence of the 22q11 microdeletion in 6/19 cases (31.6%). Pregnancy and fetoneonatal outcome was as follows: 8 (34.8%) terminations of pregnancy, 2 (8.7%) intrauterine deaths, 5 (21.7%) post-natal deaths (before or after surgery). The remaining 8 (34.8%) neonates are alive and thriving after surgery (6 cases) or awaiting surgery (2 cases). Conclusions: CAT can be reliably diagnosed and characterized in prenatal life, although differentiation from PAVSD is sometimes challenging. The association with chromosomal anomalies is consistent (8.7%), but there is a higher risk of 22q11 microdeletion (31.6%), in agreement with post-natal studies. The relatively poor survival rate (34.8%) is due to the high rate of terminations and the unfavorable cardiac anatomy in some cases.

**PCR quantitation of fetal cells in maternal blood is significantly compromised by presence of cell free fetal DNA.**

*X. Zhong, W. Holzgreve, S. Hahn.* Dept. Ob/Gyn, Univ Basel, Basel, Switzerland.

Fetal cells enriched from the blood of pregnant women still presents an enticing alternative for the development of a safe and efficacious non-invasive method for prenatal diagnosis. However, although promising in small studies, most enrichment methods used to date have failed to realise the long sought after goal. These failures have raised the questions of whether the enrichment methods were sub-optimal or whether there were no fetal cells present in the maternal blood sample being analysed. In order to answer these issues we have attempted to address a problem which has long beset research in this field, namely that no reliable method exists to determine the frequency of fetal cells in a given maternal blood sample. As we have considerable experience with the use of the Taqman real-time quantitative PCR system, we have now used this technology to address this task. In our analysis we used both a single copy gene on the Y chromosome (SRY) as well as a multi-copy sequence (DYS14). Our examination of cell free fetal DNA in maternal plasma samples indicated a very good concordance regarding the determination of fetal sex and the concentrations of cell free fetal DNA. We next addressed the issue of the number of fetal cells in maternal blood. As the concentration of cell free fetal DNA in maternal blood is much higher than fetal cell numbers we were concerned that the presence of the high levels of cell free fetal DNA may compromise the PCR quantitation. Hence, we examined paired samples which had been washed extensively or from which the plasma had been removed by standard centrifugation. Our study showed that the number of fetal genome equivalents detected in the unwashed samples was indeed significantly higher than in the washed samples. Therefore previous analyses may have been misled by this feature. We, furthermore, observed that fetal cells are too scarce to be detected by the use of single copy gene sequences such as SRY, and that even with the use of high copy sequences such as DYS14, their numbers did not exceed 2 fetal cells per mL of maternal blood.

**Prenatal Diagnosis of Trisomy 3 Mosaicism.** *A. Zaslav<sup>1</sup>, G. Pierno<sup>2</sup>, A. Fougner<sup>2</sup>, J. Jacob<sup>1</sup>, R. Kazi<sup>1</sup>, D. Blumenthal<sup>3</sup>, S. Sturim<sup>2</sup>, M. Shaham<sup>4</sup>, J. Davis<sup>5</sup>, J. Fox<sup>3</sup>.* 1) Dept of Laboratory Medicine, Long Island Jewish Medical Ctr, The Albert Einstein College of Medicine, New Hyde Park, NY; 2) SonoScan Genetic Sciences, Forest Hills, NY; 3) Dept of Peds, Schneider Children's Hosp, The Albert Einstein College of Medicine, New Hyde Park, NY; 4) Genzyne Genetics, Yonkers, NY; 5) Weill College of Medicine/Cornell University, New York, NY.

Trisomy 3 mosaicism has rarely been reported. We present a prenatally diagnosed case of trisomy 3 mosaicism. Amniocentesis was performed for AMA. The karyotype was 47,XX,+3[8]/46,XX[27]. Trisomy 3 was found in eight cells from three different culture vessels, meeting the criteria for true mosaicism. A repeat amniocentesis confirmed mosaicism for trisomy 3 (i.e., 47,XX,+3[1]/46,XX[18]). PUBS was performed at 19 weeks and showed 46,XX in 100 cells. A high-resolution ultrasound was performed at 18 weeks and fetal echocardiogram was performed at 20 weeks and neither revealed abnormalities. The infant was delivered at 34 weeks and had a normal examination, with the exception of symmetric IUGR. Apgar scores were 8 and 9 at one and five minutes, respectively. Chromosome analysis of 50 cells each from peripheral blood, placenta and umbilical cord revealed 46,XX in all cells. There was no evidence of trisomy 3 mosaicism. At 6 months the baby was progressing normally. Only two prenatally diagnosed cases of mosaic trisomy 3 have been reported. One resulted in a normal live born male. The other case resulted in an abnormal live born male with multiple congenital anomalies who died at 18 months due to congenital heart disease. Trisomy 3 was confirmed in skin fibroblasts and amnion cultures, whereas blood cultures were normal in 100 cells counted (Hsu, et al., 1997, *Prenat Diag* 17(3):201-242). The absence of trisomy 3 cells postnatally in our patient indicates that the trisomy 3 mosaicism was most likely placental, which resulted in IUGR. Prenatally diagnosed chromosome mosaicism is problematic for both patient and clinician. This is only the third report of trisomy 3 mosaicism. Additional cases of prenatally diagnosed mosaicism for rare trisomies are necessary to more accurately assess the significance of these findings.

Program Nr: 2498 from 2003 ASHG Annual Meeting

**Giant Omphalocele: Prenatal Diagnosis, Short and Long Term Outcomes.** *R.D. Wilson, J.M. Biard, M.P. Johnson, H.L. Hedrick, A.W. Flake, T.M. Crombleholme, S.N. Adzick.* Ctr Fetal Diag/Treatment/Wood, Children's Hosp Philadelphia, Philadelphia, PA.

**Objective:** To review prenatal features, short and longterm outcomes in prenatally diagnosed giant omphaloceles (GO) managed at a single institution (1996-2001).

**Study Design:** This retrospective study evaluated prenatal features and short and long term outcomes in pregnancies referred with prenatal diagnosis of GO. Parents and medical providers were surveyed by written questionnaire about the child's health . Quality of life(PedsQL4.0)tool was used in the older children . IRB 2002-2-2683 was obtained.

**Results:** GO was evaluated in 17 pregnancies ( 8 live born, 4 termination , 2 IUFD, 3 no follow-up). Complete extra-abdominal liver within peritoneal sac, ascites and extreme levocardia were prenatal findings in the survivors . Live born cases were delivered by C section at 37 weeks gestation with a mean BW 2903 gms. All neonates required intubation. Two infants died within 1 year. Four of the 6 survivors had respiratory insufficiency (mean ventilation 76 days, range 12-101 days ). Respiratory and feeding problems (first oral feed mean 250 days , range 15-577 days) complicated the early neonatal period. Long term follow-up was available for 5 patients (mean 33.2 months ). Asthma, recurrent pulmonary infections, feeding problem, gastroesophageal reflux, and failure to thrive were the major concerns. Both male survivors had bilateral inguinal hernias requiring repair. Developmental delay was present in 2 of 5 patients. Mean hospital stay for survivors was 148.4 days (range 23-316).

**Conclusions:** Respiratory and feeding problems were the most common neonatal and longterm management issues. Parents need to be aware of the probability of multiple surgeries and long hospitalization following birth.

**Evaluating Genetic Counseling Methods and Attitudes of Obstetrician/Gynecologists in Austria.** *V. Moser, M.A. Spence, M. Bocian.* Dept Pediatrics, Univ California, Irvine, Orange, CA.

Austria has no specially trained genetic counselors. This study surveyed the attitudes and practices of obstetrician/gynecologists in Austria regarding prenatal genetic counseling. A questionnaire consisting of demographics and eighteen questions was distributed to 931 Austrian obstetrician/gynecologists. A total of 269 (28.9%) respondents' questionnaires were returned and analyzed. Prenatal counseling in Austria is similar to that in America with regard to content and ideology, although not as standardized or thorough as that conducted by masters level genetic counselors. A three or more generation family history is seldom done (only 16% always do so) and the majority of physicians (56%) do not ask about their patients ethnicity. Only 76% of respondents explain normal male/female karyotypes to a patient when discussing amniocentesis. Most respondents felt confident overall in their role as providers of genetic information, although the majority also thought that the field of genetics is expanding too rapidly to keep up (67%). The majority felt competent to explain Down syndrome (83%), spina bifida (80%) and cystic fibrosis (58%) to patients (etiology, prognosis, recurrence risk), although more respondents indicated difficulty with cystic fibrosis (20% versus ~5% for each Down syndrome and spina bifida). When asked whether Austria already has sufficient expert personnel to address all the needs and questions of patients, the majority (74%) of respondents indicated their belief that Austria has enough resources, which appears contrary to the finding that 67% felt genetics is expanding too rapidly to keep up. The results of this study suggest a need in Austria for better training, continuing education, and standardization of practice in prenatal genetic counseling to cope with the rapidly increasing changes in genetics. Austria would also benefit from genetics experts, such as masters trained genetic counselors, as primary and/or secondary contact persons for at-risk patients.

**PRENATAL SCREENING FOR DOWN SYNDROME IN THE HISPANIC POPULATION.** *J. Santolaya-Forgas, J. De Leon-Luis.* TTUHSC, Amarillo, TX.

Our objective was to determine if Hispanics had similar first (free-bhCG, PAPP-A) or second trimester (AFP, hCG and uE3) maternal serum values than Caucasians. We have evaluated 200 pregnant women who had consented to donate blood for biochemical research early in pregnancy. We excluded 56 patient because they developed obstetrical complications. 144 patient reached term and had appropriate for gestational neonates. 123/144 and 129/144 patients had donated their blood at first and second trimester, respectively. All results were expressed as MoMs for gestational age. 62% were Caucasian, 29% Hispanic, 4% African-A. and 5% of other cultural backgrounds. Table 1 shows summary statistics in mean (S.D.).

MATERNAL AGE	MATERNAL WEIGHT	AGE AT FIRST TRIMESTER	AGE AT SECOND TRIMESTER
24 (5) years	86 (18.8) Kg	11.9 (1.5) weeks	16.8 (1.3) weeks
AGE AT DELIVERY	NEONATAL WEIGHT	APGAR	pH UMBILICAL VEIN
39.1 (1.1) weeks	3338.5 (420) grs	9 (0.5)	7.3 (0.07)

Table 2 shows mean values expressed in MoM for Caucasians and Hispanics.

	PAPP-A	Free Beta h CG	AFP	HCG	UE3
CAUCASIAN	1.5	1.5	1.11	1.27	0.97
HISPANIC	1.1	0.8	1.13	1.23	1.16
p-VALUE	0.26	<0.01	0.82	0.75	<0.02

These results suggest that the risk for Down syndrome might be underestimated in the Hispanic population using current first and second trimester algorithms. Further studies are recommended.

**Response to a newly formed University Genetic Screening Program in a USA semi-rural area.** *V.P. Noble, R. Yebra, I. Galn, J. De Leon-Luis, J. Santolaya-Forgas.* OB/GY, TTUHSC, Amarillo, Te.

Maternal age (MA), maternal serum markers (MS) and ultrasound (U/S) are commonly used prenatal screening procedures. Our aim was to evaluate acceptance rate for US-guided diagnostic testing after a positive MA, MS or U/S screening in our population. A single geneticist attends a population of 180,000 people with ~ 4200 deliveries/year. We report on 736 pregnant women referred for prenatal genetic counseling between 2000-2002 (1324 total consultations). The cultural backgrounds of the study population was: 62% European; 31% Hispanic; 4 % African-American and 3% other. 47% of patients had private insurance (P) and 53% were on Medicaid (M). 299 (40.6%) patients were referred due to family history of genetic disorders, mental retardation or congenital anomalies, recurrent miscarriage, maternal conditions such as diabetes, exposure to teratogens, etc., and for the purpose of this study were excluded from further analysis.

	(N)	P	M	%TOTAL PREG. POPULATION	ACCEPTANCE PREN. TESTING		
					P	M	
MA	174	122	52	174/8500 (2%)	35 %	30 %	(p. less than 0.05)
MS	128	43	85	128/8500 (1.5%)	37 %	35.2 %	(ns)
U/S	135	62	73	135/8500 (1.6%)	29 %	31.5 %	(ns)

The lower than expected referral rate for any of the prenatal screening categories may reflect a combination of lack of genetic education and limited availability of genetic services in our community prior to October 2000. After non-directive genetic counseling the acceptance rate for further prenatal testing is similar to that of other inner city USA University centers.

**Pre-implantation genetic diagnosis for Sanjad-Sakati syndrome.** A. Al-Aqeel<sup>1, 2</sup>, C. Serdar<sup>3</sup>, N. Sakati<sup>2</sup>, K. Jarodi<sup>3</sup>, P. Ozand<sup>2</sup>, A. Hellani<sup>3</sup>. 1) Dept Pediatrics, Riyadh Military Hosp, Riyadh, Saudi Arabia; 2) Dep of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh Saudi Arabia; 3) Dep of Reproductive Medicine, King Faisal Specialist Hospital & Research Centre, Riyadh Saudi Arabia.

The Sanjad-Sakati syndrome (SSS), MIM 241410 is an autosomal recessive disorder characterized by congenital hypoparathyroidism, growth and mental retardation. In Saudi Arabia the disease is caused by a deletion of 12bp of Tubulin Cofactor E (TBCE gene), starting from nucleotide 156 until nucleotide 166. In a Saudi family with two affected siblings with SSS, pre-implantation genetic diagnosis (PGD) was undertaken, fluorescent PCR (F-PCR) was performed on DNA showing heterozygosity and homozygosity status of the parents and the affected children. F-PCR was then used on a single cell using one round of amplification. Our allelic drop out (ADO) in lymphocyte was 0% since all the cells showed matched diagnosis. Our blastomere diagnosis showed 5 heterozygous, 3 homozygous and 3 normal, a mendelian percentage reflecting a negligible ADO. One heterozygous and one normal embryo were transferred because of their very good quality (morula). A singleton pregnancy was ensured and prenatal diagnosis by CVS confirmed a normal fetus. This is the first PGD for SSS families. Moreover, this is the first report showing negligible ADO in one round of F-PCR without linked markers.

**Prenatal diagnosis of Brachmann-de Lange syndrome using 2-D and 3-D ultrasonography.** *L. Applewhite<sup>1</sup>, B. Rochelson<sup>1</sup>, J. McLaughlin<sup>2</sup>, N. Vohra<sup>1</sup>, M.G. Bialer<sup>2</sup>.* 1) Divisions of Maternal Fetal Medicine and; 2) Medical Genetics, North Shore Univ Hosp/NYU Med Center, Manhasset, NY.

A 26 year old woman was referred at 21 wk gestation for comprehensive ultrasound (U/S) after a screening U/S reported fetal edema, possible ascites and a small left ventricle of the heart. The pregnancy had been essentially uncomplicated. There had been a urinary tract infection treated with Keflex. A triple screen had been performed which gave a risk for open neural tube defects of 1 in 260 and a Down syndrome and trisomy 18 risk of 1 in 5000. The couple were not consanguineous and the family history was not significant. The 2-D U/S findings included frontal bossing, micrognathia, thickened nuchal fold, diffuse skin edema, diaphragmatic hernia, shortening of the fetal long bones with missing fingers, pleural effusion and a VSD. The differential diagnosis discussed with the couple included trisomy 18, Brachmann-de Lange syndrome (BDLS) and Miller syndrome. 3-D U/S confirmed the above findings and showed flexion contractures of the upper extremities with severe oligodactyly and facial dysmorphisms including ocular hypertelorism, anteverted nares, micrognathia and downturned mouth. Amniocentesis was performed and chromosomes were normal 46,XY. The patient chose to terminate the pregnancy at 21 wk 3 days by induction to permit an examination of the fetus. Findings included ocular hypertelorism, synophrys, low-set posteriorly rotated ears, anteverted nares, flat nasal bridge, downturned mouth and webbed neck. The forearms were hypoplastic with no visible hand and a single finger bilaterally. There were bilateral elbow pterygia. The features were diagnostic of BDLS. There have been several previous sonographic prenatal diagnoses of BDLS using 2-D U/S. Diaphragmatic hernia with limb anomalies are suggestive of this diagnosis. In this case, the 3-D U/S assisted in making the diagnosis by revealing dysmorphic features that would be difficult to determine on 2-D. 3-D U/S can help the perinatologist and geneticist make a prenatal diagnosis and improve the counseling of the patient.

***De novo* mutation in the 21-hydroxylase gene detected in two patients with congenital adrenal hyperplasia (CAH): implications for complexity in genetic diagnosis of the disease.** R. Mao<sup>1</sup>, J. McDonald<sup>1</sup>, M. Cantwell<sup>2</sup>, W. Tang<sup>1</sup>, K. Ward<sup>1</sup>. 1) DNA Diagnostic Laboratory, University of Utah School of Medicine, Salt Lake City, UT; 2) Obstetrical Diagnostic Center, University of Utah Health Science center, Salt Lake City, UT.

**Objective:** We studied 37 unrelated families with history of congenital adrenal hyperplasia (CAH) for 8 common mutations and gene deletion in the 21-hydroxylase CYP21 gene and found *de novo* mutations in the CYP21 gene in two CAH patients. **Methods:** Analysis for eight common mutations in the 21-hydroxylase gene as well as deletion of the entire gene was accomplished using polymerase chain reaction (PCR) followed by amplified created restriction site (ACRS) and southern blot followed by hybridization to a CYP21 specific probe. Linkage analysis was performed using microsatellite markers flanking the CYP21 gene. Moreover, 10 STP markers have been used to confirm the parentage in the two *de novo* mutation cases. **Results:** In two prenatal cases, the Intron 2 A->G mutation was identified in the proband, not in the fetus, although they had identical linkage markers. Subsequently, this mutation was confirmed absent in the parent's genome and misparentage has been ruled out. **Conclusion:** Our findings are consistent with the other studies with a frequency of *de novo* mutation of approximately 1.0 to 1.5% in the CYP21 gene. This high new mutation rate relative to the rate of 1 in 1 million for the other autosomal recessive disorders, must be considered and discussed in prenatal diagnosis and genetic counseling for this relatively common inherited disorder. The *de novo* mutation in the CYP21 gene is non-negligible.

**Expansion of fetal cells in the maternal circulation occurred using Progenitor RosetteSep<sup>TM</sup> enrichment procedure with IL-3, SCF and G-CSF.** A. Sharma<sup>1</sup>, H. Elicha Gussin<sup>1</sup>, D. Marquz-Do<sup>2</sup>, D. Martinez<sup>2</sup>, C. Horne<sup>2</sup>, D. Lewis<sup>2</sup>, R. Hoffman<sup>3</sup>, S. Elias<sup>1</sup>, J.L. Simpson<sup>2</sup>, F. Bischoff<sup>2</sup>. 1) Dept OB/GYN, UIC, Chicago, IL; 2) Dept OB/GYN and Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Dept Hematology/ Oncology, UIC, Chicago, IL.

Expansion of fetal cells in maternal blood could be an ideal method of non-invasive prenatal diagnosis, but its results have been inconsistent. We have continued this pursuit with the Progenitor RosetteSep<sup>TM</sup> cocktail (StemCell Technologies) to deplete unwanted lineage positive maternal blood cells (T cells, NK cells, thymocytes, myelomonocytic cells, neutrophils, macrophages, B cells and granulocytes). We investigated whether cells isolated from maternal blood could be expanded in vitro, and whether the expanded cells were of fetal origin.

**Methods:** Peripheral blood from 12 pregnant women in the first trimester of gestation was obtained. The RosetteSep<sup>TM</sup> cocktail was added to whole blood, which was then layered over Ficoll (1.077 g/ml) and centrifuged. The enriched progenitor cell fraction was placed in culture for expansion for 14 days, using three different conditions: **Condition A:** SCF, M-CSF, GM-CSF, G-CSF; **Condition B:** IL-3, SCF, G-CSF; **Condition C:** IL-3, SCF, G-CSF M-CSF, GM-CSF. Cells were analyzed by FISH using direct-labeled X- and Y- probes. **Results:** Expansion of cells occurred in 11 out of 12 subjects, under each of the three conditions. Samples from 5 women with male fetuses, and from one with a female fetus, were analyzed. FISH results predictably showed no Y in the cells from the subject with a female fetus. For subjects with male fetuses, male cells (range: 1-5 cells) were found in cultures in condition B in three specimens (gestational age 10 1/7 to 10 5/7 weeks); no male cells were found in conditions A or C for these same samples. One male cell was found in the A culture from another specimen (GA: 12 4/7 weeks).

Cells isolated from maternal blood using the Progenitor RosetteSep procedure can be expanded in vitro. Male cells were found in 4 of 5 samples from women carrying male fetuses, and optimal culture conditions for such fetal cells may differ based on gestational age.

**Investigation of a marker chromosome unmasks a de novo cryptic chromosome 22 rearrangement with 22q subtelomere and ARSA duplication.** *E. Mak-Tam, P.R. Wyatt, L. Grierson, D. Allingham-Hawkins, E. Capua, G. Johnson, J. Kennedy, N. Neill.* Dept Genetics, North York General Hosp, Toronto, ON, Canada.

We report unexpected FISH findings while investigating a satellited marker in an amniotic fluid. A healthy 34 year old female presented at the genetics clinic because of a positive integrated prenatal screen (IPS): elevated Beta hCG and slightly elevated AFP. The family history was negative. Fetal ultra sound showed an apparently normal fetus with mild right hydronephrosis. Fetal echocardiogram showed a normal fetal heart. Chromosome results on amniotic fluid was 47,XX,+mar in all cells examined. A chromosome 22p- variant was noted but was not seen in either parent. Parental karyotypes were normal. The marker was C-Band positive and appeared to be bisatellited. Various CEP and paint probes were used for marker identification. The marker was positive only for the alpha satellite 14/22 probe. No euchromatin was detected. Additional FISH workup detected cryptic abnormalities on the "normal" 22p- chromosome. The VYSIS DiGeorge/VCF probe showed two signals for the ARSA locus located on opposite ends of the chromosome. The CytoCell 22qTel probe also showed two signals similarly placed. We could not resolve if the extra signals were just below or above the centromere. The patient was counseled for risks associated with the de novo abnormalities of chromosome 22. Termination was performed out of country because of advanced gestation. The fetal X-ray was normal. The fetus (from photographs) appeared to have micrognathia, abnormal position of fetal fingers and a broad nasal bridge. The abnormal 22 in this case was a serendipitous finding and not detectable with routine G-Banding. It is difficult to determine how much testing is sufficient. However, in view of this case, if the origin of a marker is determined and a variant is noted on the chromosome of origin, further studies may be warranted to rule out cryptic changes.

**Fetal Cell Recovery from Whole Maternal Blood: A Comparison of Two Protocols.** *H. Stroh, B. Berlin, D.W. Bianchi, K.L. Johnson.* Division of Genetics, Department of Pediatrics, Tufts-New England Medical Center, Boston, MA.

**Objective:** Fetal cells are present in the maternal circulation although their low frequency inhibits their retrieval. We compared fetal cell recovery from maternal whole blood using a detachable immunomagnetic bead technique to that of a human progenitor cell enrichment cocktail.

**Methods:** Pregnant women identified as high risk (e.g. abnormal ultrasound or serum screening) or undergoing an invasive procedure were enrolled in the study. Blood samples were processed within 24 hours using a CD71 immunomagnetic detachable bead isolation procedure (Dynal, Inc.) (n=22) or the RosetteSep progenitor cell cocktail (Stem Cell Technologies, Inc.) (n=61) according to the manufacturers specifications. Male fetal cells were identified by FISH using X and Y chromosome-specific probes and/or real-time PCR amplification of DYS1. Fetal sex was confirmed by amniocentesis, plasma PCR, or delivery.

**Results:** Overall, the sensitivity of detection of fetal cells from women carrying male fetuses by FISH was comparable between the Dynal and RosetteSep protocols (30 and 24%, respectively), and higher for the detection of cells from aneuploid fetuses using the RosetteSep procedure (75% [3 of 4] versus 40% [2 of 5]). By PCR, the overall detection rate was 20% with no false positive results using Dynal, and 4% with one false positive result using RosetteSep. The RosetteSep protocol resulted in a higher total number of cells isolated.

**Conclusions:** The large number of maternal cells isolated using RosetteSep resulted in time-consuming manual FISH analysis, and PCR analysis was confounded by the high background of maternal DNA present. FISH following Dynal isolation was more rapid, and likely more amenable to automation. Although the detection rate of aneuploid cells was higher using RosetteSep, this represents a small number of aneuploid samples analyzed, and the overall sensitivity by both FISH and PCR favors the Dynal procedure. Taken together, these results suggests that the Dynal immunomagnetic detachable bead system should be refined and further explored in a larger number of subjects.

**Preimplantation genetic diagnosis (PGD) for couples at risk of X-linked disease and for balanced translocation carriers.** *S. Weremowicz<sup>1</sup>, C. Racowsky<sup>1</sup>, D.J. Sandstrom<sup>1</sup>, A. Nureddin<sup>1</sup>, K.V. Jackson<sup>1</sup>, L.E. Wilkins-Haug<sup>1</sup>, C.C. Morton<sup>1</sup>, P.M. Miron<sup>2</sup>.* 1) Brigham and Women's Hospital, Boston, MA; 2) UMass Memorial Medical Center, Worcester, MA.

Since July 2000, PGD has been offered at Brigham and Womens Hospital for couples at risk of X-linked disease and carriers of reciprocal translocations. FISH with differentially labeled probes was employed to identify the sex of the embryo or the unbalanced chromosome rearrangements. Prior to clinical application, probe validation was performed on 22 couples and controls. All couples from the X-linked disease group proceeded with PGD by interphase FISH on blastomeres biopsied from three day pre- embryos with probes specific to chromosome X (DXZ1) and chromosome Y (DYZ1). For 5/15 couples with the reciprocal translocation [t(Y;15)(q11.23;p11.1), t(4;13)(q33;q21.2), t(14;16)(q32.3;q11.2), t(1;18)(q42.1;p11.2), t(15;20)(p11.2;q11.2) probes were individualized and included D15Z4 (at 15cen), RB1 at 13q14, BAC14c2 at 13q31, as well as short and long arm specific telomere probes of chromosomes 16, 18 and 20. In four couples, aneuploidy for chromosome 21 was assessed with the LSI21 probe. All probes but one (BAC14c2) were from Vysis Inc. In the X-linked disease group 11 cycles resulted in 135 biopsied embryos; 42/135 were classified as XX. The remaining (n=93) were classified as XY, abnormal or uninterpretable. In total, 27 embryos were transferred in 11 cycles resulting in four pregnancies in 3/7 (43%) couples with deliveries of three healthy females and one twin pregnancy with no follow-up. For translocation carriers, 13 cycles were performed and 86 embryos were biopsied; 16/86 embryos (19%) were assessed as chromosomally normal or balanced. Fifteen embryos were transferred in eight cycles resulting in pregnancy in 3/5 (60%) couples. Three healthy babies were delivered and one pregnancy is ongoing. Although in our institution, PGD is considered a screening modality and not to supplant genetic amniocentesis or CVS, we believe it represents a critical aspect of a test menu for genetic disease, and that its availability provides an efficacious alternative.

**GENE TRANSFER OF SP-C PROMOTER DRIVEN HUMAN EXTRACELLULAR SUPEROXIDE DISMUTASE (hEC-SOD) PLASMID cDNA USING POLYETHYLENIMINE (PEI) CARRIER EXPRESSES THE PROTEIN IN LUNG EPITHELIUM OF ADULT MICE 7 DAYS AFTER TREATMENT.** *M. Ahmed, M. Whorton, N. Mason, R. Auten.* Dept Pediatrics/Neonatology, Duke Univ Medical Ctr, Durham, NC.

Rationale: Transgenic overexpression of hEC-SOD in mice protects against oxygen toxicity. Since oxygen toxicity may contribute to chronic lung disease of prematurity, gene therapy may target sufficient antioxidant protection to the most vulnerable compartment. Method: We mixed 2.6 mg PEI, a cationic polymer (av. MW=25kDa), with 2 mg hEC-SOD cDNA, at a nitrogen (PEI):phosphorus (cDNA) molar equivalent ratio = 10:1, and administered it once by aerosol to adult mice in 95% air 5% CO<sub>2</sub> (to increase minute ventilation) over 30 min. Mice were sacrificed at 1, 3, and 7 days after treatment, and lungs were inflation fixed for immunohistochemical detection of hEC-SOD expression using an affinity purified rabbit anti-hEC-SOD IgG. hEC-SOD transgenic mice and wild type mice were used as positive and negative controls. Results: Wild type mice showed no hEC-SOD expression, while hEC-SOD transgenic mice showed strong alveolar and bronchiolar expression. At 1 day after PEI-hEC-SOD treatment, there was strong alveolar and bronchiolar expression that persisted at reduced levels on days 3 and 7. Conclusion: PEI gene transfer of SP-C promoter driven hEC-SOD cDNA can provide hEC-SOD expression in alveolar and bronchiolar epithelium up to 7 days. Speculation: Gene therapy that leads to transient EC-SOD overexpression may protect the lung against oxidant stress of short duration.

**Maternal MTHFR Genotype is a Predisposing Factor for Nonsyndromic Cleft Lip/Palate.** *F. Desposito<sup>1</sup>, M. Schwalb<sup>1</sup>, M. Royle<sup>2</sup>, D. Streck<sup>1</sup>, J. Dermody<sup>1</sup>*. 1) Center for Human & Molecular Genetics, UMDNJ-NJ Medical School, Newark, NJ; 2) NJ State Department of Health and Senior Services, Trenton, NJ.

The thermolabile forms of MTHFR have been implicated in a variety of medical problems including coronary artery disease, spina bifida and complications of pregnancy. Previous studies of the correlation of this polymorphism in infants with CL/P have shown both positive and nonsignificant results (Mills, et al 1999; Shaw, et al 1998). We examined a group of affected children and their mothers gathered from a national CDC study of birth defects. DNA was extracted from buccal swabs from 17 non-Hispanic Caucasian mothers and their affected children diagnosed with either cleft lip, cleft palate or both. The patients were ascertained as part of the CDC's National Birth Defects Prevention Study. All of the specimens in this study were collected in New Jersey. Of the 17 samples available for testing, nine mothers of affected children with apparent non-syndromic CL/P had the homozygous 677T/677T genotype. Of the eight non-homozygous 677T/677T, three mothers were compound heterozygotes 677T/1298C. Four of the affected children also had the 677T/677T genotype. A control group of 18 had one person homozygous for 677T. The preliminary observation that nine of 17 (53%) mothers of infants ascertained with CL/P displayed the 677T/677T thermolabile form of MTHFR suggests that this maternal genotype may be a major predisposing factor in the risk of a child having nonsyndromic CL/P. Our control group showed a frequency of 5.5% consistent with a recent population study, which showed a frequency of 7.2% for this genotype in Caucasians (Esfahani, et al 2003). We are currently analyzing additional families, the possible role of maternal compound heterozygosity 677T/1298C, and implications for primary prevention by prenatal vitamin supplementation for women with homozygous MTHFR genotypes.

**HERMANSKY-PUDLAK IN PREGNANCY: A risk factor for obstetrical hemorrhage.** *S. Klugman, D. Barbouth, S.M. Carter, P. Dar, P.S. Bernstein, S.J. Gross.* Albert Einstein College of Medicine, Montefiore Medical Ctr, Bronx, NY.

**Background:** Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder that presents with oculocutaneous albinism, bleeding diathesis and ceroid storage disease primarily affecting the lungs and gut. While HSP has been described in many ethnic groups, its prevalence is rare (1/500,000). However, among the Puerto Rican population, the prevalence rate is 1/1800. Molecular testing of the HPS1 gene is available specifically for those of northwest Puerto Rican descent and mutation analysis of the HPS3 gene is likewise available for patients of central Puerto Rican and Ashkenazi Jewish heritage. Mutations in the HPS1 gene have a detection rate of 97%. Pregnancy in patients with HPS has been rarely reported, with only two previous case reports that discuss pregnancy complications. We report another case of HPS in a pregnant Puerto Rican woman who has experienced significant bleeding in all three of her pregnancies.

**Case:** The proband, a 22 year old G3P1011, had an uncomplicated first pregnancy and was delivered of a term female infant by spontaneous vaginal delivery who was unaffected. The postpartum course was complicated by bleeding that required a platelet transfusion. Following this pregnancy, she had a significant episode of bleeding two weeks after an elective termination, which required platelet transfusion. The current pregnancy is with a different partner, who underwent molecular analysis for the HPS1 gene and was negative. At the time of publication, the patient was 35 weeks pregnant and has had an episode of epistaxis that required platelet transfusion.

**Conclusion:** Despite the general tendency towards increased risk of clotting during pregnancy, our patient exhibited bleeding complications common in HPS. Because these complications increase morbidity and potential mortality, pregnant patients with HPS require careful surveillance. Because of the high frequent carrier status in Puerto Rico, routine carrier testing should be considered in those of Puerto Rican descent.

**MSAFP screening from 21-24 weeks gestation: the Manitoba experience.** *N.K. Björklund<sup>1</sup>, K.M. MacDonald<sup>1,2</sup>, J.A. Evans<sup>1,2,3</sup>, B.N. Chodirker<sup>1,2</sup>.* 1) Biochemistry & Medical Genetics; 2) Pediatrics & Child Health; 3) Community Health Sciences; University of Manitoba, Winnipeg, Canada.

Most maternal serum screening programs do not interpret samples taken after 21 weeks gestation. The Manitoba policy has been to interpret the MSAFP for samples drawn before 25 weeks gestation. Risks for chromosomal anomalies are only interpreted up to 21 weeks. The purpose of this study is to review the Manitoba experience with MSAFP screening done at a late gestation defined as 21 weeks and <25 weeks. The Manitoba Maternal Serum Screening Program database was reviewed to determine descriptive statistics, including screen positive rate, for all 1st samples drawn at a late gestation (with correction of dates by ultrasound if available). Samples from twin pregnancies or with diabetes were excluded. Samples screened from 16 weeks to <17 weeks were used as a control group. We also reviewed all cases of neural tube defects (NTDs) identified with an MSAFP sample at 21-25 weeks to determine the sensitivity. 4870 patients (3.4% of the total) were screened at a late gestation over 13 years (1990-2002). Of these, 181 were elevated. The screen positive rate for the late samples was therefore 3.72% versus 2.49% for controls. The mean MOM for the late samples was 1.08 ( 0.67) compared to 1.03 ( 0.56). The medians were 1.19 and 1.12 respectively. While these differences are statistically significant ( $p < 0.001$ ), they are clinically unimportant. There were 8 late drawn routine screening tests associated with an NTD and 3 late samples after an anomaly was seen on ultrasound. 10 were elevated and one was normal. The one normal MSAFP was drawn at 23 weeks and spina bifida was diagnosed at birth (a "poorly covered" L5 defect). 7 of the 11 prenatally diagnosed cases of NTDs resulted in pregnancy terminations. Two cases of gastroschisis were also detected by late screening. Although MSAFP screening should ideally be done before 21 weeks gestation, we conclude that screening between 21 and 25 weeks gestation is feasible, with acceptable sensitivity and screen positive rates and late screening would still allow for intervention in affected pregnancies in many jurisdictions.

**Undetectable unconjugated estriol associated with Antley-Bixler syndrome: Further evidence for abnormal steroidogenesis.** *R.J. Hopkin<sup>1</sup>, N.P. Mulrooney<sup>2</sup>, S. Trumpy<sup>3</sup>*. 1) Dept Human Genetics, Cincinnati Children's Hosp Medical Ctr, Cincinnati, OH; 2) Dept Neonatology, Cincinnati Children's Hospital Medical Ctr, Cincinnati, OH; 3) Bethesda North Hospital Department of Obstetrics and Gynecology, Cincinnati OH.

Antley-Bixler syndrome (ABS) is a rare disorder characterized by radiohumeral synostosis, craniosynostosis with resultant midface hypoplasia, characteristic facial dysmorphism, bowing of the femurs, multiple joint contractures, and urogenital defects. Based on reports of affected siblings and affected children born to consanguineous couples ABS has been considered an autosomal recessive condition; however, other modes of inheritance have also been suggested. Genetic heterogeneity is likely. Several reports have invoked errors of steroid metabolism in the pathogenesis of ABS. Evidence for this has included reported association with maternal luteomas, fetal 21-hydroxylase deficiency, early pregnancy exposure to fluconazole, and lanosterol 14-alpha-demethylase deficiency. We report siblings with classic features of ABS. In the first pregnancy ultra sound documented facial dysmorphism, radiohumeral synostosis, ambiguous genitalia and femoral bowing. Examination after delivery confirmed the diagnosis of ABS. Chromosomes were normal, 46,XY. During the second pregnancy ultrasound including 4-D images again demonstrated findings suggestive of ABS. Amniocentesis revealed a normal karyotype 46,XX. Molecular studies of FGFR2 were negative. The diagnosis of ABS was confirmed following delivery. At 8 months 17-OH-progesterone, cortisol and ACTH response were normal. Maternal serum screening had demonstrated undetectable maternal serum unconjugated estriol (uE3) in each of the affected pregnancies implicating abnormal steroid metabolism in these children. Undetectable uE3 has been associated with a variety of errors in steroidogenesis: steroid sulfatase deficiency, congenital adrenal hyperplasia, and Smith-Lemli-Opitz syndrome, but to our knowledge has not been reported in association with ABS. This finding adds to the evidence that abnormal steroidogenesis plays an important role in the pathogenesis of this complex disorder.

**The influence of fetal loss on the presence of fetal cell microchimerism: a systematic review.** *D.W. Bianchi<sup>1</sup>, K. Khosrotehrani<sup>1</sup>, J. Lau<sup>2</sup>, D.H. Cha<sup>1</sup>, K. Johnson<sup>1</sup>*. 1) Division of Genetics, Department of Pediatrics, Tufts-New England Medical Ctr, Boston, MA; 2) Division of Clinical Care Research, Tufts-New England Medical Ctr, Boston, MA.

**Purpose.** Fetal cells enter the maternal circulation during most pregnancies but persist for years in only some women. We have previously shown that terminations of pregnancy result in a higher fetal cell transfusion into the maternal circulation (1). In addition, we reported, using DNA polymorphism analysis, that fetal microchimeric cells persisting in the liver of a woman originated from a miscarried fetus 19 years earlier (2). The objective of this study was to determine if pregnancy history influences the persistence of fetal microchimeric cells long after pregnancy.

**Methods.** We reviewed all published studies on fetal cell microchimerism, defined as the detection of male DNA in maternal tissue, that describe individual pregnancy histories, disease diagnoses and microchimerism status of their study subjects. The number of total pregnancies, births and sons, and history of fetal loss (spontaneous abortion and elective termination) were tested as factors potentially associated with the persistence of microchimeric cells.

**Results.** One hundred twenty-four subjects from eleven studies met the inclusion criteria. Only fetal loss was significantly associated with the presence of microchimerism (odds ratio 2.4, 95% confidence interval: 1.2-6.0).

**Conclusion.** These results suggest that fetomaternal cell trafficking following fetal loss may be important for the engraftment of microchimeric cells in maternal tissue. This may be due to an increased amount of fetomaternal transfusion or transfer of a cell type that is more likely to engraft. We recommend that future studies on microchimerism report detailed pregnancy information, as these data are critical for the understanding of factors that influence the development of fetal cell microchimerism.

**Prenatal Diagnosis and Deletion Screening of Duchenne Muscular Dystrophy in Iranian Families.** *A. Tabarrokhi, R. Kariminejad, N. Almadani, H. Najmabadi.* Molecular Genetic , Kariminejads najmabadi genetic, Tehran, Tehran, Iran.

Duchenne Muscular Dystrophy (DMD) is one of the most common X-linked genetic disorders seen in children. Mutation in the DMD gene, coding for the protein called dystrophin, causes the severe muscle wasting disorders leading to wheelchair dependence by 10 to 12 years of age and progress relentlessly until death by the early 20s. In the absence of a cure, prenatal diagnosis (PND) appears to be the best approach to reduce the burden for these families. In the last 5 years, we have studied 80 families for deletion screening and linkage analysis. Initially three sets of Multiplex PCR were used for screening of 20 exons in the dystrophin gene. Followed by, three intragenic RFLPs (pERT 87-15/ BamHI, pERT87-8/TaqI, pERT 87-15/XmnI) and also two CA repeats (5- Dys MSA and 3 Dys MSA). Our findings indicate that, deletions were observed in 43 affected boys (approximately 54 percent). The most common deletions were found in exons 49, 50 and no deletion was detected in the Promoter (Pm) region. In 32 numbers of cases, the deletions were confined to the distal hot spot (exons 44-60), and in 11 numbers of cases deletions were related to the proximal hot spot (exons 4-17). In 53 families these three intragenic RFLPs were utilized and in 34 families one or more of these RFLPs were informative (64 percent). The most informative RFLPs in our population was BamHI (46 percent) and the least one was TaqI (28 percent). In 31 families Microsatellite repeat analysis was performed to identify the mutant alleles and in 12 families 5-DYS was informative and in one family 3-DYS was informative. Prenatal diagnosis was performed for 21 families (15 cases were C.V.S and 6 cases were Amnion). 13 fetuses had male sex which 11 cases were normal and two of which were affected. Also 8 fetuses had female sex which 3 of them were normal and 5 of which were carriers. So, multiplex PCR technology and three intragenic RFLPs, can be used effectively for PND and also carrier detection, but in Iranian families CA repeats 3- Dys MSA was found out that has minimum heterogeneity.

**Single cell co-amplification of microsatellite markers for preimplantation genetic diagnosis by haplotype analysis of Xq28 disease genes.** *N. Gigarel<sup>1</sup>, N. Achour-Frydman<sup>2</sup>, P. Burlet<sup>1</sup>, V. Kerbrat<sup>2</sup>, M. Vekemans<sup>1</sup>, R. Frydman<sup>2</sup>, A. Munnich<sup>1</sup>, P.F. Ray<sup>1</sup>.* 1) Dept Genetics, Hop. Necker Enfants Malades, Paris, France; 2) Dept Obs and Gynae, Hop. A.Beclere, Clamart, France.

Preimplantation Genetic Diagnosis first consisted in the selection of female embryos for patients at risk of transmitting X-linked recessive diseases. Advances in molecular biology now allow the specific diagnosis of almost any pathology. For families with an identified X-linked disease causing mutation, non-specific diagnosis by sex identification can be considered as sub-standard since it involves the unnecessary disposal of healthy male embryos and reduces success rate by diminishing the pool of embryos eligible for transfer. The most telomeric part of the X-chromosome long arm is a highly gene-rich region encompassing disease genes such as haemophilia A, X-linked adrenoleukodystrophy, X-linked hydrocephalus and incontinentia pigmenti (IP). To circumvent the risk of misdiagnosis due to a meiotic recombination between the gene of interest and the marker it is important to analyse at least two markers located on each side of the disease gene. We developed five single cell triplex amplification protocols with different combinations of microsatellite markers DXS1073, BGN, G6PD, DXS1108, DXS8087 and F8C. The choice of the set to use then depends on the diagnosed pathology and on the informativity of the markers for the concerned families. These tests will allow the diagnosis of all diseases previously mentioned providing that the genetic material of an index case allowing the identification of the morbid allele can be obtained. Amplification rates on single lymphocytes of the different markers ranged from 93-97% with allele dropout rates comprised between 0 and 19%. Familial linkage analysis was carried out for 10 couples. For each couple there was at least one of the multiplex primer set in which 2 markers were informative. So far PGD has been carried out for three patients at risk of transmitting X-linked adrenoleukodystrophy, X-linked hydrocephalus and hemophilia A. The latter is now undergoing a normal pregnancy.

**Validation of a test for aneuploidy in pre-embryo blastomeres at a USA national reference laboratory. A.**

*Anguiano<sup>1</sup>, V. Sulcova<sup>1</sup>, S. Ziebe<sup>2</sup>, I. Agerholm<sup>3</sup>, M. Bungum<sup>4</sup>, K. Erb<sup>5</sup>, K. Lyby<sup>6</sup>, C. Grondahl<sup>6</sup>, C.M. Strom<sup>1</sup>.* 1) Cytogenetics, Quest Diagnostics, Nichols Ins, San Juan Capistrano, CA; 2) Fertility Clinic, Rigshospitalet, Copenhagen, Denmark; 3) Fertility Clinic, Braedstrup Sygehus, Braedstrup, Denmark; 4) Fertility Clinic, Skive Hospital, Skive, Denmark; 5) Fertility Clinic, Odense University Hospital, Odense, Denmark; 6) Novo Nordisk A/S, Bagsvaerd, Denmark.

Preimplantation Genetic Diagnosis (PGD) for aneuploidy detection has been shown to increase IVF success rates in women of advanced maternal age. As PGD gains wider acceptance, it will be necessary to increase the number of laboratories capable of performing PGD with proficiency documentation. For assay validation, we tested blastomeres from 45 donated surplus pre-embryos that were obtained following informed consent from 4 centers in Denmark. No information was received on methods of cycle inductions nor medical history of donors. The pre-embryos were disaggregated, and individual blastomeres prepared and fixed on a coated glass slide. Commercially available probes for chromosomes 13, 16, 18, 21, 22 (MultiVysion PB, Vysis Inc.) were used. Additionally, a sequential hybridization for X and Y centromeres was performed. A control slide from metaphases from peripheral blood of a male individual was run with each assay. From morphological evaluation, 104 blastomere nuclei were expected. Giemsa staining demonstrated 97 nuclei (concordance 93%), and FISH results were informative in 93 (96%), partially informative in 2 (2%), and uninformative in 2 (2%). Of the 93 informative nuclei, 23 showed a diploid count for all tested chromosomes, 10 exhibited one chromosome aneuploidy, and 60 had more than one abnormality (of these, 6 were suggestive of triploidy). These results fulfill our requirements for assay validation and enable us to consider offering PGD for aneuploidy as part of our menu of FISH tests.

**Polar Body and Blastomere Analysis for Spinal Muscular Atrophy (SMA); SMN1 and SMN2 Exon 7 - 8 Deletion Detection Together With Single-Copy and Multi-Copy Flanking STR Markers.** *R.S. Ozen, S. Rechitsky, T. Sharapova, K. Laziuk, O. Verlinsky, A. Kuliev, Y. Verlinsky.* Reproductive Genetics Institute, Chicago, IL.

Spinal muscular atrophy (SMA) is an autosomal recessive disorder with a prevalence of 1/10,000 and a carrier frequency of 1 in 40-60 individuals. All types of SMA are caused by mutations in the survival motor neuron gene (SMN) locus mapped on chromosome 5q11.2-13. The SMN gene is present in two highly homologous copies, SMN1 and SMN2. Homozygous loss of functional survival motor neuron 1 (SMN1) alleles results in SMA, while homozygous absence of SMN2 gives no clinical phenotype. Since most SMA patients lack both copies of SMN1 exon 7, preimplantation genetic diagnosis (PGD) for SMA is based on the avoidance of SMN1 homozygous deletions, which is complex because of the sequence similarity between SMN1 and SMN2 genes, and requires simultaneous linkage analysis with STR markers. We performed PGD for SMA carriers, using polar body (PB) and blastomere analysis of exon 7 and exon 8 deletions in SMN1 and SMN2 genes together with closely linked STR markers. To test paternal SMN1 and SMN2 deletion patterns on each chromosome by blastomere analysis, single sperm testing was performed to establish the haplotype of normal and deleted alleles with multicopy STR marker D5S1556 (Ag1-CA), located on promoter region of both gene copies, and single copy STR markers D5S435, D5S351 and D5S610. We analyzed 49 PB and 36 blastomeres from 5 In Vitro Fertilization (IVF) cycles resulted in 4 ongoing pregnancies, two with confirmed twins and two with singletons (one confirmed by CVS and one is pending). The results show that the above system is reliable for PGD of SMA both by PB and blastomere analysis.

