

**Nuclear matrix attachment regions associated with chromosomal translocations in cancer.** *M. Goldman, M. Wuerth.* Dept Biol, San Francisco State Univ, San Francisco, CA.

Most cancers display genomic instability, including chromosome rearrangements. An understanding of the mechanism of cancer-associated gene rearrangement requires an accurate map of key features of chromatin that might be important in determining the location of breakpoints. We have analyzed chromosomal regions associated with recurrent translocations found in human cancers for the occurrence of nuclear matrix attachment regions (MARs or SARs). DNA sequences for genes associated with recurrent chromosome translocations found in human cancers were obtained from the National Cancer Institutes Cancer Genome Anatomy Project.

One hundred twelve genes associated with recurrent chromosome translocations found in human cancers were analyzed using MARFinder. Twenty-eight of those genes (25%) were predicted by MARFinder to have MARs in the immediate vicinity. Genes associated with translocations found in human cancers with predicted MARs were found on every chromosome except for chromosome 7. Nine of the 28 genes associated with chromosome translocations found in human cancers with predicted MARs were transcription factors or activators, and seven coded for zinc finger proteins. As a control, forty human housekeeping genes were also analyzed. Seven of those genes (17%) were predicted to have MARs, suggesting the MARs may be more highly represented in the vicinity of translocations. Showing an association between MARs and genes associated with chromosome translocation in human tumors could provide an important clue to understanding cell proliferation in human cancers. An association between MARs and translocation sites may provide insight into the mechanisms of chromosome translocation. The identification of MARs near translocation sites may provide information that could be used to improve diagnosis and detection of these key rearrangements, or in the discovery of drug targets for cancers associated with chromosomal translocations. Acknowledgment: This research was supported in part through the MBRS SCORE Program and a Research Infrastructure in Minority Institutions from the National Institutes of Health.

**Genomic Imbalances in Schwann Cells of Neuroblastic Tumors.** *G. Kim<sup>1</sup>, S. Park<sup>2</sup>, S. Park<sup>3</sup>, C. Kim<sup>4</sup>.* 1) Perinatology Research Branch, National Institute of Child Health and Human Development, Department of Obstetrics and Gynecology, Wayne State University/Hutzel Hospital, MI, USA; 2) Department of Anatomy, Ehwa womans University College of Medicine, Seoul, Korea; 3) Institute of Human Genetics, Brain Korea 21 Biomedical Sciences, Korea University College of Medicine, Seoul, Korea; 4) Department of Pathology, Seoul National University College of Medicine, Seoul, Korea.

Neuroblastic tumors are characterized by their potential for differentiation *in vivo* and *in vitro*. *In vivo* differentiation into neuroblastic/ganglionic cells and Schwannian stromal cells are frequently encountered and it has been believed that neural crest-derived sympathetic precursor cells undergo differentiation into both lineages. However, some of the recent studies raised a possibility that Schwannian stromal cells are nonneoplastic cells, which have been recruited from surrounding milieu. We assessed this issue by comparative screening of genetic constitution of neuroblastic/ganglionic cells and Schwannian stromal cells using degenerated oligonucleotide primed-PCR comparative genomic hybridization. A total of five cases of ganglioneuroblastoma and a case of ganglioneuroma were analyzed. Both cell types had frequent gains and losses showing that Schwannian cells are also neoplastic. Schwannian stromal cells shared some of the genetic changes with neuroblastic/ganglionic cells in same tumors. We additionally screened lymph node metastasis of neuroblastic tumors and could easily demonstrate S-100 positive Schwannian cells in metastatic lymph nodes. Genomic imbalances and metastatic potential of Schwannian stromal cells clearly indicate that Schwannian stromal cells are neoplastic. In the context that Schwann cells interact with neuronal cells via several signals, biological pathways driving the neoplastic cells to differentiate into Schwannian stromal cells are worth to be further investigated.

**Genomic imbalance changes associated with malignant potential in gastrointestinal stromal tumors.** *Y. Chen*<sup>1</sup>, *C.C. Tzeng*<sup>2</sup>, *C.P. Liou*<sup>2</sup>, *M.Y. Chang*<sup>2</sup>, *C.F. Li*<sup>2</sup>, *C.N. Lin*<sup>2</sup>. 1) Department of Surgery, Chi-Mei Foundation Hospital, Tainan, Taiwan, Republic of China; 2) Department of Pathology, Chi-Mei Foundation Hospital, Tainan, Taiwan, Republic of China.

Gastrointestinal stromal tumors (GIST) are the most common mesenchymal tumors of gastrointestinal tract. Current criteria for the diagnosis of malignant GISTs do not always reliably predict patient outcome. In order to search for genetic markers with prognostic potential, chromosomal imbalance changes in 28 GISTs were analyzed using comparative genomic hybridization and correlated with clinicopathological characteristics. Except a small rectal tumor, all other GISTs, including 14 from stomach, 11 from small intestine, one from esophagus, and one from rectum, exhibited chromosomal alternations. Losses were more common than gains. The median number of chromosomal changes in high-risk GIST was significantly higher than in low-risk GIST (5.602.59 vs. 3.382.55), especially for the changes of loss (4.601.84 vs. 2.632.13). Loss of 14q was the most common change, not only in low-risk GISTs (70.6%, 12/17) but also in high-risk GISTs (54.5%, 6/11). Several other additional changes detected in more than 25% of high-risk GISTs were losses of 1p, 10q, 13q, 15q, 18q, and 22q and gains of 5p, 12q, 17q, and 20q. Among these changes, more frequently detected in high-risk GISTs than in low-risk GISTs were losses of 13q (5/11 vs. 1/17,  $P = 0.044$ ) and 22q (7/11 vs. 3/17,  $P = 0.038$ ). Finally, the most striking finding was loss of 10q, with minimal overlapping on q11-q22, which was identified only in two metastatic small intestinal GISTs and one esophageal GIST. Our finding, together with results reported by previous studies, first indicated that loss of 10q, probably on q11-q22, seems to be chromosomal loci potentially harboring tumor suppressor gene(s), which may relate to early recurrence and/or metastasis of GISTs during malignant transformation.

**Some three way translocations arise in two steps.** *H.A. Aviv, A. Gonzalez, I. Maxwell, P. DeAngelo, S. Szardenings.* Pediatrics/Genetics, MSB F669, UMDNJ-New Jersey Medical School, Newark, NJ.

The 9;22 translocation in chronic myeloid leukemia (CML) can be a simple reciprocal translocation or a three way translocation involving an intermediate chromosome. The latter also results in Philadelphia (Ph) chromosome positive classical CML. Patients with both types of translocations usually have the same prognosis. The mechanism by which three way translocations are formed is unknown, but it is assumed that all three chromosomes undergo breakage and rearrangement simultaneously. We present a patient with acute lymphoblastic leukemia (ALL) and the classical 9;22 translocation at diagnosis. At relapse, the patient had a three way translocation involving chromosomes 9, 22 and 6. The apparent three way translocation thus arose from a second translocation involving the derivative chromosome 9 and chromosome 6. The pattern of 2 fusion signals obtained with BCR/ABL dual fusion probes also supports this conclusion. The mechanism of two consecutive translocations masquerading as a three way translocation may be more common in hematological malignancies due to increased chromosomal instability. Patients with "pseudo" three way translocations may have a more advanced disease and worse prognosis than patients with "classical" three way translocations. The use of dual fusion probes, when available, helps to distinguish between the two types of translocations. The use of dual fusion probes, when available, helps to distinguish between the two types of translocations. Complex constitutional translocations may also be formed by the same mechanism. We are currently investigating the origin of other three way translocations, both acquired and constitutional.

**Cytogenetic characterization of thyroid tumors and cell lines using comparative genomic hybridization, spectral karyotyping and G-banding.** *T. Foukakis*<sup>1,2,3</sup>, *S.R. Thoppe*<sup>1</sup>, *S. Lagercrantz*<sup>1</sup>, *T. Dwight*<sup>1,2</sup>, *A. Svensson*<sup>3</sup>, *W.O. Lui*<sup>1</sup>, *G. Wallin*<sup>3</sup>, *J. Zedenius*<sup>2</sup>, *C. Larsson*<sup>1</sup>. 1) Endocrine Tumor Unit, Department of Molecular Medicine, Karolinska Hospital CMM L8:01, Stockholm, Sweden; 2) Centre for Metabolism & Endocrinology, Department of Surgery, Karolinska Institutet at Huddinge University Hospital, Stockholm, Sweden; 3) Department of Surgery, Karolinska Hospital P9:03, Stockholm, Sweden.

To further delineate the role of chromosomal aberrations in thyroid tumors, we performed karyotypic analyses of thyroid cell lines and primary tumors. We cytogenetically characterized five established thyroid cancer cell lines (MRO, DRO-90, ARO-81, CGTH W-1, CGTH W-3) by comparative genomic hybridization (CGH), spectral karyotyping (SKY) and regular G-banding. By CGH, the most common gains were detected at chromosomes 1,5,7,10,11,17,19,20 and 21, whereas losses were most common at chromosomes 4, 5, 6, 9, 10 and 18. SKY, in combination with G-banding revealed karyotypic abnormalities, structural and numerical, in all five cell lines. Moreover, we karyotyped 16 primary thyroid tumors using SKY. Three of the 11 thyroid carcinomas studied exhibited abnormal karyotypes. In case T1, a follicular thyroid carcinoma, we observed translocations t(2;10), t(2;5) and losses of chromosomes 10 and 22. In tumor T2, a papillary thyroid carcinoma (PTC), we observed a balanced translocation t(3;15), while T3, a case of metastatic PTC, carried several clonal translocations involving chromosomes 1,2,3,5,14,15,16,17 and 19. Numerical aberrations were observed in two of the five follicular adenomas we analyzed. CGH was later performed for the cases harboring abnormal karyotypes, and the copy number changes correlated well with the karyotypic findings. Our results provide evidence of chromosomal regions frequently involved in thyroid tumorigenesis, while further characterization of the observed translocations may lead to the identification of novel fusion oncogenes for thyroid cancer.

**Molecular cytogenetic characterization of a case of Müllerian Adenosarcoma.** *E. Drozd-Borysiuk<sup>1</sup>, B. Issa<sup>1</sup>, B. Hong<sup>1</sup>, J. Stratton<sup>1</sup>, A. Brothman<sup>1</sup>, C. Coffin<sup>2</sup>, K. Albritton<sup>3</sup>, Z. Chen<sup>1</sup>.* 1) Pediatrics/Cytogenetics, University of Utah, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT; 3) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

A variety of tumors of Müllerian origin, composed of both epithelial and mesenchymal elements, have been described in the literature. These tumors range from benign entities, such as a papillary adenofibroma, through the locally aggressive adenosarcoma to the fully malignant forms of malignant mixed Müllerian tumors. Müllerian adenosarcoma is a distinctive type of mixed Müllerian tumor of the female genital tract. So far no cytogenetic data have been documented on Müllerian adenosarcoma in the literature. We report here the chromosomal findings of a Müllerian adenosarcoma in a 15-year-old female. Cytogenetic and molecular cytogenetic analysis revealed a complex karyotype involving chromosomes 2, 8, 10, 13, 19, and 21. These numerical and structural abnormalities may be of etiologic significance. This report may highlight the potential value of molecular cytogenetic analysis in differential diagnosis of Müllerian tumors. More cases are warranted to further genetically characterize this type of neoplasm.

**Does FISH improve the cytology detection in urothelial bladder carcinoma? A Brazilian experience. G.J.F.**

*Gattas*<sup>1,2</sup>, *A.C. Bomfim*<sup>3</sup>, *M. Srougi*<sup>3</sup>, *K.R.M. Leite*<sup>2</sup>, *L.H. Camara-Lopes*<sup>2</sup>. 1) Dept of Legal Med, Bioethics and Occup Health, Medical School, São Paulo University, São Paulo, Brazil; 2) Molecular and Surgical Pathology Laboratory of Sirio Libanês Hospital, São Paulo, SP, Brazil; 3) Division of Urology, Federal University of São Paulo, São Paulo, SP, Brazil.

The urothelial carcinoma (UC) is the most common malignancy of the urinary tract. Bladder tumors are grossly staged by superficial (pTa-T1 stages) or invasive (pT2-T4 stages) related to the bladder wall invasion. We prospectively evaluated the sensitivity and specificity of cytology and FISH for the detection of UC in voided urine specimens of three groups: group 1 with 53 UC patients (33 men: 72,87 yo; 20 women: 67,414 yo) with tumor identification by cytology and histopathology (17 pTa, 17 pT1, 9 pT2, 7 pT3, 2 pT4); group 2, 23 individuals (mean age 6510 yo) with previous history of UC; group 3, 42 patients (mean age 6712 yo) with prostate hyperplasia. For FISH evaluation we used UroVysion Multi-color Probe (Vysis) and the positive criteria recommended. For the group 1 the cytology and FISH was positive for 35/53 (66%) and 38/49 (77,5%) and the analysis was not possible in 4 FISH cases; group 2 cytology and FISH was positive for 6/24 (25%) and 9/24 (37,5%); group 3 the cytology and FISH was positive for 11/42 (26%) and 7/39 (17,9%) with 3 FISH cases not analysed. Only the FISH was 100% positive for tumors from pT1-pT4 stages (32/32). For both techniques the pTa stage tumors were poorly identified (35%). The FISH sensitivity was higher (77%) compared with cytology (66%) although the specificity was very similar for both (75% FISH; 74% cytology). In superficial tumors the recurrence risk (70-90% in ten years) and the progression to invasive tumor (pTa: 2-4%; pT1:20-30%) are very important. If we considered that in the pT1 stage tumors the patients treated by endoscopy resection are at risk of 20-30% for progression to pT2-T4 stages, with poor prognosis, the FISH was more informative than cytology. We are increasing the sample to better understand the contribution of each test in urine UC diagnostic. This study was supported by FAPESP.

**Molecular and cytogenetic characterization of a novel translocation 4;22 involving BCR and PDGFRA in a patient with chronic myelogenous leukemia (CML).** *B.K. Goodman<sup>1</sup>, A.M. Safley<sup>2</sup>, S. Sebastian<sup>1</sup>, C.A. Tirado<sup>1</sup>, T. Collins<sup>3</sup>, T.T. Stenzel<sup>4</sup>, J.Z. Gong<sup>1</sup>.* 1) Department of Pathology; 2) School of Medicine; 3) Department of Medicine, Duke University Medical Center, Durham, NC; 4) Vysis, Inc., Downers Grove, IL.

We report a case of Philadelphia chromosome-negative chronic myelogenous leukemia (CML) with translocation (4;22)(q12;q11.2) juxtaposing the breakpoint cluster region (BCR) and platelet-derived growth factor-alpha (PDGFRA) loci. The patient, a 57 year-old male with a history of stage IV diffuse large B-cell lymphoma status post six cycles of combination chemotherapy in 1999, presented in August 2002 with enlarged lymph nodes, anemia and marked leukocytosis, consistent with a myeloproliferative disorder (MPD). A bone marrow biopsy showed granulocytic hyperplasia, neutrophilia and mild eosinophilia. Initial evaluation using interphase FISH for BCR-ABL, to rule out the translocation 9;22, showed a variant signal pattern consistent with rearrangement of BCR at 22q11.2, but not ABL at 9q34. Analysis of patient cDNA by reverse transcription polymerase chain reaction (RT-PCR) for the BCR-ABL transcript was negative. Routine G-band chromosome analysis of the patient's bone marrow showed, instead, an abnormal clone with rearrangement of chromosomes 4 and 22. We performed RT-PCR using primers for BCR and a candidate gene at 4q12, and sequenced the product, demonstrating an in-frame 5'-BCR/3'-PDGFRA fusion transcript that includes a short intronic region. PDGFRA encodes a receptor tyrosine kinase and shares structural and organizational homology with the c-kit and colony stimulation factor-1 receptor genes. While the incidence of MPD involving translocations of PDGFRB has been well established, to our knowledge there has been only one previous report describing a BCR-PDGFRA fusion gene, in two patients diagnosed with atypical CML. Here we present molecular and cytogenetic characterization of BCR-PDGFRA-positive MPD in a patient who is showing regression of leukocytosis following treatment with imatinib mesylate, which targets the tyrosine kinase domain of the ABL locus.

**Analysis of 25 cases of gastric adenocarcinoma with CGH.** *S. Cheng*<sup>1</sup>, *C. Wang*<sup>1</sup>, *W. Chuang*<sup>2</sup>, *T. Hwang*<sup>3</sup>. 1) Dept Anatomy, Chang Gung Univ, Col Medicine, Kweishan, Taoyuan, Taiwan; 2) Dept Pathology, Chang Gung Memorial Hospital, Kweishan, Taoyuan, Taiwan; 3) Dept Surgery, Chang Gung Memorial Hospital, Taipei, Taiwan.

Gastric adenocarcinoma specimens were collected from the tissue bank in the Department of General Surgery, Chang Gung Memorial Hospital, Linkou, Taiwan. With cryosection and hematoxylin and eosin staining the tumor tissues were identified, and the specimens with primarily tumor tissue were selected. The genomic DNAs were extracted from selected tissues for labeling with biotin-16-dUTP by nick translation. The DNAs from normal male and female are served as control, and are labeled with digoxigenin-11-dUTP. The technique comparative genomic hybridization (CGH) was used for examining the copy number change of chromosomes of individual gastric tumor cases. Among 25 cases examined 14 cases are of tubular type, and 11 cases are signet-ring cell type according to WHO classification. Basing on Lauren classification 14 cases are of intestinal type. The 14 cases are same as the 14 cases of WHO classification. The other 11 cases are of diffuse type. The CGH analyses were completed with Quips software (Applied Imaging). Among the 14 cases of tubular type 50% have a gain at 1q, 43% at 3q, and 36% at 4q; while 29% have a loss at 9p. Among the 11 cases of signet-ring cell type 55% have a gain at 4q and 5q, 45% at 6p and 8q, 36% at 3q, 5p, and 8p, and 27% at 1q, 20p, and 20q; while 36% have a loss at 9q, 16q, 21q, and 22q, 27% at 1q, 13p, 16p, 17q, and 22p.

**Homozygous deletion of p16 gene in childhood acute lymphoblastic leukemia : clinical outcome and prognostic significance.** *S. Barrette*<sup>1</sup>, *S.K. Murthy*<sup>2</sup>. 1) Departments of Haematology and Oncology, Sainte Justine Hospital, Montreal, PQ, Canada; 2) Department of Pathology, Cytogenetics Laboratory, Sainte Justine Hospital, Montreal, PQ, Canada.

Cytogenetic abnormalities involving chromosomal band 9p21-22 has been reported in 7% to 13% of acute lymphoblastic leukemia (ALL). Homozygous deletion of both p16 and p15 genes occur in at least 60% of T- and 20% of B-cell lineage cases, and is the major means of gene inactivation in childhood ALL. It is mainly associated with higher relapse rates and poor outcome. We present here a case of childhood B-ALL with homozygous deletion of p16. At age 3 1/2 years, she presented with WBC count of 27,000/uL, CNS negative, no mediastinal mass, and was treated according to the standard risk protocol of DFCI 95-001 (Dana Farber Cancer Institute), with no cranial irradiation. Cytogenetic analysis at initial diagnosis showed a normal karyotype. RT-PCR for t(9;22), t(12;21), t(4;11), t(1;19) and FISH for 11q23 were negative. She responded well to the therapy which ended in Sept 2001. In Nov 2001 she presented with facial palsy and relapse in both bone marrow and CNS was diagnosed. Chromosome analysis showed presence of del(9p) in 7 out of 24 cells. She was then treated according to the high-risk arm of DFCI 2000-01. Remission was attained within a month of treatment and was consolidated with a fully matched unrelated bone marrow transplantation. She did well for 124 days post transplant, but again had a marrow and CNS relapse. FISH analysis with LSI p16/CEP9 probe (Vysis) showed homozygous deletion of p16 in 61% cells and heterozygous deletion in 13% cells. The patient died in Sept 2002 at age 6. The second case is a 23 months old female with pre B-cell ALL. Her karyotype at diagnosis was 45,XX,i(9)(q10),der(20) and FISH with p16 probe showed homozygous loss in 80% of cells. She is still under treatment. Subtle cytogenetic rearrangements involving p16 may be missed by routine cytogenetics and thus a careful molecular cytogenetic analysis is recommended to identify this subgroup of standard risk patients with increased risk of treatment failure, and poor outcome.

**Genetic abnormalities in human Langerhans Cell Histiocytosis derived cell line (DOR-1) detected by Comparative Genomic Hybridization.** *J. GOGUSEV<sup>1</sup>, L. TELVI<sup>2</sup>, I. MURAKAMI<sup>1</sup>, C. GLORION<sup>3</sup>, F. JAUBERT<sup>4</sup>.* 1) INSERM U507, Necker Hosp, Paris; 2) Cytogenetics Laboratory, Paris; 3) Orthopaedic Surgery Department, Paris; 4) Pathology Department, Paris, France.

Langerhans cell histiocytosis (LCH) is a disease characterized by the presence of destructive granulomas containing CD1a+ Langerhans-like dendritic cells admixed with lymphoid and eosinophilic cells. Recent molecular genetic studies indicated monoclonal cell expansion and chromosomal abnormalities in both unifocal and disseminated LCH. Very recently, we established in our laboratory a LCH-derived cell line, called DOR-1. This cell line was established from an unifocal lytic lesion of bone from a three years old girl. DOR-1 cells grow as a flat adherent stromal-like cells. On R-banding a notably complex karyotype was observed with numerous aberrant chromosomes including a large dicentric marker present in more than 10% of cell metaphases. In addition, a structural rearrangement t(9;17) was found in approximately 20% of the metaphase spreads indicating clonal abnormality. The t(9;17) was confirmed by dual-color FISH using specific whole chromosomes painting probes specific for chromosomes 9 & 17 and by CGH technique. Repeated CGH experiments demonstrated genomic aberrations in DOR-1 cells appearing as a DNA copy number losses located on chromosomes 1p, 5p, 7p, 9q, 13q, 16p, 17p & 18. DNA copy number gain was observed on chromosomes 2 & 12. For comparison, CGH analysis was applied to the identification of genomic changes in a histologically defined area from the original LCH lesion. DNA copy number losses were detected on chromosomes 1p, 5, 6, 7, 9, 16, 17 & 22q. Gain of DNA copy number was observed on chromosome 2q, 4q & 12. These findings indicate that DOR-1 cells exhibit complex molecular cytogenetics anomalies and share certain molecular features with the original LCH tissue. The structural t(9;17) and the large dicentric chromosome might be serve as a remarkable new chromosomal markers in early diagnosis and treatment of patients.

**Cellular Leiomyoma: A Genetically Distinct Entity Among Benign Uterine Tumors.** *N. Christacos*<sup>1,3</sup>, *P. Dal Cin*<sup>2,3</sup>, *C.C. Morton*<sup>1,2,3</sup>, *B.J. Quade*<sup>2,3</sup>. 1) Department of Obstetrics, Gynecology and Reproductive Biology, Brigham and Womens Hospital, Boston, MA; 2) Department of Pathology, Brigham and Womens Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA.

Uterine leiomyomata (UL) are the most common pelvic tumors in women. These tumors occur in nearly 77% of women of reproductive age. Cytogenetic analysis of UL show that about 40% of these tumors have simple, clonal chromosomal rearrangements. In contrast, leiomyosarcomas (LMS), typically have complex numerical and structural abnormalities. Currently, little is known about the cytogenetics and molecular genetics of the histologic variants of UL. From the subset of karyotypically abnormal UL out of ~ 1000 karyotyped tumors, we identified a group of 8 cases exhibiting near diploid karyotypes with loss of almost the entire short (p) arm of chromosome 1 (del(1)(p11p36)). Loss of 1p was frequently associated with other aberrations. The histological diagnosis was available in 5 of the 8 tumors. Four tumors were diagnosed as cellular UL; and one tumor displayed both hypercellularity and nuclear atypia. LOH for chromosomal regions 1p36.2 and 1p11.1 using PCR on archival DNA from 5 UL with the histological diagnosis of cellular or atypical leiomyomata and matched myometrium was performed. The cytogenetic analysis of these archival UL was unknown. We found that UL from 2 out of 5 individuals demonstrated LOH for either the majority of the short arm of chromosome 1 (del(1)(p11p36)) or part of the short arm of chromosome 1 (del(1)(p11)). RNA from selected tumors was profiled using Affymetrix GeneChips and those profiles were compared to previously reported expression profiles of myometrium, UL, and uterine LMS using 153 probe sets. The transcriptional profile of two tumors with chromosome 1 abnormalities were more similar to those of LMS than to profiles of myometrium and UL as determined by hierarchical cluster analysis. Loss of 1p in UL appears to define a subgroup of tumors distinct from those previously recognized. Further, 1p- appears to be associated with a specific histologic phenotype. The similarity between the transcriptional profiles of LMS and UL with 1p- supports a common pathogenetic mechanism.

**Clonal evolution in a case of acute promyelocytic leukemia.** *S.R.S. Gottesman<sup>1</sup>, A. Babu<sup>2</sup>, R. Zeng<sup>2</sup>, V.*

*Mizhiritskaya<sup>2</sup>, M.J. Macera<sup>2</sup>.* 1) Department of Pathology, SUNY Downstate Medical Center, Brooklyn, NY; 2) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

A 69 year old female, at preadmission for insertion of a cardiac pacemaker, was found to be severely neutropenic with normal red blood cell counts and normal platelets. A repeat test, one month later, showed that she had a neutrophil count of 179/L with normal platelets (166K/L), decreased lymphocytes (1024/L) and slightly decreased red blood cells ( $3.7 \times 10^6/\text{fL}$ ). The patient received granulocyte-colony stimulating factor after which she raised her white blood cell count only minimally but increased her percentage of mature neutrophils. Within two weeks, her platelets dropped to a critical level of 17K/L and a bone marrow was performed. Chromosome analysis of the bone marrow revealed three separate cell lines, 46,XX, der(5)t(5;12)(p13;q15), ?del(11)(p11.2p12),der(12)(1qter1q25::12p1312q15::5p135pter),t(15;17)(q22;q21) [30]/46,XX,t(5;12)(p13;q15),?del(11)(p11.2p12),t(15;17)(q22;q21),add(20)(p12)[11]/46,XX [9]. The presence of the t(15;17) was confirmed by FISH analysis. The cytogenetic hallmark of acute promyelocytic leukemia (APL, M3) is the presence of a translocation between chromosomes 15 and 17, as the t(15;17) is present in close to 100% of the reported cases and therefore is diagnostic for APL (AML-M3). Unlike other leukemias, the t(15;17) is generally seen as a sole cytogenetic abnormality. Clonal evolution typically proceeds with minimal abnormalities and then additional abnormalities are acquired as the disease progresses; here both cell lines have three common abnormalities, the t(15;17), t(5;12) and the del (11), with an acquired unique abnormality. This case is very interesting because of the complex abnormalities associated with the t(15;17) and its rather rapid clonal evolution as evident from two distinct sidelines (clones). It is essential to follow up such rare cases for they may provide information that is helpful towards understanding the course of the disease and its therapeutic respons.

**Incidence of mono- and bi-allelic deletions involving 13q14 in B-cell chronic lymphocytic leukemia (B-CLL) as detected by fluorescence in situ hybridization (FISH).** *A.W. Block<sup>1</sup>, J.M. Panasiwicz<sup>1</sup>, K.C. Miller<sup>2</sup>, Z.P. Bernstein<sup>2</sup>, A. Chanan-Khan<sup>2</sup>.* 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst, Buffalo, NY; 2) Department of Medicine, Roswell Park Cancer Inst, Buffalo, NY.

B-CLL, the most common leukemia in adults, is a malignant disorder characterized by progressive accumulation of mature appearing functionally compromised B-lymphocytes. Conventional cytogenetic (CC) and FISH-based studies have identified recurrent numerical and structural chromosome abnormalities with prognostic significance in B-CLL. Patients with 13q14 deletion, the most common aberration, are reported to have favorable prognosis. Using a FISH panel that identified specific numerical and structural abnormalities (+12, del(13q), del(11q), del(17p), 14q32 abn), we studied peripheral blood and bone marrow from 55 unselected B-CLL patients (pts) to investigate the incidence and clinical relevance of mono- and bi-allelic deletions involving the 13q14 region. The Vysis, Inc. LSI 13 (containing RB1) and D13S25 (1.6 cM distal to RB1) probes were co-hybridized to determine copy number and estimate deletion size. 24/55 pts (15 males, 9 females; median age 61, range 38-85 yrs) had either a mono- (n=14) or bi-allelic (n=10) deletion of 13q14. Range in deletion size was noted with mono-allelic deletion of D13S25 and mono-allelic deletion of both RB1 and D13S25 in 9/24 and 5/24 pts, respectively. 10/24 pts showed bi-allelic deletion of D13S25 with 4/10 also having mono-allelic deletion of RB1. Cell populations were heterogeneous with losses of 1-2 copies of D13S25 in 7/24 pts. Two or more concurrent aberrations were seen in 7/24 pts with 6/7 pts having del(11q); these pts had chemotherapy refractory advanced stage disease and poor clinical outcome. A model has been proposed for B-CLL pathogenesis, suggesting deletion of putative enhancer sequences and/or genes resulting in inactivation of tumor suppression by haploinsufficiency. Alternatively, inherent instability in this region may lead to the interstitial deletions of 13q14 that are also seen in other neoplasms including multiple myeloma, mantle cell and peripheral T cell lymphoma, prostate cancer, and squamous cell carcinoma of the head and neck.

**Ubiquinol cytochrome-c reductase (UQCRFS1) gene amplification in primary breast cancer core biopsy samples.**

*Y. Ohashi<sup>1</sup>, R. Young<sup>1</sup>, S. Kaneko<sup>2</sup>, T. Copples<sup>3</sup>.* 1) Dept OB/GYN, Univ South Carolina, Columbia, SC; 2) Dept OB/GYN, Nagoya City Univ, Nagoya, Japan; 3) Dept Radiology, Palmetto Health Alliance, Columbia, SC.

Ubiquinol cytochrome-c reductase (UQCRFS1), otherwise known as the Rieske Fe-S protein, is a key subunit of the cytochrome bc1 complex (complex3) in the mitochondria. This protein is important in redox reactions. Although UQCRFS1 is used primarily in mitochondria, the gene itself is located in the nuclear genome (19q12). We recently reported amplification of UQCRFS1 gene in ovarian carcinoma using FISH probes. Including our previous study on ovarian carcinoma, there have been just two articles reporting UQCRFS1 amplification associated with malignancy. However, there has thus far been no report of UQCRFS1 gene amplification associated with breast cancer. The purpose of this study is to evaluate gene copy number of UQCRFS1 gene in primary breast cancers.

Samples were obtained from image-guided core-needle biopsies in forty patients with non-treated breast cancers. Twenty-nine cases were histopathologically classified as invasive ductal carcinoma, 1 as ductal carcinoma in situ, 9 as invasive lobular carcinoma and 1 as invasive mixed carcinoma. To examine UQCRFS1 gene copy number, we employed FISH using BACs RP11-46I12 (19q12-19q13) which harbors UQCRFS1 gene, RP11-110J19 (19p11-19q11) which overlap to RP11-46I12 and CA125 (19p13.2) as a control gene. A sample with a copy number ratio (UQCRFS1/CA125) greater than 2.0 was considered to be amplified. The data were evaluated blindly of histopathological factors. UQCRFS1 copy number per cell ranged from 1.9 to 18.6, the mean was 3.3. CA-125 copy number per cell ranged from 1.0 to 3.6, the mean was 2.3. Amplification of UQCRFS1 gene was found in five of 39 specimens (12.8%). All of these amplified cases showed between 4.0 and 18.6 signals per cell. The specimens with amplified UQCRFS1 gene were significantly associated with high grade of cancer cells ( $p=0.005$ ). Our results suggest that the UQCRFS1 gene appears to be involved in development of more aggressive phenotype of breast cancer.