**Spectral karyotyping for use in preimplantation genetic diagnosis and detection of chromosome aneuploidy. R.**

*Owen<sup>1,2</sup>, J. Tong<sup>2</sup>, J. Ciselak<sup>3</sup>, Y. Verlinsky<sup>3</sup>, J.F. Weier<sup>2</sup>, R. Reijo<sup>2</sup>.* 1) University of California, San Francisco, Dept. of Pediatrics; 2) University of California, San Francisco, Dept. of Obstetrics, Gynecology and Reproductive Sciences; 3) Reproductive Genetics Institute, Chicago, IL.

Many couples enlist the help of in vitro fertility (IVF) clinics to aid in producing a successful pregnancy. Likewise, more women of advanced maternal age and families with a history of known genetic disorders are visiting IVF clinics to undergo preimplantation genetic diagnoses (PGD) to increase their probability of having a healthy child. Unfortunately, even with assisted reproductive technology and advances in molecular testing, the success rate is still low. Objective traits such as embryo quality, for example, do not always dictate the chance of pregnancy. Alternatively, chromosomal abnormalities may be a leading contributor to a significant proportion of unsuccessful pregnancies. Currently, screening for chromosomal abnormalities is performed by polar body or blastomere biopsy using interphase FISH analysis. However, commercially available kits used in screening can only detect the more common aneuploidies 13, 16, 18, 21, 22 and sex chromosomes. Here, we present spectral karyotyping (SKY) results used to determine its application to PGD in exploration of aneuploidy in single blastomeres. We have analyzed 39 metaphase spreads from 14 different couples hybridized with chromosome specific probes. Approximately 50% of these spreads were analyzable; those failed were due to lost chromosomal material or lack of chromosome spreading. None of those examined were identified as having a normal karyotype. Spectral karyotyping, in the future, with adequate technical expertise and optimal chromosome condensation and spreading may be able to predict aneuploidy and structural abnormalities, however, our results suggest it is not ready for clinical use.

**PREIMPLANTATION HLA TYPING.** *Y. Verlinsky, S. Rechitsky, O. Verlinsky, I. Tur-Kaspa, A. Horwitz, A. Kuliev.*  
Dept Molec Genet, Reproductive Genetic Inst, Chicago, IL.

We performed 378 cases of preimplantation genetic diagnosis (PGD) for 54 different conditions, including single gene defects, dynamic mutations and some medically relevant genetic variations. Unaffected embryos were pre-selected in 333 (88.1%) of them, resulting in 110 (33%) clinical unaffected pregnancies. The PGD protocols used provided an option not only for avoiding an affected pregnancy, but also for performing HLA typing to pre-select the HLA compatible donors for transplantation therapy in affected siblings. Single biopsied blastomeres were tested by multiplex nested PCR analysis to analyze simultaneously for mutations, linked markers, chromosomal aneuploidy and HLA genes, allowing the pre-selection and transfer back to patients only those unaffected embryos, which were HLA matched to the affected sibling requiring stem cell transplantation. The method was applied for the HLA genotyping in 24 cases in combination with PGD for thalassemia, Fanconi anemia, hyper immunoglobulin M syndrome, X-linked adrenoleukodystrophy and Wiscott-Aldrich syndrome, confirming the usefulness of preimplantation HLA matching as part of PGD. In addition, we performed 13 cases of preimplantation HLA typing without testing for causative gene, such as for different leukemias. This resulted in the embryo transfer of HLA matched embryos in 11 cycles, yielding 5 clinical pregnancies of which three have already resulted in the birth of HLA-matched healthy children to become potential HLA compatible donors for children requiring bone marrow transplantation. The data provide a realistic option for the couples desiring to establish a pregnancy potentially providing an HLA match progeny for treatment of affected siblings.

**Validation of Preimplantation Genetic Diagnosis for Clinical Applications.** *H. Tyson<sup>1</sup>, S. Chong<sup>1</sup>, A. Benner<sup>1</sup>, Z. Al Hasnan<sup>1</sup>, S. Katsanis<sup>1</sup>, K. Thrift<sup>2</sup>, A. Lawler<sup>2</sup>, G. Stetten<sup>2</sup>, Y. Zhao<sup>2</sup>, G.R. Cutting<sup>1</sup>.* 1) Inst Genet Med, JHU, Baltimore, MD; 2) Dept of OB/GYN, JHU, Baltimore, MD.

While prenatal diagnosis for single gene disorders using DNA from amniocytes or chorionic villus cells is performed almost exclusively in clinical laboratories with established quality assurance and quality control procedures, Preimplantation Genetic Diagnosis (PGD) is not widely available in the clinical setting. Since PGD offers a new testing option for couples at risk for single gene disorders, we have addressed this issue by validating a PGD test for the common autosomal genetic disorder cystic fibrosis (CF). All validation experiments were performed in a masked fashion and at least one wash blank was provided for every cell analyzed. To detect the CF mutation deltaF508, exon 10 of the *CFTR* gene was amplified by nested PCR of single lymphoblast cells heterozygous for deltaF508. Although 91% (61/67) of single lymphoblasts were amplified, the deltaF508 mutation was correctly identified in only 58% (34/59). Redesign of primers increased detection of deltaF508 to 98% (131/134), and wash blanks accompanying the lymphoblasts were not contaminated (0/38). While 86% (25/29) of de-identified discarded blastomeres were amplified for *CFTR* exon 10, 9% (6/67) of the accompanying wash blanks were contaminated. To address this issue, two washes were added to the blastomere biopsy procedure, reducing contamination to 2% (3/124). Since contamination remained, we incorporated a fluorescent polymorphic DNA marker (ID2) to detect non-fetal contaminating DNA. Reagent blank contamination was observed in 1/19 experiments which prompted a re-design of the protocol for assembling the PCR mastermix. Using the optimized PGD protocol, exon 10 and ID2 were amplified from 90% (18/20) of donated IVF blastomeres with no wash or reagent contamination detected (0/70). For couples with a mutation other than deltaF508, four previously published linkage markers flanking *CFTR* (D7S480, D7S486, D7S490, and D7S523) have been validated. We demonstrate that errors of single cell analysis can be detected and addressed by extensive validation thus allowing PGD test implementation in a clinical DNA diagnostic lab.

**A look at a minority population, primarily hispanic, in an urban prenatal diagnostic center: referral reasons, amniocentesis uptake, and abnormalities detected.** *C. Guze*<sup>1,2</sup>, *D. Baker*<sup>2</sup>, *R. Hassan*<sup>1</sup>. 1) Dept OB/GYN, King Drew Medical Ctr, Los Angeles, CA; 2) Dept Biology, California State Univ Dominguez Hills, Carson, CA.

**OBJECTIVE:** To describe the population referred to our inner city Los Angeles Prenatal Diagnostic Center (PDC) with a primarily Hispanic clientele. Specifically, we wanted to assess trends in referral reasons and amniocentesis uptake and to also assess the abnormalities found during the seven-year period (1995-2001). **METHODS:** All 3085 patients referred to the Genetics Unit for genetic counseling between January 1, 1995 and December 31, 2001 were evaluated through a retrospective review of records maintained by the unit. Patient records included race, age, referral reason, referral clinic, amniocentesis decision and results, and abnormalities. **RESULTS:** A total of 3085 patients received genetic counseling during the 7-year study period (1995-2001). The patient population consisted of 75.9% Hispanic, 22.4% African American and 1.7% other. The primary referrals were for AMA (48.3%) and MS-AFP (32.6%). The overall amniocentesis acceptance rate was 51.5%: AMA amniocentesis acceptance rate was 45.6% and the MS-AFP screen positive rate was significantly higher at 64.4%. There was a significant difference between the overall amniocentesis acceptance rate for Hispanics (47.7%) and African Americans (62.8%) and a significant trend downward of amniocentesis uptake between 1995 (63%) and 2001 (39%). This trend held for both ethnic groups. However, the acceptance rate for African Americans was consistently higher than the Hispanic acceptance rate by year and by referral reason. There were 151 (4.9%) abnormalities detected by ultrasound and amniocentesis among the 3085 patients referred. **CONCLUSIONS:** The acceptance of amniocentesis in the Hispanic and African American population in our PDC is significantly lower than what has been previously reported in the literature for Caucasians and the overall California statewide acceptance rate, and has significantly declined over the 1995-2001 time period. Supported by NIH MBRS R25 GM62252.

**In-vitro expansion of trophoblasts isolated from the maternal circulation: potential application in non-invasive prenatal diagnosis.** *E. Guetta, L. Gutstein-Abo, G. Barkai.* Danek Gertner Institute of Human Genetics, Sheba Medical Center, Tel-Hashomer, Israel.

The application of non-invasive prenatal diagnosis based on isolation of rare fetal cells from maternal blood will become a feasible alternative to the invasive procedures currently in use only if in-vitro expansion and subsequent metaphase chromosome analysis can be achieved. Trophoblasts originating from the placenta are present in the maternal circulation, albeit, at a frequency corresponding to a rare cell event. In an initial effort to develop a method that could potentially provide cycling cells for chromosome analysis, improve the efficiency of fetal cell detection and increase the cell yield, we studied the possibility of growing trophoblasts isolated from maternal blood in an in-vitro culture system. HLA-G, a trophoblast marker, aids in targeting these cells for application in non-invasive prenatal diagnosis. Thus, trophoblasts were isolated from maternal blood with magnetic activated cell sorting (MACS) and anti-HLA-G antibodies. The HLA-G positive fractions of cells were either directly analyzed or seeded in culture for 3-5 days. Fluorescent in-situ hybridization with sex chromosome probes was applied in order to identify fetal trophoblast cells in samples from women carrying a male fetus. The average number of fetal trophoblast cells expressing HLA-G increased 5-fold after culture ( $p < 0.01$ ). Accurate sex identification was accomplished in 93% of the samples when the in-vitro culture protocol was tested in a group of samples analyzed in the absence of prior knowledge of fetal sex. Improvement of this system may facilitate the development of a reliable, clinically applicable method for non-invasive prenatal diagnosis.

**Prenatal Ultrasound findings in Lissencephaly.** *S. Ghai<sup>1</sup>, K. Fong<sup>1</sup>, A. Toi<sup>1</sup>, S. Blaser<sup>2</sup>, A. Pai<sup>1</sup>, D. Chitayat<sup>1</sup>.* 1) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Canada; 2) Medical Imaging, Hospital for Sick Children, Toronto, Canada.

Lissencephaly is a neuronal migration disorder characterized by the absence of sulcation of the cerebral hemispheres. The condition is difficult to diagnose prenatally prior to 24 weeks gestation. Fetal ultrasound findings in 16 fetuses with lissencephaly who were followed prenatally at our institution were reviewed. Lissencephaly was confirmed by prenatal/postnatal MRI, and/or autopsy. In cases with Miller-Dieker syndrome (MDS), this was confirmed by FISH analysis for deletion 17p13.3. There were 6 cases with MDS and 10 cases with Walker-Warburg syndrome (WWS). Ultrasound examination was performed at 15-41 weeks gestation. Ultrasound images were reviewed for intra/extracranial findings with an emphasis on cerebral cortical development. The sylvian and parieto-occipital fissure, calcarine and ingulate sulcus and the sulci on the convexity of the brain were evaluated. One or more cerebral abnormalities were found in all fetuses. Ventriculomegaly was the most common finding and was present in 12 fetuses. In three cases it was isolated and in 9 cases it was associated with other findings. In 5 fetuses the initial findings were ventriculomegaly detected at 20 wks gestation or earlier. In the 11 remaining fetuses one or more findings of delayed cortical development were noted on ultrasound. The earliest gestational age lissencephaly could be suspected was 23 weeks. Other cranial findings included microcephaly (2), corpus callosum dysgenesis (1), absent septi pellucidi and cavum (2), Dandy-Walker malformation/variant (5), encephalocele (1), and lemon-shaped head (2). Extracranial findings included: eye and facial abnormalities (4), omphalocele (1), renal anomalies (1) and growth-restriction (3). The earliest and most common cranial abnormality which should raise the suspicion for possible lissencephaly is ventriculomegaly. Thus, follow-up ultrasound at 23-24 weeks in the third trimester with a detailed survey of the brain sulcation and gyration should be part of the investigation of mild ventriculomegaly. Fetal brain MRI as well as FISH for deletion 17p13.3 can assist in making the diagnosis.

**Invasive prenatal diagnosis in the Netherlands 1991-2000: a trend analysis in 117.430 pregnancies.** *N.J Leschot<sup>1</sup>, H.T.C. Nagel<sup>2</sup>, A.C. Knegt<sup>1</sup>, M.D. Kloosterman<sup>3</sup>, H.I.J. Wildschut<sup>4</sup>, F.P.H.A. Vandenbussche<sup>5</sup>.* 1) Dept. Clinical Genetics, Academic Medical Centre, Amsterdam, The Netherlands; 2) Dept. Obstetrics/Gynecology, Bronovo Hospital, The Hague, The Netherlands; 3) Dept. Obstetrics/Gynecology, Rijnstate Hospital, Arnhem, The Netherlands; 4) Dept. Obstetrics, Erasmus Medical Centre, Rotterdam, The Netherlands; 5) Dept. Obstetrics, Leiden University Medical Centre, The Netherlands.

Objective: The findings in the first 10 annual reports of the Dutch Working Party on Prenatal Diagnosis were combined and analysed for trends. In the Netherlands the same (standard) indications are used in all 13 centres. The annual number of births is about 200.000. There is no official screening program for Down syndrome and/or neural tube defects. Methods: In each annual report detailed data on all prenatal diagnostic procedures are listed. Follow up data about continuation or termination of pregnancy (TOP) for each indication are available for the last 5 years. Findings: The proportion of women that chose for prenatal diagnosis, about 5-6%, was rather stable, despite an increase in the total number of pregnant women of 36 years or older from 15.140 in 1991 to 25.730 in 2000! In a total of 117.430 pregnancies maternal age was the indication in 72%. The proportion of women of 36 years or older that chose for prenatal diagnosis was stable up to 1994 (47%) and then decreased to 34% in 2000. The reason is that, despite the absence of an official screening program, an increasing number of women with this indication asks for maternal serum screening or for nuchal translucency measurement. The total number of abnormal laboratory findings increased from 362 in 1991 to 638 in 2000. In 71% the parents chose for TOP. For the years 1996-2000: 88% of all trisomy 21 pregnancies (n=989) were terminated, for pregnancies with sex chromosome abnormalities (n=386) 54% were terminated. The mean annual number of TOP's was about 400, this is about 2% of all annual abortions in our country. The proportion of chorionic villi samplings decreased from 39%(1991) to 27%(2000).

**Prenatal Diagnosis of Hydrocephalus due to congenital stenosis of aqueduct of Sylvius (HSAS) by fetal MRI.** A. Kennedy<sup>1,2</sup>, J. Carey<sup>3</sup>, R. Hulinsky<sup>1</sup>. 1) OB Diagnostic Center, Univ of UT Hospital, Salt Lake City, UT; 2) Radiology, Univ of UT Hospital, Salt Lake City, UT; 3) Pediatrics, Univ of UT, Salt Lake City, UT.

Hydrocephalus is a common birth defect detected easily by ultrasound. X-linked hydrocephalus is the most common form of genetic hydrocephalus accounting for approximately 5% of aqueductal stenosis related hydrocephalus. Hydrocephalus due to congenital stenosis of aqueduct of Sylvius (HSAS; MIM #307000) is characterized by hydrocephalus, adducted thumbs, spasticity, agenesis of the corpus callosum, and mental retardation. HSAS along with MASA and X-linked spastic paraplegia type 1 are associated with mutations in the L1CAM gene. We report a 30-year-old G3 P2002 female who presented for prenatal care at 34 weeks gestation. Severe hydrocephalus was noted by ultrasound with cranial biometry out of chart range. Visualization of cranial contents was further compromised by skull ossification. MRI was requested for further evaluation specifically to differentiate severe hydrocephalus from hydranencephaly as this would influence mode of delivery (C-section contraindicated with hydranencephaly). Fetal MRI showed severe hydrocephalus and normal cerebellum with intact vermis. Visualization of fetal hands by ultrasound was difficult, however by MRI bilateral adducted thumbs were noted, highly suggestive of X-linked aqueductal stenosis as the etiology. Upon taking a detailed family history the mother reported a son from a previous relationship that has CP. Upon review of the child's CT and MRI, it was confirmed that he had agenesis of the corpus callosum. Due to family history, presence of adducted thumbs, and severe hydrocephalus the fetus was determined to have HSAS possibly due to a mutation in the L1CAM gene. The patient presented at 37 weeks gestation in labor and the child was delivered via C-section due to fetal head size. Postnatal CT scan confirmed aqueductal stenosis. Postnatal exam confirmed presence of bilateral adducted thumbs. Correlation between prenatal findings and postnatal outcome will be demonstrated using images from ultrasound, MRI, and postnatal exam. This case illustrates the usefulness of fetal MRI in conjunction with ultrasound to determine antenatal diagnosis.

**Simultaneous determination of fetal trisomies 18 and 21 by real-time quantitative PCR.** *W. Holzgreve<sup>1</sup>, B. Zimmermann<sup>1</sup>, L. Levett<sup>2</sup>, S. Hahn<sup>1</sup>.* 1) Dept OB/GYN, Univ Basel, Basel, Switzerland; 2) The Doctors Laboratory, London, UK.

The detection of gross chromosomal abnormalities is a major focus of prenatal diagnostics, of which the most common cytogenetic anomaly in live births is trisomy 21, also known as Down's Syndrome. Currently, prenatal diagnosis of genetic anomalies relies on invasive procedures such as amniocentesis and chorionic villus sampling (CVS), from which the full fetal karyotype is usually determined using cultured cells. The two week period needed for cultivation and subsequent analysis has proven to be associated with considerable parental anxiety. This two-week delay is also associated with considerable medical problems in those situations requiring therapeutic intervention. In order to address these needs, more rapid methods for the prenatal diagnosis of fetal chromosomal aneuploidies have recently been developed and implemented, such as multi-colour fluorescence in-situ hybridisation (FISH) as well as quantitative fluorescent PCR analysis of short tandem repeats (STRs). With the advent of real-time PCR it is now possible to measure nucleic acid concentrations with an accuracy that was not deemed possible only a few years ago. Examples are the analysis of gene expression or gene duplications / losses, where two-fold differences in nucleic acid concentration have routinely been determined with almost 100% accuracy. As our primary interest is in prenatal diagnosis, we have investigated whether real-time PCR could be used for the diagnosis of chromosomal anomalies, in particular the aneuploidies such as trisomy 21, where the difference in copy number is only 50%. The feasibility of such an approach was first tested in a pilot study, wherein we were able to demonstrate that trisomy 21 samples could be detected with 100% specificity and sensitivity. We have now modified this test to permit the simultaneous analysis of trisomies 18 and 21 and have in a large scale analysis demonstrated that our approach can be used for the highly reproducible and robust detection of only 1.5 fold differences in gene copy number. Our studies have also underscored that several criteria need to be met such as template preparation and primer purity.

**Is preterm delivery a risk factor for autistic disorders?** *N. Luscri, T. Stroud, J. Miles, N. Takahashi.* Dept Child Health, Div Med Gen, Univ Missouri Hospital, Columbia, MO.

Prematurity is a major risk factor of illness & disability. This study attempts to determine if prematurity is a risk factor in autistic disorders. This may assist clinicians in earlier diagnosis allowing a more favorable prognosis. Methods: Gestational age was available for 402/422 patients, all of whom met DSM-IV diagnostic criteria for autistic disorder, PDD-NOS or Aspergers. The average DOB was 1989, range 1943-2001. Preterm delivery was defined as gestational age <37 weeks, & very preterm delivery <32 weeks. The rates of preterm delivery for 402 probands were compared to Missouri population rates in 1991 (11.4% preterm; 1.9% very preterm). Phenotypic subgroups were analyzed individually to determine if prematurity predisposes to different outcomes or occurred in specific subgroups. Results: For the entire group, 12.9% (52/402) were preterm, & 2% (8/402) were very preterm. Children with physical or neurologic risk features (dysmorphism, brain abnormality, abnormal EEG, microcephaly, seizures), type of onset (regressive), and different autism behavioral phenotypes (typical vs mild social, communication or repetitive behavior impairments) and IQ/DQ subgroups were analyzed individually. There was no significant increase or decrease in preterm delivery rates for any of these subgroups. When analyzing patients for prenatal and perinatal complications, high levels of complications correlated with higher rates of preterm delivery: high prenatal complications [ $<37$  wk = 42.9% (6/14),  $p=.02$  &  $<32$  wk = 28.6% (4/14),  $p<.0001$ ]; high perinatal complications [ $<37$  wk = 50% (11/22),  $p<.0001$  &  $<32$  wk = 22.7% (5/22)  $p<.0001$ ]. Other potential risk factors such as socioeconomic status, maternal age, prenatal infection, APGAR scores, genetic syndromes, and other chromosome abnormalities were analyzed. Only low APGAR scores showed a significant correlation with prematurity. Conclusion: Autism is an etiologically and clinically heterogeneous disorder. Prematurity does not, however, occur more frequently in any of our recognized autism subgroups, in the classical autism diagnostic categories or in groups with severe vs mild symptoms in the three phenotypic domains.

**Fetomaternal hemorrhage identified through high MS-AFP and resulting in a brain infarct.** *D. Myles Reid<sup>1</sup>, J. Kingdom<sup>2</sup>, H. Sroka<sup>1</sup>, S. Blaser<sup>3</sup>, A. Toi<sup>4</sup>, D. Chitayat<sup>1</sup>*. 1) Medical Genetics, Mount Sinai Hospital, Toronto, ON, Canada; 2) Department of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, ON, Canada; 3) Department of Pediatrics, Division of Medical Imaging, The Hospital for Sick Children, Toronto, ON, Canada; 4) Department of Medical Imaging, Mount Sinai Hospital, Toronto, ON, Canada.

We report a case of elevated second trimester maternal serum alpha-fetoprotein (AFP) associated with fetomaternal hemorrhage which resulted in fetal brain infarct. The patient was a 28-year-old primigravida woman of Colombian descent, who was referred following a high MS-AFP of 16.05 MoM detected on MSS done at 16.6 weeks gestation. The uE3 was 1.14 MoM and the hCG was 3.09 MoM. Detailed fetal ultrasound performed at 18.2 weeks gestation demonstrated normal fetal anatomy, excluding a fetal structural abnormality as the cause of the raised MS-AFP. In addition, Doppler studies were normal suggesting normal placental function. MSS repeated at 18.4 weeks gestation showed increase in the MS-AFP of 162 MoM and high hCG of 5.54 MoM. Maternal abdominal ultrasound as well as total body MRI showed no evidence of a tumor. A repeat MS-AFP at 19 weeks gestation was 170 MoM. Fetal MRI performed at 20 weeks gestation did not detect any abnormalities to account for the elevated AFP levels. Betke-Kleihauer test was completed and the results were consistent with an estimated fetomaternal transfusion of 25ml. Since the fetal-placental blood volume at this gestation is approximately 150ml/kg the estimated fetal blood loss was 25%. In view of these findings we repeated the fetal MRI which showed bilateral cystic changes in the region of the middle cerebral artery. In addition, the posterior parietal and occipital lobes were thinner than expected suggesting cell loss in these regions. The fetal head growth was also lagging. The appearance was suggestive of an in utero ischemic event within both middle cerebral artery territories. It is likely that the fetus experienced a profound hypoperfusion episode at the time of the fetomaternal hemorrhage.

**The prenatal molecular karyotype: DNA microarray analysis of cell-free fetal DNA (cffDNA) in amniotic fluid.**

*P.B. Larrabee<sup>1</sup>, E.S. LeShane<sup>1</sup>, E. Pestova<sup>2</sup>, K. Wilber<sup>2</sup>, U. Tantravahi<sup>3</sup>, J.M. Cowan<sup>1</sup>, K.L. Johnson<sup>1</sup>, D.W. Bianchi<sup>1</sup>.*

1) Division of Genetics, Department of Pediatrics, Tufts-New England Medical Center, Boston, MA; 2) Vysis, Inc., Downers Grove, IL; 3) Department of Pathology, Women and Infants' Hospital, Providence, RI.

**Background:** Prenatal cytogenetic diagnosis traditionally consists of metaphase karyotype analysis of cells obtained by amniocentesis or CVS. We have previously shown that large quantities of cffDNA are present and easily amplified in amniotic fluid (Clin Chem 2001;47:1867-9). The use of cffDNA may allow for more rapid and detailed molecular analysis of fetal genetic material, thus enhancing the current standard of care. **Methods:** With IRB approval, 6 frozen amniotic fluid supernatant samples were obtained from mid-trimester pregnant women carrying 4 male and 2 female fetuses. After thawing and, in some cases, removing residual intact cells, cffDNA was extracted, labeled, and hybridized to the GenoSensor™ Array 300 (Vysis, Inc.) This microarray allows for the quantitative analysis of DNA sequences from all human chromosomes, including subtelomeres. All analyses were performed blindly without knowledge of fetal karyotype. **Results:** Samples from all 4 male fetuses showed increased hybridization signals on SRY and decreased hybridization signals on DXS580, DMD, KAL, STS, AR, DXS7132, XIST, and OCRL1 when compared to female reference DNA. Samples from both female fetuses showed the reverse when compared to male reference DNA. Because these markers had an overall analytical sensitivity of 90% and specificity of > 99%, the gender of every specimen tested was therefore identified correctly. Work is in progress on the evaluation of abnormal samples confirmed by karyotype, including whole chromosome gains such as trisomy 21. **Conclusions:** The preliminary results suggest that microarray technology can be applied to cffDNA extracted from amniotic fluid. Correct identification of fetal gender was achieved in all cases. The use of DNA microarrays for prenatal genetic analysis of cffDNA in amniotic fluid may allow for rapid screening of amniotic fluid samples and the enhanced diagnostic capabilities of a molecular approach.

**The logistics of integrated prenatal screening for Down syndrome in Ontario, Canada.** *T. Huang, I. Lasis, C. Meier, A. Summers.* Genetics Prog, North York Hosp, Toronto, ON, Canada.

Although second trimester triple marker screening is effective in detecting Down syndrome (DS), there has been concern over its high false positive rate (FPR) of 7%. The Integrated Prenatal Screening (IPS) is expected to reduce the FPR to 1.5% while improving the detection rate (DR) from 72% to 85%. IPS is carried out in two steps. The first step, between 10 and 14 weeks of gestation, involves an ultrasound for nuchal translucency (NT) and a blood sample for pregnancy-associated plasma protein A (PAPP-A). The second blood sample, taken between 15 and 18 weeks of gestation, is for alpha-fetoprotein, unconjugated estriol, and human chorionic gonadotrophin. The final result is based on the integration of the two parts. IPS was introduced at North York General Hospital (NYGH) in November 1999. IPS was first offered by geneticists and genetic counsellors at NYGH, and then expanded to physicians of patients delivering at NYGH, and finally to health care providers (HCP) within our region. Prior to the introduction of IPS, a screening protocol, patient brochure, counselling guideline and requisition were developed. Education sessions and rounds were organized to educate HCP at NYGH and in the region. Sonographer specific medians based on 50 NT images were established for each ultrasonographer before they were enrolled in the programme. A three-page requisition was used for the IPS. The first page is for NT first and then PAPP-A, the second page is for the second blood sample; the last page is for the patient's chart. Patients are advised to have the NT measured prior to the first blood sample, and then return for the second blood sample at an appropriate gestation. All screen positive women were counselled in the Genetics Program at NYGH. To date, ~15,000 women have been screened using IPS. The drop out rate for IPS is ~5%. The number of sonographers enrolled in the IPS programme has increased from 3 to 133. Initially, limited availability of NT was a problem, but now the vast majority of patients have NT measured. IPS has been successfully introduced into our practice, it has performed as expected and currently comprises 50% of our screening volume.

**Inter-laboratory comparison of fetal DNA detection from common maternal plasma samples using real-time PCR.** *K.L. Johnson, D.W. Bianchi, S. Elias, W. Holzgreve, J.L. Simpson, K.W. Klinger.* NICHD Fetal Cell Isolation Study (NIFTY).

**Background:** Analysis of cell-free fetal (cff) DNA from maternal plasma offers great potential for non-invasive prenatal genetic diagnosis. To further evaluate the clinical utility of this assay, we developed and validated a standard protocol to determine if cffDNA sequences could be reproducibly amplified and measured. We then compared its performance across multiple laboratories using a common set of specimens. **Methods:** Each of five participating centers collected 20 mL of peripheral blood from 20 pregnant women (10-20 weeks). The plasma fraction was separated according to a common protocol, divided, and frozen in five aliquots. One aliquot was shipped to each participating laboratory, where DNA was extracted according to a standard protocol. All plasma samples were then analyzed blindly for the presence and quantity of total DNA (GAPDH) and male fetal DNA (SRY) by real-time PCR. Genomic DNA was isolated from female and male cells at one center, quantified, and shipped to the others to serve as GAPDH and SRY standards, respectively. **Results:** Efficiency of amplification of known quantities of DNA was consistent amongst all centers. The mean quantity of male DNA amplified from maternal plasma when the fetus was male ranged from 51.14 to 228.20 genome equivalents (GE)/mL. The sensitivity of the assay for detection of male DNA when the fetus was male varied from 31.4 to and 97.1% among centers. Centers that extracted and amplified more DNA per mL of maternal plasma had superior sensitivities of Y chromosome sequence detection. A total of four false positive results were obtained, yielding more consistent specificity (92.8 to 100%). **Conclusions:** All centers were able to consistently amplify standard DNA that was frozen and had been shipped considerable distances. This demonstrates that DNA is a stable analyte and that the PCR technique used here is reliable and reproducible. Differences in sensitivity demonstrate that for assay reproducibility, emphasis should be placed on development of a robust and thoroughly optimized protocol for the extraction of DNA from maternal plasma to provide for a clinically relevant analytical tool.

**Development of highly sensitive allele-specific PCR based allelic discrimination method for non-invasive prenatal detection of cystic fibrosis mutations.** *O. Nasis, G. Sathe, L. Jackson, T. Otevrel.* Center for Molecular Diagnostics and Genome Research, Department of Obstetrics and Gynecology, Drexel University College of Medicine, Philadelphia, PA 19102.

Cystic Fibrosis is a genetic disease caused by mutations in the membrane conductivity gene, CFTR. Many individuals are non-affected carriers of this disease and can pass the defective gene to their children. If both parents are carriers of the mutated gene, a high probability exists that the child will inherit both mutated copies and will be affected with cystic fibrosis. In such high-risk cases, it is important to conduct prenatal screening. The current prenatal diagnostic tests are highly reliable; however, they are invasive techniques that carry a risk of fetal loss. To reduce the need for these procedures, our efforts are focused on the development of non-invasive prenatal screening methods using maternal blood samples. Fetal cell-free DNA is known to be present in maternal circulation during pregnancy, but its extremely low quantity and the overwhelming amount of maternal DNA causes difficulty in fetal genetic analysis. Our approach employs an allele specific PCR technology that has been improved to enable allelic discrimination and detection of mutations in samples containing 200 - 20,000 fold excess of wild type gene sequences. The procedure has been developed and tested for cystic fibrosis mutations deltaF508 and D1152H. The method would be applicable in situations when both parents of the fetus are carriers of the cystic fibrosis mutations, but have a defect in different parts of the CFTR gene. In this case, the presence or absence of paternal mutation can be determined in DNA isolated from blood of the pregnant woman. Exclusion of the paternal gene defect would then eliminate the need for an invasive prenatal diagnostic procedure.

**Cell-Free Fetal DNA Levels in Maternal Plasma before and after Elective First Trimester Termination of Pregnancy.** *T. Wataganara*<sup>1</sup>, *A.Y. Chen*<sup>2</sup>, *E.S. LeShane*<sup>1</sup>, *L.M. Sullivan*<sup>3</sup>, *L. Borgatta*<sup>2</sup>, *D.W. Bianchi*<sup>1</sup>, *K.L. Johnson*<sup>1</sup>.  
1) Division of Genetics, Departments of Pediatrics, Obstetrics and Gynecology, Tufts-New England Medical Ctr; 2) Departments of Obstetrics and Gynecology, and; 3) Departments of Mathematics and Statistics, Boston University Medical Ctr, Boston, MA.

**Objective.** Quantitation of fetomaternal hemorrhage (FMH) may be useful in certain clinical situations. Several methods have been investigated to measure FMH, but none has proven to be reliable. This has led to debate about the presence/extent of FMH. We investigated levels of cell-free fetal DNA (cfDNA) in maternal plasma before and after elective surgical and medical first trimester termination of pregnancy (TOP) to explore the possibility of using this analyte as a novel marker of FMH. **Methods.** With IRB approval, pre and post-procedure blood samples were drawn from 71 and 63 pregnant women undergoing surgical and medical TOP, respectively. DNA was extracted from plasma by standard protocols. Real-time quantitative PCR was used to measure the levels of *DYS1* as a marker of cfDNA, and  $\alpha$ -globin as a marker of total DNA. Post-termination levels were adjusted based on the half-life of cfDNA in maternal blood. Fetal gender was confirmed by analysis of placental tissue. **Results.** cfDNA was detected in gender unknown pre-termination samples from 27 (38%) and 29 (46%) of the subjects in the surgical and medical arms, respectively, as early as 32 days of gestation. cfDNA increased 4.2 genome equivalents/mL/week. In the surgical arm, the sensitivity of pre-procedure cfDNA detection was 92.6% (27 of 29 known male fetuses). The mean level of adjusted post-termination cfDNA was higher than expected based on the anticipated increase in cfDNA due to advancing gestation (paired t test,  $P=0.0017$ ). In the medical arm, 6 patients had increased cfDNA levels for up to 11 days following TOP. **Conclusions.** cfDNA can be reliably quantified in early first trimester maternal plasma. The elevation of cfDNA that occurs shortly after surgical TOP may reflect FMH or destruction of trophoblastic villi, and may remain elevated for several days following medical TOP. These data suggest that cfDNA is a sensitive and reliable marker to quantify FMH.

**Identifying fetal cells in maternal circulation by FISH - Feasibility for prenatal diagnosis.** *S. Shimizu, M. Sherwood, R. Wapner, L. Jackson.* Department of Obstetrics and Gynecology, Drexel University College of Medicine, Philadelphia, PA.

Fetal cells in maternal circulation are a potential source of non-invasive prenatal genetic diagnosis. Hamada et al (1993) and Krabchi et al (1999, 2001) quantified male fetal cells in a few maternal blood samples predominantly at 18 to 22 wks gestation using no cell separation or enrichment and counting cells with a Y fluorescence *in situ* hybridization (FISH) signal. To further assess this approach for prenatal diagnosis in a larger series at earlier gestation, we obtained blood samples from pregnant women between 10 and 16 wks gestation. Consecutive unselected maternal blood samples were processed to yield 16 male and 16 female fetus containing pregnancies. 2 ml of maternal blood was processed without enrichment by simple hypotonic pretreatment and Carnoy fixation of all nuclei. FISH was performed, and fetal XY cells were identified and counted in a background of maternal XX cells. Both manual and automated fluorescent microscopic scanning was performed. All 16 male pregnancies yielded XY positive cells by FISH. The number of such cells varied between 1.5 and 10 per ml of maternal blood. No XY positive cells were found in 16 female pregnancies. Automated microscope scanning of fewer samples found similar results. Higher numbers of cells were found in a small number of samples of pregnancies carrying fetuses with various chromosomal aneuploidies. This study confirms and extends the findings of Hamada and Krabchi that there is a small but consistent population of fetal cells present in maternal blood samples (95% c.i. 94-100% of pregnancies). The type and origin of these cells cannot be determined from this study as the method removes potentially identifying cytoplasmic characteristics. This study further demonstrates that these cells are present in late first trimester at a time when early prenatal diagnosis is desired. The method is inadequate for any real clinical application but indicates that sufficient cells are present in a small maternal blood volume for further development of a clinically useful diagnostic approach using these cells.

**Prenatal Diagnosis of Mosaic Trisomy 14: A Case Report and Literature Review.** *E. Wood, K. Blakemore, G. Stetten.* Johns Hopkins University, Baltimore, MD.

Trisomy 14 mosaicism is associated with a distinct phenotype which was established based on fifteen cases ascertained postnatally due to mental and physical anomalies. This phenotype includes growth and mental retardation, dysmorphic facial features, congenital heart defects, and abnormal genitalia in males. Tissues showing the trisomy 14 cell line include blood and skin. Fives cases of prenatally diagnosed trisomy 14 mosaicism have been published, ascertained by amniocentesis for advanced maternal age. Two of these five cases were terminated; one after a sonogram revealed hydrocephaly, and one which was found to have low-set ears, transverse palmar creases, clinodactyly, clubfeet, and an abnormal hip at autopsy. In three of the five cases, the pregnancy was continued. All three infants were reported as grossly normal at the time of birth, although long-term follow-up is not available. Additional tissue studies on these three cases, including in utero fetal blood, and blood and skin samples after delivery revealed normal chromosomes with no evidence of trisomy 14. The present case was ascertained when amniocentesis for advanced maternal age in a 41 year old, para 1011 Caucasian woman, revealed 2/17 colonies to be trisomic for chromosome 14. These colonies were on two separate coverslips. A second amniocentesis and an intrahepatic fetal vein blood sampling revealed a normal female karyotype in 21 colonies and 126 cells, respectively. UPD studies showed normal, biparental inheritance of chromosome 14. A sonogram and fetal echocardiogram at 20 weeks gestation revealed no fetal anomalies. Follow-up studies after delivery showed a 46,XX karyotype in 100 cells from a placental biopsy and 100 cells from cultured cord blood. This child, now 3 weeks old, is non-dysmorphic and showing normal development. This case serves as another example of the difference in phenotype when trisomy 14 mosaicism is diagnosed prenatally versus postnatally.

**Oculoauriculofrontonasal Syndrome (OAFNS): Early Prenatal Diagnosis and Autopsy Findings.** *J. Pierre-Louis<sup>1</sup>, J. Johnson<sup>2, 3</sup>, S. Keating<sup>4</sup>, D. Chitayat<sup>1, 2</sup>.* 1) Prenatal Diagnosis & Medical Genetics Program; 2) Depts. of Obstetrics & Gynecology; 3) Medical Imaging; 4) and Laboratory Medicine & Pathobiology, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

Oculoauriculofrontonasal dysplasia (OAFNS) is a rare developmental field defect with findings of both frontonasal dysplasia sequence and oculoauriculovertebral spectrum. It represents an abnormal morphogenesis of the frontonasal eminence. A total of 23 cases have been reported and the etiology is unknown. We report the prenatal ultrasound and autopsy findings in a case. A 46-year old, G3P1SA1L1 woman of British descent presented with a pregnancy conceived through donor intra-uterine insemination. An ultrasound at 12.4 weeks gestation for nuchal translucency screening showed an abnormal profile with retrognathia and suspected cleft lip and palate. The nuchal translucency measured 1.6mm and the nasal bone was absent. The patient was counseled and decided to have CVS that showed a normal female karyotype. A 3-D ultrasound showed an extensive craniofacial abnormality including severe micrognathia, a large facial cleft extending from the upper lip to the inner canthus of the right eye and back to the pharynx. There was a second less severe cleft on the left side, severe hypertelorism, low set ears and an abnormal nose. The couple decided to terminate the pregnancy. The autopsy confirmed the prenatal findings consistent with oculoauriculofrontonasal syndrome including bilateral cleft lip and palate, absent auricle and ear canal on the right, hypoplastic low-set and posteriorly rotated auricle and obliterated ear canal on the left, absent eyelid on the right and fused eyelids on the left, notched broad nasal tip, ocular hypertelorism and severe micrognathia. OAFNS has been described in the literature, but to the best of our knowledge this case is the first early diagnosis of this severe condition. In this instance, 3D ultrasound provided critical information enabling the couple to make an informed decision with respect to the management of the pregnancy. It also illustrates the ability to evaluation the fetal profile in details at the time of the 11-14 week scan.

**False negative interphase FISH assay on three prenatal cases of trisomy 18.** *C. Yu<sup>1</sup>, J. Bofill<sup>2</sup>*. 1) Dept Preventive Medicine; 2) Dept Obstetrics and Gynecology, University of Mississippi Med Ctr, Jackson, MS.

Prenatal interphase FISH assay is a powerful tool for determining the common aneuploid, and is becoming increasingly demanded in the prenatal diagnostic laboratory. However, when only limited numbers of nuclei are analyzed, the results of the prenatal interphase FISH study should be interpreted with caution. We report here three cases with false negative FISH studies and reemphasize the importance of conventional cytogenetic analysis. **Case 1.** KC, a 21-year-old black female at 26-weeks-gestation, referred for diagnosis due to polyhydramnios. Interphase FISH showed a male fetus with normal number 13,18 and 21. Cytogenetic study revealed a 46,XY,der(13)t(13;18)(p11.2;q11.2) karyotype. **Case 2.** BJ, a 21-year-old black female at 20-weeks-gestation, referred for diagnosis due to multiple fetal anomalies. Interphase FISH showed a male fetus with normal number 13, 18 and 21. Cytogenetic study indicated a 46,XY,i(18)(q10) karyotype. **Case 3.** IL, a 38-year-old white female at 34-weeks-gestation, referred for amniocentesis because of AMA and a fetal heart anomaly. Interphase FISH showed a female fetus with normal number 13, 18 and 21. Cytogenetic study revealed a 47,XX,+18cen- karyotype. In case 1, the derivative chromosome 13 contained no 18 centromere, in case 2, the isochromosome 18 contained only a single 18 centromere, and in case 3, one of the 18 centromeres had only a weak fluorescent signal that was missed during the process of image capturing. Prenatal interphase FISH study is a rapid and precious method for aneuploid detection, however, there are also pitfalls. The FISH analysis must be performed extremely carefully, and with a critical eye - especially when the information leads to clinical decisions without complete traditional cytogenetic analysis.

**Application of comparative genomic hybridization using microarrays to routine prenatal diagnosis.** *B.L. Shaffer<sup>1</sup>, P.D. Cotter<sup>2</sup>, A.B. Caughey<sup>1</sup>, M.E. Norton<sup>1</sup>.* 1) Ob/Gyn and RS, Univ Calif San Francisco, San Francisco, CA; 2) Children's Hosp Oakland, Oakland CA.

Complete genomic hybridization using microarrays (aCGH) has great potential for application in clinical genetics, including prenatal diagnosis. Compared to standard cytogenetics, aCGH provides increased resolution, more rapid results and potentially lower cost. We evaluated the utility of aCGH if applied to routine prenatal karyotyping by reviewing results from the UCSF Prenatal Diagnosis Program from 1984-2000 (n=45,833). We retrospectively determined which abnormal results would have been detected or missed using the UCSF HumArray, which includes 2464 clones. Using population frequencies, we also estimated the number of additional abnormalities not detected by routine karyotyping that would have been identified by aCGH. 1351 karyotype abnormalities were present (2.9%). 829 (62%) were trisomies and monosomies detectable by aCGH. 61 (4.5%) other unbalanced abnormalities would also have been identified as abnormal (9 deletions, 6 duplications, 36 unbalanced rearrangements and 10 triploidies (69,XXY). 209 balanced rearrangements, 10 triploidies (69,XXX), and 2 tetraploidies (92,XXXX) (16%) would not have been detected. Of 240 (18%) mosaic results (76 amniocentesis, 164 CVS), an uncertain percentage would have been identified. In a population of 45,833 patients, there would be approximately 94 clinically significant microdeletions, including cryptic subtelomere abnormalities, identifiable via aCGH. Use of aCGH for prenatal diagnosis in this population would have resulted in detection of 890 of the 902 cases (98.7%) of unbalanced abnormalities of definite phenotypic significance to the fetus, missing 12 cases of triploidy or tetraploidy and 209 balanced rearrangements. Of the 240 mosaic results, 164 were CVS samples, with most due to confined placental mosaicism. aCGH provides some clear advantages, detecting the majority of phenotypically significant abnormalities as well as many not identified with current technology. The trade off is primarily in missing abnormalities of lesser or unknown significance to the fetus, such as mosaics and balanced translocations.

**Cavum Veli Interpositi: Prenatal diagnosis and long term follow up.** *P. Shah<sup>1</sup>, S. Blaser<sup>2</sup>, A. Toi<sup>3</sup>, R. Babul-Hirji<sup>4</sup>, K. Chong<sup>4,5</sup>, D. Chitayat<sup>4,5</sup>.* 1) Department of Pediatrics, Mount Sinai Hospital, Toronto, ON, Canada; 2) Department of Pediatrics, Division of Medical Imaging, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 3) Department of Medical Imaging, Mount Sinai Hospital, The University of Toronto, Toronto, Ontario, Canada; 4) Department of Pediatrics, Division of Clinical and Metabolic Genetics, The Hospital For Sick Children, University of Toronto, Toronto, Ontario, Canada; 5) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

**Objective:** To describe the prenatal findings and the postnatal outcome in two cases diagnosed with cavum villi interpositi. **Case 1:** Diagnosis of cavum villi interpositi of 3.5 x 3.0 x 1.2 size was made on routine prenatal screening at 33 weeks in non-consanguineous parents. There was no history of prenatal exposure to infection, drugs or toxins. No dysmorphic features were identified at birth. The absolute size of the cyst did not change during follow up MRI at 1 year of age, however relative size decreased. There was normal increase in the head circumference. Neurodevelopmental assessment revealed normal milestones at 2 years of age. **Case 2:** Diagnosis of cavum villi interpositi 3.2 X 1.1 X 1.7 size was made on a routine prenatal screening at 33.5 weeks gestation. The parents were consanguineous and their previous child died of lethal multiple congenital malformations. There was no history of prenatal infection, drugs, or toxins. No dysmorphic features were noted at birth. Serial ultrasonography at monthly intervals revealed minimal decrease in size. MRI at 9 months of age revealed unchanged CVI but dilated cavum septum pellucidum and cavum vergae. The rise in head circumference was within normal range. Neurodevelopmental examination at 11 months was age appropriate. **Conclusions:** Cavum villi interpositi is a rare finding on prenatal ultrasound screening. Despite the appearance of a large intracerebral cystic structure on pre and postnatal cranial imaging, CVI is associated with normal head growth and development.

**A novel approach for enrichment of fetal cells using a microfabricated silicon membrane.** *C. Somprasit<sup>1</sup>, D.A. Marquez-Do<sup>1</sup>, D. Yamanishi<sup>2</sup>, J.L. Simpson<sup>1</sup>, F.Z. Bischoff<sup>1</sup>.* 1) Dept OB/GYN, Baylor College of Medicine, Houston, TX; 2) AVIVA Biosciences, San Diego, CA.