**Do cytogenetic abnormalities precede morphological abnormalities in developing malignant conditions? J.K.**

*Northup<sup>1</sup>, Y. Ge<sup>1</sup>, S. Gadre<sup>1</sup>, L.H. Lockhart<sup>2</sup>, G.V.N. Velagaleti<sup>1,2</sup>.* 1) Department of Pathology; 2) Department of Pediatrics, University of Texas Medical Br, Galveston, TX.

Cytogenetic evaluation of bone marrow and neoplastic tissues plays a critical role in determining patient management and prognosis. Here we highlight two cases in which the cytogenetic studies challenge the common practice of using hematological and morphological changes as key factors in malignant disease management. The first case is that of a lymph node sample from a 40-year-old male with a history of non-Hodgkins lymphoma sent to determine if the lymphoma had progressed to high-grade. Cytogenetic studies from bone marrow showed multiple clonal abnormalities, most notably a der(18) from a t(14;18) which is associated with high-grade NHL. Results of hematological studies of the same tissue showed no evidence of transformation to high-grade (less than 15% blasts with rare mitotic figures). In spite of two cycles of chemotherapy with fludarabine, the patient has not shown any improvement clinically. The non-responsiveness of this patient to traditional chemotherapy suggests possible progression to high-grade lymphoma as suggested by cytogenetic analysis. The second case is of a patient with a history of HIV and blastic NK leukemia/lymphoma. Hematological studies of ascitic fluid classified the patient as having primary effusion lymphoma (PEL). Hematological studies on bone marrow from this patient were normal with no evidence of malignancy. Cytogenetic evaluation of the bone marrow showed multiple clonal abnormalities including a t(8;14). This rearrangement is commonly associated with Burkitts lymphoma (BL). To our knowledge, this is the first case wherein a morphologically normal bone marrow showed presence of clonal abnormalities consistent with BL or PEL. After two cycles of CHOP chemotherapy, the patients general condition and ascitis improved and she was discharged. These studies clearly demonstrate that genetic changes often precede morphological change in a developing malignant condition. Therefore, the critical information needed to manage patient care of malignant disorders may be incomplete or inaccurate if cytogenetic evaluation is overlooked.

**Cytogenetic and molecular cytogenetic evidence of distinct cell populations with bcr/abl fusion involving M-bcr and m-bcr breakpoints in a patient with chronic myeloid leukemia.** *A.S. Kulharya<sup>1,2</sup>, K.L. Satya-Prakash<sup>1,2</sup>, Y. Nalamolu<sup>2</sup>, F. Mazella<sup>2</sup>, J. Hiemenz<sup>2</sup>.* 1) Dept Pediatrics, Medical Col Georgia, Augusta, GA; 2) Dept Pathology and Medicine, Medical Col Georgia, Augusta, GA.

In 95% of cases of chronic myeloid leukemia (CML), the BCR-ABL fusion involves a break within the major breakpoint cluster region (M-bcr) resulting in a p210 fusion protein. Rare cases of CML have been described involving a break within the minor breakpoint cluster region (m-bcr) resulting in a p190 fusion protein. In several studies co-expression of p190 and p210 has been shown in CML patients in chronic phase. The co-expression of major and minor transcripts has been demonstrated only by RT-PCR analysis. We present a 40-year old leukemia patient with distinct cell populations of BCR/ABL fusion involving minor and major breakpoints in the BCR gene. Cytogenetic analysis of bone marrow showed two distinct abnormal clones, one with classic Ph chromosome and another with translocation of BCR gene to a rearranged chromosome 9. The karyotype is: 46,XY,t(9;22)(q34;q11.2)[2]/46,XY,der(9)inv(9)(p13q34)t(9;22)(q34;q11.2)[18]. FISH was performed using a BCR/ABL fusion probe that detects M-bcr and m-bcr breakpoints within the BCR gene. Eighty percent of the cells analyzed are consistent with a fusion at the minor breakpoint and 15% cells are consistent with a fusion of bcr and abl at the Major breakpoint. The remaining 5% cells do not show any bcr/abl fusion. It is concluded from these observations that the translocation involving chromosome 9 with an inversion represents the clone with the m-bcr breakpoint while the smaller clone with an apparent classic Ph chromosome represents a break at the M-bcr in the BCR gene. Alternative splicing of the BCR gene is thought to be responsible for the co-expression of M-bcr and m-bcr transcripts as two distinct cell populations have not been shown previously. Our patient provides physical evidence of two distinct cell populations that individually involve the M-bcr and m-bcr breakpoints in the fusion of BCR and ABL gene. These two cell populations indicate that independent clonal events are responsible for co-expression M-bcr and m-bcr products.

**Chromosome Analyses of 16 Cases of Wilms Tumor: Different Pattern in Unfavorable Histology.** A. Mohamed<sup>1</sup>, E. Peres<sup>2</sup>, B. Cushing<sup>2</sup>, S. Abella<sup>2</sup>, S. Savasan<sup>2</sup>. 1) Dept Pathology, Cancer Cytogenetics, Wayne State Univ, Detroit, MI; 2) Division of Pediatric Hematology/Oncology, Childrens Hospital of Michigan, Barbara Ann Karmanos Cancer Institute, Wayne State University School of Medicine, Detroit, MI, 48201.

Wilms tumor is the most common malignant tumor of the kidney in the pediatric population, accounting for 98% of childhood renal cancers. The incidence of Wilms tumor is 1 per 10,000 children, with the majority of cases being diagnosed before the age of 6 years. Cytogenetic analyses of 16 cases of Wilms tumor with abnormal karyotype were reviewed. Fifteen cases had unilateral tumors and one was bilateral. Three tumors exhibited the unfavorable histology whereas the remaining tumors were categorized into the favorable histology group. Of the 17 tumors with abnormal clonal aberrations: nine tumors were hyperdiploid (53%), seven had pseudodiploid karyotypes (41%), and one was hypodiploid (6%). The most common numerical aberrations in descending order were gain of chromosomes 12, 8, 6, and loss of chromosome 16. Structural rearrangements mostly involved chromosome 1 followed by chromosomes 7, 14, and 17. Clustering of breaks around 1p22-31pter resulting in partial loss of 1p was the most frequent structural aberration. Additionally, i(7q) was observed as a sole abnormality in two tumors and a 7p translocation in two other tumors. Other interesting recurrent abnormality was a partial deletion of 14q, seen in three tumors and complete loss of 14 in one tumor. All three Wilms tumors with unfavorable histology had abnormalities of 17p resulting in P53 gene deletion. These findings provide further support for the importance of gains of chromosomes 12, 8, and 6, and loss of 1p in the development of Wilms tumor. The results also support the association of unfavorable histology Wilms tumors with P53 deletion. The nonrandom losses of 16/16q, 7p, and 14q may represent the importance of genomic imbalance in the pathogenetic consequence and progression of Wilms tumor.

**Karyotypic complexity of the NCI-60 drug-screening panel.** *I. Kirsch<sup>1</sup>, A. Roschke<sup>1</sup>, G. Tonon<sup>1</sup>, K. Gehlhaus<sup>1</sup>, N. Mctyre<sup>1</sup>, K. Bussey<sup>2</sup>, S. Lababidi<sup>2</sup>, D. Scudiero<sup>3</sup>, J. Weinstein<sup>2</sup>.* 1) Genetics Branch, National Cancer Institute, Bethesda, MD; 2) Laboratory of Molecular Pharmacology, National Cancer Institute, Bethesda, MD; 3) SAIC-Frederick Cancer Research and Development Center, Frederick, MD.

We used SKY to provide a detailed analysis of karyotypic aberrations in the diverse group of cancer cell lines established by the National Cancer Institute for the purpose of anti-cancer drug discovery. Along with the karyotypic description of these cell lines we defined and studied karyotypic complexity and heterogeneity (metaphase-to-metaphase variations) based on three separate components of genomic anatomy: 1) ploidy, 2) numerical changes, and 3) structural rearrangements. A wide variation in these parameters was evident in these cell lines, and different association patterns between them were revealed. Analysis of the breakpoints and other specific features of chromosomal changes across the entire set of cell lines or within particular lineages, pointed to a striking lability of centromeric regions that distinguishes the epithelial tumor cell lines. We have also found that balanced translocations are as frequent in absolute number within the cell lines derived from solid as from hematopoietic tumors. Important similarities were noticed between karyotypic changes in cancer cell lines and those seen in primary tumors. This dataset offers insights into the causes and consequences of the destabilizing events and chromosomal instability that may occur during tumor development and progression. It also provides a foundation for investigating associations between structural genome anatomy and cancer molecular markers and targets, gene expression, gene dosage, and resistance or sensitivity to tens of thousands of molecular compounds.

**Emergence of deletion on derivative chromosome 9 in CML with t(9;22) during disease progression: a new clone vs. clonal evolution.** *N. Mitter*<sup>1</sup>, *P. Berry*<sup>1</sup>, *P. Patel*<sup>2</sup>, *M. Donskoy*<sup>1</sup>, *J. Lovell*<sup>1</sup>, *M. Graham*<sup>1</sup>. 1) Dianon Systems (Lab Corp, Inc.), Stratford, CT; 2) Stuart Oncology Associates, Stuart, FL.

Many patients with CML show acquired deletions 5 of ABL and 3 of BCR on the derivative chromosome 9, associated with a reduced long-term survival. Empirical observations suggested that such deletions occur at the time of "Philadelphia" chromosome rearrangement, t(9;22), and they do not reflect genomic instability during disease progression. Emergence of such deletions later in the course of CML disease progression may question the validity of this conclusion. We describe here a patient who initially presented with profound leukocytosis and severe anemia. Flow cytometry results on patient's bone marrow biopsy suggested CML, and cytogenetics confirmed presence of t(9;22). Patient was started on Gleevac, 400 mg/day, with favorable initial response, but his platelet count started declining. A FISH evaluation using triple probe/3-color system (Vysis), confirmed presence of ABL/BCR rearrangement with normal probe signals for ASS, ABL and BCR genes on the derivative chromosome 9. In response to shifting platelet counts, Gleevac dose was periodically adjusted. A repeat FISH evaluation, three months later, again demonstrated ABL/BCR rearrangement, but the derivative chromosome 9 showed a deletion of the ABL gene. Abnormal cells (with BCR/ABL rearrangement) had increased from 65% to 85%. If the hypothesis that deletions of der(9) always occur at the time of Ph chromosome translocation event were true, two possible explanations are: (1) there were two clones to start, with the clone with del(9) not detected during the first FISH analysis, but it proliferated more rapidly, becoming the only detectable clone in three months, or (2) the clone with del(9) is a therapy related de novo occurrence with a proliferative advantage over the already existing clone without del(9). The alternate explanation is that the cell line with del(9) represents a clonal evolution from the parent clone without del(9), thus associated with a genomic instability during disease progression. Additional follow-up studies on CML patients, especially those refractory to Gleevac therapy, may help clarify this issue.

**Induction and expression of cyclin D3 in Korean Hepatocellular carcinoma.** *Y. Kang<sup>1</sup>, G. Kim<sup>2</sup>, K. Uhm<sup>1</sup>, S. Cho<sup>3</sup>, S. Park<sup>1</sup>.* 1) Institute of Human Genetics, Department of Anatomy, Brain Korea 21 BioMedical Sciences, Korea university College of Medicine, Seoul, Korea; 2) Perinatology Research Branch, National Institute of Child Health and Human Development, Department of Obstetrics and Gynecology, Wayne State University/Hutzel Hospital, MI, USA; 3) Department of Pathology, Hallym University, College of Medicine, Seoul, Korea.

Human cyclin D3 gene (CCND3) located on 6p21.1 is important in regulating the G1 checkpoint and involved in the regulation of the G1-S phase transition of the cell cycle. Overrepresentation of 6p21-p23 was frequently found in Korean hepatocellular carcinoma (HCC). We evaluated the intricate relationship between expression of cyclin D3 and the process of HCC development using immunohistochemistry and TUNEL assay on 43 paraffin embedded tissues. Cyclin D3 was mainly expressed in the nucleus, and in some cases, cytoplasmic staining was also detected. Cyclin D3 immunoreactivity was more frequently observed in the tumors with high histologic grade and the tumors with metastasis, and more frequently expressed in HCCs with cirrhotic background and gain of 6p21.1 when compared with those with non-neoplastic tissue. Apoptotic cells were more common in tumor with cirrhotic background, amplification of 6p21.1 and expression of cyclin D 3 when compared with HCCs with lower level of cyclin D3 expression. Also, some of the cyclin D3 positive cells and apoptotic cells were co-localized. From these results, it is suggested that over-expression of cyclin D3 may contribute to more rapid cell turn-over in the background of HCC, and balance between proliferation and apoptosis is a role in the progression of HCC with cirrhotic background.

**CHROMOSOME MICRODISSECTION AND FISH FOR THE IDENTIFICATION OF THE GENES**

**RESPONSIBLE FOR DRUG RESISTANCE.** *F. Mahjoubi*<sup>1</sup>, *G. Peters*<sup>2</sup>, *R. Hill*<sup>3</sup>. 1) Dr. F. Mahjoubi Dept. of Clinical Genetics, NRCGEB, Tehran, Tehran, Iran; 2) Dr. G. Peter Dept of Genetics, The New Children Hospital at Westmead, Sydney, Australia; 3) Dr. R. Hill Dept. of Molecular Sciences, CSIRO, Sydney, Australia.

The use of anticancer drugs in appropriate combinations has led to major improvements in the treatment of malignant disease. Unfortunately, in many cases such success is limited by the development of resistance to the chemotherapeutic drugs. Studies with model cell lines have revealed that simultaneous resistance to unrelated drugs, or multidrug resistance (MDR), can readily develop in mammalian cells. This raises the possibility that similar MDR tumor cells may also arise *in vivo* in human cancers, limiting a patient's response to chemotherapy. Our laboratory became interested in studying MDR cell sub-lines developed by treatment of the T-cell leukemia cell line CCRF-CEM with increasing levels of the anthracycline, epirubicin. The MDR phenotype is associated with an expanded chromosomal region (ECR). We have been interested in the nature of this extra DNA and the molecular events that give rise to amplification. As part of these studies, we have compared the content of the amplified unit in different derived E sub-lines. We microdissected this expanded region and PCR amplified the chromosomal DNA in order to produce sufficient DNA to determine its chromosomal origin and for use as a source of material to investigate candidate drug resistance genes. We demonstrated that the selection against epirubicin actually elevated the level of the multidrug resistance associated protein (mrp) gene. The probes prepared by chromosome microdissection should be useful for studying the organisation and function of DNA sequences within the ECR. We have also demonstrated a useful role for chromosome microdissection in this field of research.

**Leiomyosarcoma of the breast: a pathological and cytogenetic study of two cases.** *S. Li<sup>1</sup>, J. Lee<sup>1</sup>, M. Torbenson<sup>2</sup>, Q.Z. Liu<sup>3</sup>, J.J. Mulvihill<sup>1</sup>, B. Bane<sup>3</sup>, J. Wang<sup>3,4</sup>.* 1) Department of Pediatrics, OUHSC, Oklahoma City, OK; 2) Department of Pathology, Johns Hopkins University, Baltimore, MD; 3) Department of Pathology, OUHSC, Oklahoma City, OK; 4) Center for Advanced Diagnostics, AmeriPath Inc. Orlando, FL.

Leiomyosarcoma is an extremely rare form of primary breast tumor with up to 20 cases reported in the literature. In this report, we present the genetic findings of two cases of primary leiomyosarcoma of the breast. The patients were 44 years and 52 years of age and they presented with circumscribed masses ranging from 3.0 and 4.5 cm. Microscopically, the two tumors showed a diffuse proliferation of spindle cells arranged in short fascicles or bundles. There was moderate cytologic atypia and mitotic figures ranged from 6 to 12 per ten high power fields. The tumor cells were strongly immunoreactive for markers of smooth muscle differentiation including desmin, muscle specific actin, and smooth muscle actin. Comparative genomic hybridization (CGH) analysis was performed using DNA extracted from formalin-fixed paraffin-embedded tissue and showed losses of 10q (2/2 cases), 13q (2/2 cases), and 17q (1/2 cases), and gains of 1q (1/2 cases) and 17p (1/2 cases). Several known tumor related genes are located within regions including RB (13q14), BRCA2 (13q12), and PTEN (10q23). In addition, the patterns of chromosomal imbalances identified in leiomyosarcoma of the breast are similar to those reported in leiomyosarcoma of soft tissue and uterus and are different from those reported for leiomyoma, indicating that these alterations may be important for the development of malignant smooth muscle tumors regardless of site or organ of origin.

**Identifying the genes for paraganglioma, gastric stromal tumors (GST), and pulmonary chondroma (Carney triad/dyad): the SDHC gene and its locus.** *L.D. Matyakhina*<sup>1</sup>, *S. McWhinney*<sup>2</sup>, *T.A. Bei*<sup>1</sup>, *S. Stergiopoulos*<sup>1</sup>, *J.A. Carney*<sup>3</sup>, *C. Eng*<sup>2</sup>, *C.A. Stratakis*<sup>1</sup>. 1) DEB, NICHD, NIH, Bethesda, MD; 2) OSU, Columbus, OH; 3) Mayo Clinic, Rochester, MN.

\*The 3 first authors have contributed equally to this work.

Carney Triad (CT) describes the association of gastric stromal tumors (GST) with extra-adrenal paraganglioma (PGL), and pulmonary chondroma (PC); 79 non-familial cases of the triad have been reported; 67 female and 12 male. One-fifth of the patients had the three tumors; the remainder had two of the three, usually the gastric and pulmonary lesions. More recent evidence supports the possibility that the combination of paraganglioma and gastric stromal sarcoma may be familial, inherited as an autosomal dominant condition distinct from CT (Carney Dyad CD). Mitochondrial complex II, succinate dehydrogenase (SDH) consists of four subunits: SDHA, SDHB, SDHC and SDHD; of these the latter three are associated with familial and sporadic PGLs. Sporadic and familial GSTs are known to be associated with gain-of-function mutations of the oncogene *c-kit* (*CKIT*). In the present study, we investigated the possibility that patients with CT or CD and/or their tumors may harbor mutations of the SDH subunits and *CKIT* gene or genetic alterations of their genomic loci. A total of 26 tumors were investigated; 15 PGLs, 7GSTs and 4 PCs. A single tumor, a GST, was heterozygous for a point mutation (IVS5+1G>A) affecting the splicing of exon 5 of the *SDHC* gene. Polymorphisms in the 5' UTR of *SDHA* were also identified in several samples. Comparative genomic hybridization (CGH) demonstrated that the pattern of chromosomal changes was similar in benign PGLs and GSTs despite their different tissue origin and histology, consistent with a common genetic etiology underlying their formation. The most frequent and greatest contiguous change was deletion of the 1pcen13-q21 region, which harbors the *SDHC* gene. In aggregate, our results show that the genetic defects in the 1pcen-q21 region and/or the *SDHC* gene may cause this unique but potentially genetically heterogeneous disorder.

**Chromosome instability and copy number effect in tumors studied in microcell cell hybrid system.** *M. Kost-Alimova, E. Darai, A. Sandlund, L. Fedorova, Y. Yang, G. Klein, S. Imreh.* Dept MTC, Karolinska Inst, Stockholm, Sweden.

We demonstrated that microcell mediated chromosome 3 transfer into tumor renal cell carcinoma cells influences their in vitro and in vivo growth and directs the cells to a new round of chromosome alterations, which result in restoration of original tumorigenic phenotype. We show that the driving force behind this restoration includes chromosome copy number dependant instability and gene copy number dependant selection for loss providing growth advantage. Chromosome copy number dependant instability was manifested as an accumulation of imbalanced translocations between chromosomes, which were originally in more than two copies. Seven out of 9 trisomic chromosomes were found at least ones rearranged, while no one from 14 disomic chromosomes was altered. The translocation breakpoint lied preferentially in pericentromeric regions. Association of structural chromosome instability with hypersomy was evident also from analysis of available SKY data for a broad spectrum of human tumors. The pericentromeric imbalanced translocations were characteristic for hyperploid tumors, while tumors with near diploid karyotype favored balanced reciprocal translocations. Location of breakpoints within the pericentromeric regions may be at least partially associated with their late replication, because the other large latest replicating segments on the chromosome 3 were also involved in rearrangements. In this respect we demonstrated that hypersomy associated chromosome instability may be caused by asynchroneous replication of the additional loci and incomplete replication within the late replicating sequences. Chromosome breakage and then translocation was accompanied by segmental losses, which often involved a whole arm. Gene copy number dependant selection in our system was displayed as a clonal expansion in vivo and in vitro of cells loosing additional copies of 3p regions (in particular so called CER1 and FER at 3p14-21) caused as we show, by dose dependent proliferation advantage.

**Subtelomeric rearrangements in patients with pancytopenia.** *J. Lee, J.J. Mulvihill, S. Li.* Department of Pediatrics, OUHSC Oklahoma City, OK.

Many etiologies could cause pancytopenia, which is an abnormal condition of the reduction of red blood cells, white blood cells and platelets in the blood. A percentage of patients with pancytopenia have preleukemic disorders, and no specific chromosomal changes have been identified. To investigate whether these patients may have subtle chromosomal changes, especially the subtelomeric rearrangements, we have studied twelve patients with pancytopenia. Of these twelve patients, two cases had clonal chromosomal anomalies, and two cases had a normal karyotype but a low mitotic index. These four patients were excluded from further studies. The remaining eight patients were examined by fluorescence in situ hybridization, utilizing commercial probes corresponding to all of the subtelomeric regions of all 22 autosomes and the sex chromosomes, X and Y, except for the short arms of the acrocentric chromosomes 13, 14, 15, 21 and 22. None of the patients had a subtelomeric deletion, duplication or translocation. Our findings, although in a limited number of cases, may suggest low frequency of subtelomeric rearrangements in patients with pancytopenia.

**Cytogenetic characterization of uterine leiomyomata with t(10;17) involve the histone acetyltransferase *MORF*.** *S.D.P. Moore*<sup>1,2</sup>, *S.R. Herrick*<sup>1</sup>, *T. Ince*<sup>1,3</sup>, *P. Dal Cin*<sup>1,2</sup>, *M. Kleinman*<sup>1</sup>, *C.C. Morton*<sup>1,2</sup>, *B.J. Quade*<sup>1,2</sup>. 1) Brigham & Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Massachusetts Institute of Technology, Boston, MA.

Uterine leiomyoma (UL) are the most common tumor in women of reproductive age and the leading cause for hysterectomy in the United States. Cytogenetic aberrations that contribute to the pathobiology of this benign smooth muscle tumor primarily involve chromosomes 6, 7, 12, and 14. Rearrangements of 10q22 have also been reported and, interestingly, have also been observed in their presumed malignant counterpart, uterine leiomyosarcoma. We have mapped the chromosomal breakpoints in a UL with a t(10;17)(q22;q21) by fluorescence in situ hybridization (FISH). The chromosome 10 breakpoint localized to the third intron of the histone acetyltransferase *MORF* (monocytic leukemia zinc finger protein-related factor or *MOZ2*). *MORF* is a member of the histone acetyltransferase (HAT) MYST family, named for its founding members *MOZ*, *Ybf2/Sas3*, *Sas2*, and *Tip60*. Several cancers have been associated with rearrangement of HAT genes. For example, the closely related *MOZ* gene (monocytic leukemia zinc finger protein) has previously been found to be involved in acute myeloid leukemia. This is the first smooth muscle tumor to involve a disruption of a histone acetyltransferase. The t(10;17) disrupts *MORF* in the N-terminal portion of the protein between a conserved domain found in histone families 1 and 5 and PHD zinc finger domains. Interphase FISH analysis of three additional UL revealed disruptions in *MORF*. Two of these tumors had rearrangements between 10q22 and 17q21 or 17q22, one as a simple translocation and the other as a four-way translocation. The other tumor had two simple translocations involving 10q22 and 4q21 and 6p21 respectively. Of note, both tumors available for pathological review were of a particular histological subtype, namely the cellular variant. Cytogenetic mapping on chromosome 17 has identified candidate genes that may be associated with potential fusion products. The involvement of *MORF* in four UL suggests a role for this histone acetyl transferase in uterine mesenchymal neoplasia.

**A rare deletion of chromosome 20p in a patient with pancytopenia.** *M.J. Macera<sup>1</sup>, S.R.S. Gottesman<sup>2</sup>, V. Mizhritskaya<sup>1</sup>, R. Zeng<sup>1</sup>, A. Babu<sup>1</sup>.* 1) Dept Molec Medicine & Genetics, Wyckoff Heights Medical Ctr, Brooklyn, NY; 2) Dept of Pathology, SUNY Downstate Medical Center, Brooklyn, NY.

An 80 year old patient with a four year history of pancytopenia was evaluated for progressive worsening of his anemia. The bone marrow was found to be hypercellular with a left shift in myeloid maturation and mild dyserythropoiesis. Cytogenetic analysis on the bone marrow specimen revealed an abnormal chromosome 20, as the sole abnormality. Deletions of the 20q arm have been reported in numerous myeloid disorders, and is most frequently observed in refractory anemia and polycythemia vera, where its presence serves as a diagnostic tool used for disease classification. Deletions in the short arm of 20, however, are extremely rare and have not been reported as the sole abnormality. Two previous cases of acute lymphoblastic leukemia have been reported (Murphy et al, 1989; Walters et al, 1990) with del(20)(p11), both with additional abnormalities. Due to the rarity of a 20p deletion, whole chromosome 20 painting probe (wcp) and sub-telomeric probes specific for both the p (20ptel) and q (20qtel) terminals of chromosome 20 were applied to confirm and clarify the abnormality. FISH analysis revealed wcp (20) signal over the entire normal homologue and the entire del(20). No wcp20 signal was observed on any other chromosome. Signal for 20qtel was seen over the q terminal of the normal homologue and the del(20). However, signal for 20ptel was only observed on the normal homologue, no 20ptel signal was observed over the del(20) or anywhere else in the genome. Based on the banding profiles, the deletion break point is at or very close to the p11.1 and p11.2 interface, most probably within the proximal end of band p11.21, which was further confirmed by Comparative Genomic Hybridization (CGH). The final karyotype was 46,XY,del(20)(p11.2).ish del(20)(20ptel-,wcp20+,20qtel+). We are not aware of any previous case of a terminal deletion in the short (p) arm of chromosome 20 as the sole abnormality.

**Genetic imbalances of six urothelial carcinoma cell lines derived from a blackfoot endemic area in Taiwan.** C. Tzeng, C.P. Liou, M.Y. Chang. Department of Pathology, Chi-Mei Foundation Hospital, Tainan, Taiwan, Republic of China.

Unusually high incidences of urinary tract urothelial carcinoma (UC) have been reported from the endemic area for blackfoot disease in southern Taiwan, a unique peripheral vascular disease related to continuous arsenic exposure. However, chromosomal changes in such tumors, which may closely associate with tumor initiation and/or progression, have rarely been investigated. In this study, we applied comparative genomic hybridization to analyze six UC cell lines derived from patients with carcinoma of pT2 or higher stage in this endemic area. All lines displayed numerous chromosomal aberrations. Repeated gains and deletions (noted in two or more lines) were detected in 14 and 17 sites, respectively. The frequent gains were observed on 8q22-ter (6/6), 7q31-34 (3/6), 9p22-ter (3/6), 11q12-14 (3/6), and 20q11-13 (3/6). The common losses were noted at Xp11-22 (6/6), Xq24-ter (6/6), 4q13-23 (4/6), 4q28 (3/6), 5q11-14 (3/6), 10q23-25 (3/6), 11p13-15 (3/6), 11q14-ter (3/6), and 15q11-21 (3/6). Many of these aberrations have been previously described in the literature, especially gains of 8q and 20q and losses of 11p or/and q. However, our study showed some intriguing and uncommon regions, different from those found in past studies. These were the amplification of 7q31-34 and 9p22-ter and deletion of Xp11-22, Xq24-ter, and 15q11-21. In spite of the very complex pattern of genetic changes in these lines, most of these uncommon aberrations have to be implicated in UC, and further molecular genetic methods are necessary to establish whether the chromosomal regions contain candidate genes, which contributed to the initiation and progression of UC in the endemic area of Taiwan.

**A novel chromosomal translocation t(3;7)(q26;q21) in myeloid leukemia resulting in overexpression of *EVII*.** C. Storlazzi<sup>1,4</sup>, L. Anelli<sup>1,2</sup>, F. Albano<sup>3</sup>, A. Zagaria<sup>1,3</sup>, M. Ventura<sup>1</sup>, M. Rocchi<sup>1</sup>, I. Panagopoulos<sup>4</sup>, A. Pannunzio<sup>3</sup>, E. Ottaviani<sup>5</sup>, V. Liso<sup>3</sup>, G. Specchia<sup>2,3</sup>. 1) DAPEG, section of Genetics, University of Bari, Bari, Italy; 2) Hematology, University of Foggia, v.le Pinto, 71100 Foggia, Italy; 3) Department of Hematology, University of Bari, p.zza G.Cesare 11, 70124 Bari, Italy; 4) Department of Clinical Genetics, University Hospital, S 221 85 Lund, Sweden; 5) Institute of Hematology L. and A. Seragnoli, University of Bologna, via Massarenti 9, 40138 Bologna, Italy.

The *EVII* proto-oncogene encodes a nuclear zinc-finger protein that acts as a transcription repressor factor. In myeloid leukemia it is often activated by chromosomal rearrangements involving band 3q26, where the gene has been mapped. Here we report two leukemia cases [a Chronic Myeloid Leukemia Blast Crisis (CML BC) and an Acute Myeloid Leukemia (AML) M4] showing a t(3;7)(q26;q21) translocation in a balanced and unbalanced form, respectively. FISH analysis revealed that both patients showed a breakpoint on chromosome 3 inside the clone RP11-33A1 containing the *EVII* oncogene and, on chromosome 7, inside the clone RP11-322M5, partially containing the *CDK6* oncogene which is a D cyclin-dependent kinase gene, observed to be overexpressed and disrupted in many hematological malignancies. RT-PCR analysis showed overexpression of *EVII* in both cases but excluded the presence of any *CDK6/EVII* fusion transcript. *CDK6* expression was also detected. Together, these data indicate that *EVII* activation is likely due not to the generation of a novel fusion gene with *CDK6* but to a position effect dysregulating its transcriptional pattern.

**Genetic alterations in intrahepatic cholangiocarcinoma by degenerate oligonucleotide primed PCR-comparative genomic hybridization.** *K. Uhm<sup>1</sup>, Y. Kang<sup>1</sup>, S. Park<sup>2</sup>, Y. Park<sup>3</sup>, S. Park<sup>1</sup>*. 1) Institute of Human Genetics, Department of Anatomy, Brain Korea 21 Biomedical Sciences, Korea University College of Medicine, Seoul, Korea; 2) Department of Anatomy, Ehwa womans University College of Medicine, Seoul, Korea; 3) Department of Pathology, Yonsei University College of Medicine, Seoul, Korea.

Intrahepatic cholangiocarcinoma (ICC), a malignant neoplasm of the biliary epithelium, is usually fatal because of difficulty in early diagnosis and lack of availability of effective therapy. Furthermore, little is known about the genetics and biology of ICC. Chromosomal aberrations in 49 Korean ICC were investigated by degenerate oligonucleotide primed - PCR comparative genomic hybridization. The common sites of copy number increases were 20q (69%), 17q (66%), 19pter~q12 (57%), 11q11~q23 (54%), 22q (48%), 7q (39%), 16p (39%), 8q (36%), 15q22~q25 (36%), 18p (36%) and 6p21 (33%). DNA amplification was identified in 18 carcinomas (54%). The frequent sites of amplification were 7q11~q22, 8q24, 16p, 17q23~qter, 19, and 20q. Chromosomal loss was less common in our series of ICC and found in 1p34~pter, 3p, 4q, 5q, 6q, 13q, 18q, and X. The recurrent gains and losses of chromosomal regions identified in this study provide candidate regions that may contain oncogenes or tumor suppressor genes, respectively.

**The deletion of retinoblastoma region (13q13-q14) detected by CGH in a patient with malignant phyllodes tumor of the breast.** *J. Wang*<sup>1,4</sup>, *J. Lee*<sup>2</sup>, *M. Torbenson*<sup>3</sup>, *Q.Z. Liu*<sup>1</sup>, *J.J. Mulvihill*<sup>2</sup>, *S. Li*<sup>2</sup>. 1) Department of Pathology, OUHSC, Oklahoma City, OK; 2) Department of Pediatrics, OUHSC, Oklahoma City, OK; 3) Department of Pathology, John Hopkins University, Baltimore, MD; 4) Center for Advanced Diagnostics, AmeriPath Inc, Orlando, FL.

Phyllodes tumor of the breast, accounting for only 0.3% of all breast tumors, is a biphasic tumor composed of benign epithelial elements and a cellular, spindle-cell stroma. It is classified as benign, borderline or malignant categories based on the features of the stromal elements. Gain of 1q and the loss of 3p were considered the common chromosomal changes. However, no correlation between clinical presentation and cytogenetic findings was established. Here we report comparative genomic hybridization (CGH) findings in a case of unusual malignant phyllodes tumor. A 55-year-old patient presented with a circumscribed mass measuring up to 13.0 cm. The tumor showed biphasic stromal and epithelial growth. The stromal component was predominant, and spindle stromal cells were strongly immunoreactive for the markers of muscle differentiation, which is an unusual finding in phyllodes tumor. CGH analysis was performed using formalin-fixed, paraffin-embedded tissue. In addition to a gain of 1q, three additional imbalanced chromosome regions, a gain of 5p and the loss of 10p and 13q13-q14, were identified. Interestingly, the region of 13q14 harbors the RB1 tumor suppressor gene, and whether the deletion of RB1 gene in this case plays a role in development of malignant phyllodes tumor of breast warrants further investigation.

**Atypical morphologies of bone marrow due to a variant translocation (8;10;21) in a patient with acute myeloid leukemia.** *K.V. Scott<sup>1</sup>, W.F. Kern<sup>2</sup>, J.B. Parkhurst Cain<sup>1</sup>, J. Lee<sup>1</sup>, J.J. Mulvihill<sup>1</sup>, S. Li<sup>1</sup>.* 1) Department of Pediatrics, OUHSC, Oklahoma City, OK; 2) Department of Pathology, OUHSC, Oklahoma City, OK.

The t(8;21)(q22;q22) translocation is one of the most common nonrandom chromosomal changes in AML and is strongly associated with the M2 subtype of AML. The marrow cells show typical morphologic features that include prominent Auer rods, homogeneous salmon-colored granules and strongly myeloperoxidase-positive blasts. Rare variant translocations have been reported; all had similar AML M2 morphology. We report a patient who was initially diagnosed with a chronic myeloproliferative disorder, possibly chronic myelogenous leukemia (CML), based on laboratory and blood/marrow morphological findings. The patient did not respond well to treatment for CML. Chromosomal analysis revealed that the patient did not have t(9;22), but a complex variant translocation t(8;10;21). Treatment regime was switched to AML protocol and the patient responded well and she is now in remission. Reviewing published literature, it is suggested that the disruption of gene(s) on chromosome 10q24 may contribute atypical AML M2 morphologic changes in our case.

**CHROMOSOMAL ABNORMALITIES IN VENEZUELAN PEOPLE WITH MULTIPLE MYELOMA. A.E.**

*Rojas-Atencio<sup>1</sup>, M. Quintero<sup>2</sup>, J. Herrera-Cepeda<sup>2</sup>, K. Urdaneta<sup>1</sup>, M. Soto<sup>1</sup>, P. Garcez<sup>1</sup>, F. Alvarez-Nava<sup>1</sup>.* 1) Genetica, Universidad del Zulia, Maracaibo, Zulia, Venezuela; 2) Servicio Hematologia, Universidad del Zulia.

The cytogenetic study is an important prognostic factor in Multiple Myeloma (MM) study, the chromosomal analysis demonstrated to be essential for the genetic advise in relation to the diagnosis, prognostic and suggesting precociously, the most appropriate treatment for the most number of hematological malignancies. The objective of this work was to identify the chromosomal abnormalities in samples of bone marrow (BM) coming from patients with diagnosis of MM in our region. The chromosomal studies were carried out in cultures of BM, following the technique described by J. Yunis in 1981, without exception it was carried out previous to any treatment with cytostatics. Twenty two samples of BM were received for chromosomal study in the Unit of Medical Genetics of the University of the Zulia (UGM -LUZ), 19/22 samples (86,36%) appropriate material was obtained by cytogenetic analysis, 6/19 (31,57%) normal karyotype, 13/19 (68.42%) they were numeric and structural chromosomal abnormalities. 100% of the chromosomal anomalies observed were compound for numerics 8 (42,10%), three case with hyperdiploidy involving chromosomes 3, 5, 7, 15, 17, 18, 19, four case with hypodiploidy involving the chromosomes 8, 16, 17, 18, X and Y. Triploidy in one case. The structural abnormalities in 4 cases (33.33%) as the deletion 5p11, 11p14, 14q32, 17p11 and 1 (8.33%) presented structural and numeric anomalies. Our study shows that their majority the patients with multiple myeloma present some type of chromosomal abnormalities, and variability in the frequency of this alterations.

**Clonal evolution in a patient with secondary myelodysplastic syndrome.** A. Podroma<sup>1</sup>, J. Sanmugarajah<sup>1</sup>, I. Yudelman<sup>1</sup>, M.J. Macera<sup>2</sup>, R. Zeng<sup>2</sup>, A. Babu<sup>2</sup>. 1) Department of Medicine, Lenox Hill Hospital, New York, NY; 2) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

A 55 year old female patient, 5 years ago, had a modified radical mastectomy for stage IIb breast cancer and underwent chemotherapy with Cytosan, Adriamycin, Fluorouracil (cyclex4) followed by autologous bone marrow transplant. The patient has been experiencing anemia for 8 months followed by 2 months of leucopenia and thrombocytopenia. Her bone marrow biopsy was hypercellular with 11% blasts. Chromosome analysis on bone marrow revealed two abnormal clones: a stemline with a deletion of chromosome 5q, 46,XX,del(5)(q14q34), in 13% and a sideline (the mainline), with several additional abnormalities, 54,idem,+1,del(6)(p21.2),+del(6)(p21.2),+8,+10,+11,+14,+15,+22, in 87% of the metaphase cells. A subsequent analysis on a peripheral blood specimen, after one week, showed only the sideline and a single normal cell. No stemline was detected in the metaphase cells of the unstimulated blood specimen. Approximately 80% of therapy related Myelodysplastic syndromes (t-MDS) show chromosomal abnormalities. These abnormalities are mostly in the form of deletions or additions and seldom are in the form of chromosome rearrangements. The present case is an additional example towards that observation. While prognosis associated with a primary event such as 5q- as a sole abnormality is good, additional abnormalities greater than 3 is considered as a basis for poor prognosis (Greenburg et al, 1997). The patient is scheduled to begin treatment with 5 Azacitidine. Additional follow up data is essential to determine the aberrations contributing towards clonal evolution, their implications on disease progression and evaluating therapeutic efficacy.

**Detection of ins(4;3)(q21;q12q27) by FISH in a case of MDS/AML with a del(5)(q13q32) and monosomy 7. D.**

*Wei<sup>1</sup>, K.H. Ramesh<sup>1</sup>, V.R. Pulijaal<sup>1</sup>, M. Zohouri<sup>1</sup>, D. Walsh<sup>1</sup>, A. Deshikar<sup>1</sup>, L.V. Vasovic<sup>1</sup>, H. Ratech<sup>1</sup>, D.S. Xu<sup>1</sup>, E.W. Friedman<sup>2</sup>, L.A. Cannizzaro<sup>1</sup>.* 1) Pathology, Montefiore Medical Center, Bronx, NY. 10461; 2) Medicine, Div. Hematology-Oncology, Montefiore Medical Center, Bronx, NY. 10467.

An 85 year-old female with a history of thrombocytosis was diagnosed with myeloproliferative disorder (MPD) in 1996. She was treated with P in 1998 and Hydrea since then. In Oct. 2002, she had worsening anemia and a leucocytosis. Flow cytometry detected 8% CD34+ myeloblasts with decreased side-scatter of mature myeloid cells. A bone marrow (BM) biopsy showed hypercellular marrow (80-100%) with absolute granulocytic and megakaryocytic hyperplasia and diffuse increase in reticulin fibers (3+/4+). In April 2003 her BM was hypercellular (80%) with hiatus in myeloid maturation and diffuse fibrosis. Flow cytometry showed an increase 12-18% CD34+, CD11b+, CD11c+, CD13+, CD33+, CD38+ and HLA-DR+ immature myeloid precursors. Peripheral blood (PB) showed an elevated WBC (94 k/ul) with blasts (Hb 5.4 g/dl, MCV 109fL, PLT 249K/CU, LDH 1848 U/L). The differential diagnosis now included refractory anemia with excess blasts (RAEB) versus acute myeloid leukemia (AML) with prior MDS. Cytogenetic and FISH analyses of BM (10/02) revealed a 46,XX,ins(4;3)(q21;q12q27),del(5)(q13q32),-7,add(18)(p11.2),+mar[20]. ish ins(4;3)(q21;q12q27)(WCP3+) karyotype. Anomalies in all the cells included a partial insertion of 3q into 4q (confirmed by FISH), an interstitial deletion of 5q, loss of 7, additional unknown chromosomal material in 18p, and an unidentifiable marker chromosome. Deletions of 5q and loss of 7 have been reported in MDS, AML, RAEB, and in MPD. However in this patient there were secondary numerical and structural chromosomal changes that continued to evolve. In April 2003, there was a terminal deletion of Xq and two copies of the add(18) anomaly, while the other abnormalities remained unchanged. The presence of deletion 5q and loss of 7, in association with other multiple chromosomal changes, are suggestive of secondary MDS/AML in this patient.

**A t(1;22)(p13;q13) in an infant with acute megakaryoblastic leukemia (M7).** *R. Sundaram<sup>1</sup>, D. Rakhman<sup>1</sup>, R. Alexis<sup>1</sup>, A. Babu<sup>2</sup>, R. Zeng<sup>2</sup>, S. Kleyman<sup>2</sup>, M.J. Macera<sup>2</sup>.* 1) Long Island College Hospital, Brooklyn, NY; 2) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

Approximately 20% of infants afflicted with AML have Acute Megakaryoblastic Leukemia (FAB classification M7). One subgroup of M7, based upon cytogenetic criteria are those patients that have the t(1;22)(p13;q13) karyotype. This group consists almost exclusively of infants, as the translocation is seldom described in children over 1 year of age. They frequently exhibit hepatosplenomegaly and show a constant presence of both blasts and megakaryocytes. Their prognosis is uniformly poor. To date there are only approximately 40 cases reported in the literature. A male child weighing 3284 gm was the product of a 39 week gestation, delivered by repeat cesarean section to a 39 year old mother. The pregnancy was complicated with a three day hospitalization for spotting and possible urinary tract infection, for which the mother received intravenous antibiotics for three days. At birth, the baby had a platelet count of 60-70,000. Three days later, his platelets had dropped to 22,000. Physical examination revealed hepatosplenomegaly and his peripheral smear revealed occasional blasts. A bone marrow revealed 12% blasts with absence of megakaryocytes. As he had guiac positive stools, he received a platelet transfusion and intravenous gamma globulin for five days. Two weeks later, a repeat marrow showed 24% blasts. Cytogenetic analysis on unstimulated peripheral blood revealed a 46,XY,t(1;22)(p13;q13)[7]/46,XY[13] mosaic. Only normal 46,XY cells were found in PHA stimulated blood, thus documenting the acquired nature of the 46,XY,t(1;22)(p13;q13) clone and establishing the M7 diagnosis. Treatment was initiated using standard chemotherapy but the patient passed away within six weeks of diagnosis. Although megakaryocytes were not documented in the marrow, this child's disease presentation: the presence of blasts, hepatosplenomegaly and having a poor prognosis, strengthens the M7 category of Acute Megakaryoblastic Leukemia in infants with the t(1;22)(p13;q13) translocation.

**A case of myelodysplasia syndrome with an unusual 46,XY,t(20;22)(q13;q11.2) karyotype.** *M. Sinha*<sup>1</sup>, *M.J. Macera*<sup>2</sup>, *V. Mizhiritskaya*<sup>2</sup>, *R. Zeng*<sup>2</sup>, *A. Babu*<sup>2</sup>. 1) Department of Oncology, Forest Hills Medical Center, Forest Hills, NY; 2) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

A 66 year old male with a history of low platelets was referred for thrombocytopenia 5 years ago. His platelets were 44k and a presumptive diagnosis of idiopathic thrombocytopenic purpura (ITP) was made. He was started on Prednisone with an excellent initial response, followed by a fall that required gamma globulins. He was continued on steroids in tapering doses and gamma globulins for 2 years, at which time, with elevated WBC, his symptoms were suggestive of myelodysplasia (MDS) or unusual chronic myelogenous leukemia (CML). He was continued on steroids and IVIG for 4 years. Cytogenetic analysis of a recent bone marrow revealed a translocation involving chromosomes 20 and 22. FISH was performed using probes for BCR/ABL, wcp 20 and the subtelomere specific regions of the short and long arms of chromosome 20 (20ptel, 20qtel). Probe for ABL was seen only over both 9s, while BCR signal was seen over the normal 22 and the der(20), establishing one breakpoint at 22q11.2. Signal for wcp 20 was found over the entire normal homologue, half of the der (20) and a small band located at the distal end of the der (22). Signal for the 20ptel probe was seen over the p arm of the normal 20 and over the der (20), while signal for the 20qtel was seen over the normal 20 and the der 22. Based on these findings, the karyotype was designated as 46,XY,t(20;22)(q13;q11.2). ish 9q34(ABLx2), der(20)(BCR+,wcp20+,20ptel+,20qtel-), der(22)(BCR-,wcp20+,20qtel+). The t(20;22)(q13;q11) translocation is extremely rare and has only been reported twice in two cases classified as CML with aberrant translocations. The BCR/ABL fusion gene was documented in one case (Ito et al 2002), establishing the involvement of ABL, located at 9q34, in the translocation. No information is available regarding BCR/ABL status in the second reported case (Becher et al 1987). Since no involvement of the ABL gene was found, this case presents an unusual translocation, t(20;22)(q13;q11.2), with unique breakpoints, not involving ABL or chromosome 9.

Program Nr: 323 from 2003 ASHG Annual Meeting

**Jumping translocation involving chromosome 21 in clear cell renal carcinoma.** *C. Sreekantaiah*. Dir, Cytogenetics Lab, Lab Diagnostics, LLC, Norwalk, CT.

Jumping translocations are rare cytogenetic aberrations that involve one donor chromosome and multiple recipient chromosomes. A nonclonal jumping translocation involving chromosome 21 was noted as the only structural rearrangement in a renal cell carcinoma, clear cell type. The translocation partners were the telomeric regions of 12p, 13p, 20q, and 21q. The karyotype of the tumor was 68-76<4n>,XX,-X,-X,-1,-1,-2,-2,-6,-6,-8,-8,-10,-10,-17,-17,-21,-21[cp8]/46,XX[12].

**Multiple Cytogenetic Abnormalities including a t(11:17)(q23;q21) in a Patient With de novo CD34 Negative Acute Myeloid Leukemia (AML).** *M. Zohouri<sup>1</sup>, L.A. Cannizzaro<sup>1</sup>, D. Wei<sup>1</sup>, V.R. Pulijaal<sup>1</sup>, D. Walsh<sup>1</sup>, T. Zhou<sup>1</sup>, L.V. Vasovic<sup>1</sup>, H. Ratech<sup>1</sup>, D.S. Xu<sup>1</sup>, B. Pimperdi<sup>2</sup>, S. Aggarwal<sup>2</sup>, L.I. Cytryn<sup>3</sup>, K.H. Ramesh<sup>1</sup>.* 1) Pathology, Montefiore Medical Center, Bronx, NY; 2) Oncology, Montefiore Medical Center, Bronx, NY. 10467; 3) Medicine, Div.Hematology-Oncology, Montefiore Medical Center, NY. 10467.

A 26 year old female reported dizziness for a period of one week in 2/2003. Peripheral blood analysis showed pancytopenia (Hb 7.2 g/dl, WBC 0.9, PLT 136K/CU) with rare blasts. Bone marrow (BM) was hypercellular marrow (100%), almost completely replaced with blasts and no normal hematopoiesis. Flow cytometry revealed CD34-, CD117+, CD33+, CD13- CD11b+, CD11c+, HLA-DR+, CD4+, CD7 (weak partial)+, TdT (weak to negative), consistent with an aberrant immature myeloid phenotype. Cytochemical enzyme studies showed that the blasts were positive for alpha-naphthyl-butyrate esterase activity. The immunohistochemical stains revealed that 50% of the blasts were myeloperoxidase positive and 75-100% were CD68 positive. Based on these findings, a diagnosis of AML with monocytic differentiation was made. Cytogenetic analysis of BM revealed a 45,XX,del(1)(p13),t(11;17)(q23;q21),-15[12]/73,idemx2,+1,+16,+20,+22[7]/46,XX [1] karyotype. In the first clone, anomalies included a terminal deletion of 1p, a translocation involving chromosome bands 11q23 and 17q21 and monosomy 15 (12/20 cells). The second clone had anomalies similar to the first, but the count was 73, with all chromosomes in 3 copies except 1, 16, 20 and 22, (4 copies)(7/20 cells). FISH with the MLL, PML/RARA and the 11p and q subtelomere probes was performed to characterize the cytogenetic anomalies. FISH proved that the break occurred at the MLL gene locus. PML/RARA confirmed loss of one 15, and translocation of RARA to 11q23. She received induction therapy with Arac and Idarubicin and achieved complete remission. After one cycle of high dose Arac she underwent allogenic BMT from a matched unrelated donor. Structural abnormalities involving the MLL gene are seen in 5-10% of acquired chromosomal rearrangements in hematological malignancies and are predictive of a poor prognosis.

**Acquired homozygosity for t(9;22) during clonal evolution in CML.** *L. Wisniewski<sup>1</sup>, P. Papenhausen<sup>1</sup>, J. Tepperberg<sup>1</sup>, P. Mowrey<sup>1</sup>, P. Singh-Kahlon<sup>1</sup>, I. Gadi<sup>1</sup>, L. Moscinski<sup>2</sup>.* 1) Cytogenetics, LabCorp of America, RTP, NC; 2) H.Lee Moffitt Cancer Center, Tampa, FL.

We wish to report an unusual case of acquired homozygosity for t(9;22) associated with clonal evolution of CML in a 57-year-old male. Previous FISH studies with BCR/ABL fusion probes performed at diagnosis and at six-month follow-up established the diagnosis of CML. Fusion signals were noted in approximately 60% of the cells examined, and conventional cytogenetic studies revealed 46,XY,t(9;22)/46,XY mosaicism on both occasions. There was no evidence of abnormalities associated with clonal evolution in either evaluation. Cytogenetic studies performed one year after diagnosis revealed a previously undetected side line with the karyotype 46,X,+X,-Y,+8,+8,-9,t(9;22)(q34;q11.2)x2,-22 in 10 of 20 metaphases analyzed. Both cell lines observed in the previous studies were also represented. Chromosome heteromorphisms in the three cell lines indicated that the side line was derived from the t(9;22) stem line, and that homozygosity for the translocation was most likely achieved by mitotic nondisjunction leading to the loss of both normal 9 and 22 homologs and duplication of both translocation derivatives. The same mechanism appeared to have also resulted in acquired homozygosity for the X chromosome. It was not clear whether the tetrasomy 8 also noted arose by the same or a different mechanism. The patient, who had developed a myeloid blast crisis and was completely refractory to induction therapy, expired three weeks after the final cytogenetic study. Although previous reports have documented that one or both derivatives of the standard t(9;22) seen in CML may be duplicated at the time of diagnosis or later, this is the first observation to our knowledge of duplication of the translocation with simultaneous loss of both normal homologs during clonal evolution. The selective advantage of the unusual sideline however, can be attributed to the presence of classic CML secondary abnormalities (duplicated Ph', +8, +8) rather than the observed homozygosity.

**A novel subtelomeric translocation t(5;9) and the deletion of RB1 gene in a patient with acute myeloid leukemia (AML-M0).** *R.K. Taylor<sup>1</sup>, J. Lee<sup>1</sup>, W.F. Kern<sup>2</sup>, J.J. Mulvihill<sup>1</sup>, S. Li<sup>1</sup>.* 1) Department of Pediatrics, OUHSC, Oklahoma City, OK; 2) Department of Pathology, OUHSC, Oklahoma City, OK.

No chromosomal rearrangements have been identified to be specifically associated with minimally differentiated acute myeloid leukemia (AML-M0). Several research groups studied the cytogenetic features of AML-M0 and found that approximately 81% of patients had chromosomal rearrangements; primarily -5/5q- and/or 7/7q- deletion or translocations involving 12p. A patient, who was diagnosed with AML eighteen months ago, was referred for cytogenetic evaluation for possible AML relapse. The routine chromosome analysis was performed on bone marrow specimen and showed an apparently normal karyotype. Incidentally, this patient was enrolled in the study of subtelomeric changes in patients with pancytopenia. Fluorescence in situ hybridization (FISH) was performed utilizing commercial probes corresponding to the subtelomeric regions of all 22 autosomes and the sex chromosomes, X and Y, except for the short arms of the acrocentric chromosomes 13, 14, 15, 21 and 22. Each of the cells analyzed had a t(5;9) (q35.3;q34.3), plus a deletion of RB1 gene. To rule out the possibility that these chromosomal changes were related to the relapse of AML in this case, we repeated the same FISH test on the specimen at initial diagnosis before any treatment. The same abnormalities were found. To our knowledge, this is the first case reported with subtelomeric t(5;9) (q35.3;q34.3) and the deletion of RB1 gene in a patient with AML-M0. Whether the translocation (5;9) combined with the deletion of RB1 gene plays an important role in the development of AML-M0 warrants further investigation.

**Relationship of chromosome 21 rearrangements with other numerical chromosome changes in patients with acute lymphoblastic leukemia (ALL).** *L. Zhang<sup>1,2</sup>, J.J. Mulvihill<sup>1</sup>, S. Li<sup>1</sup>.* 1) Dept Pediatrics, OUHSC, Oklahoma City, OK; 2) Dept Hematology, The First Affiliated Hospital of China Medical University, Shenyang, P.R.China.

Numerical or structural changes of chromosome 21 have been recognized to be very common in patients with ALL and have values of predicting the outcome of treatment. Some of these structural rearrangements are very difficult, even impossible to be diagnosed by routine chromosome analysis, such as t(12;21), but easily done by fluorescence in situ hybridization (FISH) utilizing a TEL/AML1 gene fusion probe. Other chromosomal changes, such as trisomies 4, 10, 17, an MLL gene rearrangement, or t(9;22), also have implication of predicting the outcome of therapy. We have studied fifty-one patients with ALL utilizing multiple locus specific DNA probes TEL/AML1, MLL, BCR/ABL and centromere probes of chromosomes 4, 10 and 17; forty-five were pediatric patients and the remaining six were adults. The male to female ratio is 2:1. All of the probes used were purchased from a commercial source (Vysis, Downers Grove, Illinois, USA). Twenty-five out of 51 patients (49%) had either structural or numerical changes of chromosome 21. The patients who had structural changes, such as t(12;21) or a ring chromosome 21, did not have numerical changes of chromosome 21, 4, 10 or 17. We believe these are two separate mechanisms that lead to the development or progression of ALL.

**Cytogenetic characterization and *p53* tumor suppressor status of SW480 human adenocarcinoma cells. P.J.**

*Rochette*<sup>1</sup>, *J. Lavoie*<sup>1</sup>, *W. Dridi*<sup>1</sup>, *N. Bastien*<sup>1</sup>, *M. Bronsard*<sup>1</sup>, *E.A. Drobetsky*<sup>2</sup>, *R. Drouin*<sup>1</sup>. 1) Unité de Recherche en Génétique Humaine et Moléculaire, Research Center, Hospital Saint-François d'Assise, CHUQ, Laval University, Quebec, QC, Canada; 2) Guy-Bernier Research Center, Maisonneuve-Rosemont Hospital, University of Montreal, Montreal, QC, Canada.

It has been clearly demonstrated that cells lacking functional *p53* are defective in nucleotide excision repair of UV-induced DNA damage. Nonetheless, we have previously found that the model *p53*-deficient human tumor strain SW480 unexpectedly exhibits normal rates of DNA repair. Towards understanding the basis for this exceptional phenotype, we aimed to characterize the precise *p53* status of SW480. Although this strain is known to bear mutations in codons 273 and 309 of *p53*, it remains unclear how many *p53* alleles it carries and whether any of these alleles are wild type. Using GTG banding and M-FISH (multi-color fluorescence in situ hybridization), we found that SW480 cells are hyperdiploid and polyclonal, but are cytogenetically stable. We have characterized many structural chromosome anomalies. Furthermore, they have three copies of chromosome 17 (i.e., 17p13.1, where *p53* is localized). The integrity of the short arm of chromosome 17 in SW480 was confirmed using FISH with probes specific for Smith-Magenis (17p11.2) and Miller-Dieker (17p13.3) syndromes. Using DNA sequencing and restriction analysis, it was revealed that all three *p53* alleles in SW480 carry point mutations in codons 273 and 309. By in vivo footprinting using ligation-mediated PCR, we are currently analyzing the ability of this mutated *p53* protein to bind the *p53* consensus sequence located at target genes such as XPC, p21, p48, GADD45.

**FANCD2 associates with BLM at telomeres in ALT-immortalized human cells.** *H. Root*<sup>1, 2</sup>, *M.S. Meyn*<sup>1,2,3</sup>. 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON; 2) Molecular & Medical Genetics, University of Toronto, Toronto, ON; 3) Paediatrics, University of Toronto, Toronto, ON.

Fanconi anemia patients have short telomeres, which correlate with genomic instability and bone marrow failure. ~10% of tumors lack telomerase and maintain their telomeres by ALT pathways, which may involve genetic recombination. We recently found that BLM, the Bloom syndrome DNA helicase, is involved in ALT. We now report data supporting a similar role for the Fanconi anemia protein FANCD2.

FANCD2 normally forms nuclear foci. In 1/3 of asynchronously growing ALT human fibroblasts, a majority of these foci colocalized with foci of BLM and with foci of TRF1, a component of telomeres. Association of FANCD2 with telomeric foci was ALT-specific, as FANCD2 and TRF1 rarely co-localized in telomerase-positive cells. FANCD2 frequently associates with BRCA1. However, in ~50% of cells showing FANCD2 colocalization with TRF1, FANCD2 foci did not colocalize with BRCA1. In addition, BRCA1 foci rarely associated with telomeric foci except when colocalized with FANCD2. This suggests that FANCD2 is not carried to telomeric foci by BRCA1, but BRCA1 may be at telomeres as part of a complex with FANCD2.

In synchronized cultures, ~90% of S-phase cells showed a majority of FANCD2 foci colocalizing with BLM and TRF1, indicating that FANCD2 and BLM preferentially associate with telomeric foci during DNA replication. The association of FANCD2 with TRF1 in ALT cells is not solely due to its localization to PML bodies, as FANCD2 colocalizes with PML in only ~50% of ALT cells in early S phase. We now are using IP and FRET techniques to test for *in vivo* interactions between FANCD2, BLM and TRF2.

We transfected fibroblasts with shRNA vectors designed to suppress FANCD2 expression and found that 8/30 telomerase-positive transformants, but 0/82 ALT transformants lacked or had markedly reduced FANCD2 expression by Western blotting, suggesting that FANCD2 may be required for proper ALT function. Our results support a model in which FANCD2 acts with BLM to facilitate recombination-driven replication of telomeres in ALT cells.

**Genomic instability in TP53-mutated breast cancer cells treated with etoposide and doxorubicin.** *M.L. De Vos, B.L. Weber.* Hematology/Oncology, University of Pennsylvania, Abramson Family Cancer Research Institute, Philadelphia, PA.

Mutations in the TP53 gene are among the most common genetic changes in cancer cells, with 20-40% of breast cancers having somatic TP53 mutations. It is hypothesized that when TP53 mutations are present in cancer cells, treatment with chemotherapeutic agents that induce double strand breaks (DSBs), such as doxorubicin and etoposide, results in greater genomic instability than in the presence of wildtype-TP53 (WT-TP53). Therefore, we are investigating the gene copy number alterations following etoposide and doxorubicin treatment of breast cancer cells with either WT- or mutated-TP53 (mut-TP53). Evaluation of the cytotoxicity of doxorubicin in MCF-7 (WT-TP53), MDA-MB-231 (mut-TP53), and T-47D (mut-TP53) breast cancer cells demonstrated that cells with WT-TP53 are more sensitive to doxorubicin than cancer cells with mutated TP53. Specifically, the IC<sub>50</sub> for cytotoxicity of doxorubicin at 24 hours was 2.0-0.8 M in MCF-7 cells, 41-7.4 M in MDA-MB-231 cells, and 97.5-31.8 M in T-47D cells. Similarly, 0.2-0.8 M doxorubicin treatment for 24 hours resulted in a larger number of DSBs in the TP53-mutated cells, as measured by  $\gamma$ -phosphorylation of histone H2AX. Finally, genomic stability in WT- and mut-TP53 cells treated with DSB-inducing chemotherapeutics will be determined using array-based comparative genomic hybridization (CGH). By determining the genomic changes in WT- and mut-TP53 cells following induction of DSBs, we will evaluate whether the DSB induction by chemotherapeutics results in random or specific gene copy number changes and determine whether these copy number changes are associated with changes in gene expression. These data may provide insight into the relative chemotherapeutic resistance of human breast cancers with TP53 mutations and allow identification of genetic factors involved in the development of drug resistance in these patients.

**A case of myelodysplastic syndrome (MDS) with a constitutional mosaicism for trisomy 21 in the skin sample of a child.** *J. Hu<sup>1,2</sup>, S. Shekhter-Levin<sup>1</sup>, P. Shaw<sup>2</sup>, C. Bay<sup>2</sup>, S. Kochmar<sup>1</sup>, U. Surti<sup>1,2</sup>.* 1) Pittsburgh Cytogenetics Lab, UPMC Magee-Womens Hosp, Pittsburgh, PA; 2) University of Pittsburgh School of Medicine, Pittsburgh, PA.

A 3 year old female presented with anemia, thrombocytopenia and blasts in the peripheral blood (PB). A bone marrow aspirate revealed MDS and was analyzed for cytogenetic abnormalities. Twenty two G-banded metaphases were analyzed from 24-hour harvests of unstimulated bone marrow. A mosaic abnormal female karyotype 46,XX,t(1;19)(q42;p13.1)[12]/47,idem,+21[3]/47,idem,+21,-7,+mar[7] was obtained. The major clone had a balanced translocation between the long arm of chromosome 1 and the proximal short arm of chromosome 19. The second clone had trisomy 21 in addition to the 1;19 translocation. The third clone revealed a loss of one chromosome 7, replaced with a marker chromosome of unknown origin, in addition to the 1;19 translocation and trisomy 21. Complete or segmental monosomy 7 and trisomy 21 has been reported in childhood MDS and is associated with unfavorable prognosis. Because the t(1;19)(q23;p13.3) was seen in every cell analyzed, we performed cytogenetic analysis on the patient's PB to rule out a constitutional abnormality. A karyotype 46,XX,t(1;19)(q42;p13.1) was found in all 20 cells analyzed, confirming the constitutional origin of this translocation. Cytogenetic analysis was also performed on skin fibroblasts. In addition to all cells having the t(1;19)(q23;p13.3), 5 cells out of 50 from 2 separate cultures contained an extra chromosome 21. The presence of 2 cell lines in multiple cultures indicates that the patient is a true low level mosaic for trisomy 21. These findings indicate the trisomy 21 found in her bone marrow is a constitutional abnormality and the leukemic clone arose from this trisomic hematopoietic precursor. The child appeared phenotypically and developmentally normal on clinical evaluation except for slightly up slanted palpebral fissures and small increased space between her 1st and 2nd toes. Growth and development to date are normal. Molecular analysis will be performed to determine meiotic or postzygotic origin of the trisomic cells.