Fetal cells in maternal blood have long been sought as a source of DNA for non-invasive genetic testing, either for direct analysis of fetal cells (aneuploidy) or for use as a complementary or additive screening test concurrent with ultrasound and maternal serum analyte screening. However, a consistently reliable enrichment technique resulting in optimal recovery of intact fetal cells has not yet been developed. Major obstacles have been cell loss during enrichment and lack of fetal specific antibodies. **OBJECTIVE:** To evaluate an alternative method of fetal cell enrichment. **DESIGN:** To investigate the feasibility of fetal cell isolation from maternal blood using a newly developed Fetal Enrichment Kit (AVIVA Bioscience). **METHODS:** Following IRB approval, peripheral blood (10 cc) from four women carrying a male fetus at 10 to 29 weeks gestation was obtained and processed using proprietary reagents. Briefly, specimens were processed within 2-24 hours using AVIwash solution and AVIPrep in order to aggregate and separate maternal RBCs. Magnetic AVI Beads coated with antibody cocktail were added to remove WBCs following one hour incubation. The recovered fraction was then enriched using a microfabricated silicon membrane to separate cells based on size (slot width of 2-4 microns). Final enriched cell population was spread onto a glass slide, air dried, and then fixed in Carnoy's solution. Using standard FISH methods, nuclei were scored for presence of the X (labeled with spectrum green) and Y (labeled with spectrum orange) chromosome-specific signals. Fetal male cells were identified on the basis of one signal for X and one signal for Y. **RESULTS:** In this pilot study, at least one fetal (XY) male cell was detected in each case with a range of 715 to 5886 total cells recovered. **CONCLUSION:** This novel enrichment approach offers promising potential in improving fetal cell isolation through use of a microfabricated silicon membrane to separate cells based on size. Further studies to compare sensitivity and specificity with alternative MACS and non-MACS based methods are ongoing.

**Quantitative detection of fetal DNA using dried maternal blood spots for generalized prenatal screening.** *J.L. Simpson<sup>1</sup>, D. Dang<sup>1</sup>, C. Somprasit<sup>1</sup>, D.I. Martinez<sup>1</sup>, D.E. Lewis<sup>2</sup>, F.Z. Bischoff<sup>1</sup>.* 1) Dept OB/GYN; 2) Dept of Immunology, Baylor Col Medicine, Houston, TX.

The accuracy and reliability of Realtime PCR to detect cell-free fetal DNA sequences in maternal plasma has been proven. However, generalized clinical application requires more effective methods for collection of large numbers of patient samples as well as protocols that minimize the potentially damaging effects of anticoagulant, storage and shipping conditions need to be incorporated. **OBJECTIVE:** Prospective examination of the efficiency of fetal DNA detection using dried maternal blood spots and Realtime PCR. **METHODS:** Prior to an invasive prenatal procedure, blood (3-5 drops) from a finger prick was placed on filter paper for each of 70 women (mean gestational age 12.6 weeks, range from 11.1 weeks to 35 weeks). Filters were coded and DNA analysis performed in a blinded study. DNA from blood spots was extracted using the QIAamp DNA blood kit. Presence of fetal Y-chromosome (DYS1) and the ubiquitous autosomal GAPDH gene sequences were measured with the TaqMan assay. **RESULTS:** In 40 of 48 (83%) cases confirmed to have a male fetus, Y-chromosome specific sequences were detected. Fetal Y-specific sequences detected ranged from 0 to 49.5 (mean 10.79) Geq/ml blood compared to 17465 to 340188 (mean 129960) Geq/ml GAPDH. In the 5 of 22 (33%) female cases in which Y-sequences were detected, mean (2.8 Geq/ml) amount detected was significantly less ( $P < 0.0003$ ) than the male cases. **CONCLUSION:** Fetal DNA detection using dried maternal blood spots is reliable, and appropriate cut-off values for fetal sequence detection can be identified. Blood spot analysis will provide a simple method for transport and collection, enabling cell free fetal DNA to be incorporated into noninvasive screening regimes (maternal serum analytes, fetal nuchal translucency).

**Prenatal diagnosis of Turner Syndrome in association with Dandy-Walker malformation.** *M. Ben-Yishay, S. Klugman, P. Dar, M. Bebbington, S.J. Gross.* Albert Einstein College of Medicine, Montefiore Medical Center, Bronx, New York.

**Background:** The Dandy Walker syndrome includes cerebellar vermis dysgenesis and cystic dilation of the fourth ventricle. The syndrome has been associated with chromosomal disorders, single gene disorders and environmental exposures. In more than 80% of cases, additional anomalies can be demonstrated. The association of the syndrome with the 45 X monosomy (Turner Syndrome) has been rarely reported and only one case diagnosed prenatally.

**Case:** We report a 31 year old primigravida with a negative family history who had abnormal findings on second trimester ultrasound. She had had an uncomplicated prenatal course including normal maternal serum screening. The sonographic findings included an absence of the cerebellar vermis, hypoplasia of the cerebellar hemispheres and a thickened nuchal fold. The rest of the exam including the ventricles was normal. The patient underwent amniocentesis which revealed 45X by fluorescent in-situ hybridization (FISH) and karyotyping.

**Conclusion:** This case highlights the relationship between Dandy-Walker malformation and Turner syndrome. Detailed scanning of the posterior fossa should be included in the prenatal evaluation of a fetus with monosomy X prior to genetic counseling as this finding can be subtle on sonography, yet have substantial consequence with respect to prognosis.

**Dandy-Walker variant and 47,XXY.** *G.A. Jervis<sup>1</sup>, J.L. Angel<sup>2</sup>, B.G. Kousseff<sup>1</sup>*. 1) Regional Genetics Program, Univ South Florida, Tampa, FL; 2) Florida Perinatal Associates, Tampa, FL.

Dandy-Walker malformation is characterized by (1) hydrocephalus, (2) cyst in posterior fossa and (3) defect in cerebellar vermis through which the cyst communicates with the 4th ventricle. Dandy-Walker variant (DMV) shows smaller 4th ventricle cyst, less vermian hypoplasia and less severe or absent hydrocephalus. Dandy-Walker malformation/variant can be part of Mendelian disorders, including Meckel-Gruber and Walker-Warburg syndromes, of chromosomal abnormalities, including trisomies 13,18,21 and Turner syndrome or due to teratogens, including alcohol, Coumadin and maternal diabetes. Klinefelter syndrome is the most common sex chromosome abnormality with an incidence of 1.18 per 1,000 births. Clinical features include postpubertal small atrophic testes, small penis, gynecomastia, tall stature and dull mentality. Twenty percent of men with Klinefelter syndrome have major malformations with no clear pattern, including cleft palate, unilateral renal agenesis, microcephaly, and omphalocele (Gorlin, *Syndromes of the Head and Neck*, 4th Edition, 2001, p 62). We present a 33-year-old Caucasian woman, G4P0030, three first trimester spontaneous abortions, with an elevated MSAFP of 2.66 MoM, resulting in a 1 in 213 ONTD risk. Prenatal sonogram at 17 weeks showed an 8.9 cm cystic mass in the posterior fossa that communicated with the 4th ventricle at the level of the inferior cerebellar vermis, Dandy-Walker variant. Amniocentesis revealed 47,XXY. Termination was performed at 19 weeks. We were able to find one case report of isolated mild ventriculomegaly and Klinefelter syndrome, one case report of a fatal cerebral AV malformation in Klinefelter syndrome and several reports of seizures and essential tremors in men with Klinefelter syndrome. The DMV and Klinefelter syndrome in our patient could be coincidental, since both conditions are relatively common. However, this case emphasizes the importance of offering chromosome analysis whenever fetal sonogram reveals CNS anomalies and suggests that DMV may be a feature of Klinefelter syndrome.

**Prenatal diagnosis dilemma: Fetus with del(5)(p13.1p14.2) diagnosed postnatally with Cornelia de Lange syndrome.** *R. Hulinsky<sup>1</sup>, H. Winesette<sup>2</sup>, K.M. Dent<sup>3</sup>, R. Silver<sup>4</sup>, J. King<sup>3</sup>, A. Lowichik<sup>2</sup>, Z. Chen<sup>3</sup>, D.H. Viskochil<sup>3</sup>.* 1) OB Diagnostic Center, Univ of Utah, Salt Lake City, UT; 2) Dept of Pathology, Univ of Utah, Salt Lake City, UT; 3) Dept of Pediatrics, Univ of Utah, Salt Lake City, UT; 4) Dept of Obstetrics/Gynecology, Univ of Utah, Salt Lake City, UT.

We report a 28-year-old G2 P1 referred for abnormal ultrasound findings. Targeted ultrasound at 20.4 weeks revealed diaphragmatic hernia, single umbilical artery, nuchal skin thickening and abnormal upper extremities. The patient's mother reported six first trimester miscarriages and a stillborn infant. The couple was counseled regarding aneuploidy as well as chromosome translocations due to the maternal history. Amniocentesis revealed a karyotype of 46,XY,del(5)(p13.1p14.2). Parental chromosomes were normal. Oligohydramnios and IUGR presented in the third trimester. The couple was counseled extensively regarding poor prognosis, specifically in the context of a chromosome deletion, oligohydramnios, and diaphragmatic hernia. The couple was undecided about delivery and postnatal management plans. Precipitous delivery at 36.4 weeks gestation resulted in a liveborn infant who died at 2 hours of life. Autopsy revealed a male infant with physical characteristics of Cornelia de Lange syndrome (CdLS). The infant had the facial gestalt of CdLS, a left-sided diaphragmatic hernia, and oligodactyly of the upper limbs. Additional findings included a cleft in the soft palate, hypoplastic kidneys, short feet, VSD, hirsutism, and hypospadias.

This case illustrates the difficulty of prenatal counseling in the context of a previously uncharacterized chromosome anomaly. Prenatal diagnosis of CdLS based on sonographic findings has been reported, yet no genetic etiology has been identified. While studies have indicated an association with partial trisomy 3q, none have been reported in association with deletion 5p. In this case, the chromosome abnormality obscured full clinical assessment of the differential diagnosis of diaphragmatic hernia with limb defects and subsequent counseling, which should include CdLS. It points out one of the difficulties inherent in prenatal diagnosis.

**Prenatal diagnosis and autopsy findings in Catel-Manzke syndrome.** *R. Teitelbaum<sup>1</sup>, L. McLeod<sup>2</sup>, A. Pai<sup>1</sup>, S. Keating<sup>3</sup>, A. Toi<sup>4</sup>, L. Velsher<sup>5</sup>, D. Chitayat<sup>1, 2</sup>.* 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, University of Toronto, Toronto, Canada; 2) Department of Obstetrics and Gynecology, Division of Maternal Fetal Medicine, Mount Sinai Hospital, University of Toronto, Toronto, Canada; 3) Department of Laboratory Medicine and Pathobiology, Mount Sinai Hospital, University of Toronto, Toronto, Canada; 4) Department of Medical Imaging, Mount Sinai Hospital, University of Toronto, Canada; 5) Department of Medical Genetics, North York General Hospital, Toronto, Canada.

Catel-Manzke syndrome is an inherited condition characterized by micrognathia, cleft palate, glossoptosis, cardiac abnormalities and an accessory (usually triangular) bone at the base of the index finger (hyperphalangism).

We report a case of Catel-Manzke syndrome detected prenatally in a female fetus. A 31-year-old healthy primigravida woman of Anglo Saxon descent was referred to our center at 20 weeks gestation with multiple congenital abnormalities.

The fetal ultrasound showed Tetralogy of Fallot, micrognathia, abnormal hand posturing, clinodactyly, talipes, and abnormal toe spacing. The fetal karyotype was normal, and FISH for deletion 22q11.2 was negative.

The autopsy confirmed the prenatal ultrasound findings including Robin sequence with micrognathia, U-shaped cleft palate, and low set ears. There was tetralogy of Fallot, persistent left superior vena cava, over-riding aorta, ventricular septal defect, and bicuspid pulmonic valve. There were bilateral talipes and a wide sandal gap. The left hand had a widened space between the third and fourth fingers. There was fifth finger clinodactyly with hypoplastic distal phalanges bilaterally.

To the best of our knowledge, this is the second case of Catel-Manzke syndrome detected prenatally. The inheritance of the condition was initially thought to be x-linked. However, the few females reported with this condition raises the possibility of an autosomal recessive or genetically heterogeneous condition.

Program Nr: 2547 from 2003 ASHG Annual Meeting

**Detecting disease associations using htSNPs.** *J.D. Cooper, J.M. Chapman, J.A. Todd, D.G. Clayton.* JDRF/WT Diabetes and Inflammation Laboratory, Cambridge Institute of Medical Research, Wellcome Trust/ MRC Building, Addenbrooke's Hospital, Cambridge, CB2 2XY.

Within small genomic regions in European populations haplotype diversity can be limited and typing all known polymorphisms may lead to considerable redundancy. Previously, our laboratory suggested that linkage disequilibrium (LD) and haplotype diversity within such regions can be captured by a much smaller subset of markers, which we termed "haplotype tag SNPs" (htSNPs). We argued that typing htSNPs could potentially capture most of the information for association between a trait and one or more causal variants. Subsequently, a number of optimal methods for choosing htSNPs have emerged. However, little attention has been given to how such studies should be designed and analysed. We propose: (1) step-up, step-down and exhaustive subset algorithms to select htSNPs, based on measuring the ability of htSNPs to predict allele frequencies at another locus using an  $R^2$  measure; (2) a two-stage procedure for genotyping htSNPs; (3) a new "multi-locus TDT" to test for association between a trait and htSNPs due to LD with one or more causal variants.

Program Nr: 2548 from 2003 ASHG Annual Meeting

**High-throughput genotyping database system to manage multivariate phenotypes in complex trait analysis.** *S.E. Fiddy, R.F. Mott.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom OX3 7BN.

Successful genetic dissection of complex traits requires handling of considerably more data than had previously been anticipated. Sample sizes of tens of thousands of individuals have been collected in some linkage study designs and genome wide association strategies are likely to need hundreds of thousands of single nucleotide polymorphisms. Managing such large datasets and reducing error to hitherto unobtainable levels can be best achieved with a high degree of automation. We have developed a relationship database system that copes with these requirements by using the Microsoft .NET framework and SQL Server 2000. The system is accessed using a web front-end for cross platform usage. As a result the system is cost-effective and easy to distribute to other users. Flexibility is a key feature enabling a variety of genotypic markers to be handled, including SNPs and microsatellites, collected from a variety of genotyping platforms. For example, the system can automatically upload genotypes from the Sequenom mass spectrometer and can quality check the genotypes using Mendelian inheritance checking. Stored data can be extracted into various file formats for further analysis using standard genetic software. A major strength of the system design is ability to amalgamate a number of phenotypes and covariates for same subject treating them as a single entity. This makes it possible to implement easily multivariate genetic analysis of complex traits.

**Grid computing in genetics: concepts, schedulers, and preliminary experiences.** *M.M. Barmada, R.E. Evans, T.J. Bates.* Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

It is increasingly becoming evident that statistical genetics requires enormous computing resources to successfully address issues such as empirical p-value estimation, complete multipoint linkage analysis, haplotype frequency estimation, and linkage disequilibrium mapping. Statistical methodologies involving coalescent theory and Markov-Chain Monte-Carlo (MCMC) based simulation methods require long runs and are highly amenable to parallel processing strategies. We present here our preliminary experiences with the development of distributed grid-based computing systems to decrease the computational time required for successful application of these techniques. This work is not intended to be an overarching review of all possible mechanisms for grid computing, but rather to introduce the concept and some of its advantages and disadvantages, and to present a system which has been of significant use at our institution. Reasons for the adoption of grid-based architectures (as opposed to the more traditional symmetric multiprocessor (SMP)-based or parallel (MPI/PVM-based) architectures) will be discussed. We evaluated two common grid-enabling open-source technologies for their performance in a statistical genetics environment: MOSIX (now OpenMosix), and Suns GridEngine. For our hardware architecture, under common (and exaggerated) usage loads the performance of GridEngine enabled systems far outranked that of OpenMosix based systems on the same hardware architecture. Other metrics used to compare the two systems included ease of setup, ease of reconfiguration (a common occurrence), and implementation across heterogeneous hardware architectures. These experiences have identified several key features of grid design and new distributed computing technologies which we feel will be of utmost importance for statistical genetics.

**On comparison of tree-based methods and neural networks using genetic data.** *C.H. Chen<sup>1</sup>, C.L. Chen<sup>1</sup>, C.J. Chang<sup>2</sup>, C.S.J. Fann<sup>1</sup>.* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Medical Research, National Taiwan University, Hospital, Taipei, Taiwan.

Data mining methodologies, such as tree-based methods and neural networks, were being used to facilitate gene mapping for complex traits. Researchers often apply these methods, by related phenotypic and genotypic covariates, to subdivide the study sample into more homogenous subgroups. In general, analyzing homogenous subgroup may increase power to detect linkage, comparing with that for the whole sample in the presence of heterogeneity. However, when dealing with smaller sample, it is unclear about the impact to the power of this approach because homogeneous subgroup also means that only fewer samples are available in the subsequent analysis. In corporation of non-parametric linkage analysis, we explore this question by empirical comparison of classification and regression tree methods and multi-layer neural networks using GAW12 simulation Data. In addition, to test the accuracy of the above classification rules, train-and-test, cross-validation, and bootstrap methods are used to estimate error rates for large, intermediate, and small sample size, respectively. Our result shows that, under some conditions, the performance of classification and regression tree methods and Neural Networks are similar in samples of large sizes.

Program Nr: 2551 from 2003 ASHG Annual Meeting

**Using Multivariate Association Modeling Algorithms to Characterize Relationships in Multivariate Data.** *C.C. Abney, R.A. Miller, D.T. Burke, N.J. Schork.* Dept. of Psychiatry, UCSD School of Medicine, La Jolla, CA.

Often researchers collect information on more than one phenotype, clinical outcome, biochemical measure, etc. with it in mind that some of these variables are likely related. Determining which subset of a larger group of variables is associated with, e.g., alleles at a particular genetic locus, is of considerable interest. We have developed a novel methodology to achieve this. This methodology leverages information about both differences in the mean (or average) level of a set of phenotypes across, e.g., genotypic categories, as well as differences in the relationships those variables might have across those categories (i.e., covariances). It essentially uses a multivariate likelihood ratio test that simultaneously assesses mean and covariance matrix differences among a set of variables. The proposed tests are therefore more comprehensive and powerful than many traditional multivariate tests which do not leverage information about both means and covariance matrices in their construction. We have developed software and a web-based interface for our methodology. We showcase the methodology on a large data set investigating the genetic basis of longevity and age-related parameters in a novel mouse cross. The proposed methodology is extremely flexible and provides new directions for QTL mapping in humans and model organisms.

Program Nr: 2552 from 2003 ASHG Annual Meeting

**PedigreeQuery - software for pedigree drawing.** A. Kirichenko. Laboratory of Genetic Analysis, Institute of Cytology and Gene, Novosibirsk, Russia.

Pedigree drawing is an important task in many studies in population genetics and epidemiology. It requires special software tools, because it is too difficult to do it manually especially if sample is very large and has intricate structure. We propose a new method of step-by-step pedigree drawing which was released in software PedigreeQuery. The method is based on expanding a pedigree by adding new nuclear families to already drawn pedigrees. This method allows drawing separate parts of pedigree, expanding in them into required direction. The principle of step-by-step pedigree drawing allows graphic representation of distribution of phenotypes in specific pedigrees and structure of kindred relations in studying sample. It also allows tracing paternal and maternal genome transfer and reconstructing an origin of rare alleles in a population. The software allows drawing pedigrees with a difficult structure, those containing consanguinity loops, individuals with multiple mates or several related families. Incoming data are data in LINKAGE format. Graphical presentation of pedigree is written into file in EPS format. Pedigrees are represented in standard form. There may be different subscribes under symbols. The symbols may be paint over according to the feature they are assigned to. The software has flexible setup system for graphic representation of the pedigree. The software, PedigreeQuery is freeware and may be downloaded from <http://mga.bionet.nsc.ru/PedigreeQuery/PedigreeQuery.html>.

Program Nr: 2553 from 2003 ASHG Annual Meeting

**Haplotype Inference in Nuclear Families.** *S. Lin, A. Chakravarti, D.J. Cutler.* Inst Medical Genetics, Johns Hopkins Univ, Baltimore, MD.

Phase information can be critical to the mapping of disease genes. From population genetics principles, it is posited that the sequences surrounding a relatively recent disease mutation but itself unchanged by recombinations and other mutations stretch on the order of several tens of kb. Acquiring accurate haplotypes on such lengths would increase the power to detect disease mutations in uncommon, complex diseases considerably. Since current statistical methods of haplotype reconstruction of individual genotypes have been found to be accurate only within regions of high LD (~10-20kb), genotypes from nuclear families are minimally necessary to achieve a high degree of accuracy beyond such lengths. Yet, even with such data, phase information is often not complete due to missing data and non-informative sites. To account for such ambiguities, we have constructed an algorithm which incorporates a probabilistic model based on a population genetic model (infinite allele sampling from a neutral population) within a Markov chain-Monte Carlo framework to reconstruct haplotypes within nuclear families. Application of the program on sequence data from eight loci spanning > 1 Mb on the human X chromosome, shows that the fraction of neighbor relations correctly called is greater than 93%. This algorithm is well suited for data sets with small families in which the haplotyping feature of Genehunter and other programs designed primarily for linkage analysis fails.

**Genetic Analysis of Function-Valued Traits.** *J. Zhao, M.M. Xiong.* Human Genetics Ctr, Univ Texas, Houston, Houston, TX.

A trait that varies as a function of a continuous variable such as age or time is referred to as a function-valued trait. Genetic analysis of function-valued traits will provide a general framework for longitudinal genetic studies that are a powerful tool for identifying complex genetic structure of common diseases and discovering strategies for prevention of diseases. However, genetic models of function-valued traits have not been well developed. In this report, we propose a general framework for genetic analysis of function-valued traits. In the proposed model, the genotypic values are decomposed into mean, additive and dominance effect functions. The developed models applied to population samples. We use two-step procedure to estimate the mean and genetic effect functions. We first use a mixed linear model to fit a longitudinal population sample data set. The mean and genetic effect functions are modeled as fixed effects. Correlation structure of repeat measurements is modeled as a random effect. The REML method is used to estimate the mean and genetic effect functions as well as variance components in the mixed linear model. Then, we use smoothing spline to smooth the raw estimators of the mean and genetic effect functions. We analytically show that the estimators of the genetic effect functions are asymptotically unbiased and converge to the true genetic effect functions in the single homogeneous population. We propose several hypotheses to test association of candidate locus with function-valued trait and to detect when the genetic factors start or cease to affect the trait. To avoid spurious association of the test in the presence of population substructure, we present a modified genetic model for function-valued traits. We analytically show that the test based on modified model is valid in the presence of population substructure. The methods are applied to simulation data to evaluate their performance and to illustrate their applications. The preliminary simulation results show that although the mathematical forms of the mean and genetic effect functions are unknown, the proposed methods can accurately estimate the mean and genetic effect functions.

**The Effect of Initial Allele Distributions on Linkage Measures in the Context of Study Design.** *F. Sievers, E.D. Kelly.* Hitachi Dublin Laboratory, Trinity College, Dublin, Dublin, Ireland.

Many bioinformatics analyses and simulations are hampered by an overly large parameter space and the difficulty of controlling these parameters during an experiment. We conduct a population simulation in which a large portion of the parameters (pedigree and the recombination pattern) is kept constant. The only parameters changed will be the alleles assigned to the founding individuals. We can therefore study the purely statistical effect of varying allele distributions while keeping familial and micro-biological effects constant. Hitachi's population generator is used to simulate extensive pedigrees comprising a large number of individuals and stretching over several generations. Off-spring are produced using rules mimicking mating and recombination patterns observed in nature. Individuals at the initial generation are each set up with two unique founder alleles that can be tracked unambiguously over time. We monitor the flow and distribution of founder alleles over time and determine the distribution of haplotype lengths identical by descent. In the second stage we assign concrete alleles to the founder alleles and compare the haplotype lengths identical by descent to the haplotype lengths identical by state. We re-assign alleles repeatedly and show the effect this has on various measures like Linkage Disequilibrium, Hardy Weinberg Equilibrium and (estimated) Haplotype Frequencies using Hitachi's Hitagene software suite. Allele re-assignment is done in two different ways: (i) alleles are simply re-shuffled, therefore preserving the (initial) allele distribution and (ii) alleles are assigned with different distributions. Fluctuations in the measures due to (ii) are not surprising but those due to (i) are investigated carefully. We also demonstrate that simulated populations in conjunction with repeated allele re-assignment can be useful in the process of study design.

**Genotype Data Merge Software.** *A. Presson*<sup>1</sup>, *E. Sobel*<sup>2</sup>, *K. Lange*<sup>1,2,3</sup>, *J.C. Papp*<sup>2</sup>. 1) Depts of Statistics; 2) Human Genetics; 3) Biomathematics, UCLA, Los Angeles, CA.

There is a growing need to merge data within and between genotyping centers and to merge current data with legacy data sets. The resulting larger sample sizes confer greater statistical power. Accurate merging is particularly important for successful association studies. However, manually merging data is time-consuming and error prone. The increasing frequency of collaboration between genotyping centers calls for automation in the interest of saving time and improving accuracy. Some factors that complicate merging include differences between genotyping hardware; binning methods; molecular weight standards; and curve fitting algorithms. The result is that genotypes from different sources do not differ by the same amount, both between and within markers. This makes it insufficient to align genotypes by adding a constant number of base pairs to the alleles of one of the data sets, even when considering individual markers. Other factors making it difficult to accurately merge data include few samples in common, and samples drawn from different ethnic groups, in which allele frequencies may vary.

We propose statistical algorithms to find the most probable correspondence between alleles by considering various aspects of the data. One method uses an algorithm that evaluates alignments by a chi-square homogeneity test (based on allele frequencies). Another method uses a Bayesian approach that chooses alignments with the greatest posterior probability. Additional procedures are necessary to incorporate information such as ethnicity, number of samples in common, data set size, and (if the user chooses) allele-lumping. When alleles with small frequencies are difficult to align with confidence, allele-lumping will allow the alleles to be combined into a single 'super allele'. We have developed software that will automate our genotype merging methods. The software evaluates the characteristics of the input data sets, allows user-specified merging options, and includes an error analysis to assign a merge-quality score. If there is too little information to confidently merge data sets, the software will recommend that they be analyzed separately.

**An ensemble method for gene discovery based on DNA microarray data.** *S.-Q. Rao<sup>1, 4</sup>, X. Li<sup>2, 3</sup>, T.-W. Zhang<sup>2</sup>, Z. Guo<sup>2, 3</sup>, K.L. Moser<sup>5</sup>, E.J. Topol<sup>1, 4</sup>, Q. Wang<sup>1, 4</sup>.* 1) Center for Cardiovascular Genetics, Dept. of Cardiovascular Medicine, the Cleveland Clinic Foundation, Cleveland, OH; 2) Dept. of Computer Science, Harbin Institute of Technology, Harbin, China; 3) Dept. of Biomedical Engineering, Biomathematics and Bioinformatics, Harbin Medical University, Harbin, China; 4) Dept. of Molecular Cardiology, the Cleveland Clinic Foundation, Cleveland, OH; 5) Dept. of Medicine, Institute of Human Genetics, University of Minnesota, MN.

The advent of the microarray technology has promised to provide new insights into the complex biological systems by monitoring activities of thousands of genes simultaneously. Current analyses of microarray data focus on classification of biological types, for example, tumor versus normal tissues. A future scientific challenge is to extract disease-relevant genes from the bewildering amount of raw data. This is one of the most critical themes in the post-genomic era, but it is generally ignored due to the lack of an efficient approach. In this paper, we developed a novel recursive-partition-tree-based ensemble method for gene extraction that can be tailored to fulfill multiple biological tasks including (1) precise classification of biological types; (2) disease gene mining; and (3) target-driven gene networking. We also gave a numerical application for (1) and (2) using a public microarray data set and discussed its application for (3).

Program Nr: 2558 from 2003 ASHG Annual Meeting

**SNP haplotype analysis for qualitative and quantitative traits in unrelated individuals and parent-offspring trios.**

*S.M. Purcell*<sup>1,2</sup>, *M.J. Daly*<sup>1</sup>, *P.C. Sham*<sup>2</sup>. 1) Daly Lab, Whitehead Institute, Cambridge, MA; 2) Social, Genetic and Developmental Psychiatry Research Centre, Institute of Psychiatry, London, UK.

A flexible mixture-of-regressions framework is used to analyze SNP haplotype association data for qualitative (logistic regression) and quantitative (linear regression) traits. When parental genotype information is available, a between/within family partitioning of haplotypic effects is possible, which allows for a test of association robust to population stratification. Furthermore, a conditioning-on-trait-values approach allows the analysis of trait-ascertained samples, including affected-only parent-offspring designs. An additional, independent secondary test based on pair-wise haplotypic similarity can increase power. These methods, along with sliding window and permutation test approaches, are implemented in the WHAP software package. Advantages of this approach are evaluated in both real and simulated data.

**A Semiparametric Regression Model for Oligonucleotide Arrays.** *G. Yin*<sup>1</sup>, *J. Hu*<sup>2</sup>. 1) Biostatistics, M.D. Anderson Cancer Center, Houston, TX; 2) Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Oligonucleotide arrays can provide a broad measure of the expression levels of thousands of genes simultaneously. It is essential to develop methods to extract valuable information from the gene expression array data sets. The parametric model-based analysis of oligonucleotide expression arrays using the difference between the perfect match (PM) and mismatch (MM) probe intensities, namely (PM-MM), is very popular and widely used to calculate the model-based expression indexes (MBEI). However, the relationship between PM and MM may not be simply linear. The misspecified linearity may bring in bias and affect the accuracy of MBEI. Therefore, a semiparametric model incorporating the spline smoothing technique is proposed to study oligonucleotide gene expression data. No specific parametric functional form is assumed for mismatch probe intensities that allows much more flexibility in the fitted model. The model specification for oligonucleotide array data is particularly appealing since PM and MBEI are of major interest, while the effects of MM are nuisance. The new approach improves the model fitting, hence the estimation of MBEI. Extensive comparisons between the parametric (PM-MM) model and our proposal are made regarding different aspects including variances, model goodness-of-fit and assessment of the gene expression indexes. Control genes are very important and valuable in many facets of the comparisons. The proposed method is applied to a data set of 18 HuGeneFL arrays. It shows that the proposed semiparametric regression model is easy to implement and outperforms the popular parametric model with (PM-MM) as the response, in terms of capturing the gene expression indexes.

Program Nr: 2560 from 2003 ASHG Annual Meeting

**A novel non-parametric approach to the analysis of genetic haplotypes and genomic pathways.** *K.M. Wittkowski.*  
General Clinical Research Center, The Rockefeller University, New York, NY.

Few diseases can be explained by a single marker and few drug effects can be explained by looking at the expression of a single gene. In either case, the assumptions underlying the linear model are difficult to justify, so that results based on classical statistical methods are difficult to interpret and conclusions can easily be misleading. We present a new family of non-parametric statistical methods to overcome these challenges.

Most of the currently available statistical approaches are based on the linear model (Euclidian distance). Combining evidence from different markers or genes by means of linear combinations (counts of high risk alleles, average mRNA), however, requires that the variables (markers) are of (a) known relative importance, (b) constant correlation, and (c) specific functional form of interaction. Unfortunately, degree of linkage disequilibrium and type of interaction (from recessive over multiplicative to dominant) within a sequence of markers (haplotype) and between haplotypes are typically unknown, as are the correlations and interactions between genes responding to treatment.

The first approach allowing for the analysis of multivariate ordinal data to assess profiles of risk factors, safety indicators, and activity parameters was based on the marginal likelihood (JASA 1992, AJPH 1998) While eminently useful, it lacked computational efficiency. We now propose a new variant, where the computational effort raises only with the square of the number of subjects, rather than the factorial. The method is a member of a new class of non-parametric methods for genetic and genomic data, which is based on u-statistics (Hum Hered 2002).

We demonstrate applications of u-statistics for multivariate ordinal data in genetics and genomics using animal and clinical data from studies on atherosclerosis and psoriasis.

Program Nr: 2561 from 2003 ASHG Annual Meeting

**Genetic psychometrics: Concepts, methods, and examples.** *L.M. Evans, J.R. Kelsoe, N.J. Schork.* Dept Psychiatry, Univ California, San Diego, La Jolla, CA.

Psychometrics encompasses the development, validation, and interpretation of scales and questionnaire-like items meant to capture aspects of human behavior and personality. The statistical procedures used in the development and validation of psychometrical scales have a long and fruitful history. In using psychometrical scales in studies attempting to identify genetic factors that influence human behaviors and personalities, however, a number of issues arise. We outline a series of statistical techniques meant to facilitate and enhance the use of psychometrical scales in genetic studies. Each of the proposed techniques is motivated by the intuition that certain subsets of the subscales or items contributing to or defining a psychometrical scale may be more directly influenced by relevant genetic factors than others. Determining which subsets are more or less influenced by relevant genetic factors is therefore the goal of our proposed techniques. Although each of our proposed techniques deserves greater scrutiny, we consider four major areas of concentration: 1. determining homogenous subgroups of individuals based on a scale that may have common genetic backgrounds; 2. the identification of subscales and items which maximize heritability; 3. the identification of subscales and items which maximize linkage information; and 4. the identification of subscales and items which maximize genetic association. We showcase many of our proposed techniques with data derived from 29 bipolar disorder families.

**Finding haplotypes with NEMO.** *D.F. Gudbjartsson, A. Kong.* Decode Genetics, Reykjavik, Iceland.

A general method that uses NEsted MOdels for studying haplotype groups is introduced. This likelihood-based method is implemented in our program NEMO, which allows for many polymorphic markers, SNPs and microsatellites, and will be distributed for free upon publication. The method is designed for case-control and quantitative trait studies where the purpose is to identify haplotype groups that confer different risks. It is also a tool for studying LD structures.

When many markers are being investigated, apart from looking at each haplotype individually, meaningful summaries often require putting haplotypes into groups. A particular partition of the haplotype space is a model that assumes haplotypes within a group have the same risk, while haplotypes in different groups can have different risks. Two models/partitions are nested when one, the alternative, is a finer partition of the other, the null, i.e, the alternative model allows some haplotypes having the same risk in the null model to have different risks. Generalized likelihood ratio tests can be used to test the two models. One common way to handle uncertainty in phase and missing genotypes is a two-step process of first estimating haplotype counts and then treating the estimated counts as the exact counts, a method that can sometimes be problematic and may require randomization to properly compute p-values. In NEMO, maximum likelihood estimates, likelihood ratios and p-values are calculated directly for the observed data, treating it as a missing-data problem. NEMO allows complete flexibility for partitions. For example, suppose that allele 1 of two SNPs in LD is associated with the disease. The alternative grouping of [(0,0)], [(0,1)], [(1,0),(1,1)] versus the null grouping of [(0,0), (0,1)], [(1,0),(1,1)] can be used to test whether SNP2 is contributing to risk after adjusting for the effect of SNP1. Another meaningful test to perform is the alternative grouping of [(0,0)], [(0,1),(1,0)], [(1,1)] versus the null grouping of [(0,0)], [(0,1),(1,0),(1,1)]. Here the issue is whether the haplotype (1,1) has higher risk than (0,1) and (1,0). Analyzing our stroke data with NEMO reveals three groups of haplotypes; the wild type, a high-risk and a low-risk group.

**Visualization of large, complex human genealogy datasets: Drawing a pedigree from European royalty genealogy data.** *J.R. Garbe, Y. Da.* Animal Science, University of Minnesota, St. Paul, MN.

Human genetic analysis often starts with drawing a pedigree from genealogy data to show the population structure, the relationship among individuals, and gene flows from generation to generation. However, for large and complex populations, visualization of the genealogy data becomes a challenge. The purpose of this research is to study the feasibility of drawing pedigrees of large complex populations with Pedigraph, a pedigree drawing program developed by the authors ([www.animalgene.umn.edu](http://www.animalgene.umn.edu)). European royalty genealogy data from the Directory of Royal Genealogical Data ([www.dcs.hull.ac.uk/public/genealogy/royal/](http://www.dcs.hull.ac.uk/public/genealogy/royal/)) was used because it is a large, complex, publicly available dataset. The full pedigree of European royalty contains 48,605 individuals spread out over 106 generations, with entries as early as the first century AD and as recent as 1997. Pedigraph produced a drawing of the full pedigree on a 2 GHz computer in 80 minutes. Color lines connecting parents and offspring were used to enhance the visibility of parent-offspring relationships. The drawing gives a good sense of the overall structure of the full pedigree and reveals highly complex inbreeding relationships, a visual effect that is impossible from reading the genealogy data. Displaying the pedigree on a computer and using magnification allows a clear view of any part of the pedigree. However, to print out a legible copy would require a piece of paper 680 feet wide and 82 feet tall. By using Pedigraph's summarization option the width of the drawing can be reduced by two-thirds. Using Pedigraph's option of extracting partial pedigrees, the pedigree of Victoria Hanover, Queen of Britain, was drawn. This partial pedigree shows 3,975 ancestors and 1,148 descendants of the queen, and is viewable without the need of an excessively large printout. The results show that visualization of large complex genealogy datasets is possible, the main limitation being the size of the pedigree printout, which could be too large to be practical.

**A comparison between different strategies for computing confidence intervals for the linkage disequilibrium measure  $D'$ .** *S.K. Kim, K. Zhang, F. Sun.* Dept. of Biological Sciences, Univ. of Southern California, Los Angeles, CA.

Many linkage disequilibrium (LD) measures have been used to study LD patterns and for haplotype block partition. We examine the properties of one of these measures, Lewontins  $D'$ , in order to understand the dependency of its confidence interval to allele frequency and sample size as well as its applications in defining haplotype blocks. This measure and its confidence intervals were used to partition haplotypes into blocks by Gabriel et al. (2002) as well as in many other applications. Gabriel et al. (2002) utilized a bootstrap approach to calculate the confidence interval for  $D'$ . Under this method, over 1000 bootstrap samples maybe needed to obtain an accurate estimate of the confidence interval for each pair of single nucleotide polymorphism (SNP) markers which can be very computationally intensive, particularly when many SNP markers are involved. We develop two alternative methods for calculating the confidence interval for  $D'$  without bootstrap: one based on the approximate variance of  $D'$  given by Zapata et al. (1997) and the other based on a maximum likelihood estimate (MLE) of  $D'$  together with Fisher Information theory. Both methods depend on normal approximation for the estimates of  $D'$  for large sample sizes. We assess and compare the coverage of the confidence intervals using the three methods through extensive simulations. We define the coverage as the fraction of times the estimated confidence interval contains the value of  $D'$ . Under all simulated conditions, the average coverage of the bootstrap method is less than the pre-specified coverage. When the sample size is small (100), the remaining two methods slightly over estimate the coverage with Zapatas method having the smallest standard error among all three methods. When the sample size is large (200), the estimated coverage from both Zapatas and MLE methods are very close to the pre-specified coverage with the MLE method having the smallest standard error among all three methods. Thus, we recommend the use of Zapatas method when the sample size is small likewise the MLE method when the sample size is large for determining the confidence intervals.

Program Nr: 2565 from 2003 ASHG Annual Meeting

**Detection of gene-gene interactions in general pedigrees.** *J.H. Moore<sup>1</sup>, L.W. Hahn<sup>1</sup>, M. Bass<sup>2</sup>, E.R. Martin<sup>2</sup>.* 1) Program in Human Genetics, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics, Duke University, Durham, NC.

The pedigree disequilibrium test (PDT) of Martin et al. (*AJHG* 67:146-54, 2000) has made it possible to carry out valid single-locus tests of linkage disequilibrium in extended pedigrees. The goal of this study is to modify the PDT method to allow the detection of multilocus effects and gene-gene interactions in extended pedigrees. To accomplish this goal, we have combined the PDT with the multifactor dimensionality reduction (MDR) approach of Ritchie et al. (*AJHG* 69:138-147, 2001). The MDR method was designed specifically for the detection of gene-gene interactions in case-control study designs using unrelated individuals. With MDR, the dependent variable is case-control status while the independent variables are multilocus genotypes. We have made the detection of gene-gene interactions in pedigrees possible by creating a new dependent variable based on within-family cases and controls. For family triads (affected offspring and both parents), transmitted and untransmitted multilocus genotypes are used. For families without parental data, multilocus genotypes of affected individuals are compared to their unaffected siblings. This new data encoding permits the MDR approach to identify the combination of genotypes that are positively associated with disease within families. As with the original MDR, cross-validation and permutation testing are used to estimate prediction errors, determine statistical significance, and control for type I error due to multiple comparisons. Using family triads simulated from nonlinear gene-gene interaction models, we have determined that the power of the new MDR-PDT approach (>80%) is equivalent to that of the original MDR approach when applied to case-control data generated from the same genetic models. Future studies will focus on simulations to evaluate the MDR-PDT in a variety of different pedigree structures. This new method provides a starting point for nonparametric and genetic model-free detection and characterization of nonlinear gene-gene interactions in general pedigrees.

Program Nr: 2566 from 2003 ASHG Annual Meeting

**PedStats: A utility for summarizing the contents of pedigree files with the ability to produce graphical output in PDF format.** *J.E. Wigginton, G.R. Abecasis.* Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

With the advent of single nucleotide polymorphisms (SNPs) and high throughput genotyping technologies, the size of the typical dataset used for pedigree analysis has increased dramatically - pedigree files with thousands of markers measured on hundreds of individuals are no longer unusual. With such large files, it is no longer practical to rely on manual inspection of data to spot patterns or anomalies. To address this issue, we've developed Pedstats, a C++ utility that produces text and graphical summaries of the family structure, trait and marker information contained in any pair of QTD, LINKAGE or MENDEL format pedigree and data files.

Pedstats checks input files for formatting and logical errors, generates summary statistics and plots of family size distributions, quantitative trait and covariate distributions, a listing of heterozygosity and allele frequency distributions for each marker, and breakdowns of affection status information. Additional features include an option to check Hardy-Weinberg equilibrium and produce a graphical synopsis of test results, the capability to calculate correlations and produce summary plots of trait distributions for different relative pairs, sex-specific output, and an option to remove uninformative individuals from pedigrees. All output can be written in either text or graphical PDF format; the latter has the virtue of being accessible and portable across a wide variety of computer platforms. Pedstats is distributed with the Merlin package, and is freely available for download at <http://www.sph.umich.edu/csg/abecasis>.

**Haplotype frequency and effect estimations for family-based association analyses.** *G. Xu<sup>1,2</sup>, Q. Yang<sup>1,3</sup>, S. Demissie<sup>3</sup>, R.H. Myers<sup>1,2</sup>.* 1) Neurology, Boston University Sch Medicine, Boston, MA; 2) Bioinformatics Program, Boston University, Boston, MA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

In many cases of family-based haplotype association studies, the parental genotypes and phase for many individuals are missing. Here we present a method utilizing SNP data, to improve haplotype frequency estimation for extended pedigrees, and which may then be applied in a mixed regression model to estimate haplotype effects for quantitative traits. For founders with missing genotypes, haplotypes are inferred from offspring genotypes. Pairs of founder haplotypes, one for each chromosome, are retained when they are compatible with all offspring genotypes. Expectation maximization (EM) algorithm is used to estimate haplotype frequencies in the population using only the compatible founder haplotypes. Haplotype association is assessed as follows: the trait is the dependent variable, with the haplotypes as fixed effects and the pedigree as a random effect. Founders haplotype information is also included as a fixed factor to adjust for population admixture. A weighted regression approach is employed to accommodate the varying certainty of different haplotype configurations. Simulation studies are performed to compare the accuracy of haplotype frequency estimates using our method with those for existing approaches. Results from the mixed regression are compared with existing family-based association tests. We apply our method to obtain haplotype frequencies for SNPs in the PARK3 region, and the mixed regression to estimate the haplotype effects against onset-age of Parkinsons disease.

Program Nr: 2568 from 2003 ASHG Annual Meeting

**A Semiparametric Method for Estimating Population Size History from Sequence Data using Markov Chain Sampling.** *A. Renwick, M. Kimmel.* Dept Statistics, Rice Univ, Houston, TX.

We present a new, likelihood-based method of inferring population size history from DNA sequence data. The approach is, first, to devise an estimator that is a function of the (unobserved) genealogy of the sampled sequences, and, then, to compute the distribution of that estimator conditioned on the (observed) sequence data. This is accomplished by embedding the estimator in a Bayesian Markov Chain Monte Carlo method of phylogenetic inference. We estimate the parameter (four times the product of population size and mutation rate) as a piece-wise constant function of time. This allows the method to be "semiparametric" in the sense that it requires a parametric model of sequence evolution but does not impose any restrictions on the nature of the population size change history. This method takes advantage of the increasing availability of sequence data by accommodating an arbitrary number of unlinked loci. We illustrate the method with applications to anthropology and epidemiology.

**Linkage analysis allowing for errors - application to SNPs.** *D. Gordon*<sup>1</sup>, *C. Haynes*<sup>1</sup>, *C. He*<sup>2</sup>, *T. Matisse*<sup>2</sup>, *S. Finch*<sup>3</sup>, *J. Ott*<sup>1</sup>. 1) Lab of Statistical Genetics, Rockefeller University, New York, NY; 2) Department of Genetics, Rutgers University, Piscataway, NJ; 3) Department of Applied Math and Statistics, Stony Brook University, Stony Brook, NY.

Genotyping errors can significantly affect power and type I error rates when performing linkage analyses. Using a maximum likelihood approach, we have developed a method that performs linkage analyses in the presence of genotyping errors and which maintains a correct type I error rate, even in the presence of errors. In addition, our method allows for the estimation of locus specific error rates under the null hypothesis (recombination fraction  $\theta = 0.5$ ) and the alternative ( $\theta < 0.5$ ). Because our method offers a selection of multiple error models, model fitting using a generalized likelihood ratio statistic can be performed to determine what error model best fits the data when the marker locus is a SNP. We have developed a software program, Linkage-AE, that uses our method. Results of the model fitting procedure with a set of 1440 SNPs genotyped on over 500 individuals in several CEPH pedigrees using the error model proposed by Sobel Papp and Lange (SPL) indicate that the average probability of an error occurring in a SNP locus is  $5.5 \times 10^{-3}$ , with a median probability of  $5.5 \times 10^{-5}$ . The largest observed probability is 0.23. Also, we observe that the probability for an error in a SNP is greater than 0.01 for 7 percent of the 1440 SNPs typed. These results indicate that the distribution of probabilities is highly skewed. Finally, we find that the most general error model for SNPs consisting of 6 error parameters is a better fit than the SPL model for 20 out of 1440 markers. These results suggest that the SPL error model is good error model for most SNPs.

**Prospective and Retrospective Variance-Component Linkage Methods for Complex Trait Data.** *M.P. Epstein<sup>1</sup>, X. Lin<sup>2</sup>, M. Boehnke<sup>2</sup>*. 1) Dept of Human Genetics, Emory Univ, Atlanta, GA; 2) Dept of Biostatistics, Univ of Michigan, Ann Arbor, MI.

Variance-component (VC) linkage analysis is a powerful and flexible tool for the mapping of genes that influence quantitative traits. However, existing VC methods typically assume the trait data (1) either follow (or may be transformed to follow) a multivariate normal distribution within a family and (2) consist of a random sample from the population. Several papers have shown that violation of the normality assumption (1) may lead to biased parameter estimates and elevated type I error rates. Violation of the random-sampling assumption (2) also yields improper inference unless one adjusts the prospective likelihood of the VC method by the sampling criterion. Unfortunately, the complex sampling schemes typically applied in genetic studies may prevent accurate implementation of such a sampling adjustment in practice.

Given the appealing design of the VC method for random normal data, we have extended the method to accommodate both non-normal trait data and non-random sampling. For the first extension, we apply the generalized-linear-mixed-modeling (GLMM) framework to accommodate trait data with known non-normal distributions, such as binary (e.g. disease) and count data. For the latter extension, we develop a retrospective variance-component framework that is independent of the sampling criterion. We believe these two extensions provide a unified VC framework that allows prospective and retrospective analyses of genetic trait data that follow a variety of known distributions. We illustrate the utility of these extensions using simulated data and quantitative trait data from the Finland-United States Investigation of NIDDM (FUSION) study.