**Detection of urothelial carcinoma: Correlation between cytology and fluorescence in situ hybridization.** *D.J. Wolff<sup>1</sup>, T. Keane<sup>2</sup>, C. Felicissimo<sup>3</sup>*. 1) Dept. Pathology/Lab Med, Medical Univ South Carolina, Charleston, SC; 2) Dept. Urology, Medical Univ South Carolina, Charleston, SC; 3) Diagnostic Genetic Sciences Program, University of Connecticut, Storrs, CT.

Urothelial carcinoma (UC) is a common cancer in the United States with >50,000 new cases reported annually. UC has a high recurrence rate and urine cytology is the standard method employed for recurrence monitoring. However cytology has a low sensitivity, particularly for low-grade disease. The FDA-approved Vysis UroVysion Bladder Cancer Recurrence kit (UroV) uses DNA probes to detect chromosomal abnormalities frequently associated with UC. We hypothesized that UroV would have a higher detection sensitivity for UC in our unselected clinic population. 100 samples were processed by FISH and urine cytology. Results were concordant in 88% of cases and discrepant for 12%; 6 cases had insufficient cells for FISH analysis. 9 cases had negative cytologic findings, but were positive by FISH. Two cases were positive by cytology and negative by FISH. Cases with conflicting findings were further clarified with surgical pathology reports and/or physicians' diagnoses. UroV results were confirmed for all but three of the discrepant cases, one questionable false positive and two cases undergoing further studies. For the 19 cases with documented neoplasia, 18 had an abnormal FISH result (overall sensitivity = 95%). This was significantly higher than the 42% sensitivity obtained with cytology. While UroV is FDA-approved only for detection of recurrent UC, 58% of our cases had FISH testing as a screen for primary UC or primary or recurrent renal or ureteral carcinoma. Diagnosis for these cases was based on traditional cytology and surgical pathology, however results were consistent with those obtained with UroV and were thus included in the overall sensitivity. UroV testing allowed for early detection of UC, consistent with the fact that chromosomal abnormalities typically occur before the formation of detectable lesions or tumors. We conclude that UroV is a sensitive detection method for recurrent urothelial carcinoma and may be useful in the early detection of UC, as well as upper urinary tract carcinomas.

**Application of Fluorescent In Situ Hybridization (FISH) to detect *BCR/ABL* fusion in patients with chronic myelogenous leukemia.** *M. Soto Quintana, A. Rojas-Atencio, F. Álvarez-Nava, K. Urdaneta.* Unidad Genética Médica, Universidad del Zulia, Maracaibo, Venezuela.

Chronic myelogenous leukemia (CML) is a clonal myeloproliferative disorder of the hematopoietic stem cell, clinically characterized by an overproduction of granulocytic cell. It is cytogenetically characterized by the presence of the Philadelphia (Ph) chromosome that arises from t(9;22)(q34;q11) or variant of this translocation. The translocation fuses the *ABL* and *BCR* genes by inserting the *ABL* proto-oncogen located at 9q34.1 to the *BCR* region at 22q11.2. This chimerical gene codes for an abnormal protein which has tyrosine kinase activity and significant leukemogenic potential. The objective of this study is to demonstrate the useful application of FISH in the identification of the *BCR-ABL* molecular complex in patients with CML. Bone marrow samples from 30 patients with CML were analyzed. To determine the *BCR-ABL* rearrangement by FISH we used the probe *LSI BCR/ABL* and hybridization protocol that were supplied by *VYSIS*. The standard cytogenetic techniques showed that 16 patients presented the t(9;22)(q34;q11), 6 patients showed a variant translocation of this anomaly and 8 patients normal karyotypes. FISH detected *BCR-ABL* fusion in all patients. Our study demonstrates the significance of this assay in the identification *BCR-ABL* fusion in patients with CML. Thus, FISH is a crucial to the accurate diagnosis and correct medical management.

**Incidence of variant FISH results in pediatric ALL.** *M. Thangavelu*<sup>1</sup>, *PA. Mowery-Rushton*<sup>2</sup>, *JL. Murata-Collins*<sup>2</sup>, *KE. Richkind*<sup>2</sup>. 1) Genzyme Genetics, Orange, CA; 2) Genzyme Genetics, Santa Fe, NM.

Interphase FISH analyses are routinely used to identify hyperdiploidy, MLL 11q23 rearrangements, t(12;21) and t(9;22) in childhood ALL. They may also identify additional abnormalities involving the loci tested. Results of 532 FISH analyses performed at Genzyme Genetics were reviewed to determine the frequency of such results and thereby determine the informativeness of interphase FISH studies, in addition to their intended purpose of identifying traditional abnormalities. 29 of 291 specimens tested for BCR/ABL showed abnormal results. 19 cases had BCR/ABL signals consistent with a t(9;22). Ten cases had the following abnormalities: additional copy of BCR/ABL[7], additional der(22)[1], ins(9;22)[1], deletion of der(9q)[1]. 48 of 164 specimens gave abnormal results with the 11q23 MLL probe. 30 cases had signals consistent with translocations involving 11q23. The remaining 18 cases had the following abnormalities: additional copy of MLL[9], one copy of MLL[5], rearrangement and deletion of MLL[2], rearrangement and additional MLL signal[1], 2 clones with two differing MLL abnormalities[1]. 47 of 138 specimens investigated for TEL/AML1 showed abnormal results. 26 cases had fusion signals consistent with t(12;21); the remaining 21 cases showed more complicated findings; gain of AML1[9], TEL/AML1 fusion with additional copy of TEL and/or TEL/AML1[5], TEL/AML1 and deletion of TEL[2], loss of TEL[3], two copies of TEL/AML1[1], reduced (split) AML1 signal[1]. Our results indicate 40% of cases, which are positive by FISH for BCR/ABL, TEL/AML1 or MLL rearrangements, will demonstrate additional or other changes involving these loci. Additionally, among cases with multiple FISH analyses, 2 cases with TEL/AML1 rearrangements also had deletion of MLL. Among cases with hyperdiploidy, 7 cases were also positive for TEL/AML1, and 8 had an abnormality involving MLL, including MLL rearrangement[2] and MLL deletion[1]. The prognostic implications of these additional abnormalities, in particular, a submicroscopic abnormality such as a deletion accompanying the traditional abnormality or the co-existence of two different traditional abnormalities, are yet to be determined.

**Modified allelic replication in genomes of patients with Beckwith Wiedemann Syndrome.** *O. Reish<sup>1</sup>, M.*

*Mashevitz<sup>1</sup>, R. Gobazov<sup>1</sup>, M. Rosenblat<sup>1</sup>, C. Sher<sup>1</sup>, V. Libman<sup>1</sup>, L. Avivi<sup>2</sup>.* 1) Genetic Inst, Assaf Harofeh Medical Ctr, Zerifin 70300 and Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 2) Department of Human Genetics and Molecular Medicine, Sackler School of Medicine, Tel Aviv University, Tel Aviv Israel.

Transcriptional activity of genes is related to their replication timing; alleles showing the common biallelic mode of expression replicate synchronously, whereas those with a monoallelic mode of expression replicate asynchronously. A loss of synchrony in allelic replication timing has been detected in lymphocytes derived from patients with various types of malignancies or premalignancies. As Beckwith Wiedemann Syndrome (BWS) is an overgrowth condition associated with an increased risk to develop malignancies, we used the fluorescence in situ hybridization (FISH) replication assay and evaluated the level of replication synchrony of three cancer-implicated genes (RB1, AML1, and CMYC) in lymphocytes derived from patients with BWS without malignancy. Ten controls and 6 patients with BWS including 2 sporadic individuals - one with paternal uniparental disomy (pat UPD), one with mosaic pat UPD and 4 individuals from the same family with enhancement of the paternal band at H19 locus, were evaluated. Karyotype analysis was normal in all patients. In cells derived from controls, each pair of alleles replicated synchronously; yet these same alleles replicated in a significantly increased asynchrony in cells derived from BWS patients. Each gene, which normally displayed synchrony in allelic replication, in the patients' cells displayed loss of synchrony. The loss of replication synchrony, of each gene, in the patients' cells was achieved by an advanced replication of a single allele, which replicated remarkably earlier than its normal scheduled timing. In addition, the second allele showed a significantly earlier replication timing than that normal for the gene. Thus, it is assumed that the BWS condition is associated with activation of cancer-implicated genes that may be the cause for over growth and an increased risk of patients to develop malignancies.

**FISH is a superior approach in the diagnostic confirmation of acute promyelocytic leukemia with PML/RARA insertions.** *G. Sun*<sup>1</sup>, *M. Owens*<sup>1</sup>, *H.Y. Dong*<sup>2</sup>, *W. Gorczyca*<sup>2</sup>, *S. Tugulea*<sup>2</sup>, *J. Weisberger*<sup>2</sup>. 1) Cytogenetics Department; 2) Division of Hematopathology, IMPATH Inc., New York, NY.

The presence of t(15;17) or the PML/RARA gene rearrangement is the hallmark of acute promyelocytic leukemia (APL). The introduction of all-trans retinoic acid (ATRA) to the chemotherapy regimen has dramatically improved clinical outcome. Given the potentially catastrophic clinical presentation and treatment stratification, a reliable and rapid diagnosis is essential. We compared the results of cytogenetics, FISH, and real-time multiplex PCR in 36 patients with APL (34 new diagnoses and 2 relapses). Cytogenetics was performed on 34 cases: there were 29 with t(15;17)(q22;q21) with or without additional chromosomal changes, 4 with a normal karyotype, and 1 with 47,XX,+8[5]/46XX[15]. FISH was performed on 12 of 36 cases using a PML/RARA dual color probe (Vysis), including all those without t(15;17). These 5 cases without t(15;17) showed unusual hybridization patterns in interphase and metaphase cells indicating insertions of a portion of the PML gene into the RARA gene (3 cases), and vice versa (2 cases). Therefore, patients suspected of having APL without a demonstrable t(15;17) may have an insertion of RARA or PML genes into chromosomes 15 or 17. APL with insertions comprised about 14% of all cases in our cohort. Nevertheless, cytogenetics has the advantage of detecting RARA gene rearrangements involving other chromosomes, such as t(11;17) and t(5;17), or additional chromosomal aberrations of potential prognostic importance. RT-PCR results from the cytogenetically cryptic 5 cases showed that 4 were positive for the long form (bcr1) transcript. One case with an insertion of the PML gene into the RARA gene was negative. Although RT-PCR is more sensitive for the detection of minimal residual disease and may provide prognostic information relating to specific fusion transcripts, these data show that FISH may detect rare cases of APL with breakpoints outside those typically detected by PCR, and also will detect a subset of APL cases with PML or RARA insertions other than the t(15;17) translocation.

**Breast cancer detection, treatment and outcome in women with hereditary breast and ovarian cancer (HBOC) - Alberta experience.** *R. Hughes<sup>1</sup>, B. Zochodne<sup>1</sup>, M. Lilley<sup>2</sup>, K. Blaikie<sup>1</sup>, S. Kieffer<sup>2</sup>, L. Wagter<sup>1</sup>, D. Gilchrist<sup>2</sup>, K. Barker<sup>1</sup>, G. Fick<sup>1</sup>.* 1) University of Calgary, Calgary, AB; 2) University of Alberta, Edmonton, AB.

Breast cancer detection and recurrence were evaluated in 41 women with BRCA gene mutations (mut) and 202 women with positive family histories (FHx) of hereditary breast and ovarian cancer (HBOC) from the Alberta Cancer Genetics Program. The average age at first breast cancer diagnosis was 42.3 yr +/- 9.0 yr SD in the mut group vs. 45.7 yr +/- in the FHx group. Right and left breasts were equally involved. The majority of breast cancers were first detected as palpable lumps (77.3% mut; 72.8% FHx) rather than by mammography (13.6% mut; 25.7% FHx). Many participants had mammograms done within the 2 years prior to breast cancer diagnosis that failed to detect the malignancies (37.5% mut; 51.5% FHx). Pathology review identified infiltrating ductal carcinomas (IDC) (93.9% mut; 88.5% FHx), infiltrating lobular carcinomas (ILC) (3.0% mut; 9.5% FHx), and mixed IDC/ILC (3.0% mut; 2.0% FHx). Choice of surgical treatment was divided between mastectomy (50% mut; 54.8% FHx) and segmentectomy/ lumpectomy (50% mut; 45.2% FHx). Subsequent breast ca diagnosis depended on initial surgical choice. mastectomy resulted in fewer recurrences and new primary diagnoses (17.6% mut; 16.5% FHx) compared to segmentectomy/ lumpectomy (41.2% mut; 27.1% FHx). Malignancies following mastectomy were more likely to occur in the contralateral breast (100% mut; 64.7% FHx) or lymph nodes/chest wall (0% mut; 35.3% FHx). Malignancies following seg/lumpectomy were more likely to occur in the ipsilateral breast (57.1% mut; 70.6% FHx). Conclusion: most breast cancers diagnosed in HBOC females are discovered by palpation. Mammograms performed within 2 years prior to diagnosis can miss tumours. Mastectomy reduces the risk of a second ipsilateral breast cancer diagnosis compared to seg/lumpectomy.

**Combining Clinical and Microarray Data for Tumor Classification.** *A. Smith<sup>1</sup>, J.M. Satagopan<sup>1</sup>, A. Stephenson<sup>2</sup>, M.W. Kattan<sup>1,2</sup>, W.L. Gerald<sup>3</sup>.* 1) Dept. of Epidemiology & Biostatistics; 2) Dept. of Urology; 3) Department of Pathology, Memorial Sloan-Kettering Cancer Ctr., New York NY.

A common objective of microarray analyses is the creation of a molecular model to classify samples into appropriate biological groups. As these studies are extremely expensive and laborious, this objective is only of value if the molecular classifier performs more reliably than existing clinical measures. There is increasing interest in the combining of clinical and molecular information to create a more robust classifier. Given an appropriate and reasonably large independent test set of samples, one can compare classification rates based on the clinical variable(s) alone, a molecular model alone, or a model which combines both. We propose a stepwise logistic regression procedure that will allow any combination of gene or clinical measures, without unduly weighting either. The procedure is demonstrated using a set of 79 prostate cancer tumor samples from Memorial Sloan-Kettering Cancer Center. The incidence of a biochemical recurrence was used to identify the response groups. Our results demonstrate that a combined model yields significantly improved classification over models based on a specific clinical measure of interest or gene expressions alone.

**Discovery and Classification of Cancer Types using Gene Expression Analysis.** *R.A. Alexandridis, S. Lin, M. Irwin.*  
Department of Statistics, Ohio State University, Columbus, OH.

Class discovery and classification are of crucial importance for determining efficient therapies in cancer treatment. Recent studies have shown that DNA microarray technology is a powerful tool for discovery and classification of cancer types and subtypes. We propose a unified approach to discovery of putative classes of cancers and classification of the interrogated tumor samples into the identified classes. Our approach is able to handle datasets with no training samples (class discovery problems), datasets where training samples exist and all the test samples belong to the known classes (classification), as well as datasets where training data exist but some of the test samples do not belong to any of the known classes (joint analysis of class discovery and classification). The method proposed is based on modeling the distribution of a gene expression profile as a finite mixture of an unknown number of distributions, with each mixture component characterizing the gene expression levels within a class. We use the expectation maximization algorithm (EM) to find the maximum likelihood estimates of the mixture model. Selection of the number of classes is achieved by Bayesian (BIC) or Akaike (AIC) information criteria. We reduce the large dimensionality by using several measures for gene selection, and explore the sensitivity of the class discovery and class prediction results to the gene selection measures and the number of selected genes. We applied our procedure to several datasets derived from the leukemia dataset of Golub et. al (1999) and to several simulation studies based on these datasets. For most leukemia datasets with 80 to 150 genes, the true number of classes is identified and the prediction accuracy rates are over 96% when there is not more than one unknown class. Even in the most difficult case, when there are three unknown classes and no training data, BIC discovers the true number of classes and the prediction accuracy rates are 89% or more for most datasets with 50 to 200 genes. The simulations further showed that our method is able to discover the true number of classes and to achieve good prediction accuracy.

**Most somatic mutations in human prostate cancer tissue conform to a specific motif.** *N. Makridakis, L. Ferraz, J.K.V. Reichardt.* Keck School of Medicine, Univ Southern California, Los Angeles, CA.

Cancer, including cancer of the prostate, is thought to progress through the accumulation of specific mutations in somatic tissue. We screened matched human prostate tumor and constitutional DNA for somatic mutations in three human genes, SRD5A2, HSD3B2 and HPRT, by direct sequencing of PCR products, in 30 patients. We identified a total of 85 somatic mutations in all three genes specifically in the tumor tissue, 84% of which are transitions. In contrast, only 55% of the constitutional DNA polymorphisms found in the same genes are transitions. In addition, we report that the sequence of 96% of the somatic mutations identified conforms to a nine nucleotide purine-rich motif. This motif is also found in all 26 H-ras gene mutations formed in the SENCAR mouse skin model, after induction of error-prone DNA repair less than one day following either benzopyrene or estradiol-3, 4-quinone treatment. 24 out of 26 (92%) of the H-ras gene mutations induced by either of these carcinogens in the mouse are also transitions. Literature searches identified the same purine-rich motif in 76 out of 80 (95%) of the somatic prostate cancer mutations of all the genes analyzed in humans, including H-ras, N-ras, Ki-ras, PTEN, and the androgen receptor gene. These data suggest that the majority of the somatic mutations in human prostate cancer tissue are transitions that occur in a specific purine-rich motif, which may be the target of a particular pathway of error-prone DNA repair.

**Replication and reproducibility in microarray experiments testing chemotherapeutic effects in an animal model.**

*W. Liu*<sup>1</sup>, *G.A. Chase*<sup>1</sup>, *W.B. Reeves*<sup>2</sup>, *X. Gao*<sup>2</sup>. 1) Department of Health Evaluation Sciences, Penn State College of Medicine, Hershey, PA 17033; 2) Department of Nephrology, Penn State College of Medicine, Hershey, PA 17033.

DNA microarray experiments measure the expression of thousands of genes simultaneously but at a high cost. One major problem facing many small labs is that of setting a minimal number of replicates for a reproducible result. Here we studied the performance of statistical significance tests for different replication schemes by analyzing two independent experiments. In our first experiment, gene expression alterations in kidney between wild type and TNF alpha knockout mice under the influence of cisplatin, a popular drug used in cancer treatment, were studied. We tested genes for significant changes in expression using permutation tests implemented by the computer software SAM. The sensitivities and false discovery rates (FDR) of the tests using four, three, two and one pair of dye-swapped replicate arrays were compared. Sensitivities were calculated with respect to the results obtained using four pairs of replicates as a gold standard. Sensitivity decreases with fewer replicates and FDR increases with fewer replicates. The overall average sensitivity of the tests using three pairs of replicates was relatively high (.89) and the average FDR was low (.034). However, the sensitivities and false discovery rates of the tests using two and one pair of replicates were unsatisfactory, especially for tests using only one pair of replicates. To verify our results we compared gene expression differences in kidney tissue between cisplatin treated and untreated mice; similar results were found. In conclusion, our results indicate that the use of one or two pairs of replicates leads to too many false positive genes and a low power to detect truly significant gene changes. We suggest the use of at least three pairs of replicates to obtain a reproducible result.

Program Nr: 342 from 2003 ASHG Annual Meeting

**CGAP and MGC - two comprehensive genomic resources for the scientific research community.** *L. Jia, D. Gerhard, L. Grouse, S. Greenhut.* Office of Cancer Genomics, National Cancer Institute, and the CGAP and MGC Project Teams, NIH, Bethesda, MD.

The NCI's Cancer Genome Anatomy Project (CGAP, <http://cgap.nci.nih.gov/>) provides a web-based information platform to study the gene expression profiles of normal, precancer, and cancer cells, leading eventually to improved detection, diagnosis, and treatment for the patient. Using CGAP's web analysis tools, researchers can examine gene expression in human and mouse tissues using either EST or SAGE data, search for SNPs, find chromosome aberrations in cancer, identify FISH-mapped BACs or cDNA clones that are useful in their research, and explore genes and their pathways. CGAP continues to add to its scientific expertise and expand its databases for the benefit of all cancer researchers. The NIH's Mammalian Gene Collection (MGC, <http://mgc.nci.nih.gov/>) provides full-length open reading frame (FL-ORF) clones for human and mouse genes. Using standard, normalization, and size-selected methods, the MGC has produced full-length cDNA libraries from over 100 human tissues and cell lines and 80 mouse tissues. To date, clones for a non-redundant set of more than 15,000 human genes and 11,000 mouse genes have been sequenced and verified to contain complete FL-ORFs. All MGC sequences are deposited in GenBank and the clones can be purchased from distributors of the IMAGE Consortium.

**Tumor classification using phylogenetic methods on expression data.** *A.A. Schaffer<sup>1</sup>, R. Desper<sup>1</sup>, J. Khan<sup>2</sup>*. 1) NCBI/NIH/DHHS, Bethesda, MD; 2) NCI/NIH/DHHS, Gaithersburg, MD.

Tumor classification is a well-studied problem in bioinformatics. Developments in the field of DNA chip design have now made it possible to measure the expression levels of thousands of genes in sample tissue from healthy cell lines or tumors. A number of studies have examined the problem of tumor classification: using the data from a DNA chip to accurately classify an unknown tumor. This problem is of high interest whether one seeks to differentiate cancerous tissue from healthy tissue, or whether one seeks to accurately classify unknown tumors according to a diagnostic or prognostic category. Our work applies phylogenetic methods to this problem. We impose a metric on a set of tumors as a function of their gene expression levels, and we seek to infer a tree structure from the distance data, using tree fitting methods borrowed from the field of phylogenetics. Phylogenetic methods provide a simple way of imposing a hierarchical relationship on the data, with branch lengths in a phylogeny representing a degree of separation. We demonstrate the flexibility and robustness of the phylogenetic method with regard to resampling methods such as jackknifing and with regard to noise perturbation of the real data. Using our methods on a published data set of 87 tissues, comprised mostly of small, round, blue-cell tumors (SRBCTs), we fit the 87 samples to a pseudo-phylogenetic tree, which neatly separated into 4 major clusters corresponding exactly to the four groups of tumors: neuroblastomas, rhabdomyosarcomas, Burkitt's lymphomas, and Ewing's sarcomas. We also tested our methods on a published data set of 22 breast tumors. The resulting tree separated tumors with BRCA1 mutations from those with BRCA2 mutations, with sporadic tumors separated from both other groups and from each other.

**Differential reduction of qkI isoforms in human glioma cell lines.** *L. Ku, Y. Feng.* Emory University, Department of Pharmacology, Atlanta, GA b.

Cytogenetic alterations at 6q25-26 has been reported to associate with a variety of human malignancies, including gliomas. However, which gene(s) at this locus may play a role as potential tumor suppressor mains unclear. The human quaking gene (Hqk) has been recently mapped to 6q25-26, which encodes a selective RNA-binding protein QKI, a member of the signal transduction activators of RNA (STAR). Three major isoforms of QKI are derived from alternative splicing of the qkI primary transcript, which are named QKI-5, 6 and7 based on the length of the corresponding mRNA. The role of QKI has been implicated in cell growth, differentiation, as well as apoptosis. In the brain, all QKI isoforms are expressed in various types of glial cells but absent in neurons. We analyzed qkI mRNA expression in 23 glioma cell lines. Our preliminary result indicated that around one third of the tumor lines showed significant reduction of the total qkI transcripts. Interestingly, qkI-7, the isoform that can act as a potent apoptosis inducer, was preferentially reduced. Moreover, qkI-6, the isoform that promotes glia differentiation was diminished in most of the glioma lines analyzed. In contrast, qkI-5, the embryonic predominant isoform remains normal in all the glioma cell lines analyzed. These results suggest that abnormalities of qkI alternative splicing may affect glial differentiation and apoptosis, potentially in turn contributes to glioma tumorigenesis.

**Increased chromosomal instability at common fragile sites in Seckel syndrome.** *S.G. Durkin, A.M. Casper, T.W. Glover.* Department of Human Genetics, University of Michigan, Ann Arbor, MI.

The partial perturbation of DNA replication induces the expression of common fragile sites. These sites are detected as gaps and breaks on metaphase chromosomes under conditions of replicative stress, such as from aphidicolin treatment or folate deficiency. Rather than arising by mutation, common fragile sites are a constant component of chromosome structure. These sites are often rearranged in tumor cells, and thus are important for understanding chromosomal instability observed in cancer. We have previously shown that ATR, a gene critical to S phase and G2/M checkpoint signaling in response to stalled replication forks, is crucial for the maintenance of chromosomal stability at common fragile sites. Cells lacking ATR are non-viable, making the effects of ATR deficiency challenging to study. Recently, however, a subgroup of patients with Seckel syndrome was reported by O'Driscoll et al. (*Nat. Genet.* 33:497-501, 2003) to have a mutation in ATR. Seckel syndrome is a heterogeneous disorder characterized by severe dwarfism, mental retardation, microcephaly, and in some cases, chromosome instability, hematological disorders and leukemia. Two Pakistani families with Seckel syndrome were found to have a silent mutation in ATR that resulted in use of cryptic splice donor sites in exon 9, leading to a frameshift. Homozygotes for this hypomorphic allele produce greatly reduced levels of correctly spliced message. We hypothesized that cells from Seckel syndrome patients would have increased instability at common fragile sites. We obtained lymphoblastoid cell lines from two affected and three unaffected members of these families. ATR deficiency in all affected individuals was confirmed by western blots. Following treatment with aphidicolin, cells homozygous for the hypomorphic allele showed a ~3 fold increase in total gaps and breaks, and in breaks at specific fragile sites, compared to unaffected controls. These results are consistent with our previous findings that ATR deficiency results in increased fragile site instability and suggest that the Seckel syndrome hypomorphic mutation provides a model for studying the biological effects of fragile site instability.

**The Association of Up-regulation of FGF3 and Hepatocellular Carcinoma Metastasis and Recurrence. X-Y.**

*Guan<sup>1</sup>, L. Hu<sup>1</sup>, D. Xie<sup>1</sup>, J.S. Sham<sup>1</sup>, J-M. Wen<sup>2</sup>, W-S. Wang<sup>3</sup>.* 1) Department Clinical Oncology, University Hong Kong, Hong Kong, China; 2) Department Pathology, Sun Yat-Sen University, Guangzhou, China; 3) Department Surgery, First Affiliated Hospital, Sun Yat-sen University, Guangzhou, China.

Hepatocellular Carcinoma (HCC) is one of the most common malignancies worldwide with poor prognosis. The poor prognosis of HCC has been associated with the tumor metastasis and recurrence. Therefore, it is imperative to completely understand the molecular mechanisms involved in the tumor metastasis in HCC. In the present study, a marker chromosome containing a homogeneously staining region (HSR) in a recently established metastatic HCC cell line (H4-M) was characterized by chromosome microdissection. The result showed that the HSR was composed of DNA sequence from 11q13. Amplification and overexpression status of CCND1-FGF19-FGF4-FGF3 gene cluster in 11q13 in H4-M was analyzed by Southern blot and Northern blot hybridizations. Amplification and overexpression of CCND1 and FGF3 were detected. The association of overexpression of FGF3 and HCC metastasis as well as recurrence was studied using a tissue microarray composed of 60 pairs of primary and matched metastatic HCCs and 30 pairs of primary and matched recurrent HCCs. The results showed that the overexpression frequency of FGF3 was significantly higher in metastatic HCC (19/40, 47.5%) than that in primary HCC (3/40, 7.5%). Similarly, the frequency of FGF3 overexpression was significantly higher in recurrent HCC (9/21, 42.86%) than that in primary HCC (1/21, 4.8%). Our results strongly suggested that up-regulation of FGF3 may play an important role in metastasis and recurrence of HCC.

**Altered Notch signaling resulting from expression of a WAMTP1-MAML2 gene fusion in mucoepidermoid carcinomas.** *F. Enlund<sup>1</sup>, A. Behboudi<sup>1</sup>, Y. Andren<sup>1</sup>, C. Öberg<sup>2</sup>, U. Lendahl<sup>2</sup>, J. Mark<sup>1</sup>, G. Stenman<sup>1</sup>.* 1) Lundberg Laboratory of Cancer Research, Dept of Pathology, Univ. Gothenburg, Sweden; 2) Dept of Cell and Molecular Biology, Karolinska Institute, Stockholm, Sweden.

Chromosome translocations in neoplasia commonly result in fusion genes that may encode either novel fusion proteins or normal, but ectopically expressed, proteins. Here we report the cloning of a novel fusion gene in a common type of salivary and bronchial gland tumor, mucoepidermoid carcinoma (MEC). The fusion, which results from a t(11;19)(q21-22;p13) translocation, creates a chimeric gene in which exon 1 of a novel gene of unknown function, designated WAMTP1, is linked to exons 2-5 of the recently identified Mastermind-like Notch coactivator MAML2. In the fusion protein, the N-terminal basic domain of MAML2, which is required for binding to intracellular Notch (ICD), is replaced by an unrelated N-terminal sequence from WAMTP1. Northern blot analyses revealed that the expression of WAMTP1 is restricted to certain fetal and adult tissues while MAML2 is expressed in most tissues. The fusion protein was found to colocalize with both MAML2 and Notch1 ICD to nuclear granules. Analysis of Notch target genes revealed altered expression of several genes in fusion positive MECs compared to normal salivary gland tissue and MECs lacking the fusion. These findings suggest that altered Notch signaling plays an important role in the genesis of neoplasms of salivary and bronchial gland origin.

**Differential Expression of a Gonadoblastoma Candidate Gene in Gonadoblastoma, Testis and Prostate Cancer Suggests a Role of the Y Chromosome in Human Oncogenesis.** *Y.-F.C. Lau, H. Lau, Y. Li, L.G. Komuves.* Dept Medicine/ VA Med Ctr/ Univ California, San Francisco, CA.

Gonadoblastoma on the Y chromosome (GBY) is an oncogenic locus that predisposes the dysgenetic gonads of XY sex-reversed females to tumorigenesis at high frequency. Recent completion of the human Y chromosome sequencing revealed the testis-specific protein Y-encoded (TSPY) gene as the only functional gene in the GBY critical region. TSPY is 2.8-kb in size and is repeated tandemly in 20.5-kb units. TSPY shares significant homology to various cyclin B binding proteins, including oncoprotein SET, some of which possess cell cycle modulating functions. TSPY is expressed at high levels in both gonadoblastoma and testicular seminoma. To further evaluate the role of TSPY in other male-specific cancers, we had examined its expression in 10 cases of prostate cancer using both in situ hybridization and immunohistochemistry. Our results demonstrated that TSPY was expressed at low levels in normal epithelial cells and benign prostatic hyperplasia, but at elevated levels in tumor cells of prostate cancer at various degrees of malignancy. Sequence analysis of RT-PCR products obtained from both prostatic and testicular tissues using primers flanking the ORF revealed a complex pattern of RNA processing of the TSPY transcripts involving cryptic intron splicing and/or intron skipping. All TSPY transcripts maintain the same ORF and encode a variety of polymorphic or shortened versions of TSPY with diverging properties ranging from 18.1 to 35.1 kDa in size and pI from 5 to 9. The abbreviated TSPY transcripts were more abundant in prostatic cancer than testis samples. GST pull-down assays demonstrated that all TSPY proteins were capable of binding to cyclin B. The binding domain was mapped to their carboxyl termini that share the most significant homology to the oncoprotein SET. Their preferential expression in cancer, diverse biochemical properties and conserved cyclin B binding function suggest that the TSPY gene/variants may be involved in the multi-step prostatic oncogenesis beside its putative oncogenic or tumor-promoting role in gonadoblastoma and testicular seminoma.

**Cancer risk assessment in Indian oral precancer patients using SCGE assay and micronucleus test.** *R. Shukla<sup>1</sup>, P.P. Reddy<sup>2</sup>, Y.R. Ahuja<sup>3</sup>*. 1) Genetic Unit, Dept.Pediatrics, AIIMS, New Delhi, India; 2) Inst of Genetics, Begumpet, Hyderabad, India; 3) Vasavi Med and Res Ctr, 6-1-91, Khairtabad, Hyderabad, India.

Carcinoma of the oral cavity is the most common malignancy in the Indian subcontinent constituting 9.8% of all cancer cases. In India, oral cancer has been causally associated with chewing of tobacco with or without betel quid, which increases exposure to carcinogenic tobacco specific nitrosamines (TSNA) and nitrosamines derived from areca nut alkaloids. An early sign of damage to the oral mucosa is the development of well-defined precancers like leukoplakia, erythroplakia, lichen planus, and submucous fibrosis. While some of the precancers regress, about one third of these may progress to invasive malignancy over a period of time. Thus, there is an urgent need for biomarkers that can predict whether a precancer will develop into an aggressive or metastasizing tumor. This study, using the micronucleus test (MNT) and single cell gel electrophoresis (SCGE) assay was planned with an attempt to understand the carcinogenic process in oral cancer, particularly with reference to DNA damage. The aim was to develop a risk index, for oral precancer patients, based on genomic damage and chromosome instability, to identify those precancer patients who are at high risk for malignant transformation. MNT and SCGE were performed on the buccal epithelial cells (BEC) and peripheral blood leukocytes (PBL) of 443 subjects (129 oral cancer patients, 138 precancer patients and 176 controls) to assess basal DNA damage, MNNG sensitivity and DNA repair. A high-risk precancer patient was identified on the basis of 4 criteria (1) high basal DNA damage in both PBL and BEC (using SCGE) (2) high incidence of chromosome damage in BEC (using MNT) (3) increased sensitivity to MNNG and (4) reduced repair capacity (using SCGE). Based on the above criteria, 4 of 138 oral precancer patients were identified as being at high risk. On follow-up, 3 of these 4 precancer patients presented with malignant lesions after about two years of initial diagnosis. This finding suggests that simple, rapid and sensitive assays such as MNT and SCGE can be included in the battery of tests used for cancer risk prediction.

**An in vitro model for human papillomavirus integration in cervical cancer.** *T. Yu, D.I. Smith.* Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Human papillomaviruses (HPVs) are the major causative agent responsible for the development of cervical cancer (CC). High-risk HPVs can efficiently immortalize cells but additional alterations are necessary to transform those cells and cause the development of invasive CC. The development of invasive CC is temporally associated with the integration of HPV sequences into the host genome. An analysis of the sites of HPV integration has revealed that integration occurs throughout the genome. This has led to the currently accepted dogma that the site of HPV integration is unimportant for the eventual CC that develops. We have been analyzing the sites of HPV16 and HPV18 integration in CC and have found that integration sites are non-random. Over half of the viral integrations occur into common fragile sites (CFS), and some regions have multiple HPV integrations, including the FHIT gene, and the region surrounding c-myc. To determine whether the sites of HPV integration play an important role in CC development we have developed an in vitro model of HPV integration. Linearized DNA will preferentially integrate into CFS regions when cells are exposed to aphidicolin. We utilized this to target the integration of HPV16 and HPV18 DNA sequences into CFS regions. We took human foreskin keratinocytes and exposed them to aphidicolin. We then electroporated an HPV16 and an HPV18 cassette (with a neomycin selectable marker) into these keratinocytes followed by G418 selection. This procedure generated large numbers of G418 resistant colonies that contained HPV sequences integrated into the keratinocytes. We have begun to analyze the sites of HPV integration using the powerful technique of restriction site oligonucleotide PCR (the technique that we previously utilized to map HPV16 and HPV18 integrations in primary cervical tumors). We have found that the HPV16 and HPV18 cassettes preferentially integrate into CFS regions. This in vitro system will enable us to compare the effect of HPV integration into CFS regions that occur in vivo in cervical tumors to integration in the exact same regions in vitro. This should enable us to determine if the sites of HPV integration play an important role in the eventual CCs that develop.

**Genomic disorganization in HCC3153, a new BRCA1 deficient breast tumor cell line.** *G.E. Tomlinson, T. Chen, N.R. Schneider, L. Girard, A. Virmani, J.D. Minna, A. Gazdar.* Dept Ped, Hamon Ctr Ther Onc, Univ TX Southwestern Med Ctr, Dallas, TX.

BRCA1 is a tumor suppressor known to be associated with a high susceptibility to breast cancer. This susceptibility is now thought to be due to a basic defect in maintaining genomic stability. Numerous studies have now documented a role of BRCA1 in nucleotide excision repair and double strand break repair. Few studies have reported changes in human BRCA1 deficient breast tumor cells at the chromosomal level. We previously described genetic changes in a BRCA1 cell line, HCC1937. We report here a new tumor cell line, HHCC3153, derived from a BRCA1 mutation carrier with a germline BRCA1-943ins10 mutation. This mutation is known to be an African American founder mutation. The cell line lacks a normal copy of BRCA1 and is also homozygous for an acquired deletion in exon 4 of the TP53 gene resulting in a protein truncation.

Karyotyping of cultured tumor cells was performed using standard methods. These cultured cells are characterized by extreme aneuploidy. No two metaphases demonstrated an identical pattern. Two overlapping composite karyotypes were constructed, one with 56-59 chromosomes and one with 125 - 161 chromosomes. Many unidentifiable chromosomal fragments were observed. There were no normal chromosomes recognized.

A genome wide survey of allelic loss using 399 fluorescent markers was also performed. The fraction of alleles which demonstrated allele loss was .34 which is moderately high, but not outside the range we usually observe in cultured breast cell lines.

Our findings suggest that in addition to playing a role in transcription coupled repair, that there is an effect of BRCA1 loss at the chromosomal level .

**Familial Melanoma, pancreatic cancer and germline CDKN2A mutations.** *A.M. Goldstein.* Genetic Epidemiology Branch, DCEG, National Cancer Institute, NIH, DHHS, Bethesda, MD.

The CDKN2A gene is the major identified high-risk melanoma susceptibility gene. CDKN2A encodes two cell-cycle regulatory proteins, p16 and p14ARF. Germline CDKN2A mutations have been observed in approximately 20 percent of familial melanoma kindreds from North America, Europe and Australasia. There is also an increased risk of pancreatic cancer in a subset of families with mutations, however, the precise relationship between the CDKN2A gene and pancreatic cancer remains unknown. This study used published data to examine the relationships between familial melanoma, pancreatic cancer and germline CDKN2A mutations. The types and frequencies of the mutations, their distributions throughout the gene, and evidence for identifiable patterns were determined. Nonparametric statistics were used to test the hypotheses of no differences in the distribution of CDKN2A mutations or families with CDKN2A mutations for the factors of interest. Overall, there were 67 different CDKN2A mutations observed in 188 melanoma-prone families. The most common types of mutations were missense (55 percent), frameshift (12 percent), and splice site (9 percent). About two-thirds of the mutations were observed only once, while the remainder recurred in different families. Comparison of all 188 melanoma-prone families to the 42 families that also contained pancreatic cancer showed no significant differences in the types of mutations ( $p=0.97$ ) or mutation location across exons ( $p=0.78$ ) or the four ankyrin (Ank) repeats ( $p=0.27$ ). There was also no significant difference whether the mutations ( $p=0.61$ ) or families ( $p=0.49$ ) altered p14ARF function. However, there was a significant difference ( $p=0.02$ ) in the numbers of families with mutations across the four ankyrin repeats with a deficit of families with CDKN2A mutations with pancreatic cancer in Ank1 and Ank2 (9 percent in Ank1-2 versus 34 percent in Ank3-4). Further research utilizing individual-specific data will be required to determine whether these patterns represent etiologic differences or incomplete reporting of cancer and mutation data.

**BRCA1-related breast cancer is characterized by a basal epithelial phenotype.** *W.D. Foulkes<sup>1</sup>, I.M. Stefansson<sup>2</sup>, P.O. Chappuis<sup>1</sup>, L.R. Bégin<sup>1</sup>, N. Wong<sup>1</sup>, M. Trudel<sup>1</sup>, L.A. Akslen<sup>2</sup>.* 1) Program in Cancer Genetics and Departments of Oncology, Human Genetics, Medicine, Surgery and Pathology; Research Institute of the McGill University Health Centre; Cancer Prevention Centre, Sir M.B. Davis-Jewish General Hospital; McGill University, Montreal, Quebec, Canada; 2) Department of Pathology, The Gade Institute, Haukeland University Hospital, N-5021 Bergen, Norway.

A basal epithelial phenotype accounts for 15% of all invasive breast cancers. Microarray studies have shown that this phenotype is characteristic of breast cancers that express neither estrogen receptor (ER) nor erbB-2 (HER2/neu). As the ER/erbB-2 negative phenotype is also characteristic of BRCA1-related breast cancer, we hypothesized that BRCA1-related breast cancer would be more likely than non-hereditary cancer to express basal keratins. Among 292 breast cancers previously analysed for ER, erbB-2, p53 and germ-line BRCA1/2 mutations, we identified 76 tumors that did not over-express ER or erbB-2. In the 72 cases with sufficient material, there were 17 BRCA1 carriers and 55 BRCA1/2 non-carriers. Forty tumors (56%) stained positively for a mouse monoclonal antibody raised against cytokeratin 5/6 (CK5/6).

The presence of CK5/6 staining was associated with high grade, lymph node negative tumors, and expression of p53. Of the 17 BRCA1-related tumors that were ER and erbB-2 negative and for whom CK5/6 results were available, 15 (88%) over-expressed CK5/6. Among non-BRCA1/2 carriers who had an ER/erbB-2 negative phenotype, only 25/55 (45%) expressed CK5/6 (odds ratio 9.0, 95% CI: 1.9-43, P = .002). These findings suggest that germ-line BRCA1 mutations are associated with a distinctive breast cancer phenotype.

Breast stem cells in rodents and humans can have a CK5/6 + profile. The pattern of genetic alterations identified in all CK5/6 + breast cancers are very similar to those observed in BRCA1-related breast cancers. Therefore, a role for BRCA1 in determining the cytokeratin profile of breast cancer, via regulation of breast stem cells is plausible.

**hMLH1 and hMSH2 mutations in Colombian families with HNPCC. Description of two novel mutations. A.**

*Giraldo<sup>1,2</sup>, A. Gomez<sup>1</sup>, A. Salguero<sup>1</sup>, H. Garcia<sup>1</sup>, F. Aristizabal<sup>1</sup>, O. Gutierrez<sup>1</sup>, L.A. Angel<sup>1</sup>, J. Padron<sup>3</sup>, C. Martinez<sup>4</sup>, H. Martinez<sup>1</sup>, O. Malaver<sup>1</sup>, L. Florez<sup>5</sup>, R. Barvo<sup>6</sup>.* 1) Instituto de Genetica & Facultad de Medicina, Universidad Nacional de Colombia, Bogota; 2) Fundacion Gillow; 3) Univ. El Rosario; 4) Hosp. Militar; 5) Hosp. San Jose. Bogota; 6) Clin. la Concepcion, Barranquilla.

In Colombia, colorectal cancer (CCR) is the fourth cause of death among different cancers. From 3 to 5% of all CCR correspond to Hereditary Nonpolyposis Colorectal carcinoma (HNPCC) or Lynch syndrome. hMLH1 and hMSH2 genes are the most frequent genes involved in HNPCC pathogenesis. We present the results observed in 17 families fulfilling Amsterdam II, or Bethesda criteria. 35 exons of hMLH1 and hMSH2 were screened by SSCP and all electrophoretic variants were automatically sequenced. We detected six germinal mutations in the analyzed families, five in the hMLH1 and one in the hMSH2, which corresponds to 35%. When analyzing the 6 families fulfilling the Amsterdam criteria we detected 83% of the mutations. Two apparently non related families, of the same geographical region share the same mutation, which suggest a founder effect. Three of the five different observed mutations have previously been reported in the International Collaborative Group Database or in the Human Gene Mutation Database. The previous reported mutation of hMLH1 gene are, a single base substitution at the donor splicing site of exon 9, a single base substitution (A/G) at codon 755 of the exon 17, and another single base substitution (G/A) at codon 681 of exon 18. The novel mutations are, a single base substitution (C/T) at codon 640 of exon 17 of the hMLH1 gene and a two nucleotide deletion (TG) at codon 184 of exon 3 of hMSH2 gene. Also, in two families a polymorphism in the intron 13 (G/A) nt 1558+14, of hMLH1 gene was detected. This polymorphism is present in 6.5% of a sample of 150 Colombian individuals. In the present study, most of the mutations, are in the hMLH1 gene which similar to that observed in other Latin American studies. This is the first study performed in Colombia and pretends to establish a prevention program.

**Familial aggregation of lymphoproliferative tumors.** *L.R. Goldin*<sup>1</sup>, *R.M. Pfeiffer*<sup>2</sup>, *M.H. Gail*<sup>2</sup>, *L. Møller*<sup>3</sup>, *J.H. Olsen*<sup>3</sup>, *K. Hemminki*<sup>4</sup>. 1) Gen Epidemiol Br, DCEG/NCI, Bethesda, MD; 2) Biostat Br, DCEG/NCI, Bethesda, MD; 3) Institute of Cancer Epidemiology, Danish Cancer Society, Copenhagen, Denmark; 4) Dept. of Biosciences at Novum, Karolinska Institute, Stockholm, Sweden.

Many case studies and population or hospital-based surveys have reported familial aggregations of Hodgkin lymphoma (HL), non-Hodgkin lymphoma (NHL), chronic lymphocytic leukemia (CLL) and multiple myeloma (MM). To quantify the familial aggregation among these lymphoproliferative (LP) tumor types, we used two large family cancer databases from Sweden and Denmark that were created by linking population registries (containing parent-offspring links) to cancer registries. We have cancer outcome data on first-degree relatives of approximately 52,000 cases of HL, NHL, CLL, or MM and on relatives from matched control groups. We used a marginal survival model comparing disease occurrence in relatives of case compared to control probands. A robust variance estimate accounts for dependencies among relatives. Testing familial aggregation corresponds to testing the null hypothesis that the hazard ratio (HR) of being a relative of a case proband compared to a control proband is 1.0. Relatives of HL cases are at significantly increased risk for HL with a HR = 3.5 in Sweden ( $p < .0001$ ) and HR=2.5 in Denmark ( $p = .03$ ) and aggregation is strongest in males, in siblings, and in relatives of early onset cases. For example, the HR in the combined samples for relatives of probands with age of diagnosis 40 and under is 3.9 ( $p < .0001$ ) compared to 1.6 (ns) for relatives of probands with age of diagnosis greater than 40. In the Swedish sample, relatives of CLL cases are at very high risk for CLL (HR=7.5,  $p < .0001$ ) and elevated risk of HL (HR=2.3,  $p = .03$ ) and NHL (HR=1.4,  $p = .06$ ), relatives of NHL patients are at increased risk for NHL (HR=1.8,  $p < .0001$ ) and HL (HR=1.5,  $p = .04$ ) and relatives of MM patients are at increased risk for MM only (HR=1.7,  $p = .04$ ). We conclude that relatives have the highest risk for developing the same LP tumor as the proband, but there are also significantly elevated risks for other related LP tumors. This suggests shared genetic etiology, especially among HL, NHL, and CLL.

**Analysis of ZBRK1 polymorphisms in high-risk non-*BRCA1/2* French-Canadian families.** *S. Desjardins, Y. Labrie, G. Ouellette, J. Simard, INHERIT BRCA's, F. Durocher.* Cancer Genomics Laboratory, CHUL Research Ctr, CHUQ, Laval University Quebec, Canada.

ZBRK1 is a BRCA1-interacting protein with an N-terminal KRAB domain and a central motif containing eight zinc fingers involved in the recognition and negative regulation of *GADD45* expression. This BRCA1-mediated repression of *GADD45* by *ZBRK1* plays an important role in cell-cycle regulation following DNA damages as well as in maintenance of genome stability. To determine the possible influence of *ZBRK1* polymorphisms on breast cancer susceptibility in non-*BRCA1/2* families, we studied the coding sequence of the *ZBRK1* gene in approximately 70 individuals from 58 high-risk French-Canadian families in which no mutation in either *BRCA1* or *BRCA2* has been identified. We analyzed 12 sequence variants, among which a new non-conservative change, R132C, was identified while another one is in the 3'UTR region. The 5 silent mutations and 6 missense mutations analyzed show similar frequencies to those reported by Struewing et al. in a North American population. Four polymorphisms are very rare (frequencies ranging from 0.01 to 0.04: I69T, R132C, S476S and V524I), 5 have a frequency between 0.05 and 0.10: C236C, P373P, T385T, S472P and S501R, and 3 display a frequency which is greater than 0.10: N35N, P66L and 1672C/T. The most frequent coding polymorphisms are located within the KRAB domain (N35N: 0.25, P66L: 0.18), a region needed for the repressor activity of ZBRK1 in concert with the BRCA-binding domain (amino acids 319 to 532), in which 6 other polymorphisms are situated. Another important region of the *ZBRK1* gene consists of eight zinc finger motifs implicated in DNA sequence recognition. Three different variations (C236C, P373P and T385T) fall within this domain. Among the non-*BRCA1/2* individuals studied, we have found 18 different combinations of these 12 polymorphisms. 79% of individuals (53/67) have one of the 4 commonest combinations, while the remaining 21% (14 individuals) seem to have a unique arrangement. There is strong linkage disequilibrium between these polymorphisms, even between the two furthest variations (N35N and 1672C/T) which are located approximately 4260 bp apart.

**Clinical response to induction chemotherapy or radiotherapy related to BRCA1 and BRCA2 mutations in familial invasive breast cancer.** *I. Coupier<sup>1</sup>, D. Stoppa-Lyonnet<sup>1</sup>, B. Sigal-Zafrani<sup>2</sup>, A. Renard<sup>3</sup>, P. Pouillart<sup>4</sup>, K.B. Clough<sup>5</sup>, B. Asselain<sup>6</sup>, A. Fourquet for the Institut Curie Breast Cancer Group<sup>3</sup>.* 1) Department of Genetics, Institut Curie, Paris, France; 2) Department of Pathology, Institut Curie; 3) Department of Radiation Oncology, Institut Curie; 4) Department of Medical Oncology, Institut Curie; 5) Department of Surgery, Institut Curie; 6) Department of Biostatistics, Institut Curie.

**Purpose:** BRCA1 BRCA2 germline mutations are associated with impaired DNA double-strand break repair. We tested whether breast cancers in BRCA mutation carriers were more responsive to induction neoadjuvant treatments than in non-carriers. **Methods:** BRCA1 and BRCA2 mutations were screened by DGGE or DHPLC through their coding sequence in a retrospective cohort of 91 patients (with 94 tumors) with a family history of breast and / or ovarian cancer, treated with induction anthracycline-containing chemotherapy and /or neoadjuvant radiotherapy. Clinical responses and breast preservation rates were correlated to BRCA1 status, and to other clinical and pathologic factors. **Results:** Following chemotherapy, a complete response (CR) was obtained in 11/24 BRCA1 tumors (46%) and in 11/51 non BRCA1 tumors (22%)( $p=0.003$ ). A major response was observed in 20/24 (83%) and 36/51 (70.5%), respectively. Following radiotherapy, a major response was seen in 5/5, and 8/14, respectively (CR: 1/5, and 3/14). Breast conservation was possible in 25/29 (86%)BRCA1 tumors and 41/65 (63%) non BRCA1 tumors ( $p=0.02$ ). BRCA1 mutation, high mitotic count, lack of estrogen receptor expression and tumor size predicted response to induction treatments. However, BRCA1 mutation was the sole predictor of breast conservation. BRCA2 analysis is still in progress. **Conclusion:** Breast conservation after induction treatment was higher in BRCA1 carriers, and clinical response was related to aggressive tumor features correlated with BRCA1 mutations. This suggests that impaired DNA repair related to BRCA1 mutations increased chemosensitivity and radiosensitivity of breast cancer. Further studies are needed to determine the long-term local outcome of these patients.

**Genomic rearrangements in *MSH2* and *MLH1* are rare mutational events in Spanish hereditary nonpolyposis colorectal cancer patients.** *S. Castellví-Bel*<sup>1</sup>, *V. Piñol*<sup>1</sup>, *M. Milà*<sup>2</sup>, *J.M. Piqué*<sup>1</sup>, *A. Castells*<sup>1</sup>. 1) Gastroenterology, Hospital Clinic, Barcelona, Spain; 2) Genetics, Hospital Clinic, Barcelona, Spain.

Hereditary nonpolyposis colorectal cancer (HNPCC) is the most frequent autosomal dominant predisposition to the development of colorectal cancer (CRC). It is caused by mutations in one of the DNA mismatch repair (MMR) genes, the majority of which occur in *MSH2* and *MLH1*. Recently, genomic rearrangements in the *MSH2* and *MLH1* genes have been reported to account for an important proportion of the mutation spectrum in these MMR genes, making advisable to begin the molecular analysis of *MSH2* and *MLH1* by screening for such rearrangements.

Patients and methods: As part of a population-based, multicenter study aimed at determining HNPCC frequency in Spain, 1,025 tumor and non-tumor paired DNA samples from CRC patients were collected in an one-year period. Patients were clinically characterized and molecular studies (microsatellite instability (MSI) and MSH2/MLH1 immunohistochemistry) were performed in all of them. Patients whose tumor showed MSI or did not express MSH2/MLH1 (n=100) were selected to undergo further molecular analyses (genomic rearrangements in the *MSH2* and *MLH1* genes and sequencing). Furthermore, 20 additional Amsterdam-positive HNPCC patients referred to our center for genetic analysis were also included. Genomic rearrangements were analyzed using the MLPA (multiplex ligation-dependent probe amplification) technology before undergoing sequencing analysis of the *MSH2* and *MLH1* genes. Control DNA samples with known genomic rearrangements in *MSH2* or *MLH1* were included.

Results: MLPA did not detect any genomic rearrangements in our study population, which included patients with extensive MMR defects, both positive and negative for HNPCC-Amsterdam II criteria. Alterations in either *MSH2* or *MLH1* were clearly detected in control DNA samples.

Conclusions: Genomic rearrangements in the *MSH2* and *MLH1* genes seem to be a rare mutational event in Spanish HNPCC patients.

***BRCA1* germ-line mutation status, distinctive cell cycle proteins expression and outcome after breast cancer.** P.O. Chappuis<sup>1</sup>, E. Donato<sup>2</sup>, J.R. Goffin<sup>1</sup>, N. Wong<sup>1</sup>, L.R. Bégin<sup>1</sup>, L. Kapusta<sup>3</sup>, J.-S. Brunet<sup>1</sup>, P. Porter<sup>2</sup>, W.D. Foulkes<sup>1</sup>. 1) Departments of Human Genetics, Oncology, Surgery, Pathology and Medicine; Research Institute of the McGill University Health Centre; Program in Cancer Genetics; Cancer Prevention Centre, Sir M.B. Davis-Jewish General Hospital; McGill University, Montreal, QC H2W 1S6, Canada; 2) Cancer Biology, Fred Hutchinson Cancer Research Centre, Seattle, WA 98109-1024, USA; 3) Department of Pathology, Sunnybrook and Womens College Health Sciences Centre, University of Toronto, Toronto, ONT M4N 3M5, Canada.

**BACKGROUND:** Elevated expression levels of the cell cycle protein cyclin E, and low levels of its inhibitor, p27<sup>Kip1</sup>, have been associated with a poor prognosis following breast cancer. Some studies have found that germ-line mutations in *BRCA1* are also associated with a worse survival. The relationship between cyclin E/p27<sup>Kip1</sup> levels, *BRCA1* status, and outcome has not been studied previously. **METHODS:** We assessed protein levels of cyclin E and p27<sup>Kip1</sup> by immunohistochemistry in an historical cohort of 288 Ashkenazi Jewish women who were diagnosed with breast cancer between 1980 and 1995 and were previously tested for *BRCA1/2* mutations. Breast cancer specific survival (BCSS) was the main outcome measured. **RESULTS:** The median follow-up was 8 years. Thirty tumors carried germ-line *BRCA1* mutations. These tumors were more likely to have high cyclin E expression levels (odds ratio (OR): 9.5,  $P < 0.001$ ) and low p27<sup>Kip1</sup> expression levels (OR: 2.8,  $P = 0.03$ ) than tumors from patients without *BRCA1/2* mutations. On univariate analysis, high cyclin E expression levels (RR: 2.6,  $P < 0.001$ ), low p27<sup>Kip1</sup> expression levels (RR: 2.3,  $P = 0.006$ ) were significant prognostic factors for a poorer BCSS. In the Cox multivariate model, high cyclin E expression (RR: 2.0,  $P = 0.02$ ) remained statistically significant. In the node negative subgroup, high cyclin E and low p27<sup>Kip1</sup> levels were both independent prognostic markers. **CONCLUSION:** High levels of cyclin E and low levels of p27<sup>Kip1</sup> are characteristic of *BRCA1*-related breast cancer. High expression of cyclin E is an independent marker of poor prognosis following breast cancer.

**Analysis of polymorphisms in genes encoding proteins interacting with BRCA1 in high-risk non-BRCA1/2 families.** *F. Guenard*<sup>1</sup>, *Y. Labrie*<sup>1</sup>, *G. Ouellette*<sup>1</sup>, *M. Houde*<sup>1</sup>, *J. Simard*<sup>1,2</sup>, *INHERIT BRCA1*, *F. Durocher*<sup>1</sup>. 1) Cancer Genomics Laboratory and; 2) Canada Research Chair in Oncogenetics, CHUL Research Center, CHUQ, Laval University, Quebec, Canada.

The BRCA1 and BACH1 proteins form a complex known to be involved in double-strand break repair. The BARD1 protein also interacts with this complex. Based on their interaction with BRCA1 and their involvement in other cancers we analysed variations in the sequence of *BACH1* (BRCA1-associated C-terminal helicase 1) and *BARD1* (BRCA1-associated RING domain 1) to verify their possible implication in breast cancer susceptibility in nearly 50 high-risk families for which no mutation in BRCA1/2 was identified. Sequencing of the *BACH1* cDNA led to the identification of two variants: a silent 2637GA change (allele frequency of A:0.40) and a P919S change (frequency S:0.50) located within the exon 19, upstream from the helicase domain. Both polymorphisms also fall into or near the region of BACH1 which binds to BRCA1 (residues 888 to 1063). To examine further other proteins involved in this complex we sequenced the coding region of *BARD1*. BARD1 is associated with the BRCA1 RING domain and the formation of the BRCA1-BARD1 complex is essential for tumor suppression activity. Five different variants were identified in this gene, one of which, 1518CT is a novel conservative variation at codon 506. Two variations (1518CT, V507M) are located in the ankyrin repeats suggesting that it could alter interactions with other proteins and have a frequency of 0.24 and 0.38, respectively. Another variant observed (P24S) is located close to the BRCA1 interacting domain and was found with an allele frequency of S:0.40. The last two variants, a silent change at nucleotide 1053GC and a non-conservative change C557S have an allele frequency of C:0.15 and S:0.02, respectively. As expected both polymorphisms in *BACH1* are in complete linkage disequilibrium (LD). The 5 variants in *BARD1* are also in strong LD and are located more than 57kb apart. Further studies are in progress to establish the profile of polymorphisms in these interacting genes which could have an impact on the stability of the complex when taken together.

**Microarray-based resequencing of the APC gene.** S. Cowie<sup>1,2</sup>, S. Drmanac<sup>3</sup>, D. Swanson<sup>3</sup>, D. du Sart<sup>2</sup>, K. Delgrosso<sup>1</sup>, R. Drmanac<sup>3</sup>, S. Surrey<sup>1</sup>, P. Fortina<sup>1</sup>. 1) Department of Medicine, Thomas Jefferson University, Philadelphia, PA, USA; 2) Murdoch Children's Research Institute, Royal Children's Hospital, Parkville, Victoria, Australia; 3) Callida Genomics, Sunnyvale, CA, USA.

Familial Adenomatosis Polyposis (FAP) is an autosomal dominant inherited form of colorectal cancer, caused by mutations in the APC gene. A wide variety of mutations has been found in the APC gene (5q21), the majority of which result in truncated proteins. Several methods of mutation detection are used, but due to the size of the gene, and the large number of mutations, results can take several months. A new quick method of detection which employs an array-based resequencing approach with combinatorial sequencing-by-hybridization (SBH) has been studied.

We initially focused on the "*second hit predictor*" (SHP) region, which contains 167 of 187 known APC mutations from codons 1194-1392 in both FAP and sporadic colon cancer. SHP is centered around codon 1309, which is the most frequently mutated site. We generated approximately 0.5, 2, 4 and 10 kb PCR products encompassing the SHP region and a much more expansive area including the entire exon 15. Each target was subjected to combinatorial SBH. A universal probe set is attached to a solid support and a second one is in solution and labelled with a fluorophore. Ligation occurs only when a complementary DNA strand from the patients PCR product perfectly anneals to both array-bound and solution phase, labelled probe, creating one long labelled probe attached to the surface. A standard array reader scores fluorescent signals at each array position.

Results are very robust for a complete sequence read out for the 0.5, 2 and 4 kb targets. This universal chip successfully detects various base substitutions and insertions, and small base deletions. We are attempting to define the longest DNA stretch (or total combined length of a pool of DNA amplicons) that can be sequenced on a single array in preparation for a continuous read out of the entire APC coding region.

**Mutation spectrum of the BRCA1 and BRCA2 genes in western Sweden.** *A. Bergman<sup>1</sup>, Y. Engwall<sup>1</sup>, J. Lundberg<sup>1</sup>, T. Martinsson<sup>1</sup>, Z. Einbeigi<sup>2</sup>, P. Karlsson<sup>2</sup>, A. Wallgren<sup>2</sup>, J. Wahlström<sup>1</sup>, M. Nordling<sup>1</sup>.* 1) Dpt of Clinical Genetics, Göteborg University, Sweden; 2) Dpt of Oncology, Göteborg University, Sweden.

Germline mutations in the hereditary breast/ovarian cancer causative genes BRCA1 and BRCA2 are considered to constitute approximately 6-10 % of these cancers. The frequency of female mutation carriers with breast/ovarian cancer depends on the population studied, and display considerable variation in coincidence with ethnic and geographical diversity. Mutations are mainly found as small insertions, deletions or substitutions, but also as exon-wide deletions. We performed mutation analyses in 146 patients, selected under informed consent, from the Sahlgrenska University Hospital, Gothenburg, Sweden. Following screening for the western Swedish founder mutation BRCA1 3171ins5 and other Swedish founder mutations, the BRCA1 and BRCA2 genes were screened using the Protein Truncation Test (PTT) for truncating mutations in exon 11 in BRCA1 and exon 10 and 11 in BRCA2. Remainder of the exons was analyzed with either DHPLC or automated DNA sequencing. DNA sequencing of the detected mutations revealed ten different frameshift mutations, four nonsense mutations and one large deletion. Five of these have not been reported earlier: BRCA1 409-410delCA; 2229-2230delAA; 3029delA; 1912 T>G and 3433delA. Mutations in either of the two BRCA genes were detected in 35 % of the screened families; this is comparable to frequencies reported in other European studies. Notably, a western Swedish founder mutation (BRCA1 3171ins5) accounted for 35 of the 51 mutations detected in the 146 families. Results from further investigations made in search for large genomic deletions, where the novel quantitative method multiplex ligation-dependent probe amplification (MLPA) have been used, will be presented at the meeting.