Program Nr: 2571 from 2003 ASHG Annual Meeting

**Unification of variance components and Haseman-Elston regression for quantitative trait linkage analysis in humans.** *W.M. Chen, K.W. Broman, K.Y. Liang.* Department of Biostatistics, Johns Hopkins Univ, Baltimore, MD.

There are two major approaches for linkage analysis with quantitative traits in humans: variance components and Haseman-Elston regression. Previously, these have been viewed as quite separate methods. We describe a general model for quantitative trait linkage analysis in general pedigrees, fit by use of generalized estimating equations (GEE), for which the variance components and Haseman-Elston methods (including the many extensions to the original Haseman-Elston method) are special cases, corresponding to different choices for the working covariance matrix.

These results have several important implications. First, this work provides new insight regarding the connection between these methods. Second, asymptotic approximations for power and sample size allow clear comparisons regarding the relative efficiency of the different methods. Third, our general framework suggests important extensions to the Haseman-Elston approach which make more complete use of the data in extended pedigrees and a natural incorporation of environmental and other covariates, while maintaining the valuable robustness properties of Haseman-Elston regression.

**How multiple data sets are combined affects autism genome screen results: 'Pooled' compared to 'sequentially updated' linkage analyses.** *R. Goedken<sup>1</sup>, J. Piven<sup>2</sup>, V. Sheffield<sup>1</sup>, T. Wassink<sup>1</sup>, J. Beck<sup>1</sup>, V. Vieland<sup>1</sup>*. 1) University of Iowa, Iowa City, IA; 2) University of North Carolina, Chapel Hill, NC.

Under conditions of intra- and inter-sample heterogeneity, pooling (concatenating) data sets and computing overall summary linkage statistics will tend to wash out true linkage signals (Vieland et al., 2001). But for standard model-free and model-based linkage statistics, pooling data sets prior to analysis is the only way to measure the aggregate strength of evidence taking all available families into consideration at once. By contrast, the posterior probability of linkage (PPL) is a mathematically rigorous approach to accumulating evidence across heterogeneous data sets via sequential updating. We illustrate the effects of data-pooling by reanalyzing genome screen data for 119 (primarily) nuclear families ascertained on the basis of at least two autistic children. The data were separated a priori into 4 subsets based on temporal and clinical factors. Complete PPL results are presented elsewhere (Vieland et al., this meeting). Here we compare the 2-point PPL results (updated) with results from pooling all families (pooled) and using either model-free multipoint analyses (ASPEX MLSs), multipoint HLODs maximized over one dominant, one recessive model (M-MMLS), or 2-point MMLS HLODs (MMLS). A very different picture is obtained across the genome depending on the method used to handle the 4 data sets. For example, on chromosome 16 we obtain a PPL of 70% in the full set of 119 families, with virtually all of the linkage signal coming from subset 1 (PPL = 77%). In subset 1 at this location we get (on the LOD scale): MLS 1.6, M-MMLS 3.3, MMLS 3.8. Pooling all 119 families we get: MLS 0.5, M-MMLS 0.7, MMLS 1.4. This represents 63%-79% drop in the lod score relative to subset 1 alone, compared to only 10% drop in the PPL. We do not know whether this is a true linkage, but it is clear that failure to appropriately accumulate evidence across disparate data sets can alter the overall conclusions of a genome screen.

Program Nr: 2573 from 2003 ASHG Annual Meeting

**A Model-Based Bayesian Transmission Disequilibrium Approach For Testing Linkage.** *V. George*<sup>1</sup>, *S. Shete*<sup>2</sup>. 1) Biostatistics, Ryals PHB #327, Univ Alabama at Birmingham, Birmingham, AL; 2) Epidemiology, Box 189, UT M. D. Anderson Cancer Center, Houston, TX.

The transmission disequilibrium test (TDT) is a powerful method for detecting a disease locus in linkage and linkage disequilibrium with a marker. Here, assuming the knowledge of mode of inheritance, we developed a Bayesian method for testing for linkage in the presence of allelic association. We used Markov chain Monte Carlo simulation approach to fit the proposed Bayesian model. We compared the proposed Bayesian TDT with the usual TDT and found that the proposed method is more powerful and that the estimated values of recombination fraction are more accurate compared to existing method. We evaluated robustness of our method when mode of inheritance is not correctly specified.

**Linkage Analysis with Adjustment for Associated Marker Genotypes in Fine-Mapping Studies.** *R.L. Hanson, W.C. Knowler.* DAES, NIDDK, Phoenix, AZ.

Association studies are often used to finely map loci identified by linkage analysis. Once a marker associated with the trait is identified, linkage analysis with adjustment for marker genotypes may help determine if the association explains the linkage. We conducted a simulation study to determine sensitivity of this procedure to extent of linkage disequilibrium and to similarity in frequency between functional and marker alleles. Families consisted of 264 nuclear families, containing 1004 offspring and 1893 sib-pairs who had participated in a linkage study. Genotypes were simulated for these individuals at: 1) a diallelic functional locus with a high-risk allele with frequency= $f_A$ ; 2) a diallelic marker locus closely linked ( $=0.00$ ) to the first with an allele of frequency= $f_1$  associated with the high-risk allele at a specified degree of linkage disequilibrium ( $D'$ ); 3) a perfectly informative marker linked ( $=0.05$ ) to the other two loci. Trait values were generated for a quantitative trait under the assumption that heritability specific to the functional locus was 25%. 500 replicates were generated for each value of  $f_A$ ,  $f_1$  and  $D'$ . The regression method of DeFries and Fulker was used to evaluate linkage between the trait and the perfectly informative marker. The LOD score from a model that included covariates for the diallelic marker was compared with the unadjusted LOD. When diallelic marker and functional loci were identical ( $D'=1.0$ ,  $f_A=f_1$ ), adjustment for the marker completely attenuated evidence for linkage, but the extent of attenuation diminished when  $D'<1.0$  and  $f_A f_1$ . For example, when  $f_A=f_1=0.2$ , median adjusted LOD=2.1 when  $D'=0.0$  (equivalent to the unadjusted LOD), while the adjusted LOD=1.4 when  $D'=0.4$ , LOD=0.6 when  $D'=0.8$  and LOD=0.0 when  $D'=1.0$ . When  $f_A=0.2$  and  $D'=0.8$ , median adjusted LOD=1.4 when  $f_1=0.4$ , LOD=1.7 when  $f_1=0.6$  and LOD=1.9 when  $f_1=0.8$ . Linkage analysis with adjustment for marker genotypes can determine if a marker accounts for the observed linkage and, thus, may be the variant directly influencing the trait. However, conditioning linkage on association with a marker in the disease gene but not identical to the causal variant and having a different allele frequency will not completely account for the linkage.

**Comparative Study of multipoint methods for genotype error detection.** *N. Mukhopadhyay<sup>1</sup>, S.G. Buxbaum<sup>1</sup>, D.E. Weeks<sup>1,2</sup>.* 1) Dept Human Genetics, Univ Pittsburgh/Sch Pub Health, Pittsburgh, PA; 2) Dept Biostatistics, Univ Pittsburgh/Sch Pub Health, Pittsburgh, PA.

Several programs, such as Merlin, SibMed, SimWalk2 and Mendel4, provide multipoint estimation of the posterior probability of genotyping errors. Very little has been done to characterize their relative behavior, power, and effects of marker spacing, pedigree structure, and size. Our simulation study is designed to address these issues.

Input data consists of 4 nuclear pedigree structures, with and without typed parents, and one with a half-sibling. Marker data consists of 11 microsatellite markers with realistic allele frequencies, and map spacings of 1, 2, and 5 cM. We simulated 5,000 replicates of each pedigree structure and marker map. About 4% of the middle marker's genotypes were switched to another genotype with uniform probability.

Initial results are from Merlin's mistyping option. Merlin assigns a low likelihood score to genotypes to indicate mistyping. We use the lower 5th percentile of Merlin scores for pedigrees without input errors as a threshold for flagging mistypings. While Merlin's default threshold is 0.025, our values range from 0.53-0.75, varying slightly by pedigree structure and marker spacing. Power to detect Mendelianly consistent errors ranges from 44%-68% decreasing with marker density. Increasing map density from 2 cM to 1 cM does not affect cutoffs or power. Pinpointing the mistyped person in a pedigree is difficult; often, a relative without erroneous genotypes is also implicated. Mistyping at a locus causes flanking markers to have an elevated false positive rate.

We are performing similar comparative studies of other error detection programs. The challenge lies in reconciling the different characterizations of genotype errors, e.g., Merlin gives likelihoods for each genotype, whereas SibMed gives the posterior genotyping error probability for a sib-pair. Our initial study is aimed at characterizing a common set of performance parameters so as to enable such comparisons.

**Comparison of Multiple SNPs and Single Microsatellites for GenomeScans.** *E. Lindholm*<sup>1</sup>, *D.A. Greenberg*<sup>1,2</sup>, *S.E. Hodge*<sup>1,2</sup>. 1) Div Stat Genetics, Columbia U; 2) NYSPI, NY, NY.

Single nucleotide polymorphisms (SNPs) are biallelic and therefore not as polymorphic as microsatellites. However, by analyzing several closely-spaced SNPs, we can increase the information content for linkage. We investigated how the lod score depends on the number of SNPs used in a linkage analysis and compared the results to information from a single polymorphic microsatellite. We examined sib pairs (without parental information) and nuclear families with varying numbers of children. We simulated 20 data sets of 50 families each with 2-5 children per family. Marker data came from 1-10 SNPs with no recombination between them and in linkage equilibrium. We generated comparable data for one microsatellite with between 3 and 9 equally frequent alleles. Allele frequencies for SNPs were either 0.5 and 0.25 and were the same for all SNP loci in an analysis. GENEHUNTER was used to calculate lod scores (see table). We found that 4 or 5 closely spaced SNPs (depending on the allele frequency) were approximately equivalent to one microsatellite with 9 equally frequent alleles. Adding more than 5 or 6 SNP loci did not improve the lod score. More than 5 SNP markers will not increase the amount of linkage information but increasing the polymorphicity of a microsatellite beyond the 9 alleles we tested will increase the information. The results indicate that about 1200-1500 SNPs would be enough to get the same information as 300 microsatellite markers for linkage analysis in nuclear families.

**A likelihood ratio test for linkage with covariates based on IBD allele sharing in affected relatives.** *L. Mirea*<sup>1</sup>, *L. Briollais*<sup>1,2</sup>, *S.B. Bull*<sup>1,2</sup>. 1) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON, Canada; 2) Department of Public Health Sciences, University of Toronto, Toronto, ON, Canada.

Gene-mapping studies of complex traits often employ linkage methods that do not model possible differences in *identical-by-descent* (IBD) allele sharing of affected relatives among sampled families. Statistical power of linkage tests can be increased by including covariates associated with different genetic mechanisms that cause variation in allele sharing. We investigate a particular extension of the one-parameter exponential likelihood model defined by Kong and Cox (1997 Allele-sharing models: LOD scores and accurate linkage tests. *Am J Hum Genet* 61:1179-1188) that, in addition to the linkage parameter ( $\theta$ ), incorporates a parameter ( $\delta$ ) measuring deviation in IBD allele-sharing between two groups of families classified by a binary covariate. Based on this extension, a likelihood ratio statistic can be formulated to test departures from the null of no linkage ( $\theta=0$ ) and no differences in allele sharing ( $\delta=0$ ) between the two covariate-defined family groups. Under asymptotic regularity conditions, the significance of the two-parameter test for linkage with the covariate ( $\theta$  or  $\delta$ ) can be evaluated using a  $\chi^2$  distribution with 2 df. In comparison, the test for linkage in the one-parameter exponential model (Kong and Cox, 1997) evaluates the square root of the likelihood ratio statistic with respect to a Gaussian distribution and considers a one-sided alternative ( $\theta > 0$ ). The linkage tests with and without the covariate were applied to family data simulated under a model of locus heterogeneity such that each replication included a mixture of linked and unlinked families with affected siblings and cousin pairs. In scenarios where the family-level covariate correctly identified linked and unlinked families, the test with the covariate can have greater power than the test without the covariate, particularly when the relative number of linked families is small and differences in allele sharing are large. Conversely, when the covariate is independent of group differences in allele sharing, power is reduced for the test with the covariate compared to the test without.

Program Nr: 2578 from 2003 ASHG Annual Meeting

**Ascertainment Corrections in Variance Component Analysis.** *J. Peng, D. Siegmund.* Statistics Department, Stanford University, Stanford, CA 94305.

Variance component methods to map quantitative trait loci require the estimation of various nuisance parameters, e.g., the trait mean, variance, and correlations between relatives. This is easily accomplished when pedigrees are randomly ascertained. Here we study ascertainment adjustments for pedigrees consisting of  $s$  siblings (with or without parents), which are ascertained on the basis of phenotypic values of  $r < s$  of the siblings. We show that two different schemes of ascertainment correction, (i) conditioning on trait values and (ii) conditioning on the event of ascertainment, are asymptotically equivalent when the number of sibships is large. We also find that of the three important nuisance parameters, the estimate of the phenotypic variance is robust against failure to correct for ascertainment, but the estimates of the phenotypic correlation and mean are not robust. Failure to adjust adequately estimates of the phenotypic mean and correlation can lead to a substantial loss of power, while failure to adjust estimates of the variance leads to negligible loss of power.

**Information Content of Multi-point Analysis and Efficiency of Two Stage Genotyping.** *D. Siegmund<sup>1</sup>, J. Peng<sup>1</sup>, H.K. Tang<sup>2</sup>*. 1) Dept Statistics, Stanford Univ, Stanford, CA; 2) Hewlett Packard Corporation, Palo Alto, CA.

By extensive simulation we examine the efficacy of multipoint methods to compensate for markers that are incompletely polymorphic (a) when pedigree founders are available for genotyping and determination of identity-by-descent (IBD) of affecteds is conditional on founder genotypes and (b) when founders are unavailable and IBD status is determined through allele frequencies. When markers are reasonably informative and closely spaced and allele frequencies are correctly specified, relatively little information is lost when founders are not genotyped; but when markers are only moderately informative, knowledge of founder genotypes can add substantially to the available IBD information. We also consider genotyping in two stages: in the first stage an intermarker distance of 20 cM is used, and in the second stage the distance is reduced to 5 cM in the neighborhood of any marker yielding a Z-score above  $z_0$  in the first stage. For the case of a single disease gene that can be detected by a 5 cM genome scan with power 0.67 or 0.9, and for  $z_0 = 1.28$  or 1.65, we find that the gene can be detected with no loss of power and 1/3 as many genotypes, except when founders are not genotyped and marker polymorphism is only moderate. In order to obtain accurate estimates of the genome wide significance level, we have used an importance sampling technique that may prove useful more generally.

**Effects of ascertainment on the power of variations of the Haseman-Elston method for a quantitative trait.** Y. Yao<sup>1</sup>, A.J.M. Sorant<sup>2</sup>, A.F. Wilson<sup>2</sup>. 1) Dept Epidemiology, Johns Hopkins Univ, Baltimore, MD; 2) IDRIB, NHGRI, NIH, Baltimore, MD.

Previous work has shown that non-random ascertainment of family data may affect the power of some methods of linkage analysis. The present study examined the effect of non-random ascertainment on the power of several versions of the Haseman-Elston (HE) method of model-independent sib pair linkage analysis, which all perform a regression on the estimated proportion of alleles shared identically by descent, using a different dependent variable for each version. The traditional HE method uses  $-.5$  times the square of the trait difference between sibs as the dependent variable (DIFF). Similarly, the revised HE method uses the mean-corrected cross-product (PROD). Other versions use half the square of the mean-corrected sum (SUM) or a weighted combination of the squared trait difference and the squared mean-corrected sum (W2) as the dependent variable. Model-independent linkage analysis was performed using each dependent variable in simulated samples of 100 nuclear families of sibships of size 4 with a quantitative trait generated under several genetic models: additive genetic heritability of 10% - 50%, with and without an additional polygenic or common sibship component. Four different ascertainment schemes were considered: random sampling (RS); selecting families with at least one sib with a high trait value (H1); at least two sibs with high values (H2); and families with extremely discordant sibs (ED). Results were summarized by counting p-values less than a critical value of .01 over 2000 replications of each experiment. For all HE analysis methods and all genetic models considered, the ED ascertainment scheme had the greatest power (169% better than RS on the average). The H1 and H2 schemes often improved power over RS for the PROD, DIFF and W2 methods. In all situations considered, the SUM method consistently had the worst power. PROD, DIFF, and W2 analysis version provided better power, with each of these methods having higher power than the others under different circumstances.

**Assessment and application of a nonparametric confidence set approach based on the mean test.** *C. Papachristou, S. Lin.* Department of Statistics, Ohio State University, Columbus, OH.

In genomewide linkage analyses one needs to adjust for the number of simultaneous hypotheses tested. Such an adjustment is very difficult due to the complex nature of dependencies amongst data arising from linkage studies. It is possible, though, to avoid dealing with multiple testing issues, by constructing confidence sets of markers tightly linked to a genetic trait through testing hypotheses that are reversal of the usual setup. Here, we examine the effect of several factors on the confidence set derived using the nonparametric mean statistic based on IBD sharing of affected sib pairs. Simulations are performed to assess the performance of the approach in terms of its true and false discovery rates, under varying conditions of the underlying single locus disease model, the amount of data, the heterozygosity of the marker, and the number of family members genotyped at the marker locus. We also provide rough guidelines for the choice of coverage probability of the confidence set that would lead to a false discovery rate of a desirable level. Our methods are then applied to the simulated data from the Genetic Analysis Workshop (GAW) 13, focusing on the high blood pressure trait. Our simulation results show that when the assumption of a single locus trait with accurate risk estimates is met, the confidence set is able to sufficiently localize the disease causing gene. However, a moderate increase of about 30% in the amount of data is necessary for the method to achieve the same power as when the marker is 100% polymorphic. Also, inaccurate estimation of the risks may compromise the power or inflate the false discovery rate of the method, particularly when genetics only plays a limited role in the disease causing mechanism. Incorrect specification of the number of disease causing genes also reduces the power of the method. Nevertheless, the results for the GAW data suggest that, despite potential reduction in power due to deviation from the ideal situation, our method can still achieve significantly higher power than standard nonparametric methods while maintaining comparable false positive rates, especially when the sample size is reasonably large.

**Detecting Gene-Gene Interactions: Linkage Designs versus Association Designs.** *S. Wang*<sup>1</sup>, *H. Zhao*<sup>1,2</sup>. 1) Department of Epidemiology & Public Health, Yale Univ, New Haven, CT; 2) Department of Genetics, Yale Univ, New Haven, CT.

Gene-gene interaction has received much attention recently both due to technological advances that have enabled researchers to study many genes simultaneously and due to a deeper appreciation of the complexity underlying human diseases with most human traits depending on several interacting genes as well as environmental factors. Gauderman (2002) and Wang and Zhao (2003, in press) have reported systematic studies on the statistical power to detect gene-gene interaction in association studies. In this presentation, we conduct a systematic study to evaluate the statistical power to uncover gene-gene interactions in linkage studies, with a focus on the affected sib pair (ASP) approach. We assume a logistic model for disease risk, and detect gene-gene interactions through correlation based on alleles shared identical-by-decent (IBD) at the two disease loci. In addition to logistic models, we also investigate the power to detect gene-gene interactions of several two-locus models with fixed penetrance effects that cannot be parameterized in logistic forms. The results of the ASP design are compared with the results of the association designs reported in Wang and Zhao (2003). Our results indicate that the association designs are far more powerful than the ASP designs for all the genetic models considered.

**Empirical Bayes Method for Incorporating Data from Multiple Genome Scans.** *T.M. Beasley, H. Wiener, D.B. Allison.* Biostatistics, University of Alabama, Birmingham, AL.

Individual genome scans can produce markedly biased estimates of QTL effects. Further, the confidence interval for their location is often prohibitively large for subsequent fine mapping and positional cloning. Given that a large number of genome scans have been conducted, not to mention the large number of variables and subsets tested, it is difficult to confidently rule out Type I error as an explanation for significant effects even when there is apparent replication in a separate data set. We adapted Empirical Bayes (EB) methods (Morris 1983) to analyze multiple datasets simultaneously and alleviate these problems while allowing for different QTL population effects across studies. We evaluated this method applied to meta-analyses of linkage studies via simulation, using actual marker spacing and allele frequencies on chromosome 11 from the NIMH Alzheimers Diseases Genetics Initiative. Under complete null conditions, the one-sided 95% rejection cutoff was close to the expected 1.64, when only one study was analyzed. For the EB method, the null cutoff value depended on the number of studies used to update the study of interest. For 5, 9, and 19 background studies respectively, the 95% cutoff values were 1.38, 1.22, and 1.05, respectively. These values were used to determine statistical significant for the non-null models. For non-null situations, phenotypes were assigned assuming 5% heritability. For data from one study, approximately 53% of the results were significant at a marker located at the same position as the affective locus. When the EB method was applied, these rejection rates rose to 78%, 91%, and 98% for 5, 9, and 19 background studies, respectively. At a marker 90cM from the affective locus, the rejection rates fell between 6.1% and 7.2%. When we compared single study results, EB results with 5 background studies, and a single study with six times the number of sibling pairs as the original study, the rejection rates for the EB method were always between the values for the other two situations. This EB method for incorporating data from multiple genome scans seems promising in that it has more power and better Type I error control.

Program Nr: 2584 from 2003 ASHG Annual Meeting

**Genomic Imprinting and Linkage Test for Quantitative Trait Loci in Extended Pedigrees.** *S. Shete, X. Zhou, C. Amos.* Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.

Genomic imprinting is a mechanism in which only one of the two copies of a gene is expressed. Some genes that affect development and behavior in mammals are known to be imprinted. Deregulation of imprinted genes has been found in a number of human diseases. Incorporating imprinting information into linkage analysis results in a more powerful test for linkage. Here we propose an efficient method to test for linkage and imprinting of quantitative traits in extended pedigrees. We compared the results obtained by using the extended pedigree analysis approach proposed here to other existing approaches. We found that the proposed method is more powerful and uses extended pedigree information most efficiently.

**Resampling-based statistical methods to improve the estimation of locus-specific effects from genome-wide studies.** *L. Sun*<sup>1,2</sup>, *S.B. Bull*<sup>1,3</sup>. 1) Dept Public Health Sci, University of Toronto, Toronto, ON, Canada; 2) Programs in Genetics and Genomics, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Ontario, Canada.

The accuracy of locus-specific effect estimates has emerged as one of the major methodological concerns in studies aimed at dissecting the genetic components of complex diseases and quantitative traits using genome-wide approaches. Some authors (e.g. Goring et al. 2001) have argued that reliable locus-specific parameter estimates can only be obtained in an independent sample; others (e.g. Allison et al. 2002) have shown that statistical methods such as moment-based procedure may be applied to the initial sample while reducing the estimation bias in some cases. Statistical resampling techniques such as cross-validation and the bootstrap have been successfully employed to address over-fitting and variable selection bias in diagnostic and prognostic prediction models in clinical settings and in microarray data analysis of gene expression. We hypothesize that, in the context of genome-wide genetic studies, these statistical techniques will also improve the estimation of locus-specific effects. In addition, they will be effective in the validation and interpretation of the initial findings. We examine different resampling techniques, such as 50-50 and 90-10 split-sample, 10-fold and 10x10-fold cross-validation, leave-one-out jackknife and bootstrap methods, and compare them with the naive method in which all data are used for both hypothesis testing and parameter estimation. Under a simple model, we derive analytically the upward bias of the naive estimator, and we show numerically the effectiveness of incorporating resampling techniques into estimation. We also consider a more realistic example in the context of genome-wide linkage analysis. Results of our preliminary simulation studies suggest that cross-validation and bootstrap can effectively reduce the estimation bias while retaining comparable power to detect linkage.

**The number of STR markers required to resolve relationships between pairs of individuals.** *S. Presciuttini*<sup>1,2</sup>, *C. Toni*<sup>3</sup>, *I. Spinetti*<sup>3</sup>, *R. Domenici*<sup>3</sup>, *J.E. Bailey-Wilson*<sup>2</sup>. 1) Dept Biomedicine, Univ Pisa, Italy; 2) Inherited Disease Research Branch, NHGRI, NIH, Baltimore MD, USA; 3) Unit of Legal Medicine, University of Pisa, Italy.

The inference about the biological relationship between pairs of individuals using genetic markers plays a central role in many areas of human genetics. We investigated the number of markers (*M*) necessary to assign a given proportion of pairs ( $1 - \alpha = 90\%$ ,  $95\%$ , and  $99\%$ ) to their correct relationship at three significance levels ( $\alpha = 0.01$ ,  $0.001$ , and  $0.0001$ ) against several alternative hypotheses. The following relationships were considered: 1) parent-child; 2) full sibs; 3) second degree, including half-sibs, grandparent-grandchild and avuncular pairs; 4) first cousins; and 5) non-relatives. For each relationship, 10,000 true pairs were simulated, and the likelihood ratio that each pair was falsely attributed to the other relationships was calculated using exact Bayesian probability equations. Simulations were carried out separately for 25 unlinked markers commonly used in the forensic practice, which were repeated a second time to reach a total number of 50 markers.

Full sibs are discriminated from non-relatives and first cousins with a relatively small number of markers even in the strictest conditions ( $1 - \alpha = 99\%$ ,  $\alpha = 0.0001$ :  $M = 32$  and  $24$ , respectively), whereas discrimination between full sibs and second-degree relatives (e.g., half sibs) is possible at  $\alpha = 0.001$  (with  $M = 42$ ); in contrast, discriminating between second-degree and more distant relationships is not practicable with only 50 independent markers. We also investigated the reduction in the number of total typed genotypes achieved by using a sequential test, based on a first set of ten markers and the addition of other sets of five markers each, while keeping  $1 - \alpha$  constant. Our analysis may be useful to assess the feasibility of studies in which genotyping is specifically performed for the purpose of verifying relationships, such as follow-up studies in linkage analysis (when genome-wide scan data are not available) and field studies in genetic anthropology.

**Estimation of critical values for genome scans.** *S. Bacanu*. Dept Psychiatry, WPIC, University of Pittsburgh Medical Ctr, Pittsburgh, PA.

It is widely recognized that the Lander-Kruglyak critical values for significant and suggestive linkage are very conservative for many linkage studies. Their conservativeness is due to imperfect information about recombination caused by limited polymorphism of markers and small, incomplete families. Simulation-based estimation of critical values is one route to obtain more pertinent thresholds. Simulation methods have the disadvantage that they are time consuming and require skill to integrate many different software/tools and results. I have been examining a different method to determine study-specific critical values. This approach uses the realized genome scan statistic data (standard normal NPL-scores) to estimate the suggestive and critical values. Stationary autoregressive models of increasing order  $p$  (AR( $p$ )) are fit to the standard normal statistics contained in the genome scan; the optimal AR order is determined via Bayesian Information Criterion (BIC). The estimated parameters of the optimal AR( $p$ ) are used to determine the estimated correlation between statistics for two adjacent markers. This correlation is used to determine the probability of up-crossing a certain boundary between any two markers on the map and, consequently, to estimate the critical values. The behavior of the proposed method is assessed via simulations of data sets based on marker allele frequencies and maps derived from Marshfield Screen Set 9 (MSS9). Three marker densities are considered in the simulations with average distance between markers of 5, 10 and 20cM. The 5 cM map is obtained by inserting a marker between any two MSS9 markers and the 20cM map is obtained by deleting every other marker from the (roughly) 10cM MSS9 map. Preliminary studies show promising results for the significant critical value but not for the suggestive one when linkage studies results are fitted by using an AR(1) process. Higher order AR (and, possibly, ARIMA) approximations are currently being investigated and the results will be presented. If this approach proves successful, it can easily be encoded in software for rapid determination of study-specific critical values.

**High Resolution Association Studies of Complex Diseases Using Parents as Controls.** *R. Fan<sup>1</sup>, M. Knapp<sup>2</sup>, C. Zhao<sup>1</sup>, M. Xiong<sup>3</sup>.* 1) Dept of Statistics, Texas A&M Univ, College Station, TX; 2) Institute of Medical Biometry, Informatics and Epidemiology, University of Bonn, D-53105 Bonn; 3) Human Genetics Center, University of Texas-Houston, TX.

Case control studies using unrelated controls are prone to false positive due to inappropriate controls, which can occur if there are population admixture or stratification. Alternatively, parental controls can be a valid option (Falk and Rubinstein 1987; Ott 1989; Schaid and Rowland 1998; Spielman, McGinnis, Ewens 1993). For parental controls, the methods of two-sample Hotelling's  $T^2$  statistic tests proposed by Fan and Knapp (2003) and Xiong, Zhao and Boerwinkle (2002) are not valid since cases and controls are correlated to each other. Not only the correlation between the haplotype blocks or markers needs to be taken into account, but also the correlation within each parent-offspring pair needs to be dealt with. One method is to perform paired Hotelling's  $T^2$  statistic tests, instead of the two-sample Hotelling's  $T^2$  statistic tests. The paired Hotelling's  $T^2$  test statistics are proposed for high resolution association study based on two coding methods: haplotype/allele coding and genotype coding, if data of multiple bi-allelic or multi-allelic markers or haplotype blocks are available. The validity of the proposed method is justified by rigorous mathematical and statistical proof under the large sample theory. The non-centrality parameters of the test statistics are calculated for power and sample size comparisons.

**Simultaneous estimation of haplotype frequencies, diplotype configurations, and diplotype-based penetrances for testing association between phenotypes and the presence of haplotypes using genotype and phenotype data. T.**

*Ito*<sup>1,2</sup>, *E. Inoue*<sup>2</sup>, *N. Kamatani*<sup>3</sup>. 1) Safety Science and Policy Dep., Mitsubishi Research Institute, Tokyo, Japan; 2) Algorithm Team, Japan Biological Information Research Center (JBIRC), Japan Biological Informatics Consortium (JBIC), Tokyo, Japan; 3) Division of Genomic Medicine, Department of Advanced Biomedical Engineering and Science, Tokyo Women's Medical University, Tokyo, Japan.

Analysis of the association between haplotypes and phenotypes is becoming increasingly important. We have created an EM (expectation-maximization)-based algorithm to test the association between a phenotype and the presence of haplotypes, and to estimate diplotype-based penetrance using individual genotype and phenotype data from cohort studies and clinical trials. The algorithm estimates, in addition to haplotype frequencies, penetrances for subjects with a given haplotype and those without it. Relative risk can thus also be estimated. The maximum likelihood under the assumption of no association between the phenotype and presence of the haplotype ( $L_{0\max}$ ) (null hypothesis; i.e. with only 1 penetrance) and the maximum likelihood under the assumption of association ( $L_{\max}$ ) (alternative hypothesis; i.e. with 2 penetrances) were calculated. The statistic  $-2\log(L_{0\max}/L_{\max})$  was used to test the association. The present algorithm was implemented in the computer program PENHAPLO. Results of analysis of simulated data indicated that the statistic followed the  $\chi^2$  distribution with 1 degree of freedom asymptotically when the data were produced under the null hypothesis. The test had considerable power under certain conditions. Analyses of 2 real data sets from cohort studies, one concerning the *MTHFR* gene and the other the *NAT2* gene, revealed significant associations between the presence of haplotypes and occurrence of side effects. We propose a method to calculate the probability that a subject with genotype data but without phenotype data develops the phenotype based on estimated penetrances. Our algorithm may be especially useful for analyzing data concerning the association between genetic information and individual responses to drugs.

**Shannon's mutual information applied to population-based gene mapping.** *J.C. Mueller<sup>1</sup>, E. Bresch<sup>2</sup>, Z. Dawy<sup>2</sup>, T. Bettecken<sup>1</sup>, T. Meitinger<sup>1</sup>, J. Hagenauer<sup>2</sup>.* 1) Institute of Human Genetics, GSF, Munich, Germany; 2) Institute for Communication Engineering, University of Technology, Munich, Germany.

Correspondence: jakob.mueller@gsf.de

Connecting phenotype with genotype is a fundamental aim of genetics. In complex traits however there are many yet unknown factors influencing the genotype-phenotype relationship. Even without the environmental effect, the behavior of genetic association patterns is expected to be complex with multiple contributing loci, epistatic effects among loci, regulation feedbacks, and different genetic transmission systems. It is therefore important to develop parameter- and assumption- free methods for genotype-phenotype association studies. Shannon's mutual information, which determines the correlation between random variables, is such a simple and direct way of measuring the information relationship among genotypes and phenotypes in complex and unknown settings. In this paper we propose and describe the basic method for case-control studies. Simulated data sets with known causal loci are used to test its characteristics and power. The method performs well with different underlying transmission modes of the causal locus and is comparable to other state-of-the-art association tests. But the advantage of our method lies in its generality, its lack of assumptions and its capability of being extended to more complex settings like multiple phenotypes, multi-locus markers, and the joint investigation of interdependent markers.

Program Nr: 2591 from 2003 ASHG Annual Meeting

**Finding the etiological combination of SNPs in a candidate gene.** *A. Jannot, E. Genin, F. Clerget-Darpoux.* Unite 535, INSERM, Villejuif, France.

Numerous studies have underlined the complexity of the relationships between gene polymorphisms and diseases and the necessity to develop appropriate methods. The SNP combination test was developed to detect the role of a gene in the presence of SNP interactions within the gene. It tests the association between a quantitative trait and all possible phased combinations of various number of SNPs taking into account tests dependency. We extend the principle of this strategy to qualitative data. We study through simulations the power of this extension to detect the role of a gene when several SNPs are involved and interact. We also evaluate the capacity of this test to discriminate between the functional combination of SNPs and SNPs that are in linkage disequilibrium. The simulations performed are based on genotypic data of a study showing the role of several interacting SNPs on P-selectin gene in coronary diseases. We demonstrate that the SNP combination test is useful both for detection and fine modeling of genetic risk factors, and particularly in complex situations.

Program Nr: 2592 from 2003 ASHG Annual Meeting

**Family-based tests for associating haplotypes with general phenotype data: application to asthma genetics. S.**

*Horvath<sup>1</sup>, X. Xu<sup>2</sup>, S.L. Lake<sup>3</sup>, S.T. Weiss<sup>2,3</sup>, E.K. Silverman<sup>3</sup>, N.M. Laird<sup>2</sup>.* 1) Human Genetics, University of California, LA, Los Angeles, CA; 2) Harvard School of Public Health, Boston, MA; 3) Harvard Medical School, Boston, MA.

We provide a general purpose family-based testing strategy for allelic association between disease phenotypes and haplotypes when phase may be ambiguous and parental genotype data may be missing. These tests can be used in candidate gene studies with tightly linked markers. The method can be used to test for linkage and/or association between the haplotype locus and any trait influencing gene. Our proposed weighted conditional approach extends the method described in Rabinowitz and Laird [2000] and underlying the FBAT software to multiple markers. It is attractive because it provides haplotype tests for family-based studies which are efficient and robust to population admixture, phenotype distribution specification and ascertainment based on phenotypes. It can handle missing parental genotypes and/or missing phase in both offspring and parents and multiallelic or biallelic tests. This extension has been implemented in the freely available software haplotype FBAT. We used the haplotype FBAT program to test for associations between asthma phenotypes and single nucleotide polymorphisms (SNPs) in the beta-2 adrenergic receptor gene. Whereas no single SNP showed significant association with asthma diagnosis or bronchodilator responsiveness (quantitative trait), a haplotype-based global test found a highly significant association with asthma diagnosis (p-value = 0.00005) and the measure of bronchodilator responsiveness (p-value = 0.016). Download the software from [www.biostat.harvard.edu/~fbat/default.html](http://www.biostat.harvard.edu/~fbat/default.html).

**A Combinatorial Searching Method for Detecting A Set of Interacting loci Associated with Complex Traits.** *S. Zhang*<sup>1</sup>, *Q. Sha*<sup>1</sup>, *R. Cooper*<sup>2</sup>, *X. Zhu*<sup>2</sup>. 1) Department of Mathematical Sciences, Michigan Technological University, Houghton, MI 49931; 2) Department of preventive Medicine and epidemiology, Loyola University Stritch School of Medicine, Maywood IL.

Complex diseases are presumed to be the results of the interaction of several genes and environmental factors, with each gene only having a small effect to the diseases. Mapping complex disease genes therefore becomes one of the greatest challenges facing geneticists. Most current approaches of association studies essentially evaluate one marker or one gene (haplotype approach) at a time. These approaches ignore the possibility that effects of multilocus functional genetic units may play a larger role than a single-locus effect in determining trait variability. In this article, we propose a Combinatorial Searching Method (CSM) to detect a set of interacting loci (may be unlinked) that predict the complex trait. In the application of CSM, a simple filter is used to filter all the possible locus-combinations and retain the candidate locus-combinations, then a new objective function based on the cross-validation and partitions of the multi-locus genotypes are proposed to evaluate the retained locus-combinations. The locus-combination with the highest value of the objective function is the final locus-combination and the permutation procedure is used to evaluate the p-value of the test of the association between the multi-locus genotypes (or partitions of the genotypes) of the final locus-combination and the trait. The simulation studies show that the CSM has reasonable power to detect the high-order interactions of the loci even if there is no main effect. The method then applied to detect the locus-combination (among 13 loci in ACE gene) that predict systolic BP (SBP) or diastolic BP (DBP). We found that four loci with gene-gene interaction can best predict SBP with an overall p-value 3.9%, and two loci with gene-gene interaction can be best predict DBP with overall p-value 5%.

**Simultaneous estimation of haplotype frequencies, diplotype configuration, and the parameters of diplotype-based distributions of the QTL and for testing the association between QTL phenotypes and the presence of haplotypes.** *K. Shibata*<sup>1</sup>, *T. Ito*<sup>2,3</sup>, *Y. Kitamura*<sup>3</sup>, *N. Iwasaki*<sup>4</sup>, *N. Kamatani*<sup>5</sup>. 1) Department of Bioinformatics, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 2) Japan Biological Information Research Center, Japan Biological Informatics Consortium, Tokyo, Japan; 3) Mitsubishi Research Institute, Inc., Tokyo, Japan; 4) Diabetes Center, Tokyo Women's Medical University, Tokyo, Japan; 5) Division of Genomic Medicine, Department of Applied Biomedical Engineering and Science and Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

We have developed an algorithm, using individual genotypes at linked loci as well as their QTL phenotypes, to estimate the parameters for the distribution of QTL phenotypes for the subjects with a particular haplotype and those without it, using EM algorithm. We assumed QTL phenotype follows a normal distribution. At the same time, the algorithm calculates the maximum likelihood ( $L_{0\max}$ ) under the null hypothesis; i.e. non-association between the haplotype and QTL phenotypes, and the maximum likelihood ( $L_{\max}$ ) under the alternative hypothesis; i.e. association between the haplotype and QTL phenotypes. Then we tested the association between the haplotype and QTL phenotypes using a statistic  $-2\log(L_{0\max}/L_{\max})$ . This algorithm was implemented as a computer program QTLHAPLO. Simulation studies using SNP genotypes followed by the analysis of the simulated results by QTLHAPLO have clarified that the estimation was accurate when the linkage disequilibrium between linked loci was rather high. In such a case, the statistic  $-2\log(L_{0\max}/L_{\max})$  followed, asymptotically,  $\chi^2$  distribution with 1 degree of freedom. Empirical power using the simulated data was high enough. To be noted is that when the difference between the means of 2 different distributions are large and when the diplotype configurations of individuals are not concentrated on single events, the estimated tended to be a little higher than the real value and type I error rate was slightly higher than expected. We applied QTLHAPLO for the analysis of the real data of the genotypes at calpain 10 gene and various laboratory data concerning diabetes mellitus.

**A new strategy for investigating multilocus genotype and haplotype effects of a highly polymorphic gene: Application to the relationship between the Apolipoprotein B (*APOB*) gene and apoB plasma level.** *N. Tahri-Daizadeh*<sup>1,2</sup>, *V. Nicaud*<sup>1</sup>, *D.A. Tregouet*<sup>1</sup>, *F. Cambien*<sup>1</sup>, *L. Tiret*<sup>1</sup>. 1) INSERM U525, Hôpital Pitié-Salpêtrière, 91 Bld de l'Hôpital, 75634 Paris, France; 2) Genset-Serono Group, RN7, 91030 Evry, France.

There is increasing evidence that a detailed exploration of the whole polymorphism of candidate genes is required to obtain deeper insight into the relationship between gene variability and complex traits. The recent convergence of the massive amount of genetic data and increasing computing power offers a new opportunity to better assess the relationship between gene variability and phenotype(s). We propose a strategy for investigating the association between a highly polymorphic gene and a phenotype, by combining a multilocus genotype analysis and a haplotype analysis. The goal is to detect the most informative and parsimonious subset of polymorphisms explaining the variability of the phenotype. For multilocus genotype analysis, we developed a data-mining tool - termed DICE (Detection of Informative Combined Effects) which is a sequential forward-stepwise algorithm aimed at identifying the best subset of polymorphisms that are, either individually or in combination, associated with the phenotype. For haplotype analysis, we used our recently developed method of haplotype-phenotype association to determine, by a backward procedure, the most informative and parsimonious haplotype model. We illustrated this strategy by studying the association between a highly polymorphic candidate gene for coronary heart disease, the *APOB* gene, and plasma apoB levels in a sample of 1442 European male subjects. Twelve common bi-allelic polymorphisms located in the 5' and coding regions of the gene were considered. DICE identified the *N4311S* polymorphism as the most informative polymorphism in relation to apoB levels. The extensive haplotype analysis led to the same conclusion. DICE selected also the *E4154K* and the *T2488T* polymorphisms in a lower order of magnitude. According to our results, these 3 polymorphisms constitute the minimum subset of polymorphisms which should be investigated in further studies on the topic.

Program Nr: 2596 from 2003 ASHG Annual Meeting

**A Semi-Parametric Test for Genetic Associations With Age at Onset under Structured Populations.** *H. Chen, S. Zhang.* Mathematical Sciences, Michigan Technological Univ., Houghton, MI.

Gene mapping for complex diseases is a challenge in genetic studies. For many complex diseases, the disease genes influence the occurrence of the disease as well as the variability in their age of onset. For family-based studies, several methods have been developed to model the age of onset data. They showed that incorporating age of onset data into linkage analysis can potentially increase the statistical power for detecting linkage. In this paper, we study the effects of disease genes on the occurrence of the disease as well as the age of onset from a sample of unrelated individuals. We will consider the survival analysis model which incorporating the age of onset. As in the linkage analysis for familial disease, we have found that it will potentially increase the statistical power of detecting linkage. It is known that when the sampled data are unrelated individuals, there may present population stratification. We utilize genomic markers to control for the population stratification. Our proposed test statistic is valid regardless of the underlying genetic models that are subjected to structured population. For power comparison, our approach is compared to other case-control design methods that only consider affected cases and control group but without taking account the onset age. In most of the cases we considered, our method has higher power than that of the case-control design study.

**Haplotype case-control association analysis with related individuals.** *S. Browning*. Population Genetics, GlaxoSmithKline, Research Triangle Park, NC.

Traditional case-control association analyses require unrelated cases and controls. When related cases are available, such as following a linkage study, these methods are inefficient as only one case may be used from each family. I have developed an approach which uses all cases by accounting for familial correlation between the individuals genotypes, yielding significantly increased power.

Families containing cases typically also contain controls, however, in the presence of association, the haplotype frequencies of such controls will be biased towards case frequencies, diluting the control pool and reducing power to detect the association. Thus, I recommend using controls unrelated to the cases, which is a requirement of the method. The controls may, however, be related among themselves, for example related controls from CEPH families.

Related individuals do not each provide as much information as a single unrelated individual because some of their alleles are identical by descent. I weight each individual in such a way as to minimize the variance of the estimated haplotype frequencies. These weights may also be interpreted as the equivalent number of unrelated individuals for comparison of statistical power. For example, two full-siblings with no other genotyped relatives will each be given weight  $2/3$ , and are thus equivalent to  $2/3$  of an unrelated individual each, or 1.3 unrelated individuals in total.

I use the weights in an approximate likelihood and construct a likelihood ratio test statistic. An expectation-maximization (EM) algorithm is used to maximize the likelihood in the presence of missing genotypes and phase. The method can be applied to single markers as an allelic test or genotypic test, or to several adjacent markers as a haplotypic test, and may be applied to markers on either the X chromosome or an autosomal chromosome.

**A genotype-based association test for quantitative trait loci using family data.** *Y-J. Li, X.J. Qin, E.R. Martin.* Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

Several family-based tests of association have been proposed to test for association between marker alleles and a quantitative trait. These methods can detect linkage disequilibrium (LD) between the marker allele and the quantitative traits locus (QTL) using parents and offspring, or sibling data. Generally, these family-based tests are constructed by observing the correlation between a particular marker allele and the quantitative trait. They are inherently allele-based tests, and cannot be used to evaluate association between the trait and marker genotypes. In practice, it is of great interest to assess association at the genotypic level to understand how the combination of alleles in an individual may contribute to variation of the trait. Here, we extended the family-based allelic association method for quantitative traits proposed by Monks and Kaplan (2000) to test for association at the genotypic level. We conducted simulation studies to examine the power and type I error rates of our genotype-based association method. Simulations of nuclear families (parents and offspring) were conducted for a range of values for genetic parameters including the heritability of the trait, allele frequencies of both marker and QTL, degree of LD, and different genetic models. Family sizes from 1 child to 6 children were simulated. Our simulations demonstrate that the method has the correct type I error. Power of the novel genotype-based test is compared to the power of the allele-based method and shows that the relative power of the tests depends on the underlying genetic model. We are currently investigating more complicated family structures. This newly extended genotype association test will help us to dissect the influence of genotype on the quantitative trait of interest.

**Analysis of case-control studies of candidate genes in the presence of epistatic interactions.** *J. Millstein, W.J. Gauderman.* Dept Preventive Medicine, Division of Biostatistics, Univ Southern California, Los Angeles, CA.

For complex diseases, accounting for possible gene-gene interactions may prove to be an integral part of any thorough strategy designed to identify susceptibility genes among a group of candidate genes. However, the number of possible interactions can be large, and the resulting multiple testing problem cannot be ignored. We developed a search strategy to address this issue. Candidate genes are tested in stages according to the order of interaction, starting with the marginal effects of each gene. We perform likelihood ratio tests based on a logistic model. Each stage considers interactions of a given level and lower order terms. Each model is compared against a null model containing an intercept term and any lower order terms that were significant in reduced models. The number of gene sets to test for possible interactions is reduced in a preliminary step of the analysis that ranks gene sets according to a chi squared statistic based on the observed vs. expected number of subjects with variant alleles at all loci in each gene set. Only the upper ranked gene sets are selected for analysis of possible epistatic interactions. We compared strategies to find susceptibility genes, not identified by their marginal effects alone, using simulated case-control data sets. Each replicate consisted of 200 cases and 200 controls, with 20 independent diallelic genes, common variants, and a binary phenotype with 10 percent prevalence. The disease odds ratio was set to 2 for carriers of 1 variant allele at each of 3 designated loci. **Results:** Single degree-of-freedom tests of interaction with Bonferroni corrections and no gene set eliminations (an approach adopted by many) were limited in effectiveness for finding additional susceptibility genes. Our approach more than doubled the number of new genes found. Our approach was further improved by pre-screening gene sets to eliminate those least likely to influence disease risk. **Conclusions:** Accounting for possible interactions using multi degree-of-freedom tests and reducing the number of gene sets considered for interactions can significantly increase the number of susceptibility genes found in the presence of epistasis.

Program Nr: 2600 from 2003 ASHG Annual Meeting

**Case-control interval estimation of haplotypic and genotypic susceptibility.** *D.V. Zaykin<sup>1</sup>, Z. Meng<sup>1,2</sup>, S.K. Ghosh<sup>2</sup>.*  
1) Population Genetics, GlaxoSmithKline, Res Triang Prk, NC; 2) Department of Statistics, North Carolina State University, NC.

Genotypic frequencies can be directly estimated from retrospective samples of cases and controls. On the other hand, genetic susceptibility depends on the prevalence - a parameter that cannot be estimated from the observed data. We study interval estimation of susceptibility that incorporates uncertainty in prevalence values. We explore this problem from both classical and Bayesian perspective. Algebraic and numerical similarity between classical and Bayesian interval estimates allows an appealing interpretation of classical intervals as bounds for genetic susceptibility. We observe that both the asymptotic classical and Bayesian interval estimates have similar length and approximate well the exact Bayesian interval estimates. Extension from genotypic to haplotypic susceptibility intervals shows that deviations from Hardy-Weinberg equilibrium induced by the retrospective design need to be taken into account.

**Confounding from Cryptic Relatedness in Association Studies.** *B. Voight, J.K. Pritchard.* Human Genetics, Univ Chicago, Chicago, IL.

It is well known that case-control studies of association may be susceptible to false positives that result from population structure. However, it is less often recognized that cryptic relatedness among the cases is another potential source of confounding (Devlin and Roeder, 1999). The basic argument is that if a trait has a (partial) genetic basis, then individuals who share the trait are more likely to be related to one another, than are random controls, resulting in extra variance (and inappropriate significance values) of the usual chi-squared test statistic for association. Until now there has been little work to assess under what scenarios this type of confounding is likely to lead to inflated rates of false positives, in practice. In order to address this question, we have modeled the relationship between the inflation factor (IF) due to confounding,  $IF$ , and the relatedness within a case-control sample, by applying the work of Risch (1990a). We find that this inflation factor depends on the relative recurrence risk ratio,  $r$ , on the model for relatedness within the study population from which the cases and controls are drawn, and on the sample size of the study. Using a Wright-Fisher model, we simulated a randomly mating population segregating a single disease locus (parameterized by  $r$ ) and observed the relationship between  $r$  and the expected value for  $IF$ . Also, we examined the distribution of relatedness in a given study population size over time, to better understand what models of cryptic relatedness one expects to observe in a given population.

Program Nr: 2602 from 2003 ASHG Annual Meeting

**Statistical approaches for genetic linkage in affected sib-pairs in the presence of genomic imprinting.** *C.C. Wu, S. Shete, C.I. Amos.* Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.

Genomic imprinting which exists in several mammalian genes describes the phenomenon in which the degree to which a gene expresses itself depends on its parental origin and has been demonstrated in a few genetic disorders, such as those for Prader-Willi syndrome, Angelman syndrome and Huntington disease. Here we present complete mathematical formulae for probability distributions of alleles shared identical by descent by affected sib pairs incorporating an imprinting parameter. We propose the corresponding variance components and their relationship to the increase in relative risk ratios. We discuss and compare the power and sensitivity of the usual significance tests and the tests incorporating an imprinting parameter for genetic linkage when the imprinting effect is present or absent.

**Case-Control studies adjusted for age of disease onset.** *S. Ghosh.* Applied Statistics Unit, Indian Statistical Institute, Kolkata, INDIA.

Genetic case-control studies for detecting allelic association do not take into account age of disease onset, that is, they ignore the fact that some of the individuals considered as controls may in reality possess the disease mutation and manifest the disease in the future. This can lead to erroneous estimates of allele frequencies among controls and hence, the power of the test for association can be greatly reduced. The purpose of this study is to propose an age of onset adjusted test using concepts from survival analysis. We use the Cox Proportional Hazard Model (1972) in which the frequency of a particular marker allele possessed by an individual is used as a covariate. The test for association is based on the regression coefficient linked to this covariate. An advantage of this model is that alleles at a polymorphic marker can be considered simultaneously, thereby circumventing the problem of multiple tests. Monte-Carlo simulations are performed under different disease models to evaluate the increase in power due to the age-adjustment. We find that the relative increase in power is more under dominant models than under recessive models. Under reduced penetrances, the increase becomes less pronounced.

**A bootstrap approach to SNP marker selection.** *C.T. Ekstrøm<sup>1</sup>, E. Budtz-Jørgensen<sup>2</sup>*. 1) Dept Mathematics & Physics, Royal Vet & Agricultural Univ, Denmark; 2) Dept Biostatistics, Univ of Copenhagen, Denmark.

Recent advances in molecular biology have made it realistic to create dense maps of single nucleotide polymorphisms (SNPs) that are required for identification of susceptibility genes of complex traits. However, the large number of genotyped SNPs makes it difficult to identify the SNP markers that influence the traits of interest -- especially in the presence of epistasis. Once influential SNP markers are identified they can be examined more closely through functional studies.

We propose a bootstrap approach for covariate (marker) subset selection. This method identifies markers that are likely to influence the trait of interest and the selection probabilities provide estimates of the relative importance of each SNP marker. In addition, the bootstrap approach can be combined with both deterministic and stochastic model selection schemes to infer the most likely model for the SNP markers, and the proposed method is applicable to both quantitative and qualitative traits.

A simulation study is used to assess the sensitivity and specificity of the proposed method for different genetic models. The simulations show that the bootstrap method has high sensitivity and specificity when the ratio of genotyped SNP markers to individuals is low (5) or when the effect of the susceptibility genes is high. Also, the posterior probability of importance of each markers provides a useful way to select SNP markers for further studies.

**Empirical significance of association tests of related cases and controls in isolated populations with known genealogy.** *P. Forabosco*<sup>1,2</sup>, *M. Falchi*<sup>2</sup>, *C. Cappio Borlino*<sup>2</sup>. 1) IGP-CNR, Alghero, Italy; 2) SharDna lifesciences, Cagliari, Italy.

In small isolated populations large pedigrees comprising multiple affected individuals may be reconstructed when genealogical records are available. The resulting pedigrees can be very complex with many inbreeding loops since extant individuals are usually related through multiple lines of descent. Linkage analysis of such pedigrees can be problematic and selection of specific sub-pedigrees greatly influences both the power and the false positive rate of the linkage studies. A powerful approach in these populations is LD mapping through the ascertainment of related affected individuals, which would enrich for genetic forms of multifactorial diseases and where a large proportion of affected individuals are likely to share the same disease-predisposing gene inherited from common ancestors. Although there are evident advantages to using related cases, genotype correlations among them will exist and their biological relationship must be accounted for in the statistical analysis, to avoid an increase in the type I error rate of the statistical test. New analytic methods have been proposed to overcome this problem. We propose a simulation-based method suitable for isolated populations with known genealogy that allows the simultaneous use of all the available biologically related cases and controls. Random chromosomes are simulated in the whole pedigree connecting all affected and unaffected subjects in order to estimate the background association due to relatedness among the individuals. Empirical significance of the association test is then assessed by counting the number of times a statistical test for association equal or greater than the one observed is obtained in the replicated samples. We investigated the validity of the approach and we present the results obtained performing 10,000 simulations on a 2166-individual pedigree that comprises close and remote affected and control members in the last generations. We obtained significant evidence of association under different ascertainment schemes, marker densities, frequencies and locations of the gene.

**A single shared haplotype among DM2 (CCTG)<sub>n</sub> expansion mutation carriers from different European origins indicates ancestral founder effect.** *L. Bachinski*<sup>1</sup>, *European Neuromuscular Centre DM2/PROMM Consortium*<sup>2</sup>, *F.A. Wright*<sup>4</sup>, *R. Krahe*<sup>1,3,5</sup>. 1) Section of Cancer Genetics, University of Texas M. D. Anderson Cancer Center, Houston, TX; 2) Lt.Gen. van Heutszlaan 6, 3743 JN Baarn, The Netherlands; 3) Human Cancer Genetics Program, Department of Molecular Virology, Immunology and Medical Genetics, Comprehensive Cancer Center, Ohio State University, Columbus, OH; 4) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 5) Folkhlsan Institute of Genetics, University of Helsinki, Helsinki, Finland.

Myotonic dystrophy (DM), the most common form of muscular dystrophy in adults, is collectively recognized as a clinically and genetically heterogeneous group of neuromuscular disorders. The causative mutations at two loci (DM1 and DM2) have been identified and found to be expansions of (CTG)<sub>n</sub> or (CCTG)<sub>n</sub> microsatellite repeats in chromosomes 19q13.3 and 3q21.3, respectively. In DM1 a single founding haplotype has been recognized in patients of Eurasian descent. To study the history and evolution of the DM2 mutation, we constructed a comprehensive physical map of the DM2 region around ZNF9. We studied disease chromosomes in 17 kindreds of European origin from geographically separate populations. As controls we included 108 members of 11 families and 10 unrelated individuals from matching ethnic backgrounds. High-resolution haplotype analysis with 5 microsatellite and 22 single nucleotide polymorphism (SNP) markers around the DM2 mutation identified extensive linkage disequilibrium (LD) and a single shared haplotype of at least 132 kb among patients from the different populations. With the exception of the (CCTG)<sub>n</sub> expansion mutation, the DM2 haplotype is identical to the most common haplotype in normal individuals. This situation is reminiscent of that seen in DM1. Taken together, these data suggest a single founding mutation in DM2 patients of European origin. We estimate the age of the founding haplotype and the DM2 (CCTG)<sub>n</sub> expansion mutation at approximately 5,000-12,000 years.

**A new powerful non-parametric two-stage approach for testing multiple phenotypes in family-based association**

**studies.** *C. Lange*<sup>1</sup>, *H. Lyon*<sup>3</sup>, *D. DeMeo*<sup>2</sup>, *B. Raby*<sup>2</sup>, *E.K. Silverman*<sup>2</sup>, *S.T. Weiss*<sup>2</sup>. 1) Department of Biostatistics, Harvard Department of Biostatistics, School of Public Health, 655 Huntington Avenue, Boston, MA 02115, USA; 2) Harvard Medical School, Channing Laboratory, 181 Longwood Avenue, Boston, MA 02115, USA; 3) Division of Genetics, Children's Hospital, 300 Longwood Avenue, Boston, MA 02115, USA.

We introduce a new powerful non-parametric testing strategy for family-based association studies in which multiple quantitative traits are recorded and the phenotype with the strongest genetic component is not known prior to the analysis. In the first stage, using a population-based test based on the generalized estimating equation approach, we test all recorded phenotypes for association with the marker locus without biasing the nominal significance level of the later family-based test. In the second stage the phenotype with the smallest p-value is selected and tested by a family-based association test for association with the marker locus. This strategy is robust against population admixture and stratification and does not require any adjustment for multiple testing. We demonstrate the advantages of this testing strategy over standard methodology in a simulation study. The practical importance of our testing strategy is illustrated by application to the Childhood Asthma Management Program Asthma data sets.

**Strategies for positional cloning within regions of established linkage: case selection using IBD status on power of case-control studies.** *M.I. McCarthy*<sup>1</sup>, *J.C. Whittaker*<sup>2</sup>. 1) Wellcome Trust Ctr for Human Genetics, Oxford, UK; 2) Dept of Epidemiology and Public Health, Imperial College, London, UK.

Given a region of convincing linkage to a complex trait, identifying the aetiological variant(s) may require case-control analyses involving vast numbers of regional SNPs. The scale of such efforts demands careful sample selection to enhance power through amplifying case-control allele/haplotype frequency differences at susceptibility sites, particularly when, as with allelotyping, frequency determination is imprecise. The value of selecting cases from multiplex sibships is established: here we consider the merits of adding selection using IBD status at the linked region. For a wide range of susceptibility-locus models (varying in dominance, effect size, allele frequency), we calculated sample size ratios that compared the relative power, for case-control analyses, of case-ascertainment based exclusively on probands from ASPs sharing IBD2 in the region with that from unselected population cases (SSR1) or ASP probands regardless of IBD status (SSR2). Optionally, analyses allowed for pooling-specific error (an extra SD of 2% in frequency difference between pools). Predictably, IBD selection was most effective for recessive models with SSR1 reaching 0.04 and SSR2 0.19 (i.e. a five-fold reduction in sample size associated with IBD-selection), but benefits were substantial across all models. For multiplicative models, assuming individual typing, SSR1 ranged from 0.16-0.44, and SSR2 from 0.55-0.69; and for allelotyping, from 0.09-0.47 and 0.45-0.71. For example, given a control allele frequency of 10% and penetrance ratio of 1.5, asymptotic case frequencies are 14.3% (unselected cases), 17.2% (unselected probands) and 20% (IBD2-selected probands). Respective sample size estimates (90% power,  $\alpha=0.05$ ) are 1219, 478 and 266 for individual typing and 2098, 792, 428 for allelotyping. We conclude that, where linkage information is available and the number of samples that can be genotyped is limited, IBD-selection represents a valuable strategy for enhancing power. Also, IBD-selection provides compensation for some of the power lost through additional experimental error when allelotyping.

**Linkage disequilibrium mapping via cladistic analysis of SNP haplotypes.** *A. Morris<sup>1</sup>, C. Durrant<sup>1</sup>, K. Zondervan<sup>1</sup>, S. Hunt<sup>2</sup>, P. Deloukas<sup>2</sup>, L. Cardon<sup>1</sup>.* 1) Wellcome Trust Ctr Human Gen, Oxford, United Kingdom; 2) Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Disease-marker association studies are recognised as having the potential to map complex disease genes. The key to this approach to mapping is linkage disequilibrium (LD) between marker SNPs and disease mutations in the same gene, generated by the recent shared ancestry of chromosomes carrying the same mutation, represented as a gene tree. Recombination breaks down LD by trimming the founder haplotype shared by chromosomes carrying the same mutation. After many generations, the founder haplotype is preserved only in the region flanking the disease gene, where a mismatch of alleles can then occur as a result of marker mutation.

Here we present a novel approach to mapping via cladistic analysis of SNP haplotypes obtained from association studies. Large genomic regions are treated as sliding windows of SNPs, with independent analyses performed within each window. Pairwise differences between haplotypes are expressed in terms of weighted marker mismatches within the window of SNPs. This metric is consistent with haplotype diversity driven by marker mutation, and corresponds to blocks of LD preserved by minimal recombination within each window.

Ignoring disease phenotype, haplotype diversity is represented by a cladogram. In windows overlapping the disease gene, the cladogram is expected to approximate the gene tree underlying the shared ancestry of sampled chromosomes. Consequently we expect correlation between disease phenotypes and clusters in the cladogram, with excess sharing of the founder SNP haplotype(s) among the high risk clade(s) of chromosomes.

Our method is developed in a logistic regression framework that can be generalised to incorporate covariates. We demonstrate the power of this approach by simulation of high density SNP data based on empirical patterns of LD across a 10Mb region of chromosome 20, highlighting substantial gains over single locus tests to detect associations for a wide range of complex disease models.

**A powerful test of linkage in the presence of association for nuclear families with arbitrary patterns of missing information.** *J.P. Lewinger*<sup>1,2</sup>, *S.B. Bull*<sup>2,3</sup>. 1) Department of Statistics, University of Toronto, Toronto, Canada; 2) Samuel Lunenfeld Research Institute, Toronto, Canada; 3) Department of Public Health Sciences, University of Toronto, Toronto, Canada.

We introduce a new test of linkage for nuclear families that overcomes some of the limitations of widely used tests such as the TDT and SDT. This linkage test uses all available family information, including unaffected siblings and homozygous parents, and it can be applied to families with any pattern of missing data. Like the TDT, it is a distribution free test, making it immune to bias due to population stratification, ascertainment, or misspecification of the genetic model. With complete parental genotypes, the distribution free property is obtained by the within-family randomization scheme proposed by Rabinowitz and Laird (Hum Hered 2000) in which the phenotypes of all individuals are kept fixed, while the children's genotypes are randomized according to the Mendelian transmission probabilities. With missing parental genotypes, a constrained randomization of the children's genotypes is required. The test statistic is a conditional likelihood ratio that yields asymptotically optimal power under the standard two point linkage model. Through a large Monte Carlo study we show that the proposed test has near optimal power for finite sample sizes, outperforming the TDT in the wide range of scenarios explored. For example, under a dominant model with incomplete penetrance, disease prevalence of less than 1% and a high level of allelic association, the proposed test achieved close to 70% power with 150 families, while the TDT had less than 10% power. Although power is reduced when parental genotypes are missing, the proposed test is always more powerful than the SDT. By randomization of the parental alleles we also construct a distribution-free and asymptotically optimal test of allelic association in the presence of linkage. However, our Monte Carlo study shows that contrary to a view held by many, testing for association in the presence of linkage is intrinsically less powerful than testing for linkage in the presence of association.

Program Nr: 2611 from 2003 ASHG Annual Meeting

**Positional Cloning by Linkage Disequilibrium.** *N. Maniatis, A. Collins, J. Gibson, N.E. Morton.* Human Genetics Division, Southampton General Hospital, Southampton University, Southampton SO16 6YD,UK.

Efforts to map genes for common diseases using parametric linkage methods have had limited success. As a result, linkage disequilibrium (LD) mapping has been the subject of much theoretical work in the last few years. Recently, LD maps were developed (Maniatis et al., 2002) which are expressed in LD units (LDU), discriminate blocks of conserved LD and have additive distances and locations monotonic with physical (kb) and genetic (cM) maps. Currently, the focus of LD research is to localize determinants of disease in the DNA sequence (positional cloning). Here we present the methodology for positional cloning using LD based on two extensive bodies of data on which currently ideas of blocks are based. The main objective is to estimate the kb location of a causal SNP as accurately as possible, with its support interval. The operating characteristics of kb and LDU maps are determined by using composite likelihood (CL) expressing regressions and correlation of SNPs. In this study we have established type I and type II errors and CL support intervals for multiple single SNPs, using simulation only for the type I error. The methodology is validated by showing that the type I error results are acceptable by the Wald theorem under all maps, metrics, and contrasts of the Malecot models. The results also shows greater power when the kb map is replaced by a map in LDU and the superiority of the regression metric. The results provide a guide to efficient positional cloning by SNPs and a benchmark against which the power of positional cloning by alternatives based on haplotypes may be measured.

**Effects of demographic histories on behavior of the linkage disequilibrium.** *S. Mano*. Department of Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa, Japan.

For the linkage disequilibrium mapping, effects of the demographic histories of the populations to behavior of the linkage disequilibrium is critical issue. For quantitative considerations, simulation based study is one possibility, although it has its own limitations which come from sampling variability and unexpected constraints. If possible, analytical treatment is more preferable. However, in contrast to the treatment of allele frequencies, the diffusion equation method for the linkage disequilibrium is not discussed in detail, especially for the transit behavior in which we are interested, because of its complicated structure. Remarkably, Xiong and Guo solved the equation for the moments analytically by recasting the equation into simpler form with an constraint that the marker frequencies in controls to be fixed. The constraint holds for rare disease causing alleles, however, for common alleles, it might do not well. Additionally, the constraint prevent us to pursue the issue on fixation of marker alleles by the genetic drift. So, unconstrained behavior of the equation might have importance in its own right. However, because of the higher order terms of the moments in the equation, without imposing some constraints, the analytical solution seems to be unavailable. Thus, in the present study, we will discuss behavior of the linkage disequilibrium, fixation of marker alleles, and so forth with the unconstrained diffusion equation for the moments by employing a numerical solving method. We hope that the method would promote our understanding of the stochastic nature of the linkage disequilibrium.

**Properties of linkage disequilibria between multiallelic loci to detect disequilibrium induced by genetic admixture.** X. Sheng, K. Teshima, G. Sun, R. Deka, R. Chakraborty. Center for Genome Information, University of Cincinnati, Cincinnati, OH.

It is well known that genetic admixture produces linkage disequilibria (LD) among loci, the magnitude of which depends on allele frequency differences between populations contributing to the process of admixture. For loci at which there are multiple segregating alleles, several alternative measures of LD can be defined. We examined relative efficiencies of these alternative LD measures to detect admixture-induced linkage disequilibrium (AILD) immediately following an admixture process. With a computer simulation approach, we constructed admixed populations resembling African Americans and US Hispanics, by considering allele frequency data on 10 independently segregating short tandem repeat loci (D3S1358, vWA, FGA, D8S1179, D21S11, D18S51, D5S818, D13S317, D7S820, and THO1), using the Spanish, Nigerian, and Southwestern Native Americans as the parental populations contributing to the admixture. For two scenarios of bi-parental admixtures (European and African, and European and Native American), the locus-pairs with the largest and the smallest allele frequency differences in parental populations (designated by ) were used for the analysis. With varying degrees of admixture, we show that the magnitude of AILD is larger for loci with higher values, but AILD is not a symmetric function of the proportion of admixture. The weighted average of normalized LD values of all pairwise combination of alleles ( $D_c'$ ) between two loci has the largest absolute AILD, in comparison with eight other measures of LD. However, simulations of haplotypes in an admixed population reveal that gene/haplotype diversity based measures of LD are more efficient in detecting the deviation of AILD from zero, even though their magnitudes are smaller than AILD computed from  $D_c'$ . This is caused by a comparatively larger sampling variance of  $D_c'$ . With respect to AILD immediately following admixture, the nine alternative LD measures form five equivalent groups, consistent with observations made in the literature. (Research supported by US Public Health Service Research grants).

**Microsatellite-based linkage disequilibria in relation to recombination distance: Effects of population growth, and rate and pattern of mutation.** *K. Teshima, R. Chakraborty.* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Stepwise mutations at microsatellite loci, together with their high rate of mutation, raise questions as to whether microsatellite-based linkage disequilibria measures decay with recombination distance, a requirement for using microsatellites for linkage disequilibrium (LD) mapping of disease genes. Using a multi-locus coalescence-based simulation model, we investigated the relationship of the weighted mean of absolute normalized LD values between all pairs of alleles at two loci, and recombination distance, by taking into account: effects of population size and past demographic history, sample size, and mutation rate and mechanism. Specifically, we studied the power of detecting significant LD at different recombination distances in the presence of the above factors. We show that with forward-backward mutations and population growth, the expected LD continues to decay with recombination distance. However, the power of detecting significant LD is affected by population history, and patterns and rates of mutations. In populations of constant sizes, detection of significant LD is easier in smaller populations. Population growth makes detection of LD more difficult. The power increases with mutation rate in constant populations, but in growing populations, markers located further than 1cM exhibit significant LD less frequently with increasing mutation rate. For multi-step stepwise mutation models, under all demographic models, power of detecting significant LD increases with average size changes of alleles caused by individual mutations. The power increases with the sample size of the study; but the relative increase of power is not appreciable for markers located 3cM or more apart. Finally, under comparable conditions, microsatellite-based LDs are easier to detect than SNP-based LDs, but in populations with a recent history of growth, these two types of markers have nearly equal powers of detecting significant LD. These theoretical predictions are consistent with data from two isolated populations, published in the literature. (Research supported by US Public Health Service Research grants).

**Model-based methods are valuable tools to identify causal genetic variants and to detect gene-environment interactions in complex diseases.** *M. Rosenberg-Bourgin, V. Chaudru, F. Demenais.* INSERM, EMI 00-06, Evry, France.

Although model-free methods are the methods of choice to map disease genes to a chromosomal region, model-based methods may be of interest to identify causal genetic variants in that region, especially when there is linkage disequilibrium (LD), and to detect gene x environment (GxE) interactions. We conducted simulations to answer to the two questions: 1) how LD can influence the power to detect GxE; 2) how ignoring GxE can affect the detection of the causal variant. Affection status, environmental factor and marker data were generated in 165 nuclear families of varying sibship size. The liability to disease was generated under a model including a common gene (G) with a small effect, a polygenic component (P) and an environmental factor (E) interacting with the gene. The proportion of total variance due to each component was : 5% for G, 15% for the GxE component, 40% for P, the remaining part being due to random environment. The disease prevalence was set to 10%. The mode of inheritance of G was either dominant or recessive with allele frequency of 0.1 or 0.5. The environmental factor was assumed to be binary with 20% frequency in the population. We generated a tightly linked SNP with varying degree of LD with that gene: no LD ( $D=0$ ), CLD ( $D=1$ ), ILD ( $D=0.5$ ). These simulated data were analyzed using the combined segregation-linkage approach based on the regressive threshold model (REGRESS program). Power of the regressive threshold model to detect GxE was between 65-82% when  $D'=1$ , 25-28% when  $D'=0.5$ , 7-13% when  $D'=0$ , depending on the characteristics of the disease gene. This power was also found to vary when modifying the strength of GxE, the frequency of E and the nature of this factor (quantitative instead of binary). Alternatively, ignoring the presence of GxE in the analysis may affect the identification of the putative causal variant. Evidence for CLD was reduced by 60-70% when ignoring GxE as compared to taking it into account, this impact being greater for a dominant gene and when E was quantitative. Use of models that take into account both LD and GxE appear to be valuable tools to disentangle the mechanisms underlying complex diseases.

Program Nr: 2616 from 2003 ASHG Annual Meeting

**Does haplotype diversity predict power for positional cloning?** *W. Zhang, A. Collins, N.E. Morton.* Human Genetics Division, University of Southampton, Southampton, UK.

Many recent studies have established that haplotype diversity in a small region is not greatly diminished when the number of markers is reduced to a smaller set of "haplotype-tagging" markers that identify the most common haplotypes. These studies are motivated by the assumption that retention of diversity assures retention of power. Using three bodies of data and three proposed measures of diversity, we cannot confirm this assumption. When the causal marker is not included, power declines precipitously as the haplotype-tagging set diminishes. Common haplotypes have especially low power when the causal marker is uncommon. These results have important implications for construction of linkage disequilibrium maps and use of haplotypes in positional cloning.

**Gain of power for detecting haplotype-phenotype associations induced by the use of missing genotypic data.** *D.A. Tregouet<sup>1</sup>, S. Escolano<sup>2</sup>, J.L. Golmard<sup>2</sup>, L. Tiret<sup>1</sup>*. 1) INSERM U525, Paris, France; 2) INSERM U436, Paris, France.

It is now widely recognized that haplotypic information can be of potential interest for investigating the genetic component underlying complex diseases. In particular, several recent works have clearly illustrated that, in the context of candidate gene association analysis performed in unrelated individuals, haplotype-based analyses can better characterize the role of gene polymorphisms in the etiology of a disease than univariate analyses. One current limitation of such haplotype analyses is that they are generally performed in the subset of individuals whose genotypic information is available for all studied polymorphisms, leading to a likely loss of power and a possible bias. While most available statistical algorithms for haplotype-based association analysis can theoretically deal with missing genotypic data, no study has investigated the impact of using these data on the estimation of the parameters characterizing the haplotype-phenotype association. Therefore, a simulation study was carried out to clarify this point in the framework of a case-control analysis where haplotypes were defined by either 4 or 6 polymorphisms. Missing genotypic data were generated according to different patterns including completely at random, and genotypic- and haplotypic-dependent missing models. Preliminary analyses carried out by use of the Stochastic-EM algorithm showed that inferring missing genotypic data during the process of the haplotype-phenotype association analysis did not introduce any bias in the estimation of haplotype frequencies nor in that of haplotype-phenotype association parameters, whatever the pattern of missing data. However, results also showed that, while not increasing the risk of detecting false haplotype effects, the use of individuals with missing genotypic data can improve the power to detect haplotype-phenotype associations. According to the sample size and the percentage of missing data, this power could even be very close to that obtained if genotypes at all polymorphisms were available for all individuals.

**A new method for computing a multipoint Bayesian posterior probability of linkage.** *M.W. Logue<sup>1</sup>, V.J. Vieland<sup>1,2</sup>.*

1) Center for Statistical Genetics Research and Division of Statistical Genetics, University of Iowa, Iowa City, IA; 2) Department of Psychiatry, University of Iowa, Iowa City, IA.

Several recent attempts to extend the Bayesian posterior probability of linkage (*PPL*) statistic to multipoint likelihoods have depended on a moving window technique to calculate a probability of a close disease gene at each location along the marker map (Wang et al. 2001, Logue et al. IN PRESS). We show that this technique results in a multipoint PPL (*MPPL*) which may perform poorly in the fine-mapping stage of a linkage study. That is, a large MPPL at a true disease gene location could be artificially depressed by the addition of more markers near the peak. In addition, the moving window MPPL represents a smoothing of the likelihood curve that tends to broaden the peak, diffusing the precision of localization. We propose, as a solution, abandoning the moving window technique in favor of a new version of the MPPL that is directly calibrated to the magnitude of the 2-point PPL. We do this by assigning each point an estimate of the PPL we would have received from a fully informative marker based on a 2-point analysis at that location with an identical model-integrated likelihood ratio at  $\ln = 0$ . These PPLs are estimated by examining 2-point PPL simulations of linked data under a variety of generating conditions (dominant/recessive, heterogeneity/homogeneity) and data structures (affected sib-pairs and nuclear pedigrees). The result is a version of the MPPL which is on the same scale as the 2-point PPL and which is not subject to deflation simply as a function of increasing marker density.

**Optimum marker spacing for QTL detection.** *N.R. London, Y. Da.* Animal Science, University of Minnesota, St. Paul, MN.

The total cost of a gene mapping project can be divided into two major components: the cost of constructing the mapping population and the cost of genotyping. Dense marker spacing requires genotyping more markers and fewer individuals, whereas large marker spacing requires genotyping more individuals and fewer markers. A model is derived to find the marker spacing for a genome scan which minimizes the total cost of a mapping project for a given statistical power. First the number of markers required to cover  $x$  Morgans of a genome was calculated as  $m = x / [-\ln(1-2r)]$ , using the Haldane map function, with  $r$  = the maximum recombination frequency between the marker and gene or QTL. Letting  $N_i$  be the number of offspring required for a desired level of power the total number of individuals to be genotyped is  $T = N_i(1 + b/F)$ , where  $F$  = the average number of individuals per family, and  $b$  = the number of parents and grandparents genotyped per family. The genotyping cost per marker,  $C_G$ , and cost of phenotyping and DNA collection of each individual,  $C_I$ , were assumed known. The total cost of the mapping project can be estimated by:  $C = mC_G T + C_I T = N_i(1 + b/F)[-x C_G / \ln(1 - 2r) + C_I]$ , where  $N_i$  is the number of individuals and usually a function of recombination frequency and type-I and type-II errors. Estimates of optimal marker spacing were obtained by minimization of the above expression with respect to  $r$ . This expression offers an approach to study optimal marker spacing for any design and any level of type I and type II error, provided that the sample size necessary for a particular level of power can be analytically expressed. Optima were found iteratively and confirmed graphically. The optimum is independent of the type I and type II error level and genome length, but these parameters affect the value at the optimum. In all cases only a single optimum existed within the realistic parameter space (marker spacing between 0-50 cM). The value of the optimum represents an estimate of the total cost of an experiment. The optimum marker spacing for a genome scan ranges from 30cM when genotyping is expensive (\$1/marker genotype) and individuals are inexpensive (\$50), to 4cM when individuals are expensive (\$2000) and genotyping inexpensive (\$0.50).

**Testing for epistasis in non-parametric linkage analysis.** *T.A. Greenwood, N.J. Schork.* Dept Psychiatry, Univ California, San Diego, La Jolla, CA.

Testing for epistasis (the interaction between two or more genes to control a single phenotype) in non-parametric family-based linkage analysis is not trivial and full of statistical and interpretational challenges. We have devised a methodology for assessing epistasis in linkage which is intuitive, flexible, and could provide greater power than many other methods. The proposed approach works with a fundamental quantity, the fraction of alleles shared identical-by-descent (IBD) by pairs of relatives, or  $\pi$ -hat. This quantity is computed as a weighted average of three probabilities: the probability that a relative pair shares 0, 1, or 2 alleles IBD. These probabilities can be computed and provided to the user by non-parametric linkage analysis software packages such as ASPEX and MERLIN. These probabilities can be used to assess evidence for epistasis by considering them jointly at combinations of loci. One can use only sibling pairs for which one of these probabilities computed for those sibling pairs is greater than some number (e.g., 0.95). This would ensure that only sibling pairs for which there is some confidence in their assigned allele sharing measures are used in the analysis. To test epistasis, one can compute log-likelihoods of joint allele sharing probabilities using a simple multinomial model. To assess significance, randomization and simulation-based tests can be used. Ultimately, however, in order to test true epistasis one must determine if there is an excess of allele sharing at two loci relative to that based on the marginal probabilities of allele sharing at each of the two loci independently. Because thousands of combinations of loci can be tested in this manner, these analyses will be exploratory and hypothesis generating. We apply our method to genotypic data obtained from a large affected sibling pair study investigating the genetic basis of autism.

**MLIP: Parallel computation of LOD scores enabling full exploration of the trait-parameter space.** *M. Govil*<sup>1</sup>, *A.M. Segre*<sup>1,2</sup>, *M.W. Logue*<sup>1</sup>, *V.J. Vieland*<sup>1,3</sup>. 1) Division of Statistical Genetics & Center for Statistical Genetics Research, University of Iowa; 2) Department of Computer Science, University of Iowa; 3) Department of Psychiatry, University of Iowa.

There is compelling evidence for complex traits that parametric linkage methods are more powerful than model-free methods. Nevertheless, fixing the trait parameters at arbitrary (wrong) values can still reduce linkage signals. In theory, the LOD score can be maximized over trait parameters, or the trait model can be treated as nuisance parameters and integrated out of a statistic such as the posterior probability of linkage (PPL). However, either of these approaches entails computing a multi-dimensional likelihood surface, which in the case of crude grid-search may involve billions of grid points. In the absence of reliable methods for approximating these surfaces, the above approaches present a significant computational challenge. MLIP (Multiprocessor LIPed) calculates two-point LOD scores by pedigree and marker over a user-specified range of disease allele frequencies, penetrances and male and female recombination fractions. Based on a well-tested program, LIPED [Ott, 1974], it uses a cluster of CPUs and relies on the NICE distributed infrastructure [Segre et al., 2002], to provide interprocessor services and communication for parallel computing. It can handle arbitrary pedigrees, including loops and large pedigrees. To enhance robustness, automatic checkpointing and fault tolerance have been built in. Results from a preliminary version of the program, for 14 dual-processor machines, show a speedup of at least 4 to 7 times over the run time on a single processor. The structure of the pedigrees and number of marker alleles were some of the factors that affected how well a parallel run performed compared to the serial. Greater speedup was observed for datasets with larger pedigrees and/or markers with more alleles. We continue to work on optimizing performance, but the current version of the program can already be used to efficiently compute LODs over the trait space. It can also be used to benchmark computationally efficient approximations to the likelihood surface as these are developed.

**Score predictions in affected sib-pair analysis - decision-making based on incomplete information.** *M. Knutsson.*  
Clinical Science, AstraZeneca R&D Molndal, Molndal, Sweden.

Linkage analysis is always based on an imperfect data set, i.e. the inheritance pattern cannot be fully traced at all positions. Furthermore, the information may display a large variation over the genome. Hence, singling out chromosomal regions for further analysis, using linkage analysis, is not a trivial task. In order to compensate for incomplete information and to account for the varying degree of information in different regions, a prediction score is derived. Using this score as a tool for guidance, true gene harbouring regions displaying nothing but noise in the original analysis may be found and labelled as promising.

The prediction score is of the same form as the NPL (nonparametric linkage) score. However, instead of performing the IBD calculations conditional on the null hypothesis of no linkage (IBD vector  $[z_0, z_1, z_2] = [0.25, 0.5, 0.25]$ ), the calculations are conditional on an alternative hypothesis ( $z_2 = 0.25$ ), estimated from the existing data. Since the outcome of complete IBD information is predicted, the gain of typing additional markers is estimated. Hence, the prediction score can help the researcher to decide whether (or not) and in which regions additional markers should be typed.

Some properties of the new score are shown and its usefulness is illustrated in an example.

**Identification of gene locations from maximum likelihood ASP linkage analysis: Are there features of the lod score curve that distinguish regions with two loci?** *E.R. Hauser, M. Bass, E.R. Martin.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

In complex diseases, lod score curves can take a variety of different shapes, making the localization of disease genes under those curves very imprecise (Hauser et al. 1997, Roberts 1999). In previous simulation studies we explored the shape of the lod score curve when simulating a single disease locus for a complex trait (Bass et al. 2001). We found that, while individual lod score curves could be multimodal and support regions discontinuous, it was not the case that the gene would be located in regions of low lod score support. We have continued these simulations to explore the shape of lod score curves when two disease loci are in the same region. We used our simulation program SIMLA (available at <http://wwwchg.duke.edu/software/index.html>) that simulates pedigree data for models including both linkage and allelic association (Bass et al. 2002). To incorporate two disease loci in a region, we simulated a genetic heterogeneity model in which either locus can be a susceptibility locus in a given family. We varied the recurrence risk ratio to sibs ( $\zeta$ ) for each disease locus, the proportion of families segregating each locus, the distance between the two loci, the map density of markers, and the number of alleles for screen markers. We found that for map densities of about 10 cM, we could not reliably distinguish peaks for models with one locus from peaks for models with two loci. Furthermore, with two disease loci of similar  $\zeta$ , the maximum lod score was often midway between the two loci. In models with two loci the lod score could be deflated by as much as 35% from models with one disease locus. For maps of 5 cM or less, the lod score curves were more often multimodal suggesting the presence of two loci. We contrast the change in the lod score curve when there are two loci to the curve shape with one locus, as well as assess the effect of genotyping error on peak shape (Bass et al. 2001). These results have implications for follow-up in regions of linkage and fine-mapping using microsatellite markers.

**Parametric linkage analysis with automatic optimization of the disease model parameters.** *K. Strauch.* Institute for Medical Biometry, Informatics, and Epidemiology, University of Bonn, Bonn, Germany.

It is necessary to specify the parameters of the trait model prior to a LOD-score analysis. In many cases, the true disease model parameters are unknown; this holds especially for genetically complex traits. If the disease allele frequency and penetrances specified for the analysis are not sufficiently close to the true values, the power to detect linkage will be reduced, and the disease locus position will not be estimated correctly. For this reason, especially if complex traits are at issue, it can be helpful to maximize LOD scores with respect to the disease model parameters. This procedure is called 'MOD-score analysis' or 'maximizing the maximum LOD score' (MMLS). It is clearly an explorative method. Here, GENEHUNTER-MODSCORE is presented, which is an extension of the linkage-analysis program GENEHUNTER. It automatically maximizes the LOD score with respect to the disease allele frequency and all penetrances. Since the software is based on the Lander-Green algorithm which handles markers and trait locus separately, the inheritance-vector distribution (given all marker information) needs to be calculated only once and is stored. When evaluating the LOD score for many models (which needs to be done for MOD-score analysis), only the disease-locus likelihood must be recalculated. Since this part of the algorithm has been thoroughly optimized, it is now possible to perform a MOD-score analysis with many markers in reasonable time. The user can restrict the heterozygote penetrance(s) to lie in between the two homozygote penetrances, or turn the restriction off, e.g. to allow for overdominance. Imprinting models, where heterozygous individuals are distinguished by the parent who transmitted the mutation, and two different heterozygote penetrances are specified accordingly, can be taken into account as well. Practically, GENEHUNTER-MODSCORE first calculates the MOD score for a given set of pre-defined models. This reduces the probability to fall into a local maximum. Then, the model which yields the maximum LOD score is used as a starting point for fine maximization, which is carried out until the MOD score has converged to its maximum.

Program Nr: 2625 from 2003 ASHG Annual Meeting

**Estimation of allele frequencies with preferential amplification in a DNA-pooling study.** *H.C. Yang, C.L. Chen, C.S.J. Fann.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

DNA-pooling association mapping is a cost-saving method for localizing susceptible disease genes relative to the individual genotyping study. However, the prerequisite of a precise mapping in a DNA-pooling study is the accurate estimation of allele frequency. The sources of variation affecting the estimation of allele frequency in a DNA-pooling study have been discussed broadly in literatures (Sham et al., 2002; Jawaid et al., 2002; Barratt et al., 2002). We focus on the different amplification abilities of various nucleotides in this project. Hoogendoorn et al. (1999) proposed a simple adjustment to account for the unequal ability of amplification. The merit of Hoogendoorn's method is simple in concept and easy to employ. However, few theoretical results have been discussed about this method. We find that the method suffers from the estimation bias in some cases. The bias becomes intolerable especially for the small sample size. In this project, we provide the alternative estimation procedures to reduce the estimation bias. Some theoretical results can be borrowed with some modifications from the well-developed topic, ratio-type estimation. The suggested estimators are either unbiased or have smaller biases compared to Hoogendoorn's adjustment. The corresponding variances are of order  $1/n$ . Some simulation studies are conducted to assess the performance of different estimators. The results show the proposed methods produce smaller bias as expected. The improvement is helpful to obtain the precise estimation of allele frequency, in turn the precise disease-genes mapping in a DNA-pooling study.

**Evaluating performance of the methods incorporating covariates into the affected sib pair (ASP) linkage analysis.** *H.-J. Tsai*<sup>1</sup>, *D.E. Weeks*<sup>1, 2</sup>. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA.

In order to increase the power to detect the signals in the linkage analysis of complex traits, genetic heterogeneity has to be taken into account. During the past few years, several statistical methods have been proposed to deal with this issue by incorporating covariate information into the affected sib pair (ASP) analysis. However, it is still not clear the performance of these methods under different gene-environment (G x E) interactions. The methods evaluated in this study are: 1. the mixture model (Devlin et al. 2002); 2. the conditional-logistic model (Olson 1999); 3. the regression model with covariates and constraints (Greenwood and Bull 1999); 4. the maximum likelihood binomial method with accounting for covariates (Alcaïs and Abel 2001); 5. ordered subset analysis (Hauser et al. 1998); and 6. the logistic regression approach (Saccibè et al. 2001). We have written simulation programs to generate genome-wide data under various G x E models and disease models. The heterozygosity of all markers is 0.8. The disease allele frequencies are varied from 0.01 to 0.4 under different disease models. Each analyzed data set contains 100 pedigrees with at least 2 affected sibs and variable sibship size ranging from 2 to 5. We have generated 16,000 null replicates to estimate empirical significance thresholds. We then evaluated the power of the methods by generating 500 replicates under 8 disease models, each with the same G x E interaction. Power to detect the signals among the methods is varied under different disease models. We estimate the power of the methods under several G x E models by including the covariate with or without G x E interaction into the analysis.

**Incorporating uncertain phase into estimation and testing of haplotype associations.** *K.M. Burkett<sup>1</sup>, B. McNeney<sup>2</sup>, J. Graham<sup>2</sup>*. 1) McDonald Research Laboratories/The iCAPTURE Centre, St. Paul's Hospital - University of British Columbia, Vancouver, BC, Canada; 2) Department of Statistics and Actuarial Science, Simon Fraser University, Burnaby, BC, Canada.

Haplotypes of single-nucleotide polymorphisms (SNPs) may affect variation in complex traits by influencing regulation or function of susceptibility genes. Alternately, blocks of SNPs may be in linkage disequilibrium with unobserved susceptibility polymorphisms. In association studies of complex traits, regression models may be used to adjust haplotype associations for the effects of nongenetic cofactors or attributes. However, resolution of haplotype phase can be problematic because data are collected on unrelated subjects. Uncertain haplotypes can be inferred on the basis of data from single SNPs. However, subsequent analyses of disease associations must account for the uncertainty in haplotype assignment in order to avoid potential errors in interpretation. We describe a likelihood approach for estimating haplotype associations and quantifying the precision of these estimates in the presence of uncertain haplotype phase. A generalized linear model of disease penetrance accommodates quantitative and dichotomous disease phenotypes, non-genetic covariates and gene-environment interactions. An EM algorithm is implemented to find the maximum likelihood estimates of associations and haplotype frequencies. The resulting estimates and standard errors reflect uncertain haplotype phase. The method is applied to real and simulated datasets comprised of information on SNPs and non-genetic covariates.

**Multivariate quantitative trait locus regression mapping.** *S. Buyske*. Statistics Dept, Hill Ctr, Rutgers Univ, Piscataway, NJ.

Not all traits can be reduced to a univariate binary or quantitative trait. A number of conditions, including syndrome X, vascular disease, and developmental dyslexia, may best be described via several correlated quantitative traits, and so require a multivariate analysis. The three predominant methods for multivariate quantitative traits are reduction to a univariate trait (generally using principal components), multivariate extensions to the new Haseman-Elston method, and multivariate variance components.

We report on a new method of multivariate quantitative trait locus mapping that extends the regression method used in Merlin (Sham et al, 2002). Merlin's regression program uses its fast gene-flow engine to regress IBD status onto univariate trait sums and difference. This regression can be extended to a multivariate trait through a modification of Merlin. The modification combines estimators from each trait individually using the individual estimators' covariance structure. We were able to use the same simulation data as in Gorlova et al (2002), which looked at the power of extension to the new Haseman-Elston method and of multivariate variance components. Simulations show that multivariate trait regression using Merlin has superior power to these other methods. Nonetheless in simulations the type I error rate approaches the asymptotic rate only in large samples, so that use of empirical p-values is recommended.

**A nonparametric genetic association test for age-at-onset data.** *A.S. Allen<sup>1</sup>, E.R. Martin<sup>2</sup>, Y-J. Li<sup>2</sup>*. 1) Biostatistics & Bioinformatics, Duke University, Durham, NC; 2) Center for Human Genetics, Duke University, Durham, NC.

The analysis of age-at-onset (AAO) is an important tool in identifying genetic variants involve in complex diseases. Several linkage and association studies have used AAO as a quantitative trait in gene mapping with great success (Li et al. 2002). However, such analyses are complicated by the fact that age-at-onset data are subject to censoring, making standard quantitative trait methodologies suboptimal. Though methods that incorporate censoring are available, their primary focus is on modeling the age-at-onset distribution of the disease and thus make difficult-to-verify parametric or semiparametric assumptions on the process that generated the data (Hongzhe Li et. al, 1998; S. Horvath et. al, 2001). Here we propose a nonparametric framework for genetic association testing of age-at-disease onset data that explicitly accounts for censoring. This approach can be used to complement previously proposed modeling strategies by providing a way to confirm model testing results without being subject to difficult-to-verify assumptions. We formulate AAO association tests in unrelated and triad-based samples and evaluate our approach in a simulation study. We conclude with a discussion of extensions of the method to more complicated pedigree structures.

**Family-based tests of association for X-linked markers.** *R. Morris*<sup>1</sup>, *E. Martin*<sup>2</sup>, *N. Kaplan*<sup>1</sup>. 1) Biostatistics Branch, NIEHS, Res Triangle Pa, NC; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC.

We propose two new family-based tests of association between an X-linked marker allele and a disease susceptibility allele that utilize families with incomplete parental-marker information. The first is a likelihood ratio test (LRT), which can be used if the sample has only families with one affected sib. If the sample contains families with more than one affected sib, then the LRT cannot be readily implemented and, therefore, we propose a TDT-like test. For both tests the E-M algorithm is used to infer missing parental data. Both tests can be parameterized to be insensitive to population stratification. Simulation results demonstrate validity and illustrate power calculations. Both tests can also be used to test for linkage in the presence of association, and therefore are competitors to the X-linked RC-TDT proposed by Horvath et al. (2000). Some results are presented comparing the power of the three tests.

**Reducing the sample size for genomewide association studies by combining evidence from multiple disease loci.**  
*B.P.C. Koeleman<sup>1</sup>, F. Dudbridge<sup>2</sup>.* 1) Department of Medical Genetics, UMCU, Utrecht, NL; 2) MRC Human Genome Mapping Project Resource Centre, Cambridge, UK.