**A sequence variation in exon 1 of the VHL gene associated with reduced penetrance of VHL-disease. A.M.H.**

*Flodin<sup>1</sup>, Y. Engwall<sup>1</sup>, J. Wahlström<sup>1</sup>, L. Wiklund<sup>1,2</sup>, M. Nordling<sup>1</sup>.* 1) Dpt of Clinical Genetics, Sahlgrenska University Hospital, Göteborg, Sweden; 2) Dpt of Neurology, University Hospital, Uppsala, Sweden.

Von Hippel-Lindau (VHL) disease is an autosomal, dominantly inherited tumor syndrome with high morbidity and mortality caused by mutations in the VHL gene. Advances in genetic and clinical management has improved the prognosis for VHL-patients, who develop hemangioblastomas, retinal angiomas, renal cancer and pheochromocytomas. Since 1995 we provide genetic and clinical investigations for Swedish VHL patients. All mutations detected so far by our group are found downstream of codon 65 and they all seem to be highly penetrant. We here report, however, observations in two families concerning codon 38 and 39 in exon 1 of the VHL gene. A 14 year old boy developed a cerebellar hemangioblastoma and was referred to us under the provisional diagnosis VHL. A sequence variation VHL 328G>C (GGC>CGC, Gly39>Arg) was detected in this proband. The variant was also detected in 3 relatives; a child of 11 years and two adults of 49 and 53 years of age. Extensive clinical investigation of these individuals, including ophthalmologic examinations, and scans of brain and upper abdomen, failed to detect any VHL manifestation. Our conclusion is that this sequence variation presents a mutation with reduced penetrance or a polymorphism. These findings seem contradictory to the previous report of a mutation in codon 38 (Li et al, Hum Mut Suppl 1:S31-33,1998). But, this Swedish family was also referred to us, and we failed to detect any sequence variation in that proband or her descendants, suggesting that the previous report was erroneous. The VHL-protein has two known translational initiation sites separated by 53 codons and two proteins with equivalent activity have been detected in cells. A variation in codon 39 should only have an affect on the larger protein suggesting a reduced influence on the activity of the VHL-protein for mutations in the 5-part of exon 1. Sequence variations in this region of the VHL-gene may thus lead to VHL disease with a reduced penetrance.

**BRCA1/BRCA2 Missense Mutations in African-American Breast Cancer Patients.** *L. Baumbach*<sup>1</sup>, *L. Gayol*<sup>1</sup>, *A. Monteiro*<sup>2</sup>, *M.E. Ahearn*<sup>1</sup>, *T. Donenberg*<sup>3</sup>, *A. Gherghina*<sup>1</sup>, *J.F. Arena*<sup>3</sup>. 1) Dept. Pediatrics/Div Genetics, Univ. Miami School of Medicine, Miami, FL; 2) Strang Cancer Prevention Center & Dept. of Cell and Dev. Biol., Weill Medical College of Cornell Univ. New York, NY; 3) FOBCC, Univ. Miami School of Medicine, Miami, FL.

Recent evidence from our laboratory as well as others suggests that specific variants in *BRCA1* and *BRCA2* are associated with increased risk of breast cancer in women of African-American (AA) ancestry. Of particular note is the increasing number of missense mutations/unclassified variants in African-Americans, particularly in *BRCA2*. We are further investigating the association of these variants with disease risk in a cohort of 35 AA probands and their families. The current study is a two-part design: collection of prevalence data for all novel variants, and assessment of functional effects for selected *BRCA1* mutations using a transcriptional assay. *BRCA1* missense mutations were found in 14% (5/35) of the families, while 32% (13/35) of the probands had *BRCA2* missense mutations. Several of the *BRCA1* variants were novel, and we are currently studying their significance. We have determined that *BRCA1* variant, W1718C, which was detected in one family segregating with breast cancer, exhibits a proven loss-of-function phenotype in transcriptional assays. Regarding *BRCA2* missense mutations 5/13 (38%) missense mutations were novel, four of these were found in one family each, with two (E425E, V2820V) being the only variant detected. One variant, S2414S, was detected in two unrelated probands with breast cancer at less than 40 years of age. Prevalence data for 3 of the novel mutations (T777T, E425E, D1923A) are currently being collected. Thus far, for T777T and D1923A, each of these was not present in 80-100 AA control chromosomes. Evaluation of the biological effect of novel *BRCA2* missense mutations awaits further development of a *BRCA2* functional assay. Completion of this study should reveal important information regarding the association of *BRCA1/BRCA2* missense mutations with breast and ovarian cancer risk in AA women.

**BRCA1/2 mutation spectrum and frequencies in Belgian breast/ovarian cancer families.** *K. Claes, B. Poppe, I. Coene, A. De Paepe, L. Messiaen.* Center for Medical Genetics, Ghent Univ Hosp, Gent, Belgium.

World-wide variation in distribution and frequencies of BRCA1/2 mutations is well recognised and for the Belgian population no comprehensive studies have been published. We analyzed the complete coding region of both genes in 300 Belgian breast/ovarian cancer families referred to a family cancer clinic by a combined approach of the protein truncation test (PTT) or direct sequencing (DS) for BRCA1 and BRCA2 exon 11, and heteroduplex analysis (HA) or denaturing gradient gel electrophoresis (DGGE) for screening all other exons and their splice sites. Furthermore, we implemented in our mutation detection strategy MLPA (multiplex ligation-dependent probe amplification; MRC-Holland), a novel method that allows rapid screening for rearrangements in the BRCA1 gene. In total, we identified 44 BRCA1 and 24 BRCA2 mutations. The large majority of the mutations were recurrent, due to founder effects. The most recurrent mutations were BRCA1 IVS5+3A>G and BRCA2 IVS6+1G>A, accounting for more than one-quarter of all mutations detected. The mutation spectrum identified suggests opportunities for the establishment of a cost-effective molecular screening strategy in Belgian patients. MLPA-analysis is not yet completed for all 300 families, but preliminary data did not reveal a major contribution of large intragenic rearrangements in the BRCA1 gene in Belgian patients. A previously reported relation between cancer risk and the location of BRCA1/2 mutations in the coding sequences was not confirmed in the population studied. We found that mutations in the 5' end of the BRCA2 gene were associated with a significantly increased risk for ovarian cancer relative to the rest of the gene. However, associations between mutation position and phenotype are not sufficiently strong to influence genetic counselling and management of individual families. Large variations in cancer risks were observed within families bearing the same mutation, suggesting the involvement of genetic and/or environmental modifiers. For counselling of affected families it may be wiser to take into account the previous history of the family.

**RET proto-oncogene Cys609Tyr mutation in large 4 generation family with medullary thyroid carcinoma and Hirschsprung disease.** *J.F. Atkin<sup>1,2</sup>, E. Couchon<sup>1</sup>, T.W. Prior<sup>3</sup>*. 1) Molecular/Human Genetics, Columbus Childrens Hospital, Columbus, OH; 2) Ohio State University, Department of Pediatrics, Columbus, OH; 3) Ohio State University, Department of Pathology, Columbus, OH.

Germline mutations in the RET proto-oncogene in the cysteine codons 609,611,618, or 620 are known to be associated with MEN2A, Familial medullary thyroid carcinoma (FMTC), and Hirschsprung disease (HSCR). A newborn male with HSCR was evaluated by genetics because his father also had HSCR. The family pedigree revealed multiple family members with FMTC on the paternal grandmother's side. The family was being followed for FMTC by calcitonin levels but none of the family members realized that there could be an association of FMTC with HSCR or that specific genetic testing could determine which family members might need treatment. At least 12 individuals in 4 generations are affected with FMTC without other evidence of MEN2A; our proband and his father are the only ones with HSCR. Testing for RET proto-oncogene was done because of the known association. Exons 10 and 11 of the RET proto-oncogene were sequenced in our proband. At codon 609 in exon 10 a nucleotide substitution was identified, TGC>TAC, which results in the substitution of tyrosine for the normal cysteine. Although this missense mutation has been observed in FMTC and MEN2A, it has not been previously reported in HSCR. Several family members have now been tested or are in the process so that appropriate surveillance, treatment and counseling can be done. This case stresses the importance of careful pedigree analysis, appropriate genetic testing, and thorough genetic counseling. HSCR with FMTC is now known to be associated with this specific missense mutation.

**Hormone replacement therapy, oral contraceptives, and reproductive history in Jewish Israeli breast cancer patients: comparison of BRCA1/2 mutation carriers with non-carriers.** R. Bruchim Bar Sade<sup>1</sup>, A. Chetrit<sup>2</sup>, A.

Figer<sup>3,6</sup>, M. Papa<sup>4,6</sup>, D. Flex<sup>5</sup>, S. Riezel<sup>5,6</sup>, E. Friedman<sup>1,6</sup>. 1) Oncogenetics Unit, Sheba Medical Center, Tel-Hashomer, Israel; 2) The Gertner Institute of epidemiology, Sheba Medical Center, Tel-Hashomer, Israel; 3) Institute of Oncology, Elias Sourasky Medical Center, Tel-Aviv, Israel; 4) Department of Oncological Surgery, Sheba Medical Center, Tel-Hashomer, Israel; 5) Institute of Oncology, rabin Medical Center, Petach Tikvah, Israel; 6) The Sazckler School of Medicine, Tel-Aviv University, Ramat Aviv, Israel.

To assess the role of reproductive factors, use of oral contraceptives (OC) and hormone replacement therapy (HRT) in modifying breast cancer risk among BRCA1 or BRCA2 mutation carriers, Jewish Israeli women with breast cancer unselected for family history of cancer (n=385) were genotyped for the three predominant Jewish mutations in BRCA1 and BRCA2, and data on reproductive factors OC and HRT use, were analyzed by mutational status using logistic regression analyses. Overall, 28/385 (7.3%) of participants [22/247 (8.9%) of the Ashkenazim] were mutation carriers. The majority of mutation carriers were Ashkenazim (n=22; 78.6%) and were diagnosed with breast cancer at or under age 49 years (n=17; 60.7%). Mutation carriers were significantly more likely than non-carriers to ever use OC (39.3% vs. 20.2% ; p=0.053, HRT (35.7% vs. 13.7% ; p=0.007), and have first menarche at or below 12 years of age (71.4% vs. 40.6% ; p=0.03). Multivariate analysis showed that Ashkenazi women diagnosed with breast cancer at or under the age of 40 years, with a positive family history of breast or ovarian cancer who were ever users of HRT were more likely to be mutation carriers, whereas no differences in OC use or other reproductive factors could be noted between carriers and non-carriers. We conclude that Jewish Ashkenazi women featuring these clinical characteristics should be offered genetic counseling and testing. HRT use is seemingly more prevalent among Jewish Ashkenazi mutation carriers.

**Higher Incidence of Rearrangements in Mismatch Repair Genes Compared to Coding Sequence Mutations Observed in a Case Series of HNPCC patients.** *A. Ganguly, M. Houseknecht, H. Messner, L. Godmilow.* Department of Genetics, Genetic Diagnostic Laboratory, University of Pennsylvania, Philadelphia, PA.

The most common form of hereditary colorectal cancer is HNPCC (hereditary nonpolyposis colon cancer). The disease is caused by mutations in 2 major DNA mismatch repair genes - hMSH2 and hMLH1. This report describes the spectrum of mutations observed in a series of 98 consecutive cases submitted for genetic testing of HNPCC. The patient pool included 26 individuals who fulfill Amsterdam criteria (AC+), 25 individuals with Bethesda criteria (BC+), 29 individuals that are unaffected but "at risk" from high risk families and 18 individuals who represent families with clustering of HNPCC related tumors.

**Methods:** Direct sequencing was performed on all the coding exons and exon-intron boundaries of hMSH2 and hMLH1. This was followed by Southern blot analysis for the presence of germline rearrangements in respective genes.

**Results and Conclusions:** Coding sequence mutations were identified in 11/26(42%) AC+ individuals, 3/25 (12%) BC+ individuals and 4/29 (14%) mutations in the "at risk" group. No mutations were detected in the other group and 6 sequence variations of unknown significance were observed. Recently a deletion in hMSH2 gene was identified in ~10% of the North American HNPCC population. We selected a subset of 24 cases of HNPCC with 10 AC+ cases and 7 BC+ cases. The remaining 7 cases were from "at risk" group. We found 1 (4%) case of the common North American founder deletion in an individual with endometrial, colon and renal cancer. In contrast, we found a second common mutation, deletion of 2.3kb between exons 2 and 4 of the hMSH2 gene, 6 times accounting for 25% of the total cases and can be separated as in 2/10 (20%) AC+ individuals, 3/7 (43%) BC+ families and 1/7 (14%) individual without any family history but incidence of sebaceous cancer only. Three other rearrangements were observed within the hMLH1 gene that have not yet been characterized. In conclusion, while coding sequence mutations accounted for 22.5% of the cases in our series, rearrangements within the hMSH2 and hMLH1 genes account for ~50% of the cases.

**A ganglioglioma in a patient with Sotos Syndrome confirmed by a NSD1 deletion.** *M. Deardorff, M. Maisenbacher, E.H. Zackai.* Clinical Genetics Center, Children's Hosp Philadelphia, Philadelphia, PA.

Patients with Sotos syndrome (OMIM 117550), a classical overgrowth syndrome, have been noted with an increased risk of tumor formation estimated to be as high as 2.2% (Cohen MM, Jr. 1999, Am J Med Genet 84:173-5). Types of tumors reported have been varied, but have included Wilms tumors, neuroblastoma and teratomas as well as other isolated tumor types making surveillance strategies difficult. The diagnosis of Sotos Syndrome in these patients has been based on clinical data. Recently, point mutations or deletions of the NSD1 gene (Kurotaki et al., Nat Genet 30:365-6 (2002)) have been reported in patients with Sotos Syndrome. Here we present the first patient with Sotos Syndrome documented to have both a mutation in NSD1 and a tumor, specifically a ganglioglioma. The patient presented at 2 years of age with complex partial seizures. MRI showed a left hippocampal mass. Due to developmental delay and increasing seizure frequency, the mass was resected at 5 years of age and was noted histologically to be a ganglioglioma. He was subsequently seen at 6 years and 9 months of age by clinical genetics due to persistent developmental delay. Symmetric overgrowth, receding hairline, prominent forehead and hypertelorism led to the clinical diagnosis of Sotos syndrome which was confirmed by a microdeletion in the NSD1 locus. Gangliogliomas are relatively rare childhood brain tumors comprising approximately 1% of childhood brain tumors. They have not been observed in other patients with Sotos Syndrome. The diagnosis of Sotos Syndrome in this patient helped to elucidate the cause of the developmental delay which was initially believed to be secondary to the ganglioglioma. This case serves to underscore the benefit of collaboration between clinical genetics and oncology particularly in syndromes known to be associated with tumor formation.

**Further evidence to support that chromosome 15 may be harboring a susceptibility variant in families with multiple polyps.** *D. Daley*<sup>1,5</sup>, *S.D. Markowitz*<sup>1,3,4</sup>, *R.C. Elston*<sup>1,3</sup>, *S. Lewis*<sup>1</sup>, *C. Ticknor*<sup>1</sup>, *P. Platzer*<sup>4</sup>, *J. Lutterbaugh*<sup>4</sup>, *M. McMillen*<sup>1</sup>, *B. Baliner*<sup>3</sup>, *J. Willis*<sup>1</sup>, *G.L. Wiesner*<sup>1,2,3</sup>. 1) Case Western Reserve University, Cleveland, OH; 2) University Hospitals of Cleveland, Cleveland, OH; 3) Ireland Cancer Center, Cleveland, OH; 4) Howard Hughes Medical Institute, Cleveland, OH; 5) University of British Columbia, Vancouver, BC, Canada.

Jaeger et al (AJHG 2003) recently reported a common haplotype shared in a large family of Ashkenazi descent, characterized by an uncommon and specific phenotype of multiple colorectal polyps defined as >3 polyps. They conclude that they have found compelling evidence for a high-penetrance colorectal tumor predisposition gene at 15q-q14 (HMPS/CRAC1), and that it remains to be seen whether HMPS/CRAC1 is also important in other ethnic groups. The Cleveland Colon Neoplasia Sibling Study (CNSS), has recently completed a genome scan in 194 families with genotyping performed by the Center for Inherited Disease Research. We identified 32 families (3 of whom are of Jewish descent) with a multiple polyps phenotype, defined as families in which one individual has >5 polyps. All these families have been screened for familial colorectal cancer, including FAP, HNPCC, and APC including the I1307K variant. In the genome scan results we identified a signal in the region of 15q-q14 using Haseman Elston (H-E) regression analysis ( $p=0.01$ ). However, this finding is not limited to the Jewish ethnic group: in fact our findings for linkage are stronger when the 3 families of Jewish descent are excluded ( $p=0.0037$ ), indicating that in our population this signal is not associated solely with the Jewish ethnic group. The peak is located at ~ 30 cM, between markers D15S165 (20.24 cM) and D15S1012 (36.0 cM). Jaeger et al. report a linked haplotype flanked by markers D15S1031 at 26.0 cM and D15S118 at 31.0 cM, with a peak signal at D15S1007 (29.9 cM). The CNSS linkage signal overlaps this region, adding further validation for a susceptibility gene in this region. Our result provides important new evidence that this locus is associated with a multiple polyp phenotype and that it is not limited to families of Ashkenazi descent.

**Sarcoma in familial multiple lipomatosis: using array-based comparative genomic hybridization to identify regions for linkage.** *J. Goren<sup>1</sup>, K. Rinaldi<sup>1</sup>, J.E. Tomaszewski<sup>3</sup>, A.M. Martin<sup>1,2</sup>, L. Aiello<sup>2</sup>, S. Nussen Lee<sup>2</sup>, B.L. Weber<sup>1</sup>, K.L. Nathanson<sup>1</sup>.* 1) Dept. Medicine, Univ of Pennsylvania Sch Med, Philadelphia, PA; 2) Pennsylvania Hospital, Philadelphia, PA; 3) Dept. Pathology, Univ of Pennsylvania Sch Med, Philadelphia PA.

Familial Multiple Lipomatosis (FML) is a rare autosomal dominant disorder with variable expression. It is characterized by multiple subcutaneous benign lipomas in the regions of the trunk, arm, and thighs with sparing of the head, neck, and shoulders. Sarcomas have been occasionally reported in associated with FML; however the frequency of sarcomas in association with FML appears to be rare given the frequency of FML. We present a patient with FML who developed a retroperitoneal sarcoma with features of both liposarcoma and leiomyosarcoma and renal papillary cancer type 1. In order to determine a possible genetic basis for FML, we performed array based comparative genomic hybridization on the different tumor types to determine if there was a common region of deletion. Several regions of deletion were common to the different tumor types, including ones at 1p24.3 and 9p21. The characterization of these deletions can be used to identify specific loci for targeted linkage studies.

**Diagnostic mutational analysis of the entire genomic sequence of the RECQL4 gene in Rothmund-Thomson Syndrome (RTS) patients.** *B. Chong<sup>1</sup>, M.R. Hegde<sup>1</sup>, D.M. Odenbaugh<sup>1</sup>, A. Gannavarapu<sup>2</sup>, L.L. Wang<sup>2</sup>, S.E. Plon<sup>2</sup>, C.S. Richards<sup>1</sup>.* 1) Diagnostic Sequencing Laboratory, Molecular and Human Genetics; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030.

Rothmund-Thomson Syndrome (RTS) is an autosomal recessive disorder characterized by presence of skin rash, small stature, sparse hair, skeletal, dental and hair abnormalities and a predisposition to osteosarcoma. Mutations in the RECQL4 gene are found in about two thirds of RTS patients and are associated with cancer risk. We have evaluated the usefulness of denaturing high performance liquid chromatography (dHPLC) as a diagnostic tool for scanning the RECQL4 gene for point mutations, small deletions, and insertions. RECQL4 is a relatively small gene with a size of 6kb and 21 exons. Our assay consists of 16 overlapping fragments to amplify the entire genomic sequence of the RECQL4 gene. All PCR reactions were amplified simultaneously using the same reaction conditions in a 96-well format and then analyzed by dHPLC, using empirically determined optimum temperatures for partial fragment denaturation. Since both homozygous and compound heterozygous mutations have been reported in RTS patients, detection by dHPLC requires mixing of wild-type and patient specimens. The approach was validated by amplifying 20 wild type controls to identify variants using dHPLC and subsequently sequenced to identify the SNPs. Previously studied DNA specimens from RTS patients were analyzed by dHPLC and all mutations were confirmed by sequence analysis. We present our validation studies of dHPLC technology for RECQL4 gene analysis in terms of sensitivity and specificity. The aim of this mutational analysis is to offer a clinical test that will aid in diagnosis of RTS and determination of osteosarcoma risk.

**MSH6 mutation analysis in a clinical series of high-risk hereditary colon cancer families.** *C.H. Buzin<sup>1</sup>, C.Y. Wen-Fong<sup>1</sup>, R. Nedelcu<sup>2</sup>, B. Estaki<sup>1</sup>, J.N. Weitzel<sup>2</sup>, S.S. Sommer<sup>1</sup>*. 1) Dept Molecular Genetics, City of Hope Medical Ctr, Duarte, CA; 2) Dept Clinical Cancer Genetics, City of Hope Medical Ctr, Duarte, CA.

Hereditary nonpolyposis colorectal cancer (HNPCC) is associated with mutations in one of five known mismatch repair (MMR) genes. In the most commonly mutated MMR genes, MLH1 and MSH2, mutations are found in only 50-60% of high-risk hereditary colon cancer families who meet Amsterdam criteria. Recent reports suggest that MSH6 may be responsible for a proportion of HNPCC families, and it is believed to be the third most commonly mutated MMR gene. In addition, MSH6 may be associated with atypical HNPCC phenotypes, in particular gynecologic malignancies. Although high level microsatellite instability (MSI) is associated with MMR defects in HNPCC, MSH6 mutations have also been linked to low level MSI. The objective of the current study is to assess the clinical utility of incorporating MSH6 analysis into clinical evaluation of HNPCC. Patients from hereditary colon cancer families, who previously tested negative for MLH1 and MSH2 mutations, were analyzed for germline MSH6 mutations by sequencing all exons and associated intronic splice junctions in DNA extracted from lymphocytes. Four of 22 patients (18%) had sequence alterations, including two with frameshift mutations and two with missense changes. Both missense alterations (A1154D and L396V) change a wild type amino acid conserved during billions of years of evolution (identical through mouse, *Arabidopsis* and yeast). Microsatellite instability analysis, previously performed on tumors from three of the four patients, was high in the patient with the A1154D alteration. Of the two frameshift mutations, one was associated with an MSI-low tumor and a predominance of gynecologic cancers in the family; the other was in a patient with an MSI-high tumor. Taken in conjunction with findings from other studies, our data suggest that proceeding to MSH6 sequencing in cases that are negative for MLH1 and MSH2 may have clinical utility.

**Identification and characterization of CDKN2A mutations in a group of Brazilian at-risk patients for hereditary melanoma.** *P. Ashton-Prolla*<sup>1,2,5</sup>, *L. Bakos*<sup>3</sup>, *G. Junqueira*<sup>5</sup>, *C. Carvalho*<sup>1</sup>, *R. Giugliani*<sup>1,2</sup>, *D. Hogg*<sup>4</sup>. 1) Serviço de Genética Médica, Hosp Clínicas Porto Alegre Brazil; 2) Departamento de Genética, UFRGS, Brazil; 3) Serviço de Dermatologia, Hosp Clínicas Porto Alegre, Brazil; 4) University of Toronto, Canada; 5) Hospital Mãe de Deus, Porto Alegre, Brazil.

A group of at-risk patients for hereditary melanoma was identified in dermatology and oncology clinics in Southern Brazil and invited to participate in a molecular study. During this first phase, we analyzed the CDKN2A gene, which has an established association with hereditary melanoma. Previous studies in North-American, European, and Australian at-risk patients have identified CDKN2A mutations in 15-25% of families with multiple melanoma or pancreatic cancer diagnoses and in around 15% of patients with multiple primary melanomas. The patients included in our study all had melanoma and additionally, fulfilled at least one of the following criteria: a) diagnosis of more than one primary melanoma; b) family history of melanoma; c) family history of pancreatic cancer; d) personal or family history of dysplastic nevi syndrome. Thirty-six patients from 34 families were identified. Of these, 29 (85%) fulfilled the criteria and 25 effectively participated in the study (25/29; 86%). In the group of 25 patients included in this study (from 24 families) only one deleterious CDKN2A mutation was found (1/24 = 4%). One patient presented a sequence variant of unknown significance (-33G>C) which was localized upstream of the initiation codon, and four patients had the A148T polymorphism, which has no functional significance and occurs in 5% of the general population. These results may be related to a relatively small average number of melanoma/pancreatic cancer cases per family or to the presence of other unidentified genetic abnormalities in this group of patients. The study of additional cases is warranted to better address this question.

**The Hereditary Spectrum of Pancreatic Cancer: The Edmonton Cancer Genetics Clinic Experience.** *M.A. Lilley<sup>1</sup>, D.M. Gilchrist<sup>2</sup>*. 1) Alberta Cancer Genetics Program, Cross Cancer Institute, Edmonton, Alberta, Canada; 2) Cancer Genetics Clinic, University of Alberta, Edmonton, Alberta, Canada.

**Objectives:** It is estimated that, in 2003, there will be 30,700 new cases of pancreatic cancer and 30,000 deaths due to pancreatic cancer in the United States. Pancreatic cancer is known to aggregate in some families and has been associated with a wide variety of cancer syndromes including BRCA2, MEN1, Li-Fraumeni syndrome, Ataxia Telangiectasia, FAP, HNPCC and hereditary pancreatitis. Our objective was to review our experience with pancreatic cancer and the range of associated cancer syndromes.

**Methods:** We reviewed the charts of all patients seen in the Cancer Genetics Clinic at the University of Alberta between 1995 and 2002.

**Results:** Forty families reported a personal or family history of pancreatic cancer in the context of a possible hereditary cancer syndrome. Three additional families reported a history of pancreatitis. Twenty-four (56%) of those families were suspected of having a hereditary breast and ovarian cancer syndrome (BRCA2). A further 7 (16%) were suspected of having HNPCC. Only 3 (7%) were felt to be at risk for a site-specific pancreatic cancer syndrome. Another 3 (7%) were suspicious for hereditary pancreatitis. The remaining family histories were suggestive of Li-Fraumeni syndrome, Von Hippel Lindau syndrome or a non-specific cancer predisposition.

**Conclusions:** With such a wide variety of hereditary cancer syndromes associated with pancreatic cancer, an accurate assessment of the family history is essential to determine the most appropriate cancer screening for at-risk family members and guide any molecular testing that may be offered.

**The Prevalence of breast and colorectal cancer among Ashkenazi Jewish Fanconi anemia and Bloom syndrome carriers.** *I. Kedar-Barnes, H. Baris, G.J. Halpern, N. Magal, M.D. Ludman, M. Shohat.* Dept. of Medical Genetics, Rabin Medical Center, Beilinson Campus Petah Tikva, Israel.

Fanconi anemia and Bloom syndrome are rare autosomal recessive disorders marked by chromosome instability. Bloom syndrome and Fanconi anemia complementation group C (*FACC*) are especially prevalent in the Ashkenazi Jewish (AJ) community. A single predominant mutation for each of these conditions has been reported in Ashkenazi Jews:  $BLM^{ASH}$  in Bloom syndrome and IVS4 in *FACC* with a carrier frequency for  $BLM^{ASH}$  of 1/111 and for IVS4 1/70-1/90. It is well established that both conditions are characterized by susceptibility for developing malignancies. However, a question was raised as to whether carriers also have an increased risk for malignancies. Gruber et al (2002) recently found that AJ with colorectal cancer (CRC) are twice as likely to be carriers of  $BLM^{ASH}$  than AJ controls without CRC. The aim of this study was to estimate the cancer rate among  $BLM^{ASH}$  and *FACC* carriers and their families over 3 previous generations in unselected AJ individuals. We studied 42 carriers of *FACC*, 28 carriers of  $BLM^{ASH}$ , and 43 controls, all of AJ ancestry, in order to estimate the relative risk of CRC, breast cancer and other types of malignancies among carriers and their families. All the subjects filled a questionnaire regarding their personal and family history of cancer for three generations back, including siblings, parents, uncles, aunts and grandparents. Among the families of carriers of *FACC* and  $BLM^{ASH}$ , we found no increased incidence of malignancies over three generations as compared with the families of controls. In a total of 333 1st & 2nd degree relatives of  $BLM^{ASH}$  carriers only 35 cancers were reported: 6 cases of breast cancer and 5 of colon cancer. In a total of 466 *FACC* relatives 46 cancers were reported: 9 breast cancers and 13 colon cancers. Controls consisted of 504 family members with 63 reported cancer cases: 11 breast cancers and 11 colon cancers. For  $BLM^{ASH}$  carriers vs. controls the  $p=0.94$  and for *FACC* carriers the  $p=0.23$ . Among the families of carriers of these genes, we found no increased incidence of cancers in at least three generations compared to the controls.

**Primary aldosteronism in a 14 year old with FAP.** *M. Marvin, C. Bos.* Inherited Colorectal Cancer Program, Spectrum Health, Grand Rapids, MI.

Familial Adenomatous Polyposis (FAP) is an inherited cancer syndrome associated with the development of hundreds to thousands of precancerous colonic polyps. Without colectomy, the development of colorectal cancer is inevitable. While the colonic findings are most striking, a number of extracolonic features are variably present. A number of studies have suggested an associated risk for adrenal masses in FAP. While the prevalence of incidentally detected adrenal masses in the general population is 1-3%, the prevalence of adrenal masses in FAP is estimated to be between 7 and 13%. Previous reports describe the adrenal masses seen in FAP patients as histologically similar to those seen in the general population. They are predominantly nonfunctioning adenomas.

We describe a 14 year old boy who presented for colonic screening secondary to a family history of FAP. He was found to have significant hypertension with a diastolic blood pressure of 115. Further evaluations revealed a potassium level of 2.5, an elevated aldosterone level, biventricular hypertrophy, and an aldosterone secreting adrenal cortical adenoma. Genetic testing revealed a truncating mutation in exon 4 (453delA) of the APC gene.

Few cases of hormone secreting adrenal adenomas in FAP patients have been reported in the literature. This case represents one of the youngest reported cases of primary aldosteronism in FAP and illustrates that adrenal adenomas associated with FAP are not always clinically benign. Blood pressure screening should be part of routine surveillance in FAP.

**Unbiased estimation of breast and ovarian cancer penetrances in BRCA1/2 mutation carriers using genetic-test results.** *F. Marroni*<sup>1,2</sup>, *P. Aretini*<sup>2</sup>, *J.E. Bailey-Wilson*<sup>3</sup>, *G. Bevilacqua*<sup>2</sup>, *G. Parmigiani*<sup>4</sup>, *S. Presciuttini*<sup>1,3</sup>, and the *Italian Consortium for Hereditary Breast and Ovarian Cancer*. 1) Dept Biomedicine, Univ. Pisa, Italy; 2) Dept Oncology, Univ. Pisa, Italy; 3) NHGRI/NIH, Baltimore, MD, USA; 4) Dept Biostatistics, JHU, Baltimore, USA.