Linkage analysis has been very successful in identifying mendelian disease genes, but has turned out to be of limited use for low risk, complex disease genes. Therefore, attention has focussed on genomewide association studies for identification of the multiple genes that are thought to underlie common disease. These studies require individual testing of a large number of markers (~100,000 or more). Consequently, the level of significance needs to be very strict to prevent inflation of type I error due to multiple testing, and large sample sizes are needed to attain sufficient power. Instead of testing each marker separately, or all simultaneously, it is more efficient to consider the combined evidence from subsets of markers. The Rank Truncated Product (RTP) combines the evidence from the  $K$  most significant markers ( $K \sim$  hypothesized number of disease loci), and has been shown to be more powerful for detecting association in complex disease models than existing methods. Here we show for different study aims and genetic models that the sample size needed to reach significance is markedly reduced for RTP compared to family-wise error or false discovery rate controlling procedures. When the aim of a study is to detect at least one disease locus with 80% power, an average of 12% (21% max) reduction in sample size is possible with RTP. Importantly, when the aim of a study is to detect at least five disease loci an average of 38% (46% max) reduction in sample size is reached. Reduction in sample size is modest when only two disease loci underlie disease, but increases significantly when more than two loci are involved in susceptibility for disease. RTP detects a set of markers of predefined size, of which at least one is associated. We show that the set of loci detected by RTP contains more true loci than competing methods, and these can be given priority according to order of individual significance in a follow-up study of much smaller size. Using this strategy with RTP, the initial sample sizes for genomewide association studies can be substantially reduced.

**Two-stage designs for fine-mapping of complex traits - a word of caution.** *J. Majewski, J. Ott.* Lab Statistical Genetics, Rockefeller Univ, New York, NY.

Non-parametric linkage studies of complex diseases generally produce broad LOD score peaks, which may be several cM away from the actual disease gene. It is of interest to refine the candidate regions at a minimum genotyping cost. For large sample sizes, fine-mapping efforts can be a considerable strain on a researchers resources. Here, we explore a two-stage design, where a collection of families is used in a genome-scan to identify candidate loci. Significant peaks are then fine-mapped with a dense marker map, but only using the families that individually show positive allele sharing within a chosen interval around the peak. Although the height of the resulting peak is not statistically meaningful, it can be expected that its location will be closer to the true locus, at a cost that is lower than that of fine-mapping the entire sample. We carry out simulations using sib-pairs and small nuclear families to determine the validity of such sub-sampling schemes. However, we find that under most conditions, selecting families according to the positive LOD scores at or near a locus of interest does not result in a refinement of the locus. In view of the simulation results, we caution against employing such two-stage designs and recommend fine-mapping the entire original sample as the most effective strategy.

**Power Study of a Novel Approach to Identifying a Minimum Candidate Gene Region in Complex Diseases.** *T.A. Thornton*<sup>1,2</sup>, *S.J. Kenealy*<sup>2,3</sup>, *J.L. Haines*<sup>2,3</sup>. 1) Program in Human Genetics, Vanderbilt Univ Med Ctr, Nashville, TN; 2) Neuroscience Grad Program, Dept of Biomedical Informatics, NLM Informatics Training Grant, Vanderbilt Univ Med Ctr; 3) Dept of Molecular Physiology and Biophysics, Vanderbilt Univ Med Ctr.

Genetic heterogeneity is a major confounding factor in the statistical analysis of complex human diseases. In linkage analysis, locus heterogeneity reduces the power to detect a true signal coming from a subset of families. A novel approach to this challenge, consensus haplotyping, was proposed by Hutcheson et al. (*Am J Med Gen* 117B: 90-96, 2003) in which locational mapping of candidate genes was combined with recombination breakpoint analysis. We have now performed simulation studies to evaluate the power of this approach.

We used the Genometric Analysis Simulation Program to simulate nuclear families with three children under a recessive disease model with 50% locus heterogeneity. A sample of 100 families was selected in which both parents were unaffected and at least two children were affected. Ten consecutive bi-allelic markers were simulated ten cM apart along with one disease locus, which was equidistant between two markers. A second disease locus was simulated to have no linkage to the first disease locus or any other marker.

We performed linkage analysis on the ten markers, identified the marker with the highest lod score, and selected those families that showed linkage to any marker within 20cM of this marker. We then performed haplotype analysis and identified which loci were shared on both haplotypes among the affected children. Our analyses found that this approach had greater than 80% power to correctly localize the disease gene within a 40cM region and over 60% power to localize the gene within a 30cM region. The simulation is being expanded to use more finely mapped markers, multiple genetic models, and various sample sizes. These results suggest that consensus haplotyping is a powerful approach toward localizing a complex disease gene given locus heterogeneity.

**Improved inference of missing parental data in a log-linear test of association by inclusion of unaffected siblings.**

*E. Rumpersaud, M.C. Speer, E.R. Martin.* Center for Human Genetics, Duke University, Durham, NC.

Candidate gene studies remain a powerful approach for studying complex diseases, but rely heavily on tests of genetic association. Weinberg et al. (1998) have developed a log-linear model for family-based association studies as a flexible likelihood-based alternative to the transmission/disequilibrium test (TDT). Like the TDT, the method uses genotype data from family triads (affected offspring and both parents), but has the advantage that the model can be generalized easily to different causal scenarios since the likelihood framework allows for inclusion of parameters to test for imprinting, maternal effects, and environmental interactions. In the situation where parental genotypes are missing, the expectation maximization (EM) algorithm is used to allow incomplete triads to contribute to the likelihood ratio test. We present an extension to this model, which incorporates additional information from the genotypes of unaffected siblings to improve assignment of incompletely typed families to theoretical mating type categories, thereby improving inference of missing parental data. We use computer simulations to evaluate type I error and power of the extended model. These simulations demonstrate the validity of the extended log-linear model under the null hypothesis of no association. We compare the power of the extended model to that of the original model, under varying levels of missing data. We examine the impact of violations of the low penetrance assumption, which is necessary for inclusion of the unaffected sibling into the model. We conclude that the proposed log-linear model will be an important tool for future candidate gene studies, particularly in the area of birth defects, where unaffected siblings often can be ascertained and where epigenetic factors such as imprinting may play a role in disease etiology.

**Genetic sampling and chiasm interference affect QTL mapping accuracy.** *J. Xu, Y. Da.* Animal Science, University of Minnesota, St.Paul, MN.

Current statistical analysis for mapping linked quantitative trait loci (QTL) relies on the assumption that chiasma interference is absent. With this assumption, a conditional analysis may be used to separate linked QTLs such that the effect of the target QTL is independent of those of linked QTLs, leading to more accurate estimation of the QTL effect and location. This type of conditional analysis is impossible when chiasma interference is present using current methods. We conducted a simulation study to evaluate the effect of genetic sampling and interference on QTL mapping accuracy. A theoretical population of over 10 million individuals were generated for seven loci without chiasma interference. The number of 10 million was chosen such that the true parameters assumed for the data simulation can be obtained reversely from the data. For computational efficiency, a sub-population of 20,000 individuals were randomly selected to represent the entire population. From this sub-population, 500 individuals were randomly selected for each of the 50 replicates in the simulation. For each replicate, pairwise recombination frequencies and interference coefficients were estimated for all seven loci, and QTL analysis was conducted for three cases: single QTL, two linked QTLs and three linked QTLs. The observed interference coefficients followed a normal distribution, and many observed interference coefficients were significantly different from zero based on t-tests (pvalue is less than 0.0001), showing that genetic sampling could result in significant observed chiasma interference even though chiasma interference in fact is absent. Ignoring chiasma interference in estimating QTL locations and effects resulted in large biases from the true parameters. When estimates of interference coefficients are included in estimating QTL locations and effects, the biases were reduced by more than half. The results show that considering chiasma interference in QTL analysis improves mapping accuracy, irrespective of whether the observed interference was true or purely due to genetic sampling, and would call for the development of QTL analysis taking into account chiasma interference.

**Evaluation of a BRCA carrier probability model with a random component for extended families. C.H.**

*Barcenas<sup>1</sup>, J. Zong<sup>2</sup>, G.M. Hosain<sup>1</sup>, L.C. Strong<sup>2</sup>, G.B. Mills<sup>3</sup>, C.I. Amos<sup>1</sup>.* 1) Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, TX; 2) Department of Clinical Cancer Genetics, The University of Texas MD Anderson Cancer Center, Houston, TX; 3) Department of Molecular Therapeutics, The University of Texas MD Anderson Cancer Center, Houston, TX.

The objectives of this study were to evaluate the accuracy and reliability of a BRCA mutation-predicting model (Antoniou et al, 2002) that allows for a residual polygene/modifier locus effect, to compare its performance with other models, and to study the impact that extended family information had upon risk estimation. We compared the performance in the prediction of BRCA1 and BRCA2 mutation status with the BRCAPRO (Duke Univ.), Myriad (I and II) and Couch (Univ. Pennsylvania) models. We generated and compared areas under receiver operator characteristics (ROC) curves for the different models from 121 pedigrees in which a family member had been previously tested for BRCA mutation by direct sequencing. Families were selected from a high-risk population from the Cancer Genetics clinics of The University of Texas MD Anderson Cancer Center. The tested individuals included 62 (51%) with breast cancer, 8 (6.6%) with ovarian cancer, and 8 males. Thirty-two (26%) families were of Ashkenazi descent, and 50% of the families had 3 or more members with breast and/or ovarian cancer. Twenty-three (19%) individuals had tested positive for BRCA1 mutation only, 15 (12%) for BRCA2 mutation only and 2 persons tested positive for both BRCA1 and BRCA2 mutations. All the models underpredicted the prevalence of BRCA1 and BRCA2 mutations in this population. The Antoniou model performed better than other models in the non-Ashkenazi families but was inferior to BRCAPRO in Ashkenazim. The extended family model performed slightly better than the model limited to second-degree family members. All models predicted BRCA1 better in the non-Ashkenazi families. The penetrance and allele frequency for BRCA1 and BRCA2 used in the Antoniou model may be low for the Ashkenazi families and may need readjustment according to clinical experience.

**Power Loss for Linkage Due to Dichotomization of Polychotomous Traits.** *J. Corbett<sup>1</sup>, C.C. Gu<sup>1</sup>, J.P. Rice<sup>1,2</sup>, T. Reich<sup>2</sup>, M.A. Province<sup>1</sup>, D.C. Rao<sup>1,2,3</sup>.* 1) Division of Biostatistics; 2) Department of Psychiatry; 3) Department of Genetics, Washington University, St. Louis, Missouri.

Some traits, while naturally polychotomous, are routinely dichotomized for genetic analysis. Dichotomization, intuitively, leads to a loss of power to detect linkage, as some phenotypic variability is discarded. To examine the magnitude of this power loss, we performed a simulation study where a trichotomous trait was simulated in a sample of 1,000 sib-pairs under various models of heritability. The study was replicated 1,000 times. Linkage analysis using a variance components method implemented in Mx was then performed on the trichotomous trait and compared with that on a dichotomized version of the trait. A comparison of the power and false positive rates of the analyses shows that power to detect linkage was increased by up to 22 percentage points simply by examining the trait as a trichotomy instead of a dichotomy. Under all models examined, the trichotomous analysis outperformed the dichotomous version. Comparable levels of false positive rates under both methods confirm that this power gain comes solely from the information in the trichotomous trait lost upon dichotomization. Thus, dichotomizing a polychotomous trait can lead to crippling power loss, especially in the case of many QTLs of small effect.

**An Integrated Approach to the Meta-Analysis of Genetic Association Studies using Mendelian Randomisation.** C. Minelli, J.R. Thompson, M.D. Tobin, K.R. Abrams, P.R. Burton. Department of Health Sciences, University of Leicester, Leicester, UK.

**BACKGROUND:**The use of genetic epidemiology to evaluate risk factors has been advocated to avoid confounding and reverse causation typical of classical epidemiology. In genetic studies a natural randomisation process occurs at conception in determining a subjects genotype (Mendelian randomisation), and unconfounded estimates of the phenotype-disease association can be obtained by combining information from gene-disease and gene-phenotype studies. **META-ANALYTICAL APPROACH:**When synthesising the evidence available, studies evaluating either gene-phenotype, gene-disease or both associations are encountered. If all the evidence regarding gene-phenotype and gene-disease associations is obtained from unrelated sources then separate meta-analyses will yield estimates of the pooled effects that can be combined to estimate the phenotype-disease relationship. Otherwise the correlation arising from studies that measure both associations must be considered. These studies allow evaluation of the interrelationships between gene, phenotype and disease and assessment of the assumptions on which Mendelian randomisation is based, in particular whether the genotype influences the disease risk only through the modification of the specific phenotype. A simple graphical approach is presented, using the example of methylene tetrahydrofolate reductase (MTHFR) gene, homocysteine and coronary heart disease for illustration. **CONCLUSIONS:**The uncertainty in the derived estimate of the phenotype-disease association is large, as it depends on the uncertainty in both estimates of genotype-phenotype and genotype-disease associations. An integrated meta-analytical approach to synthesise gene-disease and gene-phenotype evidence may not only increase precision, but also provide crucial information on the appropriateness of Mendelian randomisation. In fact, although Mendelian randomisation offers a powerful way of deriving unconfounded estimates of the phenotype-disease association, it is based on assumptions about the pathway from gene to disease, and serious biases may arise if these assumptions are not met.

**Quantifying the relationship between gene expressions and clinical traits in general pedigrees.** *Y. Lu<sup>1</sup>, P.Y. Liu<sup>1</sup>, H.W. Deng<sup>1,2,3</sup>*. 1) Osteoporosis Research Center, Creighton University, Omaha, NE; 2) Department of Biomedical Science, Creighton University, Omaha, NE; 3) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, ChangSha, Hunan, P. R. China.

Standard methods of quantitative genetic analysis can be applied to microarray data. Treating messenger RNA transcript abundances as quantitative traits and examining their relationship with clinical traits have been pursued using analysis approach of quantitative genetics. Recent advances in microarray technology have increased interests in testing association between clinical traits and gene-expression levels by sampling subjects from multiplex pedigrees. However, use of these related subjects without accounting for their biological relationship can inflate type I error rate of statistical tests. We propose a general linear model approach for family-based microarray data analyses. Our method can accommodate covariance between relatives in the unmeasured genetic effects and model covariates of clinical importance in the mean structure of the model. A permutation test is described for situations in which families of small size were sampled. The efficacy and validity of our methods are demonstrated by using simulated data. We find that the proposed statistic has correct type I error rate, and higher power than Pearsons correlation statistic and family expression association test (FEXAT). We also develop a corresponding software for real data analyses.

**Association studies in stratified populations: correcting using genomic controls.** *D. Shmulewitz, D.A. Greenberg.*  
Div Stat Genetics, Dept Psych, Columbia Univ, and NYSPI, New York, NY.

Case-control association studies in stratified populations can result in spurious disease-marker associations if disease prevalence and marker frequencies differ in the subpopulations. Drawing subjects from different subpopulations shifts the standard  $\chi^2$  distribution rightward when testing for disease-marker associations in cases and controls, increasing the mean  $\chi^2$  and the p-value above expected. Reich and Goldstein suggested correcting the  $\chi^2$  distribution with the mean- $\chi^2$  value from unlinked markers. Devlin and Roeder suggested using the median- $\chi^2/0.456$ . We tested how well these correction factors corrected the stratification bias. We simulated two subpopulations with different disease and SNP allele frequencies (100 SNPs) and without any marker-disease association. We generated the subpopulations with a disease ratio (prevalence pop 1/prevalence pop 2) range of 0-1, mixed them, and used 45 datasets of 100 cases/controls. For each mixed population, we calculated the  $\chi^2$  statistic for disease association with each marker in all datasets. When a population showed evidence of stratification (mean  $\chi^2 > 1$  and p-value  $> 0.05$  over all datasets), we applied the two correction procedures, to test how effectively dividing by the mean or median/0.456 eliminated excess false associations. Without correction, up to 63% of the markers yielded significant associations. Using the mean  $\chi^2$  from 100 markers to correct the  $\chi^2$  values, false positives were reduced to 4.03%-4.91%, near the nominal 5% level. The median/0.456 was more conservative, with 4% or fewer significant associations. Using 60 markers, correcting by the mean resulted in 3.98%-5.56% significant associations, while the median/0.456 was anti-conservative ( $> 5\%$ ) for smaller disease ratios (0.02-0.4), but similar to the mean at ratios  $> 0.4$ . These data suggest that correcting by the mean is superior to the median/0.456 because the behavior of the mean does not change with different disease ratios. Case-control association studies in stratified populations can eliminate excess false positives by correcting the  $\chi^2$  distribution with the mean  $\chi^2$  from unlinked markers.

**Controlling false discoveries and minimizing genotyping burden in the search for disease mutations.** *E. Van den Oord.* Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA.

Geneticists are increasingly faced with the challenge to find a limited number of disease mutations from a very large set of possible candidates or markers. This brings along the risk of false discoveries and makes it expensive to systematically scan for disease mutations. We propose a method for designing gene-finding studies that allows researchers to control false discoveries and set true discoveries at desired proportions, while minimizing the genotyping burden. The approach is illustrated for a whole-genome LD scan assuming 500,000 SNPs. Results show that a design where earlier stages are characterized by very high false discovery rates (FDR) followed by an abrupt change to the required FDR in the final stage can result in a 50-75% reduction in genotyping. Neither sample size nor controlling the false discoveries will present major problems in whole-genome scans. Mainly depended on the proportion of true effect one wants to find, the amount of genotyping will be very large even is the study is completely designed to minimize the genotyping. The method is not restricted to a concrete study and can for instance be applied to the kind of multiple testing that occurs when a geneticist or the research community as a whole may have typed many candidate genes before a significant result is obtained. The implications of the method for general models of gene discovery are also discussed.

**On the probability that a novel variant is a disease-causing mutation.** *A. Mitchell, A. Chakravarti, D. Cutler.*  
Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

When a novel single nucleotide polymorphism (SNP) is identified in a patient and not found in a group of healthy controls, the variant is considered to be a candidate for the disease-causing mutation in that patient. Until now, no sampling theory existed for computing the probability that the novel SNP is a harmless variant. We have developed a population genetics based method for calculating a p-value for a mutation detection effort. The p-value depends upon the size of the control group, the length of sequence examined and the putative mode of inheritance. Our method can be applied to a heterozygous patient, a homozygous patient, with or without inbreeding, or to a patient who is a compound heterozygote.

For instance, we show that for complete resequencing of a 10kb candidate gene, the probability of finding a neutral variant in the patient that is not observed in 100 control chromosomes is 0.14 - 0.15. Our interpretation of these results is that a significant fraction of reported disease-causing mutations are likely to be low-frequency neutral polymorphisms. Our findings are consistent with current sequence-based polymorphism surveys. In a large resequencing study performed by our group, 39% of SNPs were seen only once in a sample of 80 chromosomes, indicating that a substantial proportion of neutral variants are likely to be rare.

**Distribution of the Coalescence Time of a Pair of Alleles for Stochastic Population Trajectories: Comparison of Fisher-Wright and O'Connell Models.** *K.A. Cyran*<sup>1, 2</sup>, *M. Kimmel*<sup>1</sup>. 1) Dept. Statistics, Rice University, Houston, TX; 2) Dept. Computer Science, Silesian Univ. of Technology, Gliwice, Poland.

The estimated values of some important parameters in population genetics (for example of the composite parameter =  $4N$ ) strongly depend on the population trajectory. The commonly used notion of effective population size, increases applicability of analytically obtained formulae to populations with changing number of members, however this approach does not introduce the stochastic elements, which play important role in small populations. On the other hand, the effective population sizes are often smaller than the observed counterparts (one of the major reasons is the bottleneck effect). Therefore, if the population has passed, in its history, through (even relatively short) period of small size, then the models describing the coalescence time in terms of deterministic effective population size, can lead to false conclusions. Stochasticity should be incorporated to obtain more realistic results. The paper discusses two ways of introducing the stochastic elements into calculation of two-allele coalescence time distribution. The first one uses classical Fisher-Wright model, where the change of the size of the population is proposed to follow the Galton-Watson branching process. The second, goes one step further, and not only uses a branching process for simulation of the population growth, but also it assumes that genealogy of the population can be described in the terms of branching processes. This latter approach has been proposed by O'Connell who then applied it to the estimation of the Mitochondrial Eve epoch. The results he obtained are biased towards long coalescence times compared to other estimations. This can be the intrinsic property of the method or just the problem of improper parameter estimation. The paper tries to compare the two models and indicate their similarities as well as conditions where their predictions are essentially different. This in turn will make easier to formulate verifiable hypotheses about experimental data describing diversity in human populations.

**Inclusion of relatives in a sample produces intra- and inter-locus association of alleles without biasing allele frequency estimates.** *H.S. Lee<sup>1</sup>, J.J. Hwang<sup>2</sup>, R. Chakraborty<sup>1</sup>*. 1) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Department of Legal Medicine, Korea University, Seoul, South Korea.

Samples of multilocus genotype data are collected for validating population genetic characteristics of markers (e.g., the assumptions of Hardy-Weinberg expectation, HWE: and Linkage equilibrium, LE) prior to their use in genetic epidemiology, DNA forensics, genetic counseling, etc. Convenient sampling strategies, the common practice of collecting such data, inadvertently may contain biological relatives. To evaluate impacts of this, we analyzed data on 155 pedigrees consisting of 882 individuals from the South Korean population, genotyped for 12 independently segregating STR loci (D3S1358, vWA, FGA, D8S1179, D21S11, D18S51, D5S818, D13S317, D7S820, THO1, TPOX, and CSF1PO). Results show that allele frequencies at individual loci are not biased with inclusion of relatives in the sample. However, 4 of the 12 loci showed significant deviation from HWE, and 58 of the 66 pairwise combinations of loci deviated from the assumption of LE, with relatives present in the sample. In contrast, in unrelated individuals of these pedigrees, no locus deviated from HWE, and 7 pairs of loci showed deviation from LE, contributed by the rare alleles at these loci. Inclusion of relatives shifted the distribution of number of shared alleles/genotypes between pairs of individuals towards higher values, in comparison with their random expectations. By classifying individuals in increasing order of kinship categories, the observed allele/genotype sharing distributions were in accordance with their expectations under the assumptions of HWE and LE within each kinship category. Analytical results also assert the unbiasedness of allele frequency estimates for these markers in samples containing relatives. In summary, these observations provide an empirical support of the notion that the presence of relatives in a sample may cause deviations from HWE and LE, and tendencies of increased allele/genotype sharing, without biasing the allele frequency estimates. (Research supported by US Public Health Service Research grants).

**Identification of polymorphic motifs using probabilistic search algorithms.** *P. Majumder*<sup>1</sup>, *A. Basu*<sup>1</sup>, *P. Chaudhuri*<sup>2</sup>. 1) Anthropometry & Human Gen Unit, Indian Statistical Inst, Kolkata, India; 2) Theoretical Stat & Math Unit, Indian Statistical Inst, Kolkata, India.

We define a set of nucleotides at multiple polymorphic sites, not necessarily contiguous, occurring with a high frequency in a collection of aligned DNA sequences as a "polymorphic motif". The problem of finding such motifs naturally arises in case-control studies of common diseases and in molecular evolutionary genetics. Although identification of such motifs by an exhaustive search is possible, it is computationally infeasible. We have devised various probabilistic search algorithms for motif finding, whether or not the motif length ( $p$ ) is known. The objective function that is maximized, by a probabilistic search of the discrete space of all possible subsequences, is the frequency of a string of nucleotides at a subset of sites (when  $p$  is known) or most frequent string of maximum length (when  $p$  is unknown). Since for a given data set, the maximum motif frequency is inversely proportional to its length, we propose a statistical procedure to determine a cut-off point on motif-length. Optimization is performed in multiple sweep steps; updation is stochastic. The stopping rule is based on the total number of sweeps performed. To avoid the possibility of convergence to a local maximum, the concept of "elitism" is also implemented in our algorithms. Performance of our algorithms was extensively assessed using synthetic and real data sets. In synthetic data sets, in which the motifs were known, the probability of correct identification varied from 60%-100%. Computation time was the minimum when a parameter ( $c$ ) controlling the probabilistic search was set = 200. In real data sets, which pertained to human mt-HVS1 sequences from global populations, our algorithms discovered motifs, many of which agreed with those that are known to be associated with mtDNA haplogroups (e.g., M and U). We have also carried out coalescent simulations under different evolutionary scenarios to discover motifs in clades of phylogenetic trees. In the vast majority (90%-100%) of the simulated data sets, discovered motifs matched perfectly with the mutational histories of the sites included in the motifs.

**Tests of population substructure based on locus-specific genetic distance calculations between genotypic categories.** *C. Nievergelt, N. Schork.* Psychiatry, UCSD, La Jolla, CA.

Many natural populations have a structure that can be difficult to discern. Although anecdotal information about events such as the founding, migratory movements, mating patterns, and local geographical isolations associated with a population may exist, the precise effects such events have on the gene pool of the population require a more detailed empirical assessment. The detection and quantification of potential cryptic (or not obvious) substructure of populations has received considerable recent attention due to the negative impact such substructure can have on gene mapping efforts (e.g., in linkage and association studies), if ignored. We describe a procedure for assessing evidence for population substructure that is based on the simple intuition that if substructure exists, there will be subtle associations between alleles at unlinked loci. Our procedure requires genotyping a sample of individuals from a population on an appropriate number of loci (e.g., microsatellites, SNPs) and then assessing evidence for genetic distance (or general allele frequency differences) between groups of individuals based on genotypic categories at each locus in turn. Our procedure is quite general and powerful and can yield information about specific alleles that might be most useful for assessing subgroups of genetically homogenous individuals within a much larger, more heterogeneous population. We showcase the utility of our method on actual data (using the Autism Genetic Resource Exchange) and simulated data and compare it to other measures designed to detect substructure, such as the methods implemented in STRUCTURE (Pritchard et al. 2000) and tree-based methods (Bowcock et al. 1994, Mountain & Cavalli-Sforza 1997). Our results have important implications for the design and interpretation of large-scale genetic epidemiology studies of humans.

**Identifying major founder events in human diversification.** *K.K. Kidd, J.R. Kidd, A.J. Pakstis.* Dept Genetics, Yale U. School of Medicine, New Haven, CT.

Data for 50 autosomal loci (on 14 chromosomes), including 29 multiallelic haplotype systems, with a total of 465 independent common alleles are now available on 38 populations (averaging 53 individuals/pop) distributed across all major geographic regions of the world. These data yield an extremely robust framework for global population relationships with "branches" corresponding to major geographic regions indicating a series of founder events. The regional founder effects can be rank ordered in size. The one associated with expansion out of Africa is the largest (bootstrap = 99.6% of 1,000 replicants); that for the Native Americans is next largest (bootstrap = 99.7%), followed by that for Europe plus S.W. Asia (bootstrap = 93%), and the smallest for the E.Asia- Pacific-Siberia group (bootstrap = 54%). Considerable shared genetic drift also accrued between the Africa-Europe (western) populations and the (E.Asia- Pacific- Siberian-Native American populations (bootstrap >97%), undoubtedly representing drift at the forefront of the initial expansion of modern humans across central Asia. Within geographic regions our ability to define relationships varies considerably. All of Europe plus S.W. Asia and one N.W. Asian population cluster but only the Northern European populations form a meaningful subcluster (bootstrap = 69%). In contrast, within Africa substructure is significant for many relationships at bootstrap values of 94% to 100%. The two Pygmy groups, for example, form a cluster with 100% bootstrap support even though one of the groups is thought to have significant admixture with Bantu-speaking farmers. Serial subclustering of Native American populations in a North to South order is supported by bootstrap values varying in the range of 91% to 62%. The E.Asian cluster has a bootstrap value of 77% as a subcluster of a larger cluster including one Siberian group (at 75%) and two Pacific populations (at 54%). The Khanty from N.W. Asia are distinct from all geographic clusters, separated from the Africa-Europe-S.W.Asia group with a bootstrap value of 97% and from the E.Asia-Siberia- Pacific-American group with a bootstrap value of 87%. Supported in part by NIH GM57672, MH62495, AA09379, and NSF BCS991202.

**Multipoint association mapping of quantitative trait loci using genotype data.** *T. Wang*<sup>1,2</sup>, *H.J. Jacob*<sup>2</sup>. 1) Division of Biostatistics, Medical College of Wisconsin, Milwaukee, WI; 2) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI.

Linkage disequilibrium (LD) approach has been successfully used in fine-scale mapping of disease genes. Reconstruction of haplotypes is essential in most of the current LD studies. In practice, however, only genotypes are observable in most situation. Departure from Hardy-Weinberg at some marker loci during the segregation may also hinder the effort. In this study, we develop a likelihood-based multipoint association mapping method for fine mapping of QTL using genotype data directly. Genotypic association between QTL and markers are examined without the assumption of Hardy-Weinberg equilibrium. From a sample of unrelated individuals within a homogeneous population, maximum likelihood estimation of the joint genotypic distribution of a QTL and markers as well as genetic effects of the QTL are derived based on an EM algorithm. The association between the QTL and each marker can then be calculated from the joint genotypic distribution of QTL and markers. Unlike the single-marker analysis, the method allows us using multiple linked markers simultaneously and would take into account the correlation information among markers. Therefore, it may be useful for fine mapping of QTL in some candidate regions that have been found by classical linkage analysis. The method is suitable for both experimentally designed populations (e.g., backcross,  $F_2$  and  $F_n$ ) and homogeneous natural populations. With the availability of dense single nucleotide polymorphisms (SNP) markers, it may be feasible to use SNP for fine mapping of QTL in a natural population.

Program Nr: 2649 from 2003 ASHG Annual Meeting

**Autosomal linked marker systems (SNPSTRs) and estimation of population divergence times: evaluating power, precision and accuracy using coalescent-based simulations.** *U. Ramakrishnan, J. Mountain.* Anthropological Sciences, Stanford University, Stanford, CA.

As the name implies, a SNPSTR is a linked molecular marker system: a Single Nucleotide Polymorphism (SNP) in close physical proximity to a Short Tandem Repeat (STR) polymorphism. Differing mutational properties of SNPs and STRs make SNPSTRs potentially very informative regarding human evolutionary history. Using coalescent-based simulations, we explore the statistical properties of  $F_{ST}$ , heterozygosity and linkage disequilibrium for SNPSTR data for a range of evolutionary histories including population divergence, bottlenecks and growth. Further, we explore how SNPSTRs improve our ability to estimate divergence times between two populations. We show that even for some simple population histories, these linked molecular marker systems increase statistical power (the ability to distinguish between alternate evolutionary hypotheses) as much as 70%. Our findings theoretically validate the potential benefits of these novel molecular markers.

**Departures from Hardy-Weinberg equilibrium for common disease models.** *J.K. Wittke, N.J. Cox.* Human Genetics, The University of Chicago, Chicago, IL.

Previous studies have explored using departures from Hardy-Weinberg equilibrium (DHW) for fine-mapping relatively simple, Mendelian recessive disorders (Feder et al., Nat. Genet. 1996; Nielsen et al., Am. J. Hum. Genet. 1999). It remains unclear whether DHW can be used in fine-mapping genetic variation underlying common diseases with complex inheritance since a thorough understanding of the nature of DHW under common disease models has not been undertaken. The number of individuals ( $N$ ) needed to detect DHW given a specified significance level is related to the difference in the observed and Hardy-Weinberg expected genotypic frequencies ( $\Delta$ ) (Weir, 1996). We show analytically that for dominant, recessive, and additive models,  $\Delta$  is a function of  $q$  (the overall frequency of the disease susceptibility allele in the general population) and  $r$ , the genotype relative risk. For the multiplicative models,  $\Delta$  is 0, and for a general disease model in which heterozygote penetrance is not simply a function of homozygotes risk,  $\Delta$  is a function of  $q$ ,  $r$ , and  $h$  (the heterozygote relative risk). For true control samples,  $\Delta$  is non-zero for all models (including the multiplicative model) and is a function of  $q$ ,  $r$  (risk in non-susceptible homozygotes),  $h$ , and  $K_p$ , the population prevalence of disease. We used these analytic functions to calculate  $\Delta$  and then  $N$  (assuming a significance level of 0.05) for cases and controls for a range of genetic models consistent with complex disorders ( $K_p$  ranging from 0.005 to 0.2 and ranging from 2 to 10). Results suggest that significant DHW can be expected in relatively small case-control samples over a wide range of allele frequencies and genetic models. For example, DHW can be expected in less than 500 patients for dominant or recessive models where  $r$  is as low as 2 over a range of population susceptibility allele frequencies between 0.11 and 0.80. Control samples of less than 500 individuals can also be expected to depart from Hardy-Weinberg equilibrium, particularly when population prevalence of disease is high ( $K_p=0.2$ ),  $h$  is 5 or greater, and  $q$  is between 0.1 and 0.7 for recessive models or 0.3 and 0.7 for multiplicative models.

**Clustering technique and association study for structured multilocus genotype data.** *T. Nakamura*<sup>1</sup>, *A. Shoji*<sup>2</sup>, *N. Kamatani*<sup>1,2</sup>. 1) Division of Statistical Genetics, Institute of Rheumatology, Tokyo Women's Medical University 10-22 Kawada-cho, Shinjuku-ku, Tokyo 162-0054, Japan; 2) Department of Advanced Biomedical Engineering and Science, TokyoWomens Medical University 10-22 Kawada-cho, Shinjuku-ku, Tokyo 162-0054, Japan.

One of the most important problems in case-control association studies using genotypic data is the structuring of the population. If the population is structured, false positive conclusions are easily obtained by the association study because the distribution of the statistics such as K.Pearson's chi square statistics for the test of goodness of fit is based on the assumption that the population is not structured. In the association study using multilocus genotype data, structuring of the population can be a confounding factor. If the confounding factor is observable like sex or age, it is possible to analyze the data by excluding the influences of the factors. However the structuring of the population is not directly observed for neither the genotype data nor the phenotype data. We proposed a method for analyzing structured multilocus genotype data. This method can suggest the association between the candidate locus and phenotype by the multilocus genotype data that may include the population structure. This algorithm consists of two parts, obtaining the population structure by the clustering algorithm and testing the association between the genotype and phenotype excluding population structure. As the clustering technique, we used the hierarchical clustering technique. The clusters were obtained by the hierarchical tree. As the method for testing association excluding the population structure, we used the Cochran-Mantel-Haenszel test, which allows the false positive to be decreased and power to be increased. The algorithms described in this manuscript have been implemented in a computer program POPSTRUCT. The program contains three modes, analysis mode, simulation mode and generate mode. The simulation results of false positive are shown. It is illustrated that POPSTRUCT can decrease type I error rate and increase power for structured data by the results.

**Computer simulation study of population stratification.** *G.A. Heiman*<sup>1</sup>, *D.A. Greenberg*<sup>2</sup>. 1) Dept. of Epi, Mailman Sch Public Hlth, Columbia Univ, New York, NY; 2) Div Stat Genetics, Dept of Biostatistics, Columbia University and NY State Psychiatric Institute, New York, NY.

**BACKGROUND:** The extent to which population stratification (PS) biases genetic association studies have been debated in the literature. Some believe that PS is not a serious concern (Wacholder, Rothman, and Caporaso 2002); while others believe that contradictory findings may be partially due to PS (Thomas and Witte 2002). Using computer simulations, we investigated what combinations of disease and marker allele frequencies will lead to artificial associations.

**METHODS:** We simulated disease and marker data in datasets of 100 cases and 100 controls. There was no relationship (association) between the marker and the disease. The parameters were the disease and marker allele frequencies. Generating disease allele frequencies were 0.05 for population 1 and 0.05, 0.02, 0.035 and 0.05 for population 2. Markers were biallelic with frequencies of 0.2 for population 1 and 0.9, 0.6, 0.2, and 0.1 for population 2. After the two populations were simulated, we merged each data set from population 1 with its counterpart in population 2. We simulated over 1000 data sets for each set parameters (N= 16 different combinations) and counted the number of datasets yielding evidence of association (false positives; nominally 5%).

**RESULTS:** There was no bias when EITHER the marker allele frequency or disease allele frequency was the same in both populations. For the other combinations of disease ratio and marker frequency difference, the false positive rate (i.e., artificial association) increased as the parameters increasingly differed in the two populations. False positive rates ranged from 6% to 99% when disease ratio was not 1 AND marker allele frequency differed in the populations. The false positive rate was often > 20% in those cases.

**CONCLUSION:** There is a narrow range of disease ratios and marker allele frequency differences that are completely free from bias in stratified populations.

**Informativeness of genetic markers for inference of ancestry.** *N.A. Rosenberg<sup>1</sup>, L. Li<sup>1</sup>, R. Ward<sup>2</sup>, J.K. Pritchard<sup>3</sup>.* 1) Program in Molecular & Computational Biology, University of Southern California, Los Angeles, CA, USA; 2) Institute of Biological Anthropology, University of Oxford, Oxford, UK; 3) Department of Human Genetics, University of Chicago, Chicago, IL, USA.

Inference of individual ancestry is useful in various applications, such as admixture mapping and structured-association mapping. Using information-theoretic principles, we introduce a general measure, the informativeness for assignment, applicable to any number of potential source populations, for determining the amount of information that multiallelic markers provide about individual ancestry. In a worldwide human microsatellite data set, we identify markers of highest informativeness for inference of regional ancestry and for inference of population ancestry within regions; these markers can be useful both in testing for and in controlling the influence of ancestry on case-control genetic association studies. Markers that are informative in one collection of source populations are generally informative in others. Informativeness of random dinucleotides, the most informative class of microsatellites, is 5-8 times that of random single nucleotide polymorphisms, but 2-5% of SNPs have higher informativeness than the median for dinucleotides.

**POPULATION GROUP ASSIGNMENT: EFFECTS OF MARKERS AND METHODS.** *B. Yang<sup>1</sup>, H. Zhao<sup>2</sup>, H. Kranzler<sup>3</sup>, J. Gelernter<sup>1</sup>.* 1) Dept Psychiatry Yale U School Med, New Haven, CT; 2) Dept EPH Yale U School Med, New Haven, CT; 3) U CT Health Ctr, Farmington, CT.

Population stratification is a critical issue for design and interpretation of genetic association studies. New methods offer the promise of more understanding of such stratification. However, little is known at this point about practical genotyping requirements for implementing these methods based on different marker types and characteristics. We evaluated the effects of number and efficiency of markers on accuracy of ethnic group assignment by STRUCTURE (Pritchard et al 2000) and a likelihood based method (LBM).  $F_{st}$  was used to evaluate marker efficiency. A panel of 37 markers [36 STRs and 1 SNP, FY-null] was genotyped for 934 individuals from the Northeastern US: 640 European-Americans (EA), 225 African-Americans (AA), and 69 Hispanics (Hisp). FY is known to be highly informative for resolving AA and EA populations. A bootstrap procedure of selecting increasing numbers of markers, to compare correlated and independent allele frequency models in STRUCTURE, showed no major difference in assignment accuracy for EA or AA. The Hisp subjects could not be clustered as a single subgroup. The relative assignment accuracy for STRUCTURE and LBM was evaluated by adding markers 1 by 1 up to 36 of the markers, with the order of  $F_{st}$  either descending or ascending. In EAs, LBM provided more accurate group assignment than STRUCTURE, with the FY locus included or excluded; the assignment accuracy reached over 0.98 using the 5 most efficient markers including FY, and using the 10 most efficient markers excluding FY. In AAs, STRUCTURE outperformed LBM with or without FY, and the assignment accuracy could reach over 0.98 when using the 15 most informative markers. Assignment accuracy was little affected by exclusion of FY for STRUCTURE, but dropped about 15% at the first marker for LBM. We conclude that by selection of the most informative markers, assignment accuracy of population groups could have the best results. LBM is an alternative to STRUCTURE in clustering population groups, but in contrast to STRUCTURE, its use depends on prior knowledge of allele frequencies in the populations studied.

**RNA interference-mediated silencing of *GJB2* expression.** *Y. Maeda*<sup>1</sup>, *K. Fukushima*<sup>2</sup>, *R.J.H. Smith*<sup>1</sup>. 1) Molecular Otolaryngology Research Laboratories, University of Iowa Hospitals and Clinics, Iowa City, IA; 2) Department of Otolaryngology, Okayama University Medical School, Okayama, Japan.

RNA interference (RNAi) is a process in which dsRNA suppresses the expression of homologous genes. Small interfering RNAs (siRNAs) are 21-23nt RNA duplex intermediates that trigger sequence-specific cleavage of mRNAs in mammalian cells. High suppression potency and sequence specificity make RNAi one of the promised tools for therapeutic application and analysis of gene function. Allele variants of *GJB2* account for half of prelingual autosomal recessive non-syndromic deafness, and several missense mutations in *GJB2* also cause autosomal dominant sensorineural deafness. To explore the possibility of applying RNAi technology to *GJB2* expression, we designed synthetic siRNAs targeting 4 different sites in the coding region of *GJB2* mRNA (siRNA1-4). These siRNAs were introduced into human HEK293 cells using the *Silencer* siRNA transfection kit (Ambion, Inc). Levels of endogenous *GJB2* expression were tested by a semiquantitative RT-PCR at 72 hours post transfection. Control and *GJB2*-targeting siRNAs were fluorescence-labeled using a Cy3-labeling kit (Ambion, Inc). The siRNAs were localized to the cytoplasm and resulted in specific reduction of *GJB2* mRNA levels. *GJB2* expression was suppressed by more than 80% of control levels by siRNA2, and by approximately 50% of control levels by siRNA1 and siRNA3 ( $P < 0.01$ ;  $n = 6-7$ ; ANOVA); siRNA4 was found to be ineffective ( $P > 0.01$ ). *GJB2* expression returned to control levels within 168 hrs post transfection. In mouse P19 cells, a murine construct homologous to siRNA2 induced significant reduction in levels of *Gjb2* mRNA ( $P < 0.01$ ); the construct homologous to siRNA4 exerted no significant effect on *Gjb2* expression levels ( $P > 0.05$ ). These results show that *GJB2* expression can be suppressed by siRNA and that there is a positional effect on the level of suppression that is observed. These data may provide a basis for controlling levels of *GJB2* expression *in vivo*, a requisite step in modulating the phenotype related to *GJB2* dysfunction. This research was supported by R01-DC02842 (RJHS).

**Hearing loss in Fabry disease: the effect of -galactosidase A replacement therapy.** *D. Hajioff<sup>1</sup>, S. Goodwin<sup>2</sup>, R.E. Quiney<sup>1</sup>, J. Zuckerman<sup>2</sup>, K. MacDermott<sup>2</sup>, A. Mehta<sup>3</sup>.* 1) Dept Otolaryngology, Royal Free Hospital, London, United Kingdom; 2) Clinical Trials Centre, Royal Free and University College School of Medicine, London, UK; 3) Dept Haematology, Royal Free Hospital, London, United Kingdom.

**Aims:** Fabry disease is a rare, X-linked lysosomal storage disease caused by deficiency of -galactosidase A. Hearing loss has been reported anecdotally in Fabry patients, but its nature and prevalence remain unclear. We aim to describe the nature and prevalence of hearing loss in Fabry disease, and its response to enzyme replacement therapy.

**Methods:** Fifteen male Fabry patients were enrolled in a randomized, double-blind study and received enzyme replacement therapy with agalsidase alfa or placebo for 6 months, followed by an open-label extension of 36 months thus far. Alongside this trial, an additional 8 men and 2 women have received open-label enzyme replacement for between 6 and 30 months thus far. Pure-tone audiometry, impedance audiometry, and otoacoustic emission testing were performed at 0 (baseline), 6, 18, 30 and 42 months.

**Results:** Nine patients (36%) had bilateral and 10 (40%) had unilateral high-frequency sensorineural hearing loss (SNHL). Three (12%) had unilateral middle ear effusions with conductive losses persisting beyond 6 months. Only 5 (20%) had normal hearing. The high-frequency SNHL deteriorated over the first 6 months in both placebo and active treatment groups by a median 6.3 dB ( $p < 0.0001$ , Wilcoxon matched pairs). This hearing loss subsequently improved above baseline by 1.5 dB at 18 months ( $p = 0.07$ ), 5.0 dB at 30 months ( $p = 0.006$ ), and 4.0 dB at 42 months ( $p = 0.01$ ).

**Conclusions:** Significant hearing loss, usually high-frequency sensorineural hearing loss, is a common manifestation of Fabry disease in adults. -Galactosidase A replacement therapy appears to reverse the hearing deterioration in these patients. This improvement, however, is gradual, suggesting the need for long-term enzyme replacement therapy.

**Investigation of the role of mannose-6-phosphate receptor (MPR300) in enzyme uptake and glycogen clearance in Pompe disease.** *D.S. Bali<sup>1</sup>, A.J. McVie-Wylie<sup>2</sup>, J. Dai<sup>1</sup>, Y.T. Chen<sup>1</sup>*. 1) Division of Medical Genetics, DUMC, Durham, NC; 2) Pharmacology and Toxicology, Genzyme Corporation, MA.

Pompe disease, a lysosomal glycogen storage disease resulting from acid -glucosidase (GAA) deficiency, is amenable to enzyme replacement (ERT) through receptor-mediated endocytosis. In vitro studies have established that the MPR300 is necessary for lysosomal enzyme uptake, however it is presently unclear if the same system is involved in vivo. Complete ablation of MPR300 expression in transgenic mice is lethal; therefore, we have generated viable tissue-specific MPR300 knockout (KO) mice to investigate this question. To further elucidate the role of MPR300 in recombinant human GAA (rhGAA) uptake and glycogen clearance in Pompe disease, muscle-specific MPR300 KO mice were crossed with GAA KO (Pompe) mice. These double KO mice were administered four weekly doses of 100mg/kg rhGAA and sacrificed 3 days after the last injection to examine enzyme levels and glycogen depletion in the target tissues. Age-matched Pompe mice were used as controls. Enzyme activity results demonstrated decreased enzyme uptake in the quadriceps and triceps of the double KO mice as compared to the Pompe mice (68% and 63% respectively); whereas in the heart rhGAA uptake was reduced only 11% compared to controls. Furthermore, glycogen content data indicated that glycogen clearance in the heart was similar in both the double KO mice and the Pompe mice; whereas in the skeletal muscle, the glycogen depletion was less in the double KO mice compared to the controls (12, 17 and 51% reduction in the double KO mice for the quadriceps, triceps and diaphragm respectively, compared to 59, 49 and 96% in Pompe mice). This data suggests that M6PR300 does indeed play a significant role in rhGAA enzyme uptake and glycogen clearance in skeletal muscle in vivo, whereas it is possible that the heart may employ alternative mechanisms for enzyme uptake and glycogen depletion. In conclusion, the tissue-specific MPR300 KO mice are an effective animal model to better define the mechanism of lysosomal enzyme uptake in vivo and this may lead to improvements in ERT currently available for Pompe and other lysosomal storage diseases.

**Aminoglycoside-induced ATM readthrough expression: A potential treatment for Ataxia-Telangiectasia.** C.H. Lai, H.H. Chun, S.A. Nahas, R.A. Gatti. Department of Pathology & Laboratory Medicine, David Geffen School of Medicine at UCLA, 90095-1713, Los Angeles, CA, USA.

Ataxia-Telangiectasia (A-T), an autosomal recessive disease, is characterized by lack of functional Ataxia-Telangiectasia mutated (ATM) protein in cells. A-T patients are disabled due to the gradual neurodegeneration. The genetic mutations found in A-T patients can be categorized as: 1) frameshifts, 2) abnormal splicing or 3) premature termination codons (PTCs). About 20% of A-T mutations in our patient mutation database ([http://www.benaroyaresearch.org/bri\\_investigators/atm.htm](http://www.benaroyaresearch.org/bri_investigators/atm.htm)) result in PTCs. Aminoglycosides, a group of widely used antibiotics, can induce and promote readthrough termination codons. The detailed mechanism of such readthrough is still not clear. Our objective was to establish the efficacy of aminoglycosides to induce translational readthrough of ATM PTC mutations, and thereby, produce small amounts of full-length functional ATM protein. Protein truncation test (PTT) was performed using templates containing different PTCs obtained by RT-PCR of different homozygous A-T lymphoblastoid cell lines (LCLs). Aminoglycoside-induced ATM expression was assessed by immunoprecipitation of nuclear extracts from treated A-T LCLs. Twelve A-T homozygous PTC containing LCLs indicated that readthrough expression in response to aminoglycosides was possible and was independent of the ATM PTC mutation. At comparable concentrations, Geneticin showed greater readthrough expression than Gentamicin. In preliminary *in vivo* experiments, low levels of full-length ATM protein were detected by immunoprecipitation from some A-T LCLs. Colony survival assays suggest that aminoglycoside-induced ATM may normalize radiosensitivity as well. These studies were prompted by the observation that A-T patients with some detectable ATM protein (e.g. <10% of normal levels), the progression of A-T symptoms are slower and milder. Thus, aminoglycoside-induced expression of ATM protein in A-T cells may provide a potential treatment for some A-T patients. This approach may also be applicable toward other genetic diseases that carry PTC mutations.

Program Nr: 2659 from 2003 ASHG Annual Meeting

**MPS I Management and Treatment Guidelines.** *J.E. Wraith, for the MPS I Consensus Guidelines Group.* Royal Manchester Children's Hospital, Manchester, UK.

**Overview:** Mucopolysaccharidosis type I (MPS I) is a lysosomal storage disorder (LSD) caused by a deficiency of the enzyme, -L-iduronidase, which leads to the accumulation glycosaminoglycans throughout the body. Because of its rarity, affecting ~1:100,000 newborns, and phenotypic heterogeneity, clinical management of MPS I is variable.

**Objective/Methods:** A working group of 11 experts met to discuss the management and treatment of MPS I. The goal of the meeting was to share recommendations that would form the basis of published international consensus guidelines. The group included specialists in pediatrics, cardiology, ophthalmology, anesthesiology, transplantation, orthopedics, and genetics. **Results:** MPS I may present with diverse symptoms; therefore, patients often receive incorrect diagnoses until they are seen by a physician familiar with LSDs. To better delineate the systemic impact of MPS I and to establish system-specific evaluation and management guidelines for both severe and attenuated MPS I, the panel organized its recommendations around core MPS I manifestations. In both severe and attenuated MPS I, global concerns include impact on skeletal, dental, and GI systems, presence of hernias, and the need for careful evaluation before procedures requiring anesthesia. The guidelines identify individual systemic parameters for evaluation, define evaluation intervals for both severe and attenuated MPS I patients, and describe intervention and management options. Current intervention and treatment options were reviewed, including hematopoietic stem cell transplantation, Aldurazyme (laronidase) enzyme replacement therapy, and palliative care. The clinical study results of Aldurazyme and its role in MPS I management were discussed. **Conclusions:** As new treatment options aimed at reversing the disease process become available for patients with MPS I, patients will require closer monitoring and standardization of care. Patients will benefit from consensus-driven clinical practice guidelines that integrate all aspects of care. Key aspects of the consensus guidelines will be presented. (Sponsored by BioMarin/Genzyme LLC).

**Effects of Aldurazyme (laronidase) on Joint Mobility in MPS I.** *M. Bajbouj*<sup>1</sup>, *M. Beck*<sup>1</sup>, *J.E. Wraith*<sup>2</sup>, *L.A. Clarke*<sup>3</sup>, *E.H. Kolodny*<sup>4</sup>, *G.M. Pastores*<sup>4</sup>, *J. Muenzer*<sup>5</sup>. 1) U Mainz, Mainz, GER; 2) U Manchester, Manchester, UK; 3) UBC, Vancouver, CA; 4) NYU, NY, NY; 5) UNC, Chapel Hill, NC.

**Objective:** To evaluate the effects of Aldurazyme (recombinant human alpha-L-iduronidase, rhIDU) on joint mobility, a major source of morbidity in MPS I.

**Methods:** Maximal active joint range of motion in the knee and shoulder was assessed in 45 patients participating in a 26-wk Phase 3 placebo-controlled study followed by an ongoing open-label extension study of Aldurazyme. Within-group changes were summarized after 48 wks (Placebo/rhIDU patients, N=23) and 74 wks (rhIDU/rhIDU patients, N=22) of treatment with Aldurazyme.

**Results:** Overall changes were small and variable. In patients who had more severe joint restriction at baseline (below median), range of motion improved in all movements assessed. Changes in knee mobility were greater in rhIDU/rhIDU patients who were treated for a longer period of time.

Joint Motion	Placebo/rhIDU	rhIDU/rhIDU
	Degrees	Degrees
Shoulder Flexion Mean	15.2 (n=12)	15.4 (n=9)
Shoulder Extension L/R	12.6 (n=8) / 8.1 (n=8)	11.9 (n=9) / 15.8 (n=12)
Knee Flexion L/R	6.6 (n=7) / 3.1 (n=7)	16.0 (n=14) / 17.8 (n=13)
Knee Extension L/R	2.0 (n=12) / 3.6 (n=12)	11.6 (n=9) / 11.3 (n=9)

**Conclusion:** Improvements in joint mobility likely contribute to the functional improvements seen in MPS I patients treated with Aldurazyme. (Sponsored by BioMarin/Genzyme LLC).

Program Nr: 2661 from 2003 ASHG Annual Meeting

**Mutation-Independent Gene Therapy Strategy for Osteogenesis Imperfecta.** *H.P. McMahon, D. Allen, P. Humphries, P.F. Kenna, S. Millington-Ward, G.J. Farrar, Ocular Genetics Unit. Genetics, Trinity College Dublin, Dublin, Leinster, Ireland.*

Osteogenesis Imperfecta (OI) is a brittle bone disorder, usually caused by the presence of mutant COL1A1 or COL1A2. To date over 150 and 80 different mutations in the COL1A1 and COL1A2 genes respectively have been characterised (1). In this gene therapy study a mutation-independent suppression and replacement strategy (2) for COL1A1-linked OI was evaluated using small interfering RNAs (siRNAs). siRNA can elicit sequence dependent gene-silencing in mammalian cells (3). In this study H1-driven COL1A1 targeting siRNAs have been assessed in cells expressing COL1A1 using real-time RT-PCR. COL1A1 expression levels were reduced by up to 98%.

**Hammerhead ribozymes targeting glycine substitutions in type 1 collagen for the therapy of Osteogenesis imperfecta.** *Y. Smicun<sup>1</sup>, M.W. Kilpatrick<sup>1</sup>, D. Basel<sup>1</sup>, R.J. Wenstrup<sup>2</sup>*. 1) Dept Pediatrics, UConn Health Center, Farmington, CT; 2) Cincinnati Childrens Hospital Research Foundation, Cincinnati, OH.

Hammerhead ribozymes are small catalytic RNA molecules capable of cleaving RNA in a sequence-dependent manner. Osteogenesis imperfecta (OI) is a genetic connective tissue disorder in which mutant collagen type I can participate in but not sustain the formation of the triple helix, thus depleting the extracellular matrix of structurally intact molecules necessary for normal fibrillogenesis. Selective ablation of mutant collagen transcript could reverse the dominant negative effect exerted by the abnormal protein. In earlier studies we have shown ribozyme can efficiently abolish the mutant transcript in a model of OI derived from the pMG155 mutant Col1A1 minigene. However, as most OI phenotypes involve substitutions for triple helical glycine residues, we have tested the efficacy of ribozymes in the specific targeting of such mutations. A cDNA segment encoding the triple helical domain of the Col1A2 gene was inserted into pMG155 to produce pMG155A2. Three separate single nucleotide substitutions were introduced into pMG155A2 to specifically mutate three glycines. Mutant specific ribozymes were produced targeting each of the glycine substitutions. Gly(A)Rz targets a G to C mutation that produces a cuc cleavage site, Gly(B)Rz a G to C mutation that produces an auc cleavage site and Gly(C)Rz a G to T mutation that produces a guc cleavage site. These three ribozymes test mutations in both the first and second bases of a glycine codon, and target three different cleavage triplets. Ribozymes Gly(A)Rz and Gly(C)Rz, cleaved their target mutant transcripts *in vitro*. The ribozymes were highly specific in that neither cleaved the wild type transcript that differed from the mutant by only a single base. Production of cell lines and transgenic mice expressing these mutations and ribozymes will allow testing of the efficacy of ribozymes targeted to glycine substitutions *in vivo*. The ability to specifically target glycine substitutions that comprise the great majority of OI mutations observed further emphasizes the potential of hammerhead ribozymes in the therapy of this disorder.

**Intravenous administration of lentiviral vector, or adeno-associated virus (AAV) vector, produces metabolic and phenotypic correction of Hurler syndrome in mice.** *C.B. Whitley<sup>1</sup>, D. Pan<sup>1</sup>, S.D. Hartung<sup>1</sup>, J.L. Frandsen<sup>1</sup>, R. Gunther<sup>1</sup>, W.C. Low<sup>1</sup>, S.U. Walkley<sup>2</sup>, R.S. McIvor<sup>1</sup>.* 1) Gene Therapy Program, University of Minnesota Medical School, Minneapolis, MN; 2) Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY.

Mucopolysaccharidosis type I is an autosomal recessive lysosomal storage disease resulting from deficiency of alpha-L-iduronidase (IDUA) and the consequent systemic accumulation of glycosaminoglycans (GAG) heparan sulfate and dermatan sulfate. The murine IDUA knock-out model is found to be a bona fide model of Hurler syndrome, the most severe clinical phenotype associated with the correspondingly severe human molecular genetic abnormalities (e.g., W402X, Q70X). To evaluate the efficacy of gene therapy for this disorder, we constructed lentiviral and AAV vectors expressing the human IDUA cDNA from a PGK, or a CAGS promotor, respectively. Following a single intravenous administration of either of the two vectors into newborn mice, we found virtually complete metabolic correction in some individuals. Throughout the 3- to 5-month period of observation, plasma levels of IDUA enzyme were increased, in some individuals reaching levels more than 10-fold above normal. Optimal treatment resulted in normal morphology of cells in liver and other organs, including the brain. Treated mice also showed reduced levels of accumulation of secondary glycosphingolipid storage products (GM2 and GM3 gangliosides) in neurons of the hippocampus and other brain regions. Notably, treated mice performed better, with near-normal results, in behavioral tests of habituation. Quantitative PCR determinations in each tissue are facilitating a quantitative comparison of the biodistribution, and relative gene expression, of lentiviral and AAV vectors. These factors will determine the minimal requisite conditions for treatment of Hurler syndrome by gene therapy.

**A preliminary study : Can donepezil improve quality of life of Down syndrome patients?** *T. Kondoh<sup>1</sup>, N. Amamoto<sup>1</sup>, T. Doi<sup>1</sup>, H. Hamada<sup>1</sup>, Y. Ogawa<sup>2</sup>, M. Nakashima<sup>3</sup>, H. Sasaki<sup>3</sup>, K. Aikawa<sup>4</sup>, M. Aoki<sup>4</sup>, K. Tanaka<sup>5</sup>, J. Harada<sup>6</sup>, H. Moriuchi<sup>1</sup>.* 1) Dept Pediatrics, Nagasaki Univ Sch Medicine, Nagasaki, Japan; 2) Dept Radiol, Nagasaki Univ Sch Med, Nagasaki, Japan; 3) Dept Hosp Pharm, Nagasaki Univ Sch Med, Nagasaki, Japan; 4) School for the Mentally Retarded, Faculty Education, Nagasaki University, Nagasaki, Japan; 5) Kakunan Yougo Gakko, Nagasaki, Japan; 6) Faculty of Education, Nagasaki University, Nagasaki, Japan.

Most Down syndrome (DS) patients develop neuro-pathological changes at age 35 or more as seen in Alzheimer disease (AD) patients. We here report the preliminary results of donepezil, an anti-AD drug, effects on QOL of DS patients. After approved by the Ethical Review Committee, we started the 24-week double-blind study with 10 otherwise healthy DS patients. The dose was started at 3 mg per day for one week, and increased to 5 mg per day. We assessed their QOL by the questionnaire and by adaptive behavior scale (ABS) examination. As adverse effects, some patients in the donepezil (D) group had moderate side effects. But those symptoms disappeared by reducing the dose. As efficacy, four of five DS patients in the D group got the impression that their childrens QOL got markedly improved. However, the results of F test of ABS before and after this trial did not show any differences between the D group and placebo group. Our first study had two implications. First, DS patients may be more sensitive to donepezil than other individuals. Second, improvement of QOL upon donepezil therapy may not be easily shown by ordinary ABS. To address these issues, we are undergoing the next study. We examined the serum concentrations of donepezil in 6 DS patients. Our results suggest that 3 mg per day is appropriate for most DS patients, and dose-up to 5 mg per day should be done only if needed, under monitoring of blood levels. To assess QOL more sensitively and objectively, we are modifying the ABS. Furthermore, we performed brain SPECT study for 6 DS patients before the donepezil therapy. Some patients showed the brain perfusion abnormalities. We will purchase this change. In conclusion, our preliminary study suggests donepezil may help some DS patients improve their QOL.

**Pregnancy-associated fetal progenitor/stem cells differentiate into various epithelial tissues in maternal organs.**

*P.K. Khosrotehrani<sup>1</sup>, K.L. Johnson<sup>1</sup>, D.H. Cha<sup>1</sup>, R. Salomon<sup>2</sup>, D.W. Bianchi<sup>1</sup>*. 1) Division of Genetics, Department of Pediatrics, Tufts-New England Medical Center, Boston, MA; 2) Department of Pathology, Tufts-New England Medical Center, Boston, MA.

**Purpose/Methods.** Fetal hematopoietic stem/progenitor cells enter the maternal circulation during pregnancy and can persist for decades (1,2). The morphology of these cells, when analyzed in tissue sections, suggests that some of them have differentiated into other cell types (3). In the present study, we performed fluorescence in situ hybridization on archived tissue specimens from eleven women with prior male pregnancies, to localize male microchimeric cells, and identified their phenotype with immunolabeling techniques to assess their capacity to differentiate. We used antibodies to cytokeratin as a marker of epithelial cells, CD45 as a hematopoietic marker, and heppar-1 as a hepatocyte marker.

**Results.** In epithelial tissues such as thyroid, cervix, intestine or gallbladder, 14-60% of fetal microchimeric cells differentiated into cells that express epithelial markers. In addition, 4% of microchimeric cells in liver parenchyma showed evidence of hepatocytic differentiation. Conversely, in hematopoietic organs such as lymph node and spleen, 90% of the cells retained a hematopoietic phenotype, as shown by the expression of CD45. Immunostaining and histologic assessment of the phenotype of microchimeric cells was highly concordant. Differentiation of the microchimeric cells occurs preferentially in areas of disease compared to healthy tissue ( $P < 0.0001$ ).

**Conclusions.** Pregnancy associated fetal progenitor cells (PAPCs) have the ability to differentiate into hepatocytes and epithelial cells. Further studies of naturally occurring fetal progenitor cells may be useful in understanding the influence of fetal microchimerism on maternal health.

**Adrenal cortical regeneration: murine models for tissue engineering.** *C. Truong*<sup>1</sup>, *M. Lam*<sup>2</sup>, *E.R.B. McCabe*<sup>3,4,5</sup>, *J. Dunn*<sup>1,2,5</sup>. 1) Dept Bioeng, Henry Samueli Sch Engr Applied Sci, UCLA, LA, CA; 2) Dept Surg, David Geffen Sch Med at UCLA, LA, CA; 3) Dept Peds, David Geffen Sch Med at UCLA, LA, CA; 4) Dept Hum Gen, David Geffen Sch Med at UCLA, LA, CA; 5) Mattel Children's Hospital at UCLA, LA, CA.

The adrenal cortex is a multi-layered organ that shows properties of renewal and regeneration consistent with the presence of adrenal cortical stem cells. Patients with inborn errors of adrenal development benefit from tissue engineering strategies. We examined potential models for investigation of adrenal cortical regeneration: adrenal autotransplantation and cell transplantation of freshly harvested adrenal cortical cells. In adrenal autotransplantation, right adrenal glands were excised from balb/c mice and transplanted into ipsilateral kidney under the renal capsule. Mice were sacrificed at weekly intervals, and kidneys were harvested, sectioned and stained with Hematoxylin and Eosin (H & E). One week after adrenal autotransplantation various zones of adrenal gland could be identified. By the second week, the adrenal gland became less densely packed, cell death became evident, and different zones became more difficult to distinguish. By week 3, the adrenal gland had increasing empty pore spaces occupying the gland. New cells and cell proliferation in empty spaces were evident. Our second approach involved harvesting of adrenocortical cells and transplanting them beneath kidney capsule of mice. Transplanted cells were confined within a space, using a small polycarbonate ring to create a virtual space beneath the renal capsule so growth and vascularization of transplanted cells could be studied. Transplanted mice were sacrificed 4-8 weeks post-transplantation, and kidneys were harvested, sectioned and stained with H&E. Eight weeks post-transplantation, a pale yellow tissue was visible within the rings with H&E staining consistent with adrenal cortical cells. We conclude that we have two model systems for investigating the regenerative potential of adrenal cortex. These investigations will permit identification of putative stem cells and will provide a foundation for future tissue engineering of adrenal cortex.

**Aldurazyme (laronidase) Enzyme Replacement Therapy for MPS I: 48-Week Extension Data.** *L.A. Clarke<sup>1</sup>, J.E. Wraith<sup>2</sup>, M. Beck<sup>3</sup>, E.H. Kolodny<sup>4</sup>, G.M. Pastores<sup>4</sup>, J. Muenzer<sup>5</sup>*. 1) UBC, Vancouver, Canada; 2) U Manchester, Manchester, UK; 3) U Mainz, Mainz, GER; 4) NYU, NY, NY; 5) UNC, Chapel Hill, NC.

**Objective:** To evaluate the long-term efficacy of Aldurazyme (recombinant human -L-iduronidase, rhIDU) for the treatment of MPS I. **Methods:** All patients from the 26-week Phase 3 randomized, double-blind, placebo-controlled study were enrolled in the Phase 3 open-label extension study. At Week 48 of the extension study, changes in forced vital capacity (FVC) and the 6-minute walk test (6MWT) were evaluated from baseline (start of double-blind study) or entry (start of open-label study) based on initial treatment group. Percent of predicted normal FVC was calculated by two methods: using baseline height to eliminate the confounding effects of rhIDU on posture and subsequent height measurements, or conventionally, using current heights at the time of FVC assessments. Patients receiving rhIDU throughout both phases of the study (N=22; total rhIDU exposure=74 weeks) were designated rhIDU/rhIDU, while those receiving rhIDU after cross-over from placebo (N=23; total rhIDU exposure=48 weeks) were designated Pl/rhIDU. **Results:** At Week 48 of the extension, rhIDU prevented further disease progression or lead to improvements in FVC from baseline or entry. Percent of predicted normal FVC calculated using baseline height improved by a mean of 6.6 percentage points in rhIDU/rhIDU patients after 74 weeks (p=0.001) and by a mean of 3.0 percentage points in Pl/rhIDU patients after 48 weeks (p=0.047). Measurements of FVC using current heights revealed that rhIDU prevented further disease progression in patients in both treatment groups with stabilization from baseline or entry despite anticipated decline in this patient population. At Week 48, patients in both groups continued to improve in the 6MWT with rhIDU/rhIDU patients showing a mean increase of 43.9 m (p=0.011) and Pl/rhIDU patients showing a mean increase of 37.6 m (p=0.046). **Conclusions:** This study demonstrates that long-term treatment of MPS I patients, many of whom had considerable pre-existing disease, with Aldurazyme leads to sustained improvements in clinically relevant endpoints. (Sponsored by BioMarin/Genzyme LLC).

**Receptor Function and Expression in Macrophages from Acid Sphingomyelinase Deficient Mice.** *R. Dhami, E. Schuchman.* Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY.

The acid sphingomyelinase (ASM) deficient forms of Niemann-Pick disease (NPD) are characterized by progressive accumulation of lipid-laden macrophages in many visceral organs, including the lung. Progressive accumulation of such macrophages was observed in the airways of acid sphingomyelinase deficient knock-out (ASMKO) mice, and this was attributed to elevated expression of the chemokines, macrophage inflammatory protein-2 and 1alpha. To investigate the mechanism(s) underlying enzyme replacement therapy for NPD, the uptake of rhASM by alveolar macrophages from the ASMKO mice was studied. Although the recombinant enzyme could bind to ASMKO macrophages, it could not be internalized efficiently. This was attributed to a defect in mannose-6-phosphate receptor trafficking and function. In contrast, the function and expression of mannose receptors appeared to be normal in ASMKO cells, consistent with the fact that a high mannose form of rhASM was taken up better by ASMKO macrophages than the complex form. However, even this enzyme form was internalized poorly by the ASM macrophages when compared to normal. These findings have important implications for the treatment of interstitial lung disease in ASM-deficient NPD patients, and suggest that the delivery of rhASM to cells promoting chemotaxis, rather than the airway macrophages themselves, may be the most effective approach.

**Aldurazyme (laronidase) Enzyme Replacement Therapy in MPS I: Preliminary Safety Data in Children Less Than 5 Years of Age.** *N. Guffon*<sup>1</sup>, *J.E. Wraith*<sup>2</sup>, *T. Braakman*<sup>3</sup>. 1) Hopital E. Herriot, Lyon, France; 2) Willink Biochemical Genetics Unit, Royal Manchester Children's Hospital, Manchester, UK; 3) Pharmacovigilance Dept., Genzyme Corp., Naarden, The Netherlands.

**Objective:** To evaluate safety and efficacy of Aldurazyme use in young children (<5 years) ineligible for hematopoietic stem cell transplantation.

**Methods:** Approximately 20 MPS I patients less than 5 years old are enrolling in a Phase 2 open-label study assessing Aldurazyme at 100 U/kg (0.58 mg/kg) once weekly for 12 months. It is anticipated that most of these patient will present the most severe MPS I phenotype. Safety monitoring will include physical examination, vital signs, ECG, clinical laboratory testing, immunogenicity testing, and adverse event monitoring. Investigators are requested to report all serious adverse events (SAEs) and infusion-associated reactions (IARs: related AEs on the day of infusion) to the Pharmacovigilance Department. Efficacy will be evaluated by assessing liver volume, urinary glucosaminoglycans (GAG) excretion, upper respiratory care requirements, sleep apnea by polysomnography, hearing, vision, growth velocity, electrocardiogram, echocardiogram.

**Results:** Study is ongoing. To date 11 patients have received 9-27 infusions (median 16). All patients had a Port-a-Cath placement to ease the infusion.

**Conclusion:** At submission date, conclusions concerning the study can not be made. Preliminary information on the safety and efficacy endpoints (urinary GAG) will be available at the time of the meeting. (Sponsored by BioMarin/Genzyme LLC).

**The One Year Experience of Enzyme Replacement Therapy for Mucopolysaccharidosis II (Hunter syndrome).** *J. Muenzer*<sup>1</sup>, *M. Calikoglu*<sup>1</sup>, *D. Towle*<sup>1</sup>, *S. McCandless*<sup>1</sup>, *A. Kimura*<sup>2</sup>. 1) Dept Pediatrics, Univ North Carolina, Chapel Hill, NC; 2) Transkaryotic Therapies (TKT), Inc, Cambridge, MA.

Mucopolysaccharidosis II (MPS II) is an X-linked recessive disorder caused by the deficiency of the lysosomal enzyme iduronate-2-sulfatase (I2S). There is no effective therapy for MPS II. The goal of this study is to evaluate the safety and clinical activity of I2S in the treatment of MPS II. Human I2S was produced by genetic engineering technology in a human cell line by TKT. The phase I/II clinical trial was a randomized, double-blind, placebo-controlled clinical study, which enrolled 12 MPS II patients (6 to 20 years of age). Three dosages of I2S (0.15 mg/kg, 0.5 mg/kg and 1.5 mg/kg) were studied. Within each dose group, patients were randomized to receive either I2S (3 patients) or placebo (one patient) by IV infusions biweekly for 6 months. All 12 patients have successfully completed the 6-month double-blind study and all elected to enroll in the open-label extension study. In the extension study, patients have currently received 6 months of open-label enzyme at the same dose, with 9 patients (3 at each I2S dosage level) receiving a total of one year of therapy. Urinary glycosaminoglycan excretion was consistently reduced at 50% and 45% after 6 months and one year of I2S treatment, respectively. Liver and spleen volumes were also reduced 27% and 26%, respectively, after one year of therapy. In addition, improvements in the 6-minute walk test (13% and 28% in the 0.5 and 1.5 mg/kg groups, respectively) and joint range of motion (4 to 7 joint motions improved in 7 of 9 patients) were observed after one year of treatment. Infusion-related reactions have occurred in 8 patients and have been successfully managed by slowing the infusion rate and using premedications. IgG antibodies developed in one patient receiving the 1.5 mg/kg dose during the first six months. An additional 5 patients in the 0.5 and 1.5 mg/kg dose groups developed IgG antibodies after 12 months. The development of low-titer antibodies appears not to have any clinical consequences. These results indicate that the I2S preparation is clinically active and is a promising treatment for somatic disease in MPS II.

**An *in vivo* comparison of the efficacy of acid -glucosidase produced in CHO cells and transgenic rabbits.** A. McVie-Wylie<sup>1</sup>, C. Rogers<sup>1</sup>, R. Gotschall<sup>2</sup>, B. Thurberg<sup>1</sup>, W. Canfield<sup>2</sup>, R. Mattaliano<sup>1</sup>, L. Andrews<sup>1</sup>. 1) Genzyme Corporation, Framingham, MA; 2) GRI, Genzyme Corporation, Oklahoma City, OK.

Pompe disease is an autosomal recessive disorder of glycogen metabolism resulting from the deficiency of the lysosomal enzyme acid -glycosidase (GAA). Enzyme replacement therapy (ERT) has been developed for Pompe disease and early phase clinical trials have been conducted, or are ongoing, using recombinant human GAA purified from the milk of transgenic rabbits (tgGAA) and from genetically modified CHO cells (rhGAA). In independent laboratory studies, both enzymes have demonstrated efficacy in the Pompe mouse animal model; however, for direct comparison, a study was designed to determine the relative efficacy under the same experimental conditions. Pompe mice were administered either tgGAA or rhGAA intravenously at three dose levels (20, 60 and 100mg/kg) weekly for 4 doses, and sacrificed 24 hours after the last injection. Results demonstrate that under the conditions of the study, and assays performed, a dose dependent decrease in tissue glycogen content was seen with both enzyme preparations tested. However, the reduction of glycogen following treatment with tgGAA was less than that observed with rhGAA. Interestingly, GAA activity measurements indicated that higher levels of enzyme were present in the tissues of mice treated with tgGAA compared to the levels detected in the tissues of the rhGAA treated mice. This finding suggests that tgGAA may be targeting to cell types other than glycogen containing myocytes within these tissues, or is less efficient at targeting to the lysosomes within the cell. However, Western blot analysis demonstrated that both enzyme preparations tested were fully processed in the tissues homogenates examined, indicating that the different enzyme preparations are reaching the lysosomes. In conclusion, the transgenic and CHO cell derived GAA enzyme both clear glycogen in a dose-dependent manner from the tissues of Pompe mice, although under the conditions of this study, the reduction in glycogen was more significant in mice treated with rhGAA produced in CHO cells.

**A Phase II Open-Label Clinical Study of Efficacy and Safety of Recombinant Human N-Acetylgalactosamine 4-Sulfatase (rhASB) Enzyme Replacement Therapy in Patients With Mucopolysaccharidosis VI (Maroteaux-Lamy Syndrome).** *P. Harmatz*<sup>1</sup>, *D. Ketteridge*<sup>2</sup>, *R. Steiner*<sup>3</sup>, *J. Simon*<sup>1</sup>, *J. Waterson*<sup>1</sup>, *S. Oates*<sup>2</sup>, *R. Giugliani*<sup>4</sup>, *I. Schwartz*<sup>4</sup>, *N. Guffon*<sup>5</sup>, *C. Sa Miranda*<sup>6</sup>, *L. Keppen*<sup>7</sup>, *E. Leao Teles*<sup>8</sup>, *J. Hopwood*<sup>2</sup>. 1) Children's Hosp & Research Ctr Oakland, CA, USA; 2) Women's & Children's Hosp, Adelaide, Australia; 3) Oregon Health & Science U, USA; 4) Hosp de Clinicas de Porto Alegre, Brazil; 5) Hosp Edouard Herriot, France; 6) Inst de Biologia Molecular e Celular, Porto, Portugal; 7) U South Dakota, USA; 8) Hosp de Sao Joao, Porto, Portugal.

Mucopolysaccharidosis VI (MPS VI; Maroteaux-Lamy syndrome) is a lysosomal storage disease caused by a deficiency of the enzyme N-acetylgalactosamine 4-sulfatase (ASB) leading to a progressive disorder with multiple tissue and organ involvement. A Phase II, open-label clinical study to evaluate the efficacy and safety of weekly treatment with 1.0 mg/kg of rhASB for 48 weeks was recently completed. Week 24 data is presented here; week 48 data will also be reported. Ten MPS VI patients were enrolled at two sites (age 6-22 yrs; 3 males). The average improvement in the 6 minute timepoint of the 12 Minute Walk Test was 62% and the 12 minute timepoint was 98%. The average improvement in the 3 minute stair climb was 110%. Joint Pain and Stiffness Questionnaire scores improved 57% and 54%, respectively. Small improvements in passive and active shoulder range of motion were noted with greatest improvements seen in patients with the most restriction at baseline. Biochemical response was documented by reduction in urinary excretion of glycosaminoglycans (GAG) by 71%. ERT was well tolerated. 13 AEs were reported: 5 during infusion and an additional 8 on the day of the infusion. In addition, 7 SAEs, 6 unrelated to drug and 1 possibly related to drug, were noted. 8 subjects developed antibodies to rhASB that did not significantly affect urinary GAG levels. In conclusion, rhASB treatment was well-tolerated, urinary GAG decreased in all patients, and positive clinical responses were present with the greatest improvements observed in assessments of endurance. (Sponsored by BioMarin Pharmaceutical Inc., Novato, CA).

**Short term enzyme replacement therapy in the mouse model of the lysosomal disease sialidosis.** *D. Wang, E. Bonten, L. Mann, T. Walker, A. d'Azzo.* Genetics and Tumor Cell Biology, St. Jude Children's Research Hospital, Memphis, TN.

Sialidosis is a lysosomal storage disorder (LSD) characterized by deficient lysosomal neuraminidase (NEU1) activity and aberrant accumulation of sialylated glycoconjugates. Cells of the reticuloendothelial system are primarily affected. *Neu1* knockout mice develop clinical abnormalities reminiscent of early-onset sialidosis in children, including severe nephropathy, progressive edema, splenomegaly, kyphosis. These mice provide a useful model for testing the efficacy of novel therapeutic strategies for this heritable disorder.

Enzyme replacement therapy (ERT) has proved effective for treating the systemic manifestations associated with LSDs. We have tested the efficacy of this therapeutic approach in the *Neu1* knockout mice by using recombinant enzymes produced in insect cells. Glycoproteins expressed in these cells carry carbohydrates modified to expose mainly core type oligosaccharides and, therefore, are poised to be internalized by macrophages via mannose receptors.

Given the dependence of NEU1 on PPCA for activation and stability, we speculate that injection with both enzymes may afford a better correction of the phenotype. We have therefore overexpressed murine Neu1 and human PPCA in insect cells using a baculovirus expression system and subsequently purified them. One-month-old *Neu1*<sup>-/-</sup> mice were injected intravenously with both recombinant enzymes twice a week for a period of two weeks. Injected enzymes were effectively taken up by many tissues. The half lives of the injected enzymes ranged from 1-4d, depending on the tissue. Restoration of enzyme activity in different tissues was achieved after treatment. Lysosomal storage was reduced in many tissues with significant correction observed in spleen, liver and kidney. Therefore, ERT with baculovirus-expressed enzyme may be an effective treatment for patients with sialidosis and possibly for other LSDs primarily involving the reticuloendothelial system. (Supported in part by NIH grants DK52025, GM60905 and Cancer Core Grant CA21765)

**Replacing a deficient enzyme in Pompe disease: two approaches, one result.** *N. Raben*<sup>1</sup>, *M. Danon*<sup>2</sup>, *A. Gilbert*<sup>1</sup>, *K. Nagaraju*<sup>3</sup>, *P. Plotz*<sup>1</sup>. 1) NIAMS, ARB, NIH, Bethesda, MD; 2) Hennepin Medical Center, University of Minnesota, Minneapolis, MN; 3) Division of Rheumatology, Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

The success of enzyme replacement therapy (ERT) in type I Gaucher disease, a deficiency of lysosomal glucocerebrosidase, has stimulated efforts to develop similar approaches for other lysosomal disorders. Repeating this success, however, has proved difficult in Pompe disease [glycogen storage disease type II; deficiency of glycogen-degrading lysosomal acid alpha-glucosidase (GAA)] - the only lysosomal storage disease in which muscle is the principal target tissue for ERT. We have evaluated the efficacy of recombinant human GAA (rhGAA from Genzyme Corporation, Framingham, MA) in a tolerant GAA knockout mouse strain. Near complete reversal of pathology was achieved in heart, while only a modest effect was observed in skeletal muscle, even in mice treated with a high dose of the enzyme. After 5 months of therapy, glycogen reduction in skeletal muscle was less than 50%, and the undegraded glycogen remained in proliferating lysosomes as shown by increased immunoreactivity for LAMP-1/LAMP-2 in glycogen-containing lysosomes. These data closely paralleled the results of inducing the GAA transgene in knockout mice - complete clearance of glycogen in the heart but strikingly uneven clearance in skeletal muscle following hepatic secretion of the enzyme - suggesting that the problem lies in the target tissue itself. We have shown that skeletal muscle has a lower density of the essential transporter, the cation-independent mannose 6-phosphate receptor (CI-MPR), than cardiac muscle. Furthermore, histochemical analysis showed increased CI-MPR immunoreactivity in slow-twitch oxidative type 1 muscle fibers, which cleared glycogen more efficiently compared to fast-twitch fibers despite their higher level of glycogen accumulation. These studies suggest that treating myopathy with ERT may require high doses of exogenous enzyme or an entirely different approach.

**The Clinical Benefit of Aldurazyme (laronidase) for the Treatment of MPS I.** *G.M. Pastores<sup>1</sup>, J.E. Wraith<sup>2</sup>, L.A. Clarke<sup>3</sup>, M. Beck<sup>4</sup>, E.H. Kolodny<sup>1</sup>, J. Muenzer<sup>5</sup>, G.F. Cox<sup>6</sup>, A.M. Skrinar<sup>6</sup>.* 1) NYU, NY, NY; 2) U Manchester, Manchester, UK; 3) UBC, Vancouver, Canada; 4) U Mainz, Mainz, GER; 5) UNC, Chapel Hill, NC; 6) Genzyme Corporation, Cambridge, MA.

**Objective:** Mucopolysaccharidosis (MPS I) is an autosomal recessive disorder caused by a deficiency of a lysosomal enzyme, -L-iduronidase, that results in the progressive accumulation of glycosaminoglycans. The spectrum of resulting MPS-related symptoms leads to functional impairment in activities of daily living, particularly in the mobility and self-care domains. The objective of this study was to document improvements in the physical function of MPS I patients treated with Aldurazyme (recombinant human alpha-L-iduronidase). **Methods:** 45 MPS I patients (ages 6-43) were randomized to participate in a Phase 3, double-blind, placebo-controlled study of Aldurazyme for 26 weeks, followed by an ongoing, open-label extension study. Improvements in physical function were assessed using the Disability Index (DI) of the Health Assessment Questionnaire (HAQ) and the Child Health Assessment Questionnaire (CHAQ). The DI scale ranges from 0 to 3, with a score of 3 representing the maximum level of disability. A reduction in score is associated with improved physical function. A change of -0.22 in HAQ DI scores has been established as the minimum clinically important difference (MCID). When mean changes in a treatment group exceed the MCID, it is expected that the majority of patients in this group will achieve clinically meaningful improvements. **Results:** Mean reductions of -0.3 were observed for the Aldurazyme/Aldurazyme group after 26 weeks of treatment in the double-blind study. Mean reductions of -0.2 were observed for the Placebo/Aldurazyme group after 24 weeks of treatment in the open-label extension study. These improvements in physical function have been maintained for an additional 24 weeks of treatment in the open-label extension study. **Conclusion:** MPS I patients treated with Aldurazyme showed mean reductions in CHAQ/HAQ DI scores consistent with MCID values. This suggests improvements in daily functioning that are both perceptible and considered clinically meaningful to the patient.

**Long Term Enzyme Replacement Therapy for Fabry Disease.** *W.R. Wilcox<sup>1</sup>, M. Banikazemi<sup>2</sup>, N. Guffon<sup>3</sup>, P. Lee<sup>4</sup>, G.E. Linthorst<sup>5</sup>, S. Waldek<sup>6</sup>, D.P. Germain<sup>7</sup>, R.J. Desnick<sup>2</sup>, for the International Collaborative Group on Fabry Disease.* 1) Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Mt Sinai School of Medicine, New York, NY; 3) Hôpital Edouard Herriot, Lyon, France; 4) National Hospital for Neurology and Neurosurgery, London, UK; 5) Academic Medical Center, Amsterdam, The Netherlands; 6) Hope Hospital, Manchester, UK; 7) Hôpital Européen Georges Pompidou, Paris, France.

Fabry disease results from deficient activity of  $\alpha$ -galactosidase A ( $\alpha$ -GAL A) and subsequent accumulation of neutral glycosphingolipids, predominantly globotriaosylceramide (GL-3). All 58 patients who were enrolled in a 20 week Phase 3 Double Blind Placebo Controlled Study of recombinant human  $\alpha$ -galactosidase A (Fabrazyme (agalsidase beta) Genzyme Corporation) have subsequently received r-hGAL (1 mg/kg IV biweekly) in an ongoing open-label extension study for an additional 30 months. As of the 30 month assessment, 50 patients remained in the study. Plasma GL-3 levels were evaluated using a new mass spectrometry assay. There was a sustained reduction in plasma GL-3 levels at 30 months of therapy. Mean serum creatinine, estimated GFR and proteinuria remained stable for up to 36 months of treatment, suggesting stabilization of renal disease. Thirty-nine of 40 (98%) patients who underwent skin biopsies at 30 months had a skin capillary endothelial cell score of zero, demonstrating sustained clearance of GL-3 from the endothelial cells. IgG antibody formation, evaluated using ELISA and a confirmatory radioimmunoprecipitation (RIP) assay, occurred in 52/57 (89%) patients. As of 30 months, 7 of these seroconverted patients tolerized (no detectable IgG antibody) and 58% of patients demonstrated a four-fold or greater reduction in antibody titer. Seroconversion did not impact reduction of plasma GL-3. The mean infusion time at 30 months was 2.2 hours; only 5 patients had an infusion time >3 hours. In summary, enzyme replacement therapy with r-hGAL continues to demonstrate a favorable safety and efficacy profile.

**Pharmacokinetics of Aldurazyme (laronidase) for the Treatment of MPS I.** *S. Swiedler<sup>1</sup>, J.E. Wraith<sup>2</sup>, L.A. Clarke<sup>3</sup>, W. Kramer<sup>4</sup>, K. Walton-Bowen<sup>5</sup>, G.F. Cox<sup>5</sup>.* 1) BioMarin Pharmaceuticals, Novato, CA; 2) University of Manchester, Manchester, UK; 3) University of British Columbia, Vancouver, CA; 4) Kramer Consulting LLC, North Potomac, MD; 5) Genzyme Corporation, Cambridge, MA.

**Objective:** To evaluate the pharmacokinetics (PK) profile of laronidase and the impact of antibody formation.

**Methods:** PK analysis was performed on a subset of 12 patients with MPS I from the Phase 3 study who received Aldurazyme at 100 U/kg (0.58mg/kg) IV weekly for 26 weeks. Infusions were administered over 4 hours using a ramp-up infusion rate protocol. Plasma laronidase concentrations were measured over 10 hours. PK parameters were estimated for the 1, 12, and 26 infusions using non-compartmental analysis. Values from week infusions 1 and 26 were compared using a paired t-test.

**Results:** The maximal plasma concentration of laronidase ( $C_{max}$ ) increased over time ( $p < 0.001$ ), possibly due to a concomitant 50% reduction in the volume of distribution ( $V_z$ ) ( $p = 0.001$ ). The reduced  $V_z$  also may have accounted for the trend towards a decreased elimination half-life ( $t_{1/2}$ ) over time ( $p = 0.010$ ). An inverse relationship observed between  $V_z$  and anti-laronidase antibody levels at infusions 12 and 26 suggested a causal interaction. Importantly, however, plasma clearance (CL) remained relatively stable after 26 infusions ( $p = 0.253$ ). In association with an infusion with Aldurazyme, plasma laronidase concentrations remained at levels above the half-maximal saturation of uptake into cells (0.7 nM; 0.01 U/mL) for a minimum of 3-9 hours. Pharmacodynamic and clinical measures improved despite antibody formation in most patients receiving laronidase.

**Conclusions:** The PK parameters of laronidase have been determined. Despite an increased  $C_{max}$  and decreased  $V_z$  on the first and 26th treatment, the unchanged CL indicates that the overall irreversible transport of laronidase out of the plasma is not affected by antibodies to laronidase. (Supported by BioMarin/Genzyme LLC).

**Intravenous retroviral gene therapy in seven-week-old dogs with mucopolysaccharidosis (MPS) VII.** *M. Haskins<sup>1</sup>, T. O'Malley<sup>1</sup>, NM. Ellinwood<sup>1</sup>, P. O'Donnell<sup>1</sup>, K. Cullen<sup>1</sup>, L. Xu<sup>2</sup>, R. Mango<sup>2</sup>, KP. Ponder<sup>2</sup>.* 1) University of Pennsylvania, Philadelphia, PA; 2) Washington University, St. Louis, MO.

MPS VII is a lysosomal storage disease due to deficient -glucuronidase (GUSB) activity. We previously reported that IV injection of  $3 \times 10^9$  transducing units (U)/kg of a retroviral vector (RV) expressing GUSB into newborn MPS VII dogs resulted in transduction of hepatocytes, which secreted GUSB into blood. One MPS VII animal that was treated with human hepatocyte growth factor (HGF) prior to neonatal IV injection of  $12 \times 10^9$  U/kg of the same RV (HGF/RV-treated) had dramatically higher serum levels (17,442 U/ml; 60 times normal), possibly due to the HGF or the higher dose of RV. Now an additional dog, not pretreated with HGF, given a log higher dose of RV than the previous HGF-treated dog has stable serum GUSB activity of 108 U/ml (36.3% of normal) 5 months after treatment, indicating that HGF was likely responsible for the extremely high serum GUSB activity in the initial dog. In all 4 of the neonatally treated dogs followed more than 2.5 years, clinical signs were minimal, and provirus and expression of GUSB were detected in peripheral blood indicating transduction of hematopoietic stem cells. Because most MPS patients are not diagnosed until 1-2 years of age, we tested if post-weaning, 7-week-old dogs could be treated by injecting  $1.7-2.2 \times 10^9$  U/kg of RV IV as 4 doses over 4 days. Four dogs were pre-treated with 2.5 mg/kg of HGF (HGF/RV); 3 were only given RV. The HGF/RV- and RV-treated dogs had  $184 \pm 109$  (54% of normal) and  $49.7 \pm 11$  (14% of normal) U/ml of serum GUSB, respectively. None of these dogs has PCR-detectable provirus in peripheral blood. We conclude that 1) 7-week-old dogs can achieve serum GUSB activity that should be associated with an improvement in clinical features, 2) HGF increased transduction over that obtained without HGF, 3) expression was surprisingly high without HGF, and 4) hematopoietic stem cell transduction in the neonatal dogs probably occurred in the liver.

**Long-term correction of ornithine transcarbamylase deficiency by tissue-restricted over-expression using a helper-dependent adenovirus.** *A. Mian*<sup>1</sup>, *V. Mane*<sup>1</sup>, *P. Ng*<sup>1</sup>, *M. Finegold*<sup>2</sup>, *W.O. Brien*<sup>1</sup>, *A. Beaudet*<sup>1</sup>, *B. Lee*<sup>1, 3</sup>. 1) Molecular and Human Genetics; 2) Pathology; 3) Howard Hughes Medical Institute. Baylor College of Medicine, Houston, TX.

The urea cycle disorders (UCDs) are important models for developing gene replacement therapy for liver diseases. Long-term correction of the most common UCD, ornithine transcarbamylase (OTC) deficiency, has yet to be achieved in clinical or preclinical settings. The single human clinical trial for OTC deficiency using an early generation adenovirus (Ad) failed to show any biochemical correction. In OTC-deficient mice, an E1/E2-deleted Ad vector expressing the mouse OTC gene, but not the human, was therapeutic for 2 months. By combining tissue-restricted expression of human OTC, a post-transcriptional enhancer and the less immunogenic helper-dependent adenoviral vector, we achieved metabolic correction of OTC-deficient mice for greater than 6 months. This was demonstrated by normalized orotic aciduria, normal hepatic enzyme activity and elevated OTC protein levels, but without chronic toxicity. Over-expressing the human protein may have overcome a proposed kinetic block at the level of mitochondrial import. Taken together, these data represent an important approach for treating cell autonomous human inborn errors of hepatocyte metabolism that require high level transduction and gene expression for clinical correction.

**Targeting In Vivo Gene Correction Using Designed DNA-Binding Proteins.** *M.C. Holmes, F.D. Urnov, J.C. Miller, A.C. Jamieson, Y.-L. Lee, S. Augustus, T. Martin, C.O. Pabo.* Sangamo BioSciences, Inc., Richmond, CA.

Progress in understanding the molecular basis of human monogenic disorders has not been followed by an increase in efficient strategies for therapeutic intervention. Many human genetic disorders are caused by hypomorphic or null mutations in genes, and restoration of even a single wild-type allele to the cell can be curative. In practice, however, the human genome is resistant to gene correction or replacement by homologous recombination (HR). As a consequence, therapeutic transgenes carrying wild-type sequences integrate at nonnative loci, and this misintegration results in aberrant genome behavior or in the failure of the transgene to express properly. We describe our recent studies towards developing a novel and efficient method for obtaining in vivo gene correction at genetic loci involved in monogenic disorders. Using engineered Zinc Finger Proteins (ZFPs) fused to the catalytic domain of the type IIS restriction endonuclease, FokI, we can introduce a double strand break (DSB) at any desired region of the human genome. Engineered ZFPs can be designed to bind virtually any DNA sequence with high affinity and specificity, enabling the tethered catalytic domain of FokI to cleave the DNA at precise sites in the genome. The introduction of targeted DSBs stimulate a potent repair pathway that facilitates the replacement of the DNA sequence at the break point with genetic information from a homologous DNA donor molecule, and thereby, provide a mechanism by which genetic errors can be permanently corrected via HR-mediated Gene Correction. In model systems, ZFP-FokI chimeras have been shown to massively potentiate HR within integrated reporter genes containing inserted ZFP-binding sites. Therefore, the use of engineered ZFP-FokI proteins to specifically target and cleave a unique region of the genome offers an unprecedented opportunity to enable locus-specific, high-efficiency gene correction for the repairing of genetic lesions encoding monogenic disorders. We will describe our recent studies toward developing a novel and efficient method for in vivo gene correction.