Accurate estimates of breast and ovarian cancer penetrance in BRCA1/2 mutation carriers are crucial in genetic counseling. Estimation is difficult because of the low frequency of mutated alleles and of the often-uncertain mechanisms of family ascertainment. We maximized the retrospective likelihood of the genetic model (allele frequencies and cancer penetrances in carriers and non-carriers) given the observed test results using a Markov Chain Monte Carlo approach. Parameter estimates obtained by maximizing the retrospective likelihood remain unbiased even when the ascertainment scheme cannot be modeled. The software BRCAPRO was used as a probability calculation tool. We estimated two different sets of four penetrance functions (breast and ovarian cancer in BRCA1 and BRCA2 carriers), which were called linear (two parameters for each function) and quadratic (three parameters), respectively. Total log-likelihood was similar for the two sets of functions, and corresponding penetrance curves were practically indistinguishable, implying one and the same underlying genetic model. The log-likelihood of the new model was 70 units higher than that of the original model. The table below shows the new penetrance estimates of breast and ovarian cancer at age 50 and 70 in carriers of BRCA1 and BRCA2 mutations, in comparison with the values of the original model (in brackets)

	Breast Cancer Age 50	Breast Cancer Age 70	Ovarian Cancer Age 50	Ovarian Cancer Age 70
BRCA1 Carriers	22% (46%)	46% (69%)	12% (11%)	52% (30%)
BRCA2 Carriers	23% (28%)	49% (67%)	2% (3%)	22% (19%)

**The RET receptor is linked to stress response pathways.** *S.M. Myers, L.M. Mulligan.* Dept Pathology, Queen's University, Kingston, ON, Canada.

The *RET* oncogene encodes a receptor tyrosine kinase involved in cell growth, differentiation and survival. Mutations of *RET* cause the cancer syndrome multiple endocrine neoplasia 2 and are found in sporadic medullary and papillary thyroid carcinomas. As a result of these mutations, RET becomes activated, leading to inappropriate stimulation of downstream signals and altered expression of downstream target genes. The nature of these specific targets is as yet not well understood. We have used cDNA microarray analyses to identify genes differentially expressed in response to RET activation. We have generated cell lines stably expressing RET isoforms (RET9 and RET51) and compared their gene expression profiles to those of RET-ve parental cells. We identified 99 ESTs differentially expressed in the presence of RET. Strikingly, we noticed increased expression of three members of the heat shock protein 70 (HSP70) gene family, *HSPA1A*, *HSPA1B* and *HSPAIL*. Validation by northern and quantitative real time RT-PCR (qRT-PCR) analyses suggested that expression of these genes increased >10-20 fold in the presence of RET. The HSP70s are members of a large group of stress response proteins that may act to promote protein folding and maturation or degradation. To assess the relationship of RET, the stress response and carcinogenesis, we looked for other genes related to stress response with altered expression in the presence of RET. Comparing our data from microarray, northern and qRT-PCR, we showed that multiple genes associated with HSP70's role in protein folding and remodeling, including certain HSP40s, *ST13* and *STIP1* were up regulated coordinately with HSP70 and RET. Conversely, a number of genes associated with an HSP70 role in protein degradation, such as some HSP40s, *STUB1* and *UBQLN2* are down regulated in response to RET. Altered expression of stress response proteins has been noted in a number of tumour types. Our data suggest that RET expression may provide a direct mechanism by which HSP70 proteins, and potentially other stress related proteins are modulated in human tumours. We are currently studying the sequence of events leading to RET activation of the cell survival stress response and carcinogenesis.

**Confirmation that an in-frame deletion of 3 bp in exon 3 of *MLH1* disrupts an exon splicing enhancer (ESE) and is the cause of HNPCC in one Quebec family.** *S. McVety*<sup>1</sup>, *W.D. Foulkes*<sup>1,2</sup>, *G. Chong*<sup>1,2</sup>. 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Department of Medicine, SMBD-Jewish General Hospital, McGill University, Montreal, QC, Canada.

Mutations in *MLH1* are an important cause of hereditary non-polyposis colorectal cancer (HNPCC). We recently identified a 3 bp deletion located at the 5' end of exon 3 of *MLH1* that, surprisingly, results in deletion of exon 3 from RNA, as detected by PTT. It has been argued that this in-frame deletion causes HNPCC because of altered binding properties of the protein. In contrast, we postulated that this mutation causes HNPCC because the 3 bp deletion disrupts an exon splicing enhancer (ESE). We based this prediction on the observations that the mutation occurs in a purine-rich region previously identified as representing an ESE in other genes, and that ESEs are often found in exons with splice signals that deviate from the consensus signals, as does the 3' splice signal in exon 3 of *MLH1*.

To test our hypothesis, the 3 bp deletion and several other mutations were created by site directed PCR mutagenesis and tested using an *in vitro* splicing assay. Both mutant and wild type exon 3 sequences were cloned into the Exon-Trapping (Invitrogen) plasmid pSPL3 and transiently expressed in Cos-1 cells. Analysis of the RNA indicates that the 3 bp deletion: del 213-215 AGA, a silent mutation: 216 TC, a missense mutation: 211 GC, and a nonsense mutation: 211 GT all cause varying degrees of exon skipping, confirming the presence of an ESE at the 5' end of exon 3. These mutations are situated in a GAAGAT sequence 3 bp downstream from the start of exon 3.

While ESEs may be up to 8 bp in length and are often purine rich sequences, the involvement of a series of adenines at the start of exon 3 in ESE activity has been excluded because the mutation 213 AC of an A adjacent to the ESE upstream does not affect exon 3 inclusion. The exon 3 ESE is not recognized by available motif-scoring matrices, highlighting the importance of RNA analysis in the detection of ESE-disrupting mutations.

**Identification of susceptibility genes for sporadic breast cancer in a genome-wide association study. S.**

Kammerer<sup>1</sup>, R. Roth<sup>1</sup>, M.R. Nelson<sup>1</sup>, J. Rehbock<sup>2</sup>, F. Ebner<sup>2</sup>, J. Atienza<sup>1</sup>, C. Rosette<sup>1</sup>, M. Denissenko<sup>1</sup>, J. Ekblom<sup>1</sup>, A. Braun<sup>1</sup>. 1) Sequenom Inc., San Diego, CA; 2) I. Frauenklinik, Klinikum Innenstadt, University of Munich, Germany.

In the U.S., over 210,000 individuals will be diagnosed with breast cancer this year, with an expected 40,000 deaths resulting from this disease. There are several well-known factors predisposing individuals to develop breast cancer, such as family history, early menarche, late menopause, alcohol consumption, postmenopausal hormone substitution and obesity. However, very few genetic links to sporadic breast cancer have been identified. We employed a set of 28,000 single nucleotide polymorphisms (SNPs) located in gene regions in an association approach to identify susceptibility genes for sporadic breast cancer. Using DNA pools of 272 cases with breast cancer and 276 age-matched controls of German descent, we identified over 50 candidate susceptibility gene regions. By applying a follow-up strategy including SNP fine-mapping and *in silico* as well as experimental biology, we obtained strong genetic and biological support for several of those novel candidates. One of the genes identified is *DLC-1*, a tumor suppressor gene previously described as a candidate for sporadic breast cancer. The encoded protein is highly homologous to a mouse protein that modulates Rho signaling pathways and was found to be deleted or mutated in several human cancer types. Other compelling novel findings include genes involved in chromosomal segregation / repair and in the AP-2 signaling pathway. For some of those candidates we have demonstrated that suppression of mRNA expression by RNAi leads to a decrease of cell proliferation, indicating that inhibition of those genes might be a promising therapeutic approach in breast cancer. In addition, a gene cluster for adhesion molecules was identified in the breast cancer scan well as in a prostate cancer scan. One of the genes in this region has previously been postulated as a predisposing gene for several cancer types.

**Strategies for Early Detection of Breast Cancer in High Risk Women Using Cytologic and Molecular Studies of Ductal Lavage Fluid.** *B. Haddad, L. Cavalli, L. Shanker, M. Freedman, B. Singh, M. Pennanen, M. Liu, A. Gallagher, J. Rone, R. Dickson, C. Isaacs.* Georgetown University, Lombardi Cancer Center, Washington, DC.

We have established a pilot study in which BRCA1 carriers and true negatives with no clinical evidence of breast abnormalities, either by physical exam or mammogram, undergo ductal lavage (DL). The DL fluid is evaluated by routine cytology and then examined for molecular genetic abnormalities such as LOH. Previous work done by our group has demonstrated LOH of the BRCA1 & FHIT wild type alleles in non-malignant breast tissues surrounding breast tumors, suggesting that these are early genetic change which could be used as markers for early detection. To date we have enrolled 30 patients in our study: 20 BRCA1 mutation carriers and 10 controls. DL was attempted on 28 subjects and was successful in 15. Of those, 8 had adequate material for cytologic analysis and only 1, a BRCA1 mutation carrier, demonstrated focal minimal atypia. The remainder had benign cytologic findings. DNA was extracted from the DL supernatant obtained from all 15 subjects for molecular studies. LOH analysis for the BRCA1 and the FHIT genes was completed on 13 subjects, 9 carriers and 4 controls. In 4 of the 9 mutation carriers we found LOH at the BRCA1 allele, and in 2 of these we also found LOH at the FHIT allele. In 1 of the true negatives LOH at BRCA1 and FHIT loci were also seen. In 1 of the 2 BRCA1 carriers with LOH at the BRCA1 and FHIT loci, minimal cytologic atypia was noted. In the other 3 either few cells were obtained or the DL yielded cytologically benign cells. The patient with minimal atypia had a recent unremarkable mammogram and physical exam. Breast FDG-PET scan showed a focal area of increased uptake in her right breast. This was biopsied and found to have invasive ductal carcinoma. She underwent bilateral mastectomy. In this carrier, LOH at the BRCA1 locus was seen in the DL fluid from both breasts. The DL specimen from her right breast (affected) had insufficient material for cellular analysis and focal minimal atypia was seen in the DL sample from the left breast. Accrual to this study is ongoing.

**Molecular and Phenotypic analyses of 35 Familial Wilms tumor pedigrees.** *S. Hanks*<sup>1</sup>, *EA. Rapley*<sup>1</sup>, *MR. Stratton*<sup>1</sup>, *K. Pritchard-Jones*<sup>2</sup>, *N. Rahman*<sup>1</sup>, *Familial Wilms Tumor Collaboration*. 1) Section of Cancer Genetics, Institute of Cancer Research, Sutton Surrey, United Kingdom; 2) Section of Paediatrics, Institute of Cancer Research, Sutton, Surrey, UK.

Wilms tumor (WT) affects 1 in 10,000 children. In 1-3% of cases, Wilms tumor clusters in families due to a presumed underlying genetic susceptibility. Mutations in the *WT1* gene underlie a minority of familial WT pedigrees. Two further familial WT loci, *FWT1* on 17q21 and *FWT2* on 19q13, have been mapped but have not been identified.

We have ascertained 35 WT pedigrees including a total of 93 WT cases. We have screened all families for *WT1* mutations, identifying only 2 families attributable to *WT1*, both of which showed genitourinary abnormalities in males. We have analysed families informative for linkage at *WT1*, *FWT1* and *FWT2*. Seven of 26 evaluable families are unlinked at all three loci indicating that at least one further familial Wilms tumor gene must exist and suggesting that the contribution of currently unknown loci to Wilms tumor susceptibility may be considerable.

The median age of onset of all familial cases was 3 years, but for the *FWT1*-linked families the median age was significantly older at 5.5 years. 9% of familial cases were bilateral and all the bilateral cases were from separate families. Childhood tumors other than WT occurred in 18% of families. 36% of families had some form of congenital abnormality (cryptorchidism, hemihypertrophy, inguinal hernia, short-stature, overgrowth, renal tract anomalies). The pathology of familial tumors was very variable and <20% had detectable nephrogenic rests.

Our analyses further demonstrate the genetic heterogeneity of familial WT susceptibility and suggest phenotypic associations related to underlying molecular sub-groups may exist. Detailed phenotypic and molecular stratification of WT pedigrees will likely facilitate the identification of the underlying predisposition genes. nazneen@icr.ac.uk.

**Invasive breast cancer following bilateral subcutaneous mastectomy in a *BRCA2* mutation carrier.** *L. Kasprzak*<sup>1</sup>, *F. Tremblay*<sup>2</sup>, *M. Galvez*<sup>1</sup>, *F. Halwani*<sup>3</sup>, *W.D. Foulkes*<sup>1</sup>. 1) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Canada; 2) Department of Surgery, McGill University, Montreal, Canada; 3) Department of Pathology, McGill University, Montreal, Canada.

We report the occurrence of invasive breast cancer in a *BRCA2* mutation carrier 33 years after bilateral subcutaneous mastectomy. A 49 year old G3P2 presented in 2002 with a benign looking subcutaneous nodule in the left breast. Excisional biopsy confirmed the diagnosis of infiltrating ductal carcinoma, apocrine type with associated ductal carcinoma *in situ*, cribriform type. Estrogen receptor status was strongly positive, progesterone receptor moderately positive and HER-2/neu was negative. Subsequently, she was referred for genetic counseling and found to carry *BRCA2*: 6503delTT, a mutation previously described in the French Canadian population. Family history was significant for breast cancer in proband's father who was diagnosed at the age of 77 and mother diagnosed at 79. A paternal cousin also affected with breast cancer was previously identified as a mutation carrier at another institution. Our patient had undergone bilateral subcutaneous mastectomy with immediate implantation of silicone prostheses at the age of 16 due to extensive fibrocystic breast disease with adenosis. At that time, there were two paternal aunts known to have been affected with breast cancer.

Prophylactic bilateral mastectomy, whether subcutaneous or total, significantly reduces, but does not eliminate, the risk of breast cancer in *BRCA1* and *BRCA2* mutation carriers. The extent of risk reduction achieved by subcutaneous mastectomy is limited given that about 5-10% of the mammary tissue remains *in situ*, but is thought to be of the order of >85%. To our knowledge this is the first case of breast cancer after any type of mastectomy in a *BRCA1/2* mutation carrier and therefore the long-term risk of breast cancer following preventive mastectomy is likely to be very low. This case illustrates the importance of long-term follow up and careful consideration of preventive potential of a less extensive surgical approach in *BRCA1/2* carriers.

**Cancer risk in xeroderma pigmentosum homozygotes and heterozygotes.** *R. Moslehi<sup>1</sup>, J. DiGiovanna<sup>2,3</sup>, A. Goldstein<sup>1</sup>, S. Khan<sup>2</sup>, P. Tucker<sup>1</sup>, K. Kraemer<sup>2</sup>.* 1) Division of Cancer Epidemiology and Genetics, NCI/NIH, Bethesda, MD; 2) Center for Cancer Research, NCI/NIH; 3) Brown Medical School, Providence, RI.

Xeroderma pigmentosum (XP), a rare (about 1 in 10<sup>6</sup>) autosomal recessive disease, is characterized by severe photosensitivity, abnormal pigmentation and increased risk of skin cancer in association with defective DNA repair. Eight XP complementation groups (XPA-XPG and XP variant) have been identified. The frequency of clinically normal appearing XP heterozygotes (about 1 in 300) is much greater than XP homozygotes but their cancer risk is not well studied. Elevated cancer risks in association with heterozygosity for mutations in other recessive disease genes such as ataxia-telangiectasia and Bloom syndrome have been reported. The only study to date on the relatives of XP patients reported a significantly higher frequency of non-melanoma skin cancer among the blood relatives of XP patients in 4 families compared to spouse controls (OR=16, p=0.0001) (Swift and Chase, 1979). This study was performed before the XP genes were identified; the carrier status of the relatives was inferred. For 48 patients ascertained at the NIH over the past several decades, we have assigned a complementation group and for 34 of them, we have identified a causative mutation. Genotype-phenotype observations suggest that the type of skin cancer, frequency of internal tumors and manifestations of neurological abnormalities differ in patients belonging to different complementation groups. We have also collected detailed multi-generation pedigrees on 19 patients. Differences in the frequency of melanoma and non-melanoma skin cancers as well as other cancer sites among obligate carriers of mutations in different XP genes may exist. We are performing a molecular epidemiology study of all consenting relatives in these XP kindreds to confirm all cases of cancer in the family and to determine which relatives are mutation carriers. We plan to compare the risk of cancer in the heterozygote carriers of different XP mutations with that of non-carrier relatives and spouse controls. This study may define the cancer risk of carriers of XP DNA repair genes.

**Molecular diagnosis of Hyperparathyroidism Jaw Tumor Syndrome - germline *HRPT2* mutation in an adolescent with recurrent kidney stones.** *D.J. Marsh<sup>1</sup>, H.J. Stalker<sup>2</sup>, A.E. Nelson<sup>3</sup>, B.G. Robinson<sup>1</sup>, R.T. Zori<sup>2</sup>, V.M. Howell<sup>1</sup>.* 1) Kolling Institute, Royal North Shore Hospital, Sydney, NSW, Australia; 2) Department of Pediatrics, University of Florida, Gainesville, FL, USA; 3) Garvan Institute of Medical Research, NSW, Australia.

A 15 year old male presented to the Urology Clinic with recurrent kidney stones and gross hematuria. Radiological assessment identified a 3.0 cm calcification in the right renal pelvis. Family history revealed that his father also had recurrent kidney stones and had previously undergone surgery to remove a gland in his neck. Eight months later, the patient presented to an otolaryngologist for evaluation of a sebaceous cyst below his left earlobe. A right neck mass was noted and subsequent ultrasound identified a well-delineated cystic mass replacing the entire right lobe of the thyroid. Blood pathology revealed markedly elevated serum calcium (13.8 mg/dL, RI: 8.4-10.2 mg/dL) and parathyroid hormone levels (488 pg/mL, RI: 15 - 65 pg/mL) leading to a diagnosis of primary hyperparathyroidism and hypercalcemia. Radiological examination revealed bone changes consistent with hyperparathyroidism and expansile cystic-like lesions in the right mandible. A single parathyroid gland was removed, and histopathology was consistent with parathyroid adenoma. Germline mutations in a newly identified gene, *HRPT2*, have been found in over 50% of families with Hyperparathyroidism Jaw Tumor Syndrome (HPT-JT). gDNA from this patient was analyzed for a mutation in *HRPT2* by dHPLC and sequence analysis. A novel germline mutation in exon 7, R234X, was identified, predicted to prematurely truncate the *HRPT2* protein termed parafibromin. A molecular diagnosis of HPT-JT has now been made for this patient that has implications for other family members. Our findings highlight the importance of considering hereditary hyperparathyroidism when presented with an adolescent with kidney stones and a family history of recurrent kidney stones.

**Microarray and *HRPT2* mutation analysis in parathyroid tumors.** V. Howell<sup>1,2</sup>, C. Haven<sup>2,3</sup>, B. Robinson<sup>1</sup>, L. Delbridge<sup>4</sup>, J. Philips<sup>4</sup>, G.J. Fleuren<sup>3</sup>, H. Dralle<sup>5</sup>, C. Hoang-Vu<sup>5</sup>, O. Gimm<sup>5</sup>, A. Nelson<sup>1</sup>, H. Morreau<sup>3</sup>, D. Marsh<sup>1</sup>, B. Teh<sup>2</sup>. 1) Kolling Institute of Medical Research, Royal North Shore Hospital (RNSH) and University of Sydney, NSW, Australia; 2) Van Andel Research Institute (VARI), MI, USA; 3) Leiden University Medical Center, Netherlands; 4) RNSH and University of Sydney; 5) Martin Luther University, Germany.

The molecular events underlying the formation of parathyroid tumors are poorly understood. Microarray analysis was undertaken to identify unique genetic profiles for these tumors. Fifty-three parathyroid tumors consisting of 38 sporadic (16 adenomas, 16 hyperplasias, 5 carcinomas, 1 lithium associated), & 15 familial (5 MEN 1, 1 MEN 2A, 5 HPT-JT, 4 FIHP) & a pool of 16 normal parathyroid tissues were studied. Microarray analysis of tumor and Universal Human Reference RNA (Stratagene) was performed using slides spotted with 19,968 cDNA clones (Research Genetics Human Clone Set). The normalized results were manipulated in CLUSTER. A subset of tumors was also characterized at the *HRPT2* locus by sequencing & LOH. Unsupervised clustering of the array data revealed 3 broad clusters. Group 1 contained all sporadic carcinomas, all HPT-JT & some FIHP tumors. Group 2 contained the majority of sporadic adenomas, all MEN 1 & some FIHP tumors. Group 3 contained the majority of hyperplasias, the lithium-associated, MEN 2A & the pooled normal specimens. All tumors sequenced in group 1 harbored at least 1 *HRPT2* mutation. Two-hits affecting *HRPT2*, were found in 6 of these 11 tumors. No mutations were found in any of the other specimens sequenced. In conclusion, gene expression profiling has identified distinct genetic groupings of parathyroid tumors. A strong association between intragenic mutations of *HRPT2* & the cluster group containing all sporadic malignant & familial HPT-JT tumors has also been identified & is supportive of a role of *HRPT2* as a tumor suppressor gene in these tumor groups.

We thank the VARI Microarray Core Facility for the microarrays.

VH & CH contributed equally to this work.

**CHEK2 and breast cancer: a validation study in Finland and expression in unselected breast tumors by tissue microarray analysis.** *O. Kilpivaara<sup>1</sup>, J. Bartkova<sup>2</sup>, H. Eerola<sup>1,3</sup>, K. v. Smitten<sup>4</sup>, K. Aittomki<sup>5</sup>, C. Blomqvist<sup>3</sup>, G. Sauter<sup>6</sup>, O.-P. Kallioniemi<sup>7</sup>, J. Bartek<sup>2</sup>, H. Nevanlinna<sup>1</sup>.* 1) Dept. Obs. & Gyn., Helsinki University Central Hospital (HUCH), Finland; 2) Inst. Cancer Biology, Danish Cancer Society, Copenhagen, Denmark; 3) Dept. Oncology, HUCH, Finland; 4) Dept. Surgery, HUCH, Finland; 5) Dept. Clinical Genetics, University of Helsinki, Finland; 6) Dept. Pathology, University of Basel, Switzerland; 7) VTT Biotechnology, Turku, Finland.

CHEK2 is a serine/threonine kinase that has a pivotal role in the cell cycle checkpoint signaling network, contributing to damage-induced transcription, DNA repair, cell cycle arrest, and apoptosis. We (Vahteristo et al., AJHG 2002) and others (The CHEK2-Breast Cancer Consortium, Nat Genet 2002) have previously reported the association of a germ line truncating mutation 1100delC with familial breast cancer; the variant is also found in 1.4% of the normal Finnish population. We have here further analyzed the germ line CHEK2 1100delC in 295 familial breast cancer cases, 285 unselected cases and 30 cases with bilateral breast cancer. CHEK2 1100delC was strongly associated with bilateral breast cancer (3/30, 10.0%,  $p=0.0001$  and with familial breast cancer (21/295, 7.1%,  $p<0.00001$ ), as compared to population controls. These results confirm our previous findings on Finnish breast cancer patients. We also studied the CHEK2 protein expression in breast cancer by immunohistochemical analysis of a tumor microarray of 611 unselected breast tumors. The CHEK2 protein expression was reduced in 21.1% of the breast tumors (93/440 tumors with an IHC staining result). The tumors with reduced CHEK2 expression had more often larger primary tumor size ( $p=0.0017$ ), particularly pT4 class ( $p=0.0003$ ) than those with normal staining. In contrast, no association was seen with hormone receptor or p53 status, histology, grade, lymph node status, or overall survival. In conclusion, these results imply a significant role for the inactivation of the CHEK2 signaling in the genetic predisposition to breast cancer and possibly also in mechanisms of sporadic tumor progression.

**Noninvasive imaging of pancreatic neuroendocrine tumors in MEN1-knockout mice.** A.L. Kennedy<sup>1</sup>, P.C. Scacheri<sup>1</sup>, J. Munasinghe<sup>2</sup>, D. Schimel<sup>2</sup>, J.S. Crabtree<sup>1</sup>, F.S. Collins<sup>1</sup>. 1) NHGRI, NIH, Bethesda, MD; 2) NINDS, NIH.

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant cancer syndrome, characterized primarily by multiple tumors of the pancreatic islet cells, parathyroid glands, and anterior pituitary. Nearly all patients who inherit an inactive copy of the MEN1 gene develop at least one endocrine tumor by age 50. The pancreatic endocrine tumors associated with MEN1 grow slowly and are difficult to recognize and treat. Developing high-resolution imaging modalities for pancreatic endocrine tumors is clearly needed to monitor tumor progression for patients with MEN1. We recently developed a mouse model of MEN1 by disruption of the mouse *Men1* homolog. Heterozygous *Men1* knockout mice develop a tumor spectrum that is remarkably similar to that of the human condition. Currently, necropsy is the only way to detect the tumors in the *Men1* mice, making it quite difficult to evaluate possible therapeutic interventions. The goal of this study was to develop noninvasive methods for detecting pancreatic endocrine tumors in live *Men1* knockout mice. Using Magnetic Resonance Imaging (MRI) we can detect small (1-4 mm) pancreatic neuroendocrine tumors on respiratory-gated images obtained with a multi-slice T2 weighted spin echo sequence. These tumors are distinguishable from the surrounding pancreas and enhanced upon administration of manganese-chloride based contrast agents. Two small (2-3 and 3-4 mm) pancreatic endocrine tumors were also detectable in a separate mouse using micro-CT (Computed Tomography). For micro-CT, the mouse was administered Gastroview to distinguish the stomach and digestive tract from the surrounding visceral organs. The size and location of the tumors detected with MRI and CT were confirmed upon autopsy. Although imaging of a variety of different tumor types in mice has been extensively reported, to our knowledge this is the first report of successful imaging of pancreatic endocrine tumors in live mice. The imaging protocols developed in this study may be adaptable to human patients with MEN1, and will be useful for future studies aimed at inducing tumor regression.

**Variants in Androgen Metabolism Pathway Genes and Testicular Cancer Susceptibility.** *K.L. Nathanson<sup>1</sup>, R. Letrero<sup>1</sup>, K. Robertson<sup>1</sup>, E. Ellis<sup>1</sup>, D.J. Vaughn<sup>1</sup>, P.A. Kanetsky<sup>2</sup>*. 1) Dept Medicine, Univ Pennsylvania Sch Med, Phila, PA; 2) Dept Epidem and Biostat, Univ Pennsylvania Sch Med, Phila, PA.

Testicular cancer is the most common cancer in men ages 20-40. Genetic and environmental factors are postulated to play important roles in testicular cancer development. We examined variants in genes involved in the androgen metabolism pathway including cytochromes P450 (*cyp*)-*3A4*, *3A5*, 5- reductase type 2 (*SRD5A2*) and the androgen receptor (*AR*) among 100 testicular cancer cases and 100 controls frequency matched by age and race. Cases were mostly white (95%). Variants in *cyp3A4*, *cyp3A5*, and *SRD5A2* did not differ significantly between the cases and controls. We hypothesized that repeat sizes in *AR* would be longer in cases than in controls, as testicular cancer is associated with a relatively estrogenic environment. Non-parametric comparisons indicated that cases had significantly longer GGC repeats ( $p=.034$ ), but shorter CAG ( $p=.0024$ ) than controls. We found that longer (17) GGC repeats and shorter (23) CAG repeats were associated with testicular cancer (OR 2.8, 95% CI 1.3-6.6 and OR 2.6, 95% CI 1.25-5.5, respectively). Since *AR* is on the X chromosome, we determined haplotypes based on the above dichotomies. Although not statistically significant, results from the haplotype analysis confirmed the single locus analyses. Compared to carriers of short CAG and short GGC repeats, carriers of short CAG and long GGC repeats were more likely (OR=2.6, 95% CI .97, 6.7), carriers of long CAG and short GGC repeats were less likely (OR=.58, 95% CI .19, 1.8), but carriers of long CAG and long GGC repeats were as likely (OR=1.1, 95% .23, 5.3) to be cases. Controversy exists about the relative importance of the CAG and GGC repeats in modulating androgen responsiveness and several studies in prostate and breast cancers have hypothesized that the GGC repeat is in fact causative with the CAG repeat associations due to linkage disequilibrium. Consistent with prior studies in other cancers, we suggest that longer GGC repeats are associated with decreased androgen responsiveness and thus testicular cancer susceptibility.

**A novel homozygous mutation in the MSH6 gene in a Turcot Syndrome family characterized by pediatric glioblastoma multiforme, lymphoma, colorectal cancer and neurofibromatosis.** *M.R. Hegde<sup>1</sup>, M.A. Blazo<sup>1</sup>, L.H. Chin<sup>1</sup>, P.A. Ward<sup>1</sup>, M.M. Chintagumpala<sup>2</sup>, J.Y. Kim<sup>2</sup>, S.E. Plon<sup>2</sup>, C.S. Richards<sup>1</sup>.* 1) Diagnostic Sequencing Lab, Department of Molecular and Human Genetics; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030.

Heterozygous mutations in one of the DNA mismatch repair genes (MMR) cause hereditary nonpolyposis colorectal cancer (HNPCC [MIM114500]). Turcot Syndrome [MIM276300] is the association of brain tumors and colorectal cancer (CRC) and has been reported to be both a dominant and recessive disorder. Homozygous and compound heterozygous mutations in MLH1 and MSH2 genes have been reported in five families characterized by hematologic malignancy, CNS tumors, and the neurofibromatosis type I (NF1) phenotype. Here we describe a non-consanguineous Pakistani family including a son who died of lymphoma and colorectal cancer diagnosed at ages five and eight, respectively. His eight-year-old sister presented with glioblastoma multiforme, atypical café-au-lait spots and axillary freckling. There was no history of malignancy in the parents generation and only one distant relative was reported to have CRC. Mutational analysis was performed for MLH1, MSH2 and MSH6 using dHPLC and sequencing to identify the mutation in the sister. A homozygous single base insertion mutation was identified (3634insT) which results in a premature stop at codon 1223 in exon 7 of the MSH6 gene. This mutation is expected to produce a truncated protein. Both parents were found to be heterozygous for the 3634insT mutation. We report here the first identification of homozygous inactivation of the MMR gene MSH6 in a family with pediatric onset brain tumor, lymphoma, CRC and NF1 phenotype. Our findings support a role for MSH6 in Turcot Syndrome and are consistent with a recessive mode of inheritance.

**Transcriptional response of human lymphoblastoid cells to ionizing radiation.** *K.Y. Jen, V.G. Cheung.* Dept Pediatrics, Univ Pennsylvania, Philadelphia, PA.

Humans are exposed to ionizing radiation (IR) through the environment and in medical diagnostic and treatment procedures. The major consequence of IR exposure is the generation of single and double-stranded breaks in DNA. This DNA damage can accumulate resulting in malignant transformation of somatic cells or heritable mutations in germ cells. To counteract this threat, human cells have complex networks of genes and proteins that are involved in response to IR exposure.

In this study, we used oligonucleotide microarrays to investigate the temporal transcriptional response of lymphoblastoid cells to IR. We irradiated lymphoblastoid cells from 10 unrelated individuals at 3 Gy and 10 Gy doses. Expression profiles of the cells prior to radiation treatment and at 1 hr, 2 hr, 6 hr, 12 hr and 24 hr after IR exposure were obtained. We identified 319 and 816 IR-responsive genes following the 3 Gy and 10 Gy of IR exposures, respectively. Among these genes, 126 genes are in common between the two doses. Many of the IR-responsive genes are involved in cell cycle, cell death, DNA repair, DNA metabolism, and RNA processing.

We will present data from our study and discuss the temporal expression profiles of the IR-responsive genes and dose-dependent IR-response in normal human cells. We will also compare the results to the gene expression profile of cells from patients with radiosensitive diseases. These findings are important for understanding processes such as radiation-induced carcinogenesis, radiation sensitivity, and the development of biomarkers for radiation exposure.

**Characterization of the *Drosophila fancd2* Homologue.** *K. McCabe*<sup>1</sup>, *C. Clay*<sup>2</sup>, *M. Forte*<sup>2</sup>, *M. Grompe*<sup>1</sup>. 1) Dept Medical & Molec Genetics, OHSU, Portland, OR; 2) Vollum Institute, OHSU, Portland, OR.