**Recombinant adenovirus mediates human glycerol kinase expression in glycerol kinase knock-out mice. N.**

*Kuwada<sup>1</sup>, K. Nagano<sup>1,2</sup>, M. Kumar<sup>1</sup>, K.M. Dipple<sup>1</sup>, E.R.B. McCabe<sup>1,3</sup>.* 1) Dept of Pediatrics, David Geffen Sch Med at UCLA and Mattel Children's Hosp at UCLA, LA, CA; 2) Dept of Pediatrics Kumamoto Univ Sch Med, Kumamoto, Japan; 3) Dept of Human Genetics, David Geffen Sch Med at UCLA, LA, CA.

Isolated X-linked glycerol kinase deficiency (GKD) may be either symptomatic or asymptomatic, and we have previously shown for point mutations that the GK genotype does not predict phenotype. A GK knock-out (KO) mouse model (Huq, et.al. Hum. Molec. Genet. 6:1997) will permit improved understanding of pathogenesis and the influence of modifier genes on the phenotype. The early death of affected murine males has limited the characterization of GKD pathogenesis. The purpose of this work was to rescue the affected males in order to investigate more thoroughly their phenotypes. We constructed an E1/E3 deleted adenovirus vector (Adeno-X: Clontech, Palo Alto, CA) with the human GK gene under control of cytomegalovirus promoter (Adeno-XGK). We injected Adeno-XGK into the superficial temporal vein of wild type (WT) and KO pups within 24 hours of birth. At ~45-48 hours post injection, the injected pups were sacrificed and the liver, kidney, heart and brown fat were isolated. The GK activity in the livers of KO mice injected with  $2.1 \times 10^8$  pfu of Adeno-XGK was 4.10.8% of WT pup's liver (n=4). When injected with  $3.0 \times 10^8$  pfu and  $6.0 \times 10^8$  pfu, the hepatic activity in KO mice was 13.422.0% (n=4) and 35.09.3% (n=3) of WT, respectively. GK activity in the other organs injected with  $6.0 \times 10^8$  pfu of Adeno-XGK were: brown fat 0.4% (n=1); kidney 1.0% (n=3); and heart 11.3% (n=1). Plasma from pups injected with  $2.1 \times 10^8$  pfu of Adeno-XGK was analyzed biochemically: plasma glycerol and free fatty acid concentrations remained high and triglyceride concentrations remained low. KO pups injected with  $6.0 \times 10^8$  pfu Adeno-XGK did not survive significantly longer, nor have significant changes in body weight compared with non-treated KO pups. We conclude that correction of hepatic GK activity by 30% is not adequate that rescue the GK KO pups. We speculate that much higher liver GK activity will have to be achieved to rescue the affected mice or expression of GK will be required in other tissue(s), for example in brown fat.

**Generation and analysis of a transgenic mouse model with a modified human rhodopsin replacement gene with therapeutic potential.** *M. O'Reilly, B. O'Neill, A. Palfi, P. Kenna, P. Humphries, J. Farrar.* Department of Genetics, Trinity College, Dublin, Ireland.

A transgenic mouse was generated that carries a human rhodopsin gene under the control of the mouse rhodopsin promoter. This rhodopsin gene encodes an identical amino acid sequence to the wild type human rhodopsin gene but has a number of nucleotide differences. These differences are designed, using the degeneracy of the genetic code, to allow transcripts from this modified rhodopsin gene when transcribed to escape cleavage by a ribozyme or siRNA molecules that target that particular site. The transgenic mice were bred onto a mouse rhodopsin knockout ( $\rho\text{-/-}$ ) background. These mice were analysed using electroretinography and histology, comparing function and retinal thickness to that of wild type mice. The modified human rhodopsin gene rescues disease pathology in a  $\rho\text{-/-}$  mouse. This is a useful animal model to study the efficacy of the gene replacement element of a therapeutic strategy for autosomal dominant retinitis pigmentosa (adRP). This model supports the idea of a mutation independent suppression and replacement therapeutic strategy for adRP, and the general strategy is also applicable to other dominantly inherited diseases. Suppression agents such as ribozymes and siRNA molecules that cleave wild type human rhodopsin transcripts at the target site should not cleave the replacement gene transcript. The suppression element of the strategy involves downregulation of gene expression in a mutation independent manner ensuring its application to patients with any mutation in a given gene. The work to be presented here demonstrates that the replacement element of the strategy works well in an animal model.

**Human CBS (Cystathionine -synthase) gene transfer mediated by recombinant adeno-associated virus vector.**

*E.S. Park*<sup>1</sup>, *S.C. Jung*<sup>2</sup>, *H.J. Oh*<sup>2</sup>, *C.H. Lee*<sup>1</sup>, *H.W. Lee*<sup>1</sup>, *J.S. Lee*<sup>3</sup>. 1) BK21 project for Medical Science, Yonsei University, Seoul, Korea; 2) Division of Genetic Disease, National Institute of Health, Seoul, Korea; 3) Department of Clinical Genetics, Yonsei University College of Medicine, Seoul, Korea.

Cystathionine -synthase (CBS) deficiency in human is the most common cause of Homocystinuria, a rare autosomal recessive disease. Patients with this disorder have premature arteriosclerosis and thrombosis, mental retardation, ectopia lentis, osteoporosis, skeletal abnormalities, which are resulted by elevated plasma homocysteine levels. About 50% of patients with CBS deficiency respond to pyridoxine therapy with a marked reduction in plasma total homocysteine, whereas the remaining subjects respond poorly. At least 60 different mutations of the gene have been described, with I278T and G307S as the most common. Interestingly, a number of patient-derived mutations in the CBS catalytic region can be functionally suppressed by either deletion of the c-terminal regulatory region or specific point mutation in this region. For the gene therapy of Homocystinuria, we constructed human CBS cDNA containing recombinant AAV vector (rAAV-hCBS). We used three kinds of hCBS cDNA, one was normal CBS cDNA, two were mutated hCBS cDNA which were deleted or mutated in the region of catalytic domain. We used adenovirus-free production system for the production of rAAV-hCBS vectors. Three kinds of rAAV-hCBS vectors were transduced into NIH3T3 for in vitro evaluation. Western blot analysis using anti-hCBS antibody demonstrated that all rAAV-hCBS vectors expressed high levels of Cystathionine -synthase enzyme. CBS enzyme activities were checked using TLC. There were no much differences among those three vectors. Following the in vitro experiment, we evaluated the transgene expression in homocystinuria mice. We administered an recombinant adeno-associated virus vector encoding hCBS to homocystinuria mice on day 6 of life via IP. The life span of mice was prolonged about 2 times than untreated disease mice. Studies are currently underway to further evaluate our vector in homocystinuria mice.

**Chimeric RNA and ethylene bridged nucleic acid-induced skipping of the exon retaining a stop mutation and led to dystrophin expression in dystrophin-deficient myocytes of Duchenne muscular dystrophy.** *Y. Takeshima<sup>1</sup>, A. Surono<sup>1</sup>, H. Wada<sup>2</sup>, M. Yagi<sup>1</sup>, M. Takagi<sup>3</sup>, M. Koizumi<sup>3</sup>, M. Matsuo<sup>1</sup>.* 1) Dept Pediatrics, Kobe Univ Grad Sch Med, Kobe, Hyogo, Japan; 2) Dept Pediatrics, Sakura Ryoikuen Hospital, Sanda, Hyogo, Japan; 3) Exploratory Chemistry Research Laboratories, Sankyo Co., Ltd., Tokyo, Japan.

Duchenne muscular dystrophy (DMD) is a fatal muscle wasting disease and characterized by dystrophin deficiency in skeletal muscle. Many studies have been done to express dystrophin in myocytes of DMD and modulation of dystrophin mRNA has been proposed to induce dystrophin expression. Here, we report that dystrophin was expressed in myocytes of DMD when skipping of the exon retaining a nonsense mutation was induced by transfection of antisense oligonucleotide. We identified a single nucleotide change in exon 41 of the dystrophin gene from a Japanese DMD case (C5899T) and the mutation converted a codon of arginine to a stop codon (R1967X), resulting dystrophin deficiency. Remarkably, two mRNAs with normal exon content or skipping of exon 41 was disclosed in lymphocytes while not in skeletal muscle. Since the novel mRNA lacking exon 41 was expected to produce dystrophin, artificial induction of exon 41 skipping was examined by using antisense oligonucleotide. As a part of antisense oligonucleotide sequence, we employed a novel modified nucleoside, named 2-0,4-C-ethylene-bridge nucleic acid (ENA) that have a high binding affinity for the complementary RNA strand and are more nuclease-resistant. An 18-mer chimeric RNA and ethylene bridged nucleic acid was sufficient to induce exon 41 skipping completely in the patients cultured myocytes. Furthermore, dystrophin expression was observed in over 80% of cells. The protein was detectable at significant level up to a week after transfection.

Our results demonstrated that skipping of exon 41 could be induced with an antisense oligonucleotide with ENA modification and this is a vital progress towards a clinically applicable for the treatment of diseases by using antisense ENA.

**Expression of the coxsackie-adenovirus receptor (CAR) in the non-neoplastic genito-urinary tract and its implications for gene therapy using adenoviral vectors.** *J. Simko*<sup>1,2</sup>, *V. Weinberg*<sup>2</sup>, *P. Carroll*<sup>2,3</sup>, *F. McCormick*<sup>2,4</sup>, *K.A. Rauen*<sup>2,5</sup>. 1) Pathology, UC San Francisco, CA; 2) Comprehensive Cancer Center, UC San Francisco, CA; 3) Urology, UC San Francisco, CA; 4) Microbiology and Immunology, UC San Francisco, CA; 5) Pediatrics, UC San Francisco, CA.

Adenoviral-based gene therapies are dependent on infectivity of the target tissue through the coxsackie-adenovirus receptor, CAR, which is the primary adenoviral receptor. Its presence is a determining factor in efficient adenoviral infection. CAR serves as the site for attachment of human adenovirus via the fiber protein to the target cell membrane. CAR is found in the tight junctions between epithelia cells and its physiologic function is believed to be important in cell-cell interaction and adhesion. We have recently demonstrated that metastatic prostate carcinoma expresses high levels of CAR, especially relative to primary tumors confined to the prostate. While studies of CAR membrane expression levels in other tumors of the genito-urinary (GU) tract are ongoing, we have evaluated the benign epithelia of the male GU system to obtain a baseline of CAR expression in these tissues. The rationale for the study is several fold: to examine the normal physiologic expression of this cell adhesion molecule so as to provide a baseline for comparing relative CAR expression levels between normal and tumor tissue, to understand how much virus may be absorbed by the benign tissue component during therapy and to know whether toxicity of normal tissues may be a serious consideration due to possible infectivity. We evaluated CAR expression in normal formalin-fixed, paraffin-embedded tissues of the male GU system which included prostate, kidney, ureter, urinary bladder, seminal vesicle, urethra and testis. The intensity of CAR staining for the normal specimens was grouped into four categories. All prostate, bladder, kidney, ureter and testis tissues demonstrated strong staining. Reduced staining was present in seminal vesicle and urethral specimens. These results indicate that the intrinsic expression level of CAR throughout the epithelia of the GU tract is high, suggesting that these tissues are potential targets for infectivity.

**AAV vector mediated gene therapy of Fabry knockout mice.** *T. Shimada*<sup>1</sup>, *K. Zenri*<sup>1</sup>, *K. Ogawa*<sup>1</sup>, *H. Takahashi*<sup>1</sup>, *Y. Hirai*<sup>1</sup>, *Y. Seino*<sup>2</sup>, *Y. Fukuda*<sup>3</sup>. 1) Dept Biochem, Molec Biol,; 2) Dept Internal Med,; 3) Dept Pathology, Nippon Medical Sch, Tokyo, Japan.

Fabry disease is an X-linked inherited metabolic disorder due to deficiency of a lysosomal enzyme  $\alpha$ -galactosidase A ( $\alpha$ -gal A). Undigested glycolipids such as globotriaosylceramide (Gb3) accumulate in systemic organs, resulting in renal and cardiac failure with increasing age.  $\alpha$ -gal A knock-out mice are considered useful for studying pathogenesis and therapeutic strategies of Fabry disease. We have recently demonstrated that AAV mediated expression of  $\alpha$ -gal A in muscle increases the enzyme level in serum and efficiently cleared Gb3 in all organs of Fabry mice. In the present study, we further evaluated histological and functional changes of Fabry mice. The therapeutic AAV vector was injected into the right quadriceps muscles of 12-week-old Fabry mice. The animals were sacrificed 25-32 weeks after vector injection. HE staining of the kidney of untreated Fabry mice showed marked swelling of glomeruli and thickening of the basement membrane. Electron microscopic examination showed that lipid inclusions with lamellar structures were accumulated in the swollen glomerular epithelial cells and tubular epithelial cells in untreated mice. Despite of such significant histological changes, the values of BUN and creatinine were within the normal range. AAV vector treatment normalized the mean diameter of glomeruli and significantly decreased the number of lipid granules. Echocardiographic examination revealed that the gene therapy approach is effective in the improvement of structural and functional parameters, including intraventricular septal thickness (IVST), posterior wall thickness (PWT), left ventricular ejection fraction (LVEF), early to late diastolic transmitral velocity ratio (E/A). These results indicate that accumulated Gb3 induces various histological changes in kidney and heart. But these defects are still reversible at this age and can be treated by AAV vector injection. AAV mediated gene therapy at an early stage may be useful for prevention of end-stage renal and cardiac failure.

**Antisense therapy for DMD in patient cells and mice.** *G.J.B. van Ommen, A. Aartsma-Rus, M. Bremmer-Bout, W.E. Kaman, E.J. de Meijer, A.A.M. Janson, J.T. den Dunnen, J.C.T. van Deutekom.* Department of Human Genetics, Leiden University Medical Center, The Netherlands.

Severe progressive Duchenne muscular dystrophy (DMD) is caused by frame-shifting mutations in the DMD gene. We are targeting adjacent exons to convert DMD into the nearest larger BMD mutation. Using antisense oligoribonucleotides (AONs) directed to exon-internal sequences, we are now able to induce 80-90% skipping of 19 different exons which would correct the DMD mutation in over 75% of patients registered in the Leiden DMD-database ([www.dmd.nl](http://www.dmd.nl)). We have presently validated the therapeutic potential and wide applicability of this strategy in cultured myofibers of 11 DMD patients affected by different deletion and nonsense mutations. Also combined skipping of two exons is efficiently achieved. Dystrophin is detectable as soon as 16 hours post-transfection, increased to significant levels at the membrane within 2 days, and was maintained for at least a week. Proper protein function was further suggested by the restored membranal expression of 4 associated proteins from the dystrophin-glycoprotein complex. Extensive *in vivo* studies in animal models, aimed amongst others at administration and safety, will be necessary prior to clinical trials with DMD patients. We have embarked on these studies and now also achieved *in vivo* exon 46 skipping in mice. Following intramuscular injections of mouse-specific exon 46 AON, exon 46 skipping occurred in a dose-dependent manner. The skipping increased gradually for two weeks and was still detectable after four weeks. We are now developing an *in vivo* exon-skip model system based on the human DMD gene, in transgenic hDMD mice carrying an integral copy of a properly expressed, full-sized 2.5 Mb human DMD gene. Thus, human DMD exon 46 has successfully been targeted *in vivo* in the mouse. Different human DMD-causing exon deletions are now being introduced in this hDMD mouse model. These will facilitate studies on evaluating different antisense AON analogs and delivery systems to ultimately establish a safe and most efficient method suitable for future clinical applications.

**The ataxin-2 (SCA2) knockout mouse phenotype: lack of neurodegeneration and development of marked obesity.**

*K.P. Figueroa*<sup>1</sup>, *A. Nechiporuk*<sup>2</sup>, *T.R. Kiehl*<sup>1</sup>, *D. Huynh*<sup>1</sup>, *X. Xu*<sup>1</sup>, *S.M. Pulst*<sup>1</sup>. 1) Burns and Allen Research Institute and Division of Neurology, Cedars-Sinai Medical Center, Departments of Medicine and Neurobiology, UCLA School of Medicine, Los Angeles, CA; 2) Department of Cardiology and Cell Biology, Harvard Medical School, Boston, MA.

Spinocerebellar ataxia type 2 (SCA2) is a human neurodegenerative disorder caused by expansion of a polyglutamine repeat in the ataxin-2 gene. To elucidate the normal function of ataxin-2 and to determine whether loss-of-function contributes to SCA2 neurodegeneration, we generated a mouse model with a targeted deletion in the *SCA2* gene by homologous recombination in a mixed C57B6/129J background. Deficiency of ataxin-2 was confirmed by Northern and Western blot analyses. Despite embryonic lethality of ataxin-2 deficiency in *C. elegans* and the widespread expression of ataxin-2 during rodent development, *SCA2* <sup>-/-</sup> mice were viable and had no obvious defects or increased morbidity. Although *SCA2* <sup>-/-</sup> mice had normal body weight at birth, we observed subsequent excessive weight gain. At 6 months, the average body weight of *SCA2* <sup>-/-</sup> mice was 26% more than that of wildtype, but we observed no differences in *SCA2* <sup>+/-</sup> mice. Controlled feeding experiments demonstrated that obesity was the result of increased food intake. When maintained in isolation on a restricted diet, no differences in food intake or weight were observed for the three genotypes. However, when provided with an *ad libitum* diet, heterozygote and homozygote mice showed increased food intake accompanied by increased weight. Average weekly food intake was 4.45 g for wildtypes, 5.60 g for heterozygotes, and 6.0 g for knockout mice ( $p < 0.01$ ). Average weekly weight gain was 0.59 g for wildtypes, 0.65 g for heterozygotes, and 0.79 for knockout mice under *ad libitum* conditions ( $p < 0.01$ ). These results suggest that obesity observed in *SCA2* <sup>-/-</sup> mice is predominantly the result of hyperphagia and not of primary metabolic abnormalities. Intermediate obesity observed in heterozygous animals strongly demonstrates that weight control is highly sensitive to ataxin-2 dosage. Supported by RO1 NS33123, the National Ataxia Foundation and the Carmen and Louis Warschaw Endowment.

**Defective bone marrow homing and engraftment in sialidosis mice.** *G. Yogalingam, E. Bonten, T. Walker, L. Mann, A. d'Azzo.* Genetics & Tumor Cell Biology, St Jude Research Hospital, Memphis, TN.

Lysosomal N-acetyl--neuraminidase (NEU1) initiates the hydrolysis of oligosaccharides, gangliosides, glycolipids and glycoproteins by catalyzing the removal of their terminal sialic acid residues. NEU1 acquires its active and stable conformation in lysosomes by associating with the serine carboxypeptidase protective protein/cathepsin A (PPCA). In lysosomes PPCA, NEU1, -galactosidase and N-acetylgalactosamine-6-sulfatase form a multienzyme complex. Sialidosis is caused by mutations in the *Neu1* locus. The disease is systemic affecting both visceral organs and the nervous system. Knockout *Neu1*<sup>-/-</sup> mice completely lack NEU1 activity and manifest a phenotype similar to type II sialidosis. These mice also develop a pronounced splenomegaly characterized by elevated numbers of hematopoietic precursors, consistent with splenic extramedullary hematopoiesis (EMH). We have generated transgenic mice that ubiquitously over-express NEU1 and PPCA gene sequences. Sub-lethally irradiated *Neu1*<sup>-/-</sup> mice were transplanted with transgenic bone marrow (BM) and analyzed one, three and five months post-bone marrow transplant (BMT). Only three out of sixteen *Neu1*<sup>-/-</sup> mice demonstrated successful BM engraftment. Of the three *Neu1*<sup>-/-</sup> mice that did exhibit successful engraftment, NEU1-expressing transgenic macrophages were identified in all organs, including the central nervous system. In comparison, all five control *PPCA*<sup>-/-</sup> mice and all eight control wild-type mice demonstrated successful engraftment following BMT with transgenic BM. A 52 kDa sialylated proteinase was detected in BM extracellular fluid from *Neu1*<sup>-/-</sup> mice with failed BM engraftment using a glycoprotein detection system and gelatin-zymography which was absent in wild-type mice. We are investigating a possible link between this sialylated proteinase and inactivation of the CXCR4/CXCL12 chemotaxis axis which is critical for the homing and retention of hematopoietic stem cells within the BM niche. These results are suggestive of a serious defect in BM homing and engraftment in *Neu1*<sup>-/-</sup> mice and have important implications for BM mediated therapies in sialidosis patients. (Supported in part by NIH grants DK52025 & GM60905).

**Alpha Mannosidosis: Effective Stabilization of Progressive Neuropsychological Decline by Hematopoietic Stem Cell Transplantation.** *S. Grewal, C. Peters, L. Charnas, L. Lockman, P. Orchard, K. Delaney, S. Abel, W. Krivit, E. Shapiro.* Pediatric Neurology, Neuropsychology and Blood & Marrow Transplantation, University of Minnesota, Minneapolis MN USA.

Alpha-mannosidosis results from an inherited deficiency of lysosomal enzyme alpha-mannosidase. Clinical features include progressive slowing in cognitive development with eventual dementia, and a shortened life span. We report the efficacy of hematopoietic stem cell transplantation (HCT) on stabilization of neuropsychological status. Four patients with alpha-mannosidosis underwent allogeneic HCT at the University of Minnesota. Age at HCT was 6.5, 3.3, 23.1 and 4.1 years respectively. Follow-up after HCT has been from 0.7 to 6 years. All patients show donor engraftment and normalization of leukocyte enzyme activity after HCT. All 4 patients showed considerable slowing of their neurocognitive development prior to HCT. Neuropsychological test results within one month prior to HCT and at last followup are summarized in Table and indicate stabilization (within a standard deviation) or improvement (>1 standard deviation) of function after HCT. No instance of significant loss of function (<1 standard deviation) was observed.

**All scores are standard scores: mean of 100 and standard deviation of 15.**

	Pt 1		Pt 2		Pt 3		Pt 4	
	at HCT	4-5 yr	at HCT	5 yr	at HCT	3 yr	at HCT	0.7 yr
<b>IQ</b>	76	79	85	90	78	72	75	ND
<b>Memory</b>	83	88	93	112	66	79	76	68
<b>Vineland</b>	105	90	77	102	50	80	66	60

**CONCLUSION:** HCT can halt the progressive slowing in development and relative decline in cognitive skills that occurs in alpha-mannosidosis. Early diagnosis and treatment is critical.

**A Biochemical Comparison of Recombinant Human Acid Alpha-Glucosidase Expressed in CHO Cells and Transgenic Rabbits.** *K.L. Lee, J. Baker-Malcom, K. Albee, T. Edmunds, R. Mattaliano.* Therapeutic Protein Research and Development, Genzyme, Framingham, MA.

Pompe disease, a deficiency of the hydrolase acid alpha-glucosidase (GAA), results in the abnormal accumulation of lysosomal glycogen. The severity of Pompe disease generally varies with the age of first clinical presentation and ranges from cardiomyopathy and severe hypotonia (e.g., infantile onset) to severe respiratory failure and proximal muscle weakness (e.g., juveniles, adults). Early phase clinical trials have been conducted or are underway in several patient populations using recombinant human acid alpha-glucosidase purified from the milk of transgenic rabbits (tg-GAA) and from genetically modified CHO cells (rhGAA). Large scale purification of rhGAA using a new CHO cell line has also led to the initiation of two new clinical trials for the treatment of Pompe disease. A biochemical comparison of the CHO-derived rhGAA and the tg-GAA was performed. The predominant GAA species in each preparation was the 110 kDa (precursor) form. N-terminal sequence analysis and LC/MS revealed that the N-terminus of rhGAA was chemically blocked with pyroglutamate, while the N-terminus of tg-GAA was not. The enzyme kinetic parameters for each of the GAA preparations were similar. IEF analysis indicated that both rhGAA and tg-GAA were a heterogeneous mixture of charge isoforms which focused over a broad pI range. The glycans of each of the GAA preparations tested in this study contained different levels of mannose-6-phosphate; however further analysis indicated that the mannose-6-phosphate residues on tg-GAA were modified by N-acetylglucosamine. Surface plasmon resonance studies indicated that rhGAA possessed a higher relative binding affinity for the soluble cation independent mannose-6-phosphate receptor than tg-GAA. Cellular uptake by Pompe fibroblasts was also higher for rhGAA and lower for tg-GAA. Biochemical and functional analyses using surface plasmon resonance and cellular uptake assays suggest that there is a higher quantity of exposed mannose-6-phosphate on rhGAA compared to tg-GAA.

**Increased lipoprotein(a) levels in a subset of patients affected with Fabry disease.** *Y. Herrera-Guzman<sup>1</sup>, M. Cambillau<sup>2</sup>, K. Benistan<sup>1</sup>, S. Sainte-Croix<sup>1</sup>, A. Bissery<sup>3</sup>, D.P. Germain<sup>1</sup>.* 1) Department of Genetics, European Hosp Georges Pompidou, Paris, France; 2) Department of Biochemistry, European Hosp Georges Pompidou, Paris, France; 3) Clinical Research Center, European Hosp Georges Pompidou, Paris, France.

Background: Fabry disease (FD) is an X-linked inborn error of sphingolipid metabolism due to the deficient activity of alpha-galactosidase A, a lysosomal enzyme. It is a multisystemic disorder characterized by progressive renal insufficiency, with added morbidity from cardio- and cerebro-vascular involvement. The recent availability of enzyme replacement therapy (ERT) emphasizes the need for better understanding of the pathogenesis, and for surrogate markers to monitor the efficacy of ERT. Methods: We investigated serum lipoprotein(a) concentrations in 20 consecutive hemizygous males prior to ERT. Results: Elevated serum concentrations of lipoprotein(a) [Lp(a)] (>30 mg/dL) were found in 35% (7/20) of FD patients. These results are to be compared with a prevalence of 4.7 to 10.3% found in numerous studies in the normal population. Increased Lp(a) levels correlated with renal function deterioration and 24h-proteinuria. Discussion: Elevated levels of Lp(a) have been determined to have both atherogenic and thrombogenic effects and various retrospective case-control studies have demonstrated an association of elevated Lp(a) with increased risk for ischemic stroke, coronary heart disease and venous thromboembolism. Although the mechanism and significance of Lp(a) elevation in FD, its relationship with kidney failure and its ability to decrease with ERT deserve further studies, our results suggest that increased Lp(a) level could play a role in the pathogenesis of FD and represent an additional risk factor of thrombosis for a subset of FD patients, especially when combined with hyperhomocysteinemia which has been demonstrated in patients with renal failure or on carbamazepin therapy. Lp(a) should be included in the baseline screening of FD patients. Whether elevated serum levels should prompt to a more aggressive therapy and will normalize on ERT is currently being investigated during follow-up studies.

**Gene therapy of murine G<sub>M1</sub> gangliosidosis by genetically modified bone marrow hematopoietic progenitor cells.**

*R. Sano, A. Tessitore, L. Mann, A. d'Azzo.* Genetics & Tumor Cell Biology, St. Jude Children's Research Hospital Memphis, TN.

-galactosidase (-gal), a lysosomal enzyme involved in the removal of -linked terminal galactosyl residues of many glycoconjugates, is deficient in the neurodegenerative lysosomal disorder G<sub>M1</sub> gangliosidosis (GM1). GM1<sup>-/-</sup> mice closely mimic the most fundamental aspects of the neuropathological and neurochemical abnormalities of the human disorder. Bone marrow progenitor cells have been used as a source of corrective protein because of their ability to repopulate the recipients and to supply functional enzyme to different cells by in trans correction. Hematopoietic progenitors transduced with a murine stem cell virus (MSCV)-based bicistronic retroviral vector overexpressing -gal and the green fluorescent protein (GFP) marker were used for transplantation into sublethally irradiated GM1<sup>-/-</sup> mice. The transduction efficiency of MSCV--gal was 25-89 % prior to the transplantation. -gal expressing bone marrow-derived cells were detected histologically and enzymatically in many tissues including spleen, liver, lung, intestine and kidney after one and three months post transplantation. GFP-expressing cells of the erythroid, myeloid or lymphoid lineage were detected by FACS analysis of peripheral blood samples, collected at different time points after transplantation. The percentage of gated cells expressing GFP varied between 1.20% and 30.98% in erythrocytes, 1.17% and 73.78% in platelets and 16.47% and 69.40% in lymphocytes. In some tissues the restoration of the enzyme activity was close to the wild type mice. Moreover cross-correction experiments using GM1<sup>-/-</sup> human fibroblasts showed the capability of internalization and processing to a mature active form of the enzyme. Taken together these preliminary results have reinforced the feasibility of using ex-vivo gene therapy for the treatment of GM1 (Supported in part by NIH grant DK 52025).

**Treatment approaches for the mouse models of globoid cell leukodystrophy.** *M.A. Rafi<sup>1</sup>, P. Luzzi<sup>1</sup>, M. Zaka<sup>1</sup>, M.A. Passini<sup>3</sup>, M.T. Vanier<sup>2</sup>, J.H. Wolfe<sup>3</sup>, D.A. Wenger<sup>1</sup>.* 1) Dept. Neurology, Thomas Jefferson Univ., Philadelphia, PA; 2) INSERM U189, Lyon-Sud Medical School, Oullins, France; 3) Dept. Pathobiology, School of Veterinary Medicine, Univ. of Pennsylvania, PA.

Globoid cell leukodystrophy (GLD) or Krabbe disease is a neurodegenerative disorder caused by the deficiency of the lysosomal enzyme galactocerebrosidase (GALC). This leads to the accumulation of psychosine, resulting in the death of myelin-producing-cells. The naturally occurring mouse model of this disease, twitcher (twi), and our newly generated transgenic (tg) mice with milder symptoms and a slightly longer life span provide excellent models for evaluating therapeutic strategies. Bone marrow transplantation (BMT) of young twi mice can prolong their lives to about 100 days from 40 days in untreated mice. In an attempt to improve the outcome of BMT, we have subjected our tg mice to BMT following pretreatment of BM cells with IGF-1. We have transplanted more than 80 tg mice. Their lifespan was extended from 50 days up to one year. Although the long-living mice still died with typical neurological symptoms, their psychosine levels were ~40 pmol/mg protein compared to ~ 200 in 50-day-old untreated mice. Pretreatment of BM cells with IGF-1 (50 ng/ml) prior to transplantation reduced the mortality from 80% to about 50% within the first 90 days post-transplantation. In addition, we have cloned mouse GALC cDNA in pZAC2.1, a type-2 adeno-associated viral vector (AAV), packaged in AAV-1, AAV-2 and AAV-5 serotypes. In vitro transduction of mouse neural cells and skin fibroblasts with these vectors showed a 5-6-fold increase in GALC activity. Subsequently, these viral vectors were injected intra-ventricularly or intra-parenchymally into newborn twi mouse brains. Two weeks after injection, frozen sections were stained with anti-GALC antibody, and transduced cells were detected by their bright perinuclear staining. There was some background staining in untransduced areas. Analysis of different brain areas 2 wks after injection revealed a 3 to 4-fold increase in GALC activity in regions near the site of injection. Further improvements are needed to provide more GALC activity to both the CNS and PNS.

**Shifting Mitochondrial DNA Heteroplasmy by Mitochondrially-Targeted Restriction Endonucleases. M.P.**

*Bayona-Bafaluy*<sup>1</sup>, *B.J. Battersby*<sup>2</sup>, *E.A. Shoubridge*<sup>2</sup>, *C.T. Moraes*<sup>1</sup>. 1) Neurology, University of Miami, Miami, FL; 2) Montreal Neurological Institute, Montreal, Quebec, Canada.

Mitochondrial DNA (mtDNA) mutations cause a number of devastating human disorders. Most pathogenic mtDNA mutations are heteroplasmic (i.e. the mutated mtDNA co-exists with the wild-type). The wild-type mtDNA fraction has a strong protective effect, and cellular defects are only observed in the presence of very high percentages of mutated mtDNA. We have developed a system to decrease specific mtDNA haplotypes by expressing a mitochondrially-targeted restriction endonucleases *in vivo*. Such system has the potential to reduce a mutated mtDNA fraction, if a restriction endonuclease site is created by a pathogenic nucleotide alteration. As a model system, we used hepatocytes from heteroplasmic mice harboring mtDNA from both BALB and NZB haplotypes. Among several nucleotide variations, these haplotypes differ by the absence of *Apa*LI sites in the NZB mtDNA and the presence of a single site in the BALB mtDNA. Transfection of mitochondrially-targeted *Apa*LI in these cells resulted in a rapid shift in heteroplasmy towards the NZB mtDNA. To better understand the timing of heteroplasmy shift, we placed the mitochondrially-targeted *Apa*LI gene in a vector system inducible by mifiprestone (RU486). Heteroplasmic hepatocyte clones containing the inducible construct treated with mifeprestone for 72 hours showed a complete shift in heteroplasmy and became homoplasmic for the NZB mtDNA. These results indicate that the heteroplasmy shift triggered by mitochondrially-targeted restriction endonucleases is extremely fast and specific. We are currently analyzing the kinetics of heteroplasmy shift and developing a mouse model to test the system in a live animal.

**MELAS and L-arginine Therapy.** *Y. Koga, Y. Akita, I. Ueki, A. Koga, T. Matsuishi.* Dept Pediatrics & Child Health, Kurume Univ Sch Medicine, Fukuoka, Japan.

**Background:** Based on the hypothesis that the stroke in MELAS are caused by impairment of vasodilation in some segment of the intracerebral artery, we administered L-arginine by infusion or by oral, and evaluate the pharmacological effects. **Methods:** We measured biochemical parameters at interictal, acute phase of 22 MELAS patients and the control subjects. On thirty-four occasions of stroke-like episodes, patients were administered 0.5g/kg/dose L-arginine or a placebo. The clinical symptoms, biochemical parameters (including aminoacids, ADMA, cGMP, and NOx) and intracranial hemodynamics were analyzed before and after administration. After administration of oral L-arginine, we evaluate the pharmacological effects on the frequencies and severity of stroke-like episodes in MELAS. **Results:** The levels of L-arginine (46.6 12.7mol/l), citrulline (23.2 10.2mol/l), and NOx (24.0 9.8mol/l) at acute phase of MELAS are significantly decreased than the control (108.1 27.6, 34.6 8.8, 45.4 30.5 mol/l), however, ADMA (0.45 0.10 mol/l) at acute is not significantly decreased. At 30 minutes after L-arginine infusion, all symptoms suggesting stroke were significantly improved in association with significantly increased levels of L-arginine, citrulline, NOx and cGMP. There was a increased uptake in the infarcted region showing improvement in rCBF in the fresh infarct region. The lactate and L/P ratio were recovered to that of interictal phase at 24 hours after L-arginine infusion. After the oral administration of L-arginine, the frequency and severity of stroke-like episodes are significantly improved. **Conclusions:** L-arginine therapy either intravenous infusion or oral administration improved the clinical symptoms and biochemical parameter, and therefore constitutes a new potential therapy for use in stroke-like episodes in MELAS.

**Transmitochondrial yeast strains containing the complete mouse mitochondrial genome: a new *in vivo* model system for analyzing mammalian nuclear-mitochondrial interactions.** Y. Yoon, M. Koob. Hum. Genet., Univ MN, Minneapolis, MN.

Although a growing number of mutations have been identified throughout the human mitochondrial genome that cause a wide range of devastating diseases and the critical importance of this genome is widely acknowledged, we still know amazingly little about many of the most basic aspects of mammalian mitochondrial molecular genetics. To a large degree detailed analyses of this genome are limited by significant technical hurdles: we still have not learned how to directly modify the mitochondrial genome *in vivo* and modifying the nuclear genes that interact with this genome is difficult. We now report that we have successfully generated strains of *Saccharomyces cerevisiae* that contain the entire mouse mitochondrial genome in their mitochondria rather than their own yeast mtDNA. This is the first report of the stable transfer of an isolated mtDNA genome into the mitochondria of a living organism. Since we can easily engineer the mouse mitochondrial genomes that we introduce into these yeast strains, we have created a new *in vivo* mammalian mitochondrial model system in which we can readily manipulate both the nuclear and mitochondrial sequences encoding mitochondrial molecular processes. Most of these processes are strictly dependent on the interaction between specific mtDNA sequences and the nuclear-encoded mitochondrial gene-products with which they have co-evolved, and so do not occur in otherwise unmodified transmitochondrial yeast. By adding the appropriate mammalian genes for nuclear-encoded mitochondrial proteins to these yeast, we will recapitulate such species-specific mitochondrial processes as transcription and the mammalian form of mtDNA replication in these transmitochondrial yeast strains. We have initiated a project in which we are utilizing this approach to determine the precise contribution from mtDNA sequences and nuclear-encoded proteins to the process of transcription initiation in the mammalian mitochondrial genome. We will present the details of the construction and early characterization of this new transmitochondrial model system as well as the results to date of our analyses of mammalian mitochondrial transcription.

**Natural History of Fabry Disease.** *M. Banikazemi*<sup>1</sup>, *R. Schiffmann*<sup>2</sup>, *J. Bultas*<sup>3</sup>, *G.E. Linthorst*<sup>4</sup>, *S. Packman*<sup>5</sup>, *S.A. Sorensen*<sup>6</sup>, *W.R. Wilcox*<sup>7</sup>, *R.J. Desnick*<sup>1</sup>. 1) Mt Sinai School of Medicine, New York, NY; 2) DMNB, NIH, Bethesda, MD; 3) University Hospital, Prague, Czech Republic; 4) Academic Medical Center, Amsterdam, The Netherlands; 5) Univ of California San Francisco, San Francisco, CA; 6) Univ of Copenhagen, Copenhagen, Denmark; 7) Cedars-Sinai Med Cntr, Los Angeles, CA.

Fabry disease results from deficient activity of  $\alpha$ -galactosidase A. Glycosphingolipids accumulate in cellular lysosomes, resulting in renal failure and cardiac and cerebrovascular complications. The natural history of the disease is not well known. We undertook a multicenter retrospective cohort study of patients with Fabry disease to determine their clinical manifestations. In all, 447 patients enrolled in this study at 27 sites. Mean age at Fabry diagnosis was 24 years for males and 30 years for females, 87% of patients had a family history of Fabry disease and 62% were males. Median plasma  $\alpha$ -galactosidase A levels for males (n=120) and females (n=64) were 0.52 and 3.99 nmol/hr/mL, respectively (normal 2.4-23.1 nmol/hr/mL). Mean duration of follow-up was 12.9 years. Median time between Fabry diagnosis and the first serum creatinine (S. Cr.) measurement was 4.3 years; for 25% of patients, the first S. Cr. value was available 13.9 years or more after diagnosis. The S. Cr. level was  $>1.5$  mg/dL among 25% of patients within 1 year of diagnosis. Once the patient's S. Cr was 1.5 mg/dL, the median time to progression (doubling of S. Cr. or development of end-stage renal disease) was 39 months. Renal function decline was rapid once S. Cr. levels reached 1.5 mg/dL. The mean age for development of cardiovascular events (MI, angina, arrhythmia, CHF, change in cardiac status) was 39 years. Cardiac arrhythmias were the most common cardiovascular events (n=162, 36%). The mean age for development of cerebrovascular events (TIA, stroke) was 42 years. Ischemic stroke was the most common cerebrovascular event (n=40, 9%). Early screening for end-organ damage should be undertaken to prevent complications of Fabry disease. Clinical trials are underway to demonstrate clinical benefit of ERT in patients with Fabry disease.

**PPAR agonist corrects fatty acid oxidation in CPT2-deficient myoblasts.** *J. Bastin, J.P. Bonnefont, A. Munnich, F. Djouadi.* INSERM U393, Hopital Necker, Paris, France.

Carnitine palmitoyltransferase 2 (CPT2) deficiency, one of the most common inborn error of mitochondrial fatty acid -oxidation (FAO) leads to recurrent attacks of rhabdomyolysis triggered by exercise, fasting or infections in childhood, or to serious cardiac damages in the neonatal period. It has been suggested that the severity of the disease is related to the residual enzyme activity and FAO capacity. Thus, we hypothesized that a drug able to stimulate FAO could have beneficial effects on CPT2 deficiency. The peroxisome proliferator-activated receptors (PPARs; and isoforms) are ligand activated nuclear transcriptional factors known to play a critical physiological role as lipid sensors and fatty acid metabolism regulators. Recent data identified PPAR as a potent FAO stimulator in C2C12 myotubes (Cell, 113: 159-170, 2003). This prompted us to test the effects of a PPAR agonist (GW0742, kindly provided by GlaxoSmithKline) on FAO in muscle cells of CPT2-deficient patients. Control or CPT2 deficient myoblasts were isolated from muscle biopsies and oxidation rates of tritiated palmitate (3H-Pal) were measured. CPT2-deficient myoblasts exhibited a 18% decrease in FAO compared to control cells (3.870.3 and 4.750.09 nmol3H-Pal/h/mg prot,  $p < 0.001$ , respectively). An overnight glucose deprivation of myoblasts resulted in an additional 24% decrease in CPT2-deficient cells (2.940.6 nmol3H-Pal/h/mg prot) and did not affect the FAO in control cells. Pretreatment of CPT2-deficient myoblasts with GW0742 (1M), 48h before glucose deprivation completely restored FAO to normal levels. Dose-response experiments (with concentrations ranging from 0.01 to 1 M) demonstrated that this PPAR agonist is very potent, as maximal effect was already reached at 0.01M. These are the first evidence of a possible pharmacological effect on CPT2 activity in myoblasts, and point out PPAR as a key regulator of mitochondrial -oxidation in human muscle cells.

**Controlled trial of Pamidronate in children with types III and IV OI: Lack of effect on motor function and pain.**

*A.D. Letocha<sup>1</sup>, H.L. Cintas<sup>2</sup>, S.M. Paul<sup>2</sup>, N.L. Gerber<sup>2</sup>, J.C. Marini<sup>1</sup>*. 1) BEMB/NICHD/NIH, Bethesda, MD; 2) Dept. of Rehabilitation Medicine, CC/NIH, Bethesda, MD.

Osteogenesis imperfecta, a disorder of type I collagen, causes severe osteoporosis and susceptibility to fractures from minimal trauma. Uncontrolled trials of bisphosphonates reported increased vertebral bone density and height, improved strength and functional level and decreased fractures and bone pain.

We completed a 2-year controlled trial of pamidronate in 18 children ages 6-14 years with types III and IV OI. Children in the treatment group received pamidronate (10 mg/m<sup>2</sup>/day for 3 days every 3 months). All children had quarterly rehabilitation assessments including measurements of function, strength, and pain. All patients were also assigned a home physical therapy regimen.

Treated patients experienced a significant ( $p=0.0003$ ) increase in vertebral BMD z-score compared to controls. They also had significant increases in L2 vertebral height and L1 and L2 area.

Motor skills related to ambulation were assessed with the 10-point BAMF. The treatment group BAMF at initiation was 6.11.8 vs 6.71.9 at 12 months ( $p=0.5$ ). The control group BAMF at the initiation was 6.62 vs 7.021.31 at 12 months ( $p=0.61$ ). Both groups, on average, used maximum gait aids. Manual muscle testing was assessed at each visit as the sum (total points 110) of abdominal, straight leg raise, hip abduction, extension, and flexion, and quadriceps strength. Lower extremity muscle strength did not change. The treatment group score was 67.120.9 at baseline vs 68.619.7 at 12 months ( $p=0.88$ ); control was 74.221.3 at initiation vs 74.614.3 at 12 months ( $p=0.97$ ). There was no significant decrease in pain in treatment or control groups on a 4-point scale.

Some patients reported increased endurance or decreased back pain, but most patients reported no perceptible changes. Thus, in contrast to reports from uncontrolled trials, we found no significant changes in ambulation level, lower extremity strength, or pain in OI children treated with pamidronate.

**Idebenone restores mitochondrial respiratory chain enzyme activities in cardiac muscle in Friedreichs ataxia.** *P. Rustin<sup>1</sup>, D. Bonnet<sup>2</sup>, D. Sidi<sup>2</sup>, A. Munnich<sup>1</sup>, A. Rötig<sup>1</sup>.* 1) INSERM U-393, Hopital Necker Enfants Malades, Paris, France; 2) Service de Cardiologie, Hopital Necker Enfants Malades, Paris, France.

The gene responsible for Friedreichs ataxia (FA) has been shown to encode a small protein, frataxin. Decreased frataxin causes a generalized deficiency of iron-sulphur proteins (ISP). Recent data support the view that frataxin plays a role in the mitochondrial synthesis of ISP that are subsequently delivered to the various compartments of the cell. Decreased amount of ISP can in turn be the target of an oxidative stress resulting from abnormal mitochondrial iron handling. This provided the rationale for an antioxidant treatment by idebenone, a drug already available and devoid of reducing effects on stored iron. A large open trial showed that idebenone had a significant effect on heart hypertrophy and function, but not on the neurological condition. The mechanism by which idebenone protects the heart remained to establish. Repeated endomyocardial biopsy showed the normalization of mitochondrial ISP activities in the first patient who was given idebenone since 1998. After 3 years of idebenone administration, heart hypertrophy had decreased to normal values and heart function had improved. Both the shortening fraction and the left-ventricular outflow obstruction had decreased, and b-adrenergic antagonist administration could be discontinued. After 5 years of idebenone administration, the heart hypertrophy has further decreased and no evidence of heart dysfunction was noted. Investigation of endomyocardial micro-biopsies showed that the activity of ISP was largely restored to normal. The striking recovery of mitochondrial respiratory chain enzyme activities brought about by idebenone parallels the improvement of ultrasound parameters and further supports the efficiency of idebenone in improving cardiomyopathy in FRDA. It also sheds light on the mechanism by which an antioxidant, such as idebenone, can have a spectacular effect on the cardiac dysfunction associated with this genetic disorder.

Program Nr: 2702 from 2003 ASHG Annual Meeting

**Chemically induced modification of DNA dynamics: towards chemogenotherapy in the repeat expansion disorders.** *D.G. Monckton, S. Mustafa, J.P. McAbney, M. Gomes-Pereira.* Institute of Biomedical and Life Sciences, University of Glasgow, Anderson College Building, 56 Dumbarton Road, Glasgow G11 6NU, UK.

Expanded repeats disorders such as myotonic dystrophy and Huntington disease share several features associated with DNA instability. In particular, somatic mosaicism of repeat length is often prominent and tends to be age dependent, tissue specific and expansion biased, properties that likely contribute toward the tissue specificity and progressive nature of the symptoms. However, pathology in these disorders is mediated via a variety of complex and unrelated routes. Thus, therapies aimed at the downstream effects of the expansion will be largely disease-specific. We propose that therapies targeted directly at the repeat mutation may have general utility in these disorders. Specifically, strategies that result in suppression of somatic repeat expansion would be expected to be of therapeutic benefit, whilst reversion of the expanded mutant repeat to within the range observed in the general population would be predicted to be curative. To this end we have determined that expanded repeat mutational dynamics may be modified in whole populations of cells by chronic exposure to genotoxic chemicals in a tissue culture model of unstable DNA. Reagents that result in both acceleration and, more importantly, deceleration of the rate of expansion have been identified. These data establish that drug induced modification of DNA dynamics is possible and suggest that chemogenotherapy presents a possible route to treatment in the repeat expansion disorders.