Fanconi anemia (FA) is an autosomal recessive cancer susceptibility syndrome characterized by birth defects, progressive bone marrow failure, and cellular hypersensitivity to DNA crosslinking agents. Six genes have been cloned (*FANCA*, *C*, *D2*, *E*, *F*, and *G*) and bi-allelic inactivation of *BRCA2* was shown in FA-B and D1 patients, genetically linking the FA and BRCA pathways. FANCD2 monoubiquitination in a cell cycle and DNA damage dependent manner requiring the FA complex (*FANCA*, *C*, *E*, *F*, and *G*), and FANCD2 phosphorylation following ionizing radiation by ATM indicate FANCD2 may be the branch point between DNA inter-strand crosslink and double-strand break repair. Perhaps most intriguing, *FANCD2* is the only FA/BRCA gene in the pathway to have a homologue outside of vertebrate organisms and may represent the evolutionary precursor of the FA/BRCA global genome repair pathway. A recently constructed 130Kd HA tagged *fancd2* will now permit us to determine if *fancd2* is post-translationally modified in a manner consistent with mammalian FANCD2. Preliminary results from RNAi knock down experiments of fly *fancd2* in Kc cells indicate there is no increase in IR sensitivity at the cell level, consistent with observations in mammalian systems. RNAi experiments examining inter-strand crosslinker sensitivity are underway. In addition, we have developed a transgenic fly carrying a *GAL4* inducible *fancd2* RNAi construct. By breeding this fly to lines carrying *GAL4* driven by various promoters we can knock-down *fancd2* in a spatially and developmentally controlled manner. Also under development is a *fancd2* knock-out fly. The results from these experiments will demonstrate if fly *fancd2* is indeed an orthologue of the FANCD2 of vertebrates. If the *Drosophila fancd2* homologue is the progenitor of the FA/BRCA pathway, future experiments examining fly *fancd2* may provide insight into the function of FANCD2 in mammals. Utilizing *Drosophila fancd2* as a model for FA/BRCA global genome repair will provide a biochemical foothold on the mammalian pathway, permitting acceleration of our understanding of Fanconi anemia, cancer predisposition syndromes, and DNA repair.

**Using synthetic lethality in *Drosophila melanogaster* for drug target discovery.** L.R. Marek, V. Busygina, A.E. Bale.  
Dept Genetics, Yale Univ, New Haven, CT.

Synthetic lethal screens are used in yeast to identify novel mutations which are not themselves lethal, but cause lethality in combination with mutations in a gene of interest. These screens have the potential to identify genes that interact with known cancer genes; thereby, identifying a novel anticancer drug target. However, many cancer genes are not conserved between yeast and humans. *Drosophila*, on the other hand, bear homologs to nearly every key cancer-related gene. For this reason, our laboratory performed a synthetic lethal screen using flies to identify novel drug targets for tumors associated with Multiple Endocrine Neoplasia Type I (MEN1).

MEN1 is an autosomal dominant disease characterized by tumors of the endocrine glands. Tumors arise from loss of both copies of the gene, MEN1. Because homozygous loss of MEN1 in *Drosophila* results in viable flies, a synthetic lethal screen was performed using MEN1 mutant flies as a model for MEN1 tumors. Flies that were homozygous mutant for MEN1 were tested against 83 deletion lines that covered chromosome 3. A single deletion line was identified that causes lethality in MEN1 mutant flies. Specifically, in a cross that generated 167 flies in the F1 generation, 25% of the progeny was expected to be MEN1 mutants carrying the deletion. Zero flies hatched with this genotype, indicating that a gene located in this deletion is interacting with MEN1 to cause lethality. This deletion spans approximately 2200 kb, deleting 248 genes. Using a series of 9 smaller deletion lines, 95 genes have been eliminated and the search will eventually be narrowed to 10-15 candidates. Genetic crosses with known mutants in the region and RNAi will ultimately identify the gene responsible for lethality. This screen has the potential to determine new drug targets whose inactivation in combination with the loss of MEN1 kills endocrine tumor cells specifically. This study is the first to validate *Drosophila* as a model organism for synthetic lethality drug target screening, and sets the stage for large-scale studies to systematically screen every gene in the *Drosophila* genome.

**Is there a biological basis for A-T heterozygote cancer risk.** *M. Lavin.* Dept Cancer Biol, QIMR, Brisbane, Australia.

The human genetic disorder ataxia-telangiectasia (A-T) is characterized by neurodegeneration, immunodeficiency, radiosensitivity, cell cycle defects, genomic instability and cancer predisposition. A-T is an autosomal recessive disorder but there is evidence for penetration of some aspects of the phenotype in heterozygotes. Carriers of a defective ATM (ataxia-telangiectasia mutated) gene exhibit intermediate levels of radiation-induced chromosome aberrations and cells in culture are intermediate between A-T and controls in their sensitivity to ionizing radiation. In addition several epidemiological studies have pointed to an increased risk for cancer, especially breast cancer, in A-T heterozygotes. However, initial mutation analysis on the ATM gene in patients with breast cancer did not correlate with the epidemiological data. It seems likely that this was due to the nature of the mutations screened for. More recent data suggest that the presence of missense mutations in ATM lead to a dominant interfering effect on wild-type ATM protein thus compromising its activity. This mechanism of interference on normal ATM function and cancer predisposition in A-T heterozygotes is supported by studies with animal models. The biological basis for increased cancer incidence in carriers of the ATM defective gene will be discussed.

**MEN1 testing in a clinical diagnostic laboratory.** *R.D. Klein, J. Bessoni, A.E. Bale.* Yale University School of Medicine, New Haven, CT.

MEN1 is an autosomal dominant syndrome characterized by parathyroid, pancreatic islet, pituitary, and occasionally, other tumors. Previous functional studies of the MEN1 protein, "menin", suggest a role as a transcriptional co-modulator. The MEN1 gene has an 1830 bp coding region spanning exons 2 through 10. Disease-related mutations of the gene occur in all portions of the coding sequence and most often produce truncated proteins. Missense mutations also occur, but there is little evidence for genotype-phenotype correlations. From October 1997 - May 2003, blood samples from 398 individuals of 287 pedigrees were received for clinical MEN1 testing. In each proband, exons 2 - 10 with the intron-exon junctions were PCR amplified and sequenced (ABI 377). Among 94 (presumably unrelated) pedigrees that tested positive, 72 mutations were found. The mutational spectrum included 17 nonsense mutations (23.6%), 18 frameshift deletion mutations (25%), 10 frameshift insertion or duplication mutations (13.9%), 11 splice site mutations (15.3%), 2 in-frame deletions (2.8%), and 14 probable missense mutations (19.4%). In-frame deletions and missense mutations were judged to be deleterious if they were not found in 200 unaffected individuals, altered highly conserved bases, and segregated with the disease in families. Among the recurrent mutations, 4 were found in >2 pedigrees including a 4-base deletion in codons 83-84 that was present in 6% of the affected pedigrees. Recurrent mutations in apparently unrelated pedigrees suggest the presence of founder effects or mutational hotspots. Broad haplotyping of the MEN1 region to distinguish these possibilities is in progress. Individuals most likely to test positive were those from families affected with parathyroid and pancreatic islet neoplasia +/- other features. Sporadic patients with these tumors were somewhat less likely to test positive, possibly reflecting somatic mosaicism. A substantial proportion of families with hyperparathyroidism alone tested positive, but the combination of parathyroid and pituitary disease without pancreatic islet neoplasia was rarely associated with an MEN1 mutation. This latter combination of tumors may represent a different genetic disease.

**Increased identification of patients at risk for hereditary colorectal cancer using a questionnaire.** *T. Monteith<sup>1</sup>, R. Bostick<sup>2</sup>, K. Brooks<sup>1</sup>, M. Seabrook<sup>3</sup>, S.R. Young<sup>1</sup>.* 1) Dept. of Ob/Gyn, USC, Columbia, SC; 2) Dept. of Family Practice, USC, Columbia, SC; 3) Consultants in Gastroenterology, Columbia, SC.

Every year, 150,00 new cases of colorectal cancer (CRC) are identified in the U.S. Of these, 5-10% are thought to be inherited. Hereditary non-polyposis colorectal cancer (HNPCC) is responsible for approximately 3-5% of CRC. Unlike familial adenomatous polyposis, HNPCC is similar in clinical presentation to sporadic CRC. A common belief is that a substantial proportion of persons at risk for HNPCC are not identified. This study's goal was to evaluate a simple, self-administered screening questionnaire to identify patients at risk for hereditary CRC, particularly HNPCC. Potential participants were sequential patients attending outpatient pre-colonoscopy appointments at a large endoscopy center. A total of 1005 patients (100% consent rate) completed the questionnaire, and were classified into four groups based on family history: 1) negative (414), 2) isolated cancer (210), 3) more than one cancer but not meeting Amsterdam criteria or Bethesda guidelines (258), and 4) meeting Amsterdam criteria or Bethesda guidelines (123). Chart reviews were conducted on group 4 as well as a randomly selected equal number from the remaining three groups. Of participants on whom chart reviews were conducted, 51 (10%) were randomly selected for family history interviews. Telephone interview was a priori considered to be the criterion standard method for identifying at risk families. The three methods (usual care, questionnaire, and interview) were compared using the Kappa (K) statistic. The questionnaire and interview were in substantial agreement (K = .672), but the chart and questionnaire and chart and interview were in moderate agreement (K = .456 and .473, respectively). These findings suggest that the use of a screening questionnaire can lead to a substantial increase in the number of patients identified as being at increased risk for hereditary CRC, especially HNPCC. Findings also suggest that a major reason that risk for HNPCC may be overlooked in usual gastroenterology clinical care is not soliciting or considering family histories of extra-colonic HNPCC-associated cancers.

**Mutational Analysis of the Mismatch Repair Genes in HNPCC Patients.** *K. Nafa, P. Peterlongo, J. Shia, L. Canale, G. Lerman, E. Glogowski, J. Guillem, A. Markowitz, K. Offit, N.A. Ellis.* Memorial Sloan-Kettering Cancer Center, New York, N.Y.

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominant cancer predisposition syndrome predominantly caused by germline mutations of the MLH1, MSH2, and MSH6 mismatch repair (MMR) genes. We have ascertained 126 families, most of which had at least three first or second degree relatives diagnosed with colorectal cancer at any age (HNPCC-like), to obtain a clinical cohort that will be useful in gene discovery. 64 families met Amsterdam criteria (AC) I or II and 54 families met HNPCC-like criteria; 8 families met Bethesda criteria. By microsatellite instability (MSI) analysis, 38 of the 95 families tested exhibited MSI (MSI-high). We used DHPLC to identify mutations in MLH1, MSH2, and MSH6 in an affected person from each of the 38 MSI-high families (31 AC, 4 HNPCC-like, 3 Bethesda) and the 31 MSI-untyped families (19 AC, 9 HNPCC-like, 3 Bethesda). Deletion analysis was performed by semi-quantitative fluorescent multiplex PCR in families lacking mutations by DHPLC analysis. Here we report 34 unique mutations identified in 47 persons (39 AC, 5 HNPCC-like, 3 Bethesda)--15 mutations in MLH1, 17 in MSH2, and 2 in MSH6. The mutation types consisted of 9 frameshift mutations, 1 nonsense mutation, 11 splice site mutations, 1 deletion of exon 8 of MSH2; 10 amino acid substitutions, and 2 single amino acid deletions. The MSH2\*IVS5+3A>T mutation was detected 5 times, the MLH1\*1411delAAGA and MLH1\*1852delAAG mutations were detected 2 times each, and the MSH2\*1906G>C (A636P) mutation was observed 8 times, occurring only in Ashkenazi Jewish families. Mutations were identified in 31 of the 38 (0.82) MSI-high families and 16 of the 31 (0.52) MSI-untyped families even though family history was similar in both groups, suggesting that MSI screening increases the mutation detection rate. In the 7 MSI-high mutation-negative families, undetected mutations may be present. With 72 (20 AC, 48 HNPCC-like, 4 Bethesda) families putatively lacking a MMR gene mutation, the cohort assembled is a starting point for the identification of previously unknown genetic susceptibility factors.

**Changes of gene expression in leukemia cells surviving ultra-short pulsed electric fields.** *M. Stacey<sup>1</sup>, P. Fox<sup>1</sup>, D. Trang<sup>1</sup>, K. Schoenbach<sup>2</sup>, S. Beebe<sup>1</sup>.* 1) Ctr Pediatric Research, Eastern Virginia Medical Sch, Norfolk, VA; 2) Ctr Bioelectrics, Old Dominion Uni, Norfolk, VA.

Ultra-short, high intensity, pulsed electric field (nsPEF) applications, and the ability to expose cells to them, have emerged from recent advances in electronics. nsPEF exposures are of high electrical intensity with pulse duration in the order of nanoseconds (billionths of a second). These are conditions that cells are unlikely to have encountered during evolution and it is therefore largely unknown how cells react to such exposures. We have measured the survival of different cell lines exposed to nsPEF and found that cells derived from leukemia and from transformed lymphoblastoid B-cells derived from patients with cancer predisposing syndromes are specifically sensitive to the killing effects of nsPEF (approx 10% survival). Those derived from solid tumors do not show the same sensitivity (70-100% survival). Surviving leukemia cells showed a significant reduction in the number of cells reaching mitosis (%mitotic index;%MI) for 4 days post-exposure compared to unexposed cells, before returning to normal levels after one week. Cell lines derived from solid tumors did not show a reduction in %MI at any time point. Here we present findings of microarray analysis on surviving cells describing changes in gene expression associated with cell survival and discuss the use of antisense drugs to maximize cell killing in leukemia cells.

**Family history of breast cancer in Mexican men with breast cancer.** *S. Vidal, M. Chavez, A. Fuentes, D. Cantu.*  
Dept Clinical Research, Inst Nacional de Cancerologia, Mexico City, Mexico.

Male breast cancer is a rare entity and accounts for approximately 1% of all breast cancers. Consequently, much less information is available regarding the disease in men. Geographic and temporal variation in the rates is modest suggesting limited environmental and life-style influence. Information regarding male breast carcinoma is nearly entirely retrospective and uncontrolled. Although the etiology of breast cancer in men is not understood, hormonal and genetic factors both appear to play a role. An increased risk of breast cancer in men has been associated with a family history of breast cancer. We retrospectively reviewed charts of all breast cancer patients between 1980 and 2001 diagnosed and treated at the National Cancer Institute in Mexico to evaluate the family history of breast cancer in these patients. In this period 10,671 breast cancers were treated in our institution, of these cases 23 were male, representing 0.21% of all cases. All of them were Mexican, age ranged from 25 to 81 years (mean 56.5). Only 2 patients (8.6%) had family history of breast cancer, 1 of them has a maternal aunt with unilateral breast cancer and the other one with bilateral breast cancer has 2 first degree relatives and 5 second degree relatives affected with breast cancer, all of them women from maternal side. Even previous investigators have indicated that family history is one of the strongest risk factors for breast cancer in men and women in this study just 2 cases were found. Clearly one of them has breast and ovarian cancer syndrome and the rest of the family must be evaluated for BRCA2 mutation. These results suggest that in Mexican patients the frequency of familial breast history is not so common. However, we can not reject the possibility that the information given for the patients were incomplete due that much of our population comes from little towns without medical services and they ignore the real cause of death of their relatives.

***PTEN* Mutation in an Adult Male Fulfilling Clinical Criteria for Bannayan-Riley-Ruvalcaba-Smith and Cowden Syndromes.** *N. Wong*<sup>1</sup>, *J.R. Jass*<sup>2</sup>, *W.D. Foulkes*<sup>1,3</sup>. 1) Cancer Prevention Centre, SMBD-Jewish General Hospital, McGill University; 2) Dept. of Pathology, McGill University; 3) Program in Cancer Genetics, McGill University.

Germline mutations in *PTEN* are known causes of Cowden syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BRRS), two hamartoma syndromes which clinically overlap. CS is characterized by multiple hamartomas of the skin, breast, thyroid, oral mucosa, GI tract, and CNS. Hallmarks features of CS are trichilemmomas and mucocutaneous papules seen in >90% of patients. Breast and thyroid cancer are also part of CS. About 40% of CS patients are macrocephalic. Typical features of BRRS include macrocephaly, lipomatosis, intestinal hamartomatous polyps and speckled penis. Increased risk for malignancy is thought not to occur in pure BRRS families, whereas in CS, lipomatosis is rare and pigmentation of the glans penis has never been reported. We report an individual with a novel mutation, Y16X, in *PTEN* meeting the clinical criteria for both CS and BRRS.

The proband is an A. Jewish male referred for colonic polyps. Physical exam revealed a head circumference >97 percentile, a prominent forehead, oral papules, florid axillary papillomas, speckled penis, plantar keratosis, and facial and inguinal papillomas. Medical history includes a multinodular goiter, hypothyroidism, and the removal of colonic polyps at age 6 and 37 and two lipomas at age 37. Re-examination of the polyps was supportive of a diagnosis of CS. The proband is a college graduate and has no learning disabilities. His parents, his 3 children, and 2 sibs were evaluated. A nonsense mutation, Y16X, was found in the proband and his offspring, confirming this is a *de novo* mutation.

Y16X is the most proximal truncating mutation thus far reported in *PTEN*. We speculate his range of features is due to the location at the extreme 5end. CS/BRRS families have been reported but this is the first documented individual meeting clinical criteria for both CS and BRRS and adds further evidence that these are in fact different manifestations of the same disorder.

**ATM variants 7271TG and IVS10-6TG among women with unilateral and bilateral breast cancer.** *S.N. Teraoka<sup>1</sup>, J.L. Bernstein<sup>2</sup>, L. Bernstein<sup>3</sup>, W.D. Thompson<sup>4</sup>, S.L. Teitelbaum<sup>2</sup>, C.F. Lynch<sup>5</sup>, K.E. Malone<sup>6</sup>, J.D. Boice<sup>7</sup>, B.S. Rosenstein<sup>2</sup>, A.L. Børresen-Dale<sup>8</sup>, R.A. Gatti<sup>9</sup>, P. Concannon<sup>1</sup>, R.W. Haile<sup>3</sup>, WECARE Study Collaborative Group.* 1) Dept Molecular Genetics, Benaroya Research Institute, Seattle, WA; 2) Mount Sinai School of Medicine, New York, NY; 3) University of Southern California, Los Angeles, CA; 4) University of Southern Maine, Portland, ME; 5) University of Iowa, Iowa City, IA; 6) Fred Hutchinson Cancer Research Center, Seattle, WA; 7) International Epidemiology Institute, Rockville MD; 8) Norwegian Radium Hospital, Oslo, Norway; 9) University of California at Los Angeles, Los Angeles, CA.

Recent reports suggest that two ATM gene mutations, 7271TG and IVS10-6TG, are associated with a high risk of breast cancer among multiple-case families. To assess the importance of these two mutations in another genetically susceptible group, young women (under age 51) with bilateral breast cancer (second primaries), we compared the frequency of these mutations in the bilateral cases and in matched controls who had unilateral breast cancer. The 1149 women included were enrolled in an on-going population-based case-control study of the genetic factors that contribute to bilateral breast cancer; they were not selected on the basis of family history of cancer. Screening for 7271TG and IVS10-6TG ATM gene mutations was conducted using DHPLC followed by direct sequencing. The 7271TG mutation was detected in 1/638 (0.2%) women with unilateral breast cancer and in none of the bilateral cases (0/511), and the IVS10-6TG mutation in 8/638 (1.3%) unilateral and in 1/511 (0.2%) bilateral breast cancer cases. Carriers of either mutation were not limited to women with a family history. Given the likelihood that young women with bilateral breast cancer have a genetic predisposition, the observed mutation distribution is contrary to that expected if these two mutations were to play an important role in breast carcinogenesis in this population.

**SMAD4 tumor suppressor in early onset colorectal cancers.** *S.G. Royce<sup>1</sup>, K.J. Alsop<sup>1</sup>, A.M. Haydon<sup>3</sup>, M.A. Jenkins<sup>2</sup>, L.J. Mead<sup>1</sup>, G.G. Giles<sup>4</sup>, J.L. Hopper<sup>2</sup>, M.C. Southey<sup>1</sup>.* 1) Genetic Epidemiology Laboratory, Department of Pathology; 2) Centre for Genetic Epidemiology, Department of Public Health, The University of Melbourne; 3) Department of Epidemiology and Preventative Medicine, Monash University; 4) Cancer Epidemiology Centre, Cancer Council Victoria, Australia.

The most frequent cytogenetic alteration in colorectal cancer is the deletion of 18q21. One of the genes located in this region, SMAD4, is a downstream regulator in the TGF- signaling pathway. Loss of SMAD4 function causes loss of transcription of genes critical in cell cycle control. SMAD4 protein is reported to be absent in 38% of colorectal carcinomas and reduced in a further 28%. Furthermore, SMAD4 may assist the well-characterized tumor suppressor E-cadherin in the re-establishment of epithelial morphology. A recent study has shown that unselected colorectal carcinoma patients with normal SMAD4 diploidy have a three-fold higher benefit from 5-fluorouracil adjuvant chemotherapy than those with a deletion. The underlying genes and molecular pathways in the majority of early onset colorectal cancers remain undefined. We investigated the role of SMAD4 mutations in a population-based case study of early onset colorectal cancer. Immunohistochemistry for SMAD4, E-cadherin and -catenin was performed on invasive carcinomas from 106 participants diagnosed before the age of 45. SMAD4 protein showed nuclear, and occasionally, cytoplasmic localization in tumor epithelial cells, 26 cases exhibited loss of staining for SMAD4 protein, 10 of these with accompanying loss of cell adhesion proteins, and 7 showed focal positive and negative SMAD4 staining. Loss of SMAD4 was not associated with degree of tumor differentiation, however loss was related to tumor site and was higher in rectal than colonic carcinomas ( $p=0.03$ ). Loss therefore appears to be a common event in early onset colorectal carcinomas. Studying the role and nature of SMAD4 mutations relative to the established molecular pathways of early onset colorectal cancer, including those involving mismatch repair and K-ras mutations, has the potential to more effectively target treatment to patients.

**Modulation of p12DOC-1, a cell growth suppressor in in-vitro mismatch repair (MMR) human/mouse expression systems.** *Z.Q. Yuan<sup>1</sup>, T.S. Kent<sup>2</sup>, Y. Wang<sup>3</sup>, A.G. Miller<sup>2</sup>, W. Edelmann<sup>3</sup>, T.K. Weber<sup>1,2</sup>*. 1) Molecular Gen, Albert Einstein Col Medicine, Bronx, NY; 2) Surgery,; 3) Cell Biology, Albert Einstein Col Medicine, Bronx, NY.

**Introduction:** p12DOC-1, a CDK2-associated protein, is a candidate cell growth suppressor. We previously demonstrated that absent or decreased p12DOC-1 expression in multiple microsatellite-unstable (MSI+) colorectal cancer cell lines, or p12DOC-1 downregulation, was associated with colorectal epithelial cell proliferation and arrest of apoptosis. To better understand the relationship between p12DOC-1 expression and MMR status, we employed purified in vitro human and mouse recombinant MMR expression systems to investigate the relationship of p12DOC-1 expression to cell cycle and apoptosis regulation. **Methods:** Three MMR expression systems were studied, 1): A human MMR-deficient system was constructed by transfecting wild-type and mutant-type hMLH1 into the cell lines, 293T, RKO, and HCT116; 2): A human MMR-proficient system (HCT116+chromosome 3); 3): A mouse embryonic stem (ES) cell (MSH2-/- knockouts) MMR-deficient system. MMR status was confirmed via hMLH1 and hMSH2 assays. p12DOC-1 mRNA and protein expression were assessed in each system by real-time PCR and Western blot. The percentage of apoptotic cells and S-phase were determined by FACS assay. **Results:** In our MMR-deficient systems, the transcription and translation of p12DOC-1 were significantly decreased. Cell proliferation was increased and apoptosis decreased. In the MMR-proficient systems, p12DOC-1 transcription and translation were significantly increased compared to MMR-deficient controls. Cell proliferation was inhibited and apoptosis increased. Mouse expression system results were consistent with human system results. **Conclusion** Our current investigation of p12DOC-1 expression, cell cycle, and apoptosis in multiple MMR expression systems confirms our earlier findings with respect to p12DOC-1 expression and cell cycle and apoptosis modulation. We conclude that p12DOC-1 is an important regulator of cell cycle and apoptosis in human colorectal cancer.

**Ecogenetics of familial pancreatic cancer.** *A.E. Weedn<sup>1</sup>, C.E. Aston<sup>2</sup>, M.A. Grim<sup>1</sup>, D.E. Bard<sup>1</sup>, J.J. Mulvihill<sup>1</sup>.* 1) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK.

To identify the ecogenetic (gene-environment) determinants of pancreatic cancer through an interdisciplinary family studies approach, the National Registry of Pancreatic Cancer Families was established in 1988 at the National Cancer Institute. Registry families meet one of two inclusion criteria: 1) at least two first-degree relatives with adenocarcinoma of the exocrine pancreas, or 2) two affected second-degree relatives connected by a relative with any type of cancer. Family members complete questionnaires on demographics, medical history, and family history; documentation is obtained to confirm cancer history. Of the 78 eligible families with confirmed diagnoses, 5 were excluded as likely *BRCA1*, *BRCA2*, or *HPNCC* families. Aggregation analysis was performed on the 73 remaining families for pancreatic cancer as well as associated cancers by the method of Chakraborty et al (1984). All families aggregated for pancreatic cancer at a 5% level of significance, reflecting our inclusion criteria. Under the most stringent statistical conditions ( $P < .001$ ), aggregation of pancreatic cancer occurred in 17 families. Inspection of associated cancers in Registry families suggests possible excesses of other cancers. Specifically, 63 (expected = 28.8) cases of breast cancer, with 15 cases of breast cancer aged 50 years or less (3.5), were reported. Aggregation occurred in 34 of the families. The observations suggest that families with two or more pancreatic cancer cases may be at an increased risk to develop other cancers, especially of the breast. The analyses identify a subset of families for a candidate gene search; additional families continue to be enrolled.

**Functional characterization of new coactivators of the AF-1 domain of estrogen nuclear receptor.** *S. Solórzano-Vargas, A. Leon-Del-Rio.* Department of Molecular Biology and Biotechnology, Instituto de Investigaciones Biomédicas, UNAM, Mexico D.F., Mexico.

Estrogen receptor (ER) is a ligand dependent transcriptional regulator that mediates the effects of estrogen on growth, metabolism and cell differentiation. ER contains two distinct transactivation domains known as AF-1 and AF-2 domains located at N-terminus and C-terminus respectively. The transcriptional activity of ER has been explained in terms of the chromatin remodeling produced by coactivators recruited by the AF-1 domain such as SRC-1, CBP/p300 and pCAF. Unlike AF-2 domain, the AF-1 region has only been poorly characterized despite it has been linked to tamoxifen (TOT) resistance in patients with breast cancer. To understand the role AF-1 in human cells and breast cancer tumors we identified cell factors that regulate the activity of ER using AF-1 as a molecular bait in a yeast two-hybrid assay. We isolated 9 different cDNA fragments representing 8 different genes. Only two of these genes have been identified previously (E3KARP and MAZ-1). The rest of the clones were named transcriptional coactivator 1-6. Transient transfection of full length TC-1, TC-2, TC-3 and TC-4 cDNAs into human cells showed an increase in the ER mediated transactivation of 216%, 169%, 246% and 174% respectively. In contrast transfection of MAZ-1 showed a discrete transcriptional repression of ER. Cotransfection of well characterized coactivator of ER SRC-1 with either E3KARP, TC-1 or TC-2 increased the ER activity up to 450% with respect to control cells. These results suggest that the TC factors may regulate the ER activity by regulating the formation or activity of the chromatin remodeling complex in the AF-2 domain. Identification of proteins involved in the transcriptional activity of AF-1 could lead to a better understanding of the ER mediated transcriptional activation and the characterization of the mechanism of TOT resistance in patients with breast cancer.

**Role of Proliferating Cell Nuclear Antigen (PCNA) mutations in inducing microsatellite instability in gliomas.**

*A.A. Pillai*<sup>1</sup>, *H.V. Easwar*<sup>2</sup>, *R.N. Bhattacharya*<sup>2</sup>, *M. Banerjee*<sup>1</sup>. 1) Human Molecular Genetics, Rajiv Gandhi Centre for Biotechnology, Thiruvananthapuram 695 014, Kerala, India; 2) SCTIMST, Thiruvananthapuram, Kerala, India.

Role of Proliferating Cell Nuclear Antigen (PCNA) mutations in inducing Microsatellite instability in gliomas. Anitha A1., H.V.Easwar<sup>2</sup>, R.N.Bhattacharya<sup>2</sup>, and M.Banerjee<sup>1</sup> | Rajiv Gandhi Center for Biotechnology, 2SCTIMST, Thiruvananthapuram. Glial tumors are the most common among the various Central Nervous System (CNS) tumors. Neoplastic transformation in the normal human brain occurs as a result of a series of genetic alterations. These multiple genetic changes gradually transform growth-limited cells into highly invasive cells. This is brought about by genes that positively control cell cycle checkpoints, which are targets for oncogenic activation, and negative regulators, such as tumour suppressor genes, that are targets for inactivation. Microsatellite Instability (MSI) is known to be a mutator phenotype for genomic instability in several cancers. Understanding the molecular details of cell cycle regulation and checkpoint abnormalities in cancer with respect to MSI pattern will provide insight into potential therapeutic strategies. We intend to evaluate the role of mutations in PCNA in causing MSI in gliomas, under the influence of stable expression of cell cycle genes. We assessed the microsatellite instability and mutations in the coding regions of PCNA, under the influence of homogenous genetic background of cell cycle genes, tumor suppressor genes and mismatch repair genes (PCNA p16, p21, p53, pTEN, hMSH2 and hMLH1) in various grades of gliomas. Under similar genetic background the astrocytic tumors of low grade show MSI in 26% of the loci, while malignant grades show MSI only in 13% of the tumors. Alterations in BAT26, D9S942 and D20S835 seem to be characteristic of astrocytic tumors. Under the unaltered expression profile of p16, p21, p53 and PCNA genes, MSI of microsatellites in proximity to PCNA could suggest for its role in MSI. Results indicate that MSI also seems to be an early event in the pathogenesis of Glial tumors.

**Screening for BRCA1 and BRCA2 germ line point mutations in 600 Italian families with breast and/or ovarian cancer: mutation prevalence according to phenotype.** *B. Pasini*<sup>1,2</sup>, *S. Manoukian*<sup>2</sup>, *V. Pensotti*<sup>2,3</sup>, *R. Crucianelli*<sup>2,3</sup>, *G.B. Spatti*<sup>2</sup>, *R.A. Conti*<sup>2</sup>, *T. Genovese*<sup>2</sup>, *B. Peissel*<sup>2</sup>, *L. Mariani*<sup>2</sup>, *M. Merola*<sup>2</sup>, *G. Casalis Cavalchini*<sup>1</sup>, *M.A. Pierotti*<sup>2,3</sup>, *P. Radice*<sup>2,3</sup>. 1) Dep. Genetics-Biology-Biochem., University of Turin, Turin, (Turin), Italy; 2) Istituto Nazionale Tumori, Milan, (Milan), Italy; 3) Istituto FIRC di Oncologia Molecolare, Milan, (Milan), Italy.

Six hundred (600) Italian families have been collected since 1991 at the National Cancer Institute of Milan eligible to BRCA1 and 2 mutation analysis. Inclusion criteria were: recurrence of breast and/or ovarian cancer in at least 2 family members, early onset cases of the latter tumors, multiple primary tumors in a single subject or male breast cancer. BRCA1 and 2 germ line point mutations were identified in 220 families (37%), including 194 "deleterious" mutations (32%) and 26 genetic variants of unknown biological effect (4.3%). The mutation detection rate for deleterious point mutations ranged between 24% in familial female breast cancer to 55% in familial breast and ovarian cancer, reaching 59% in familial ovarian cancer. Early onset or pre-menopausal breast cancer and multiple primary tumors were the most effective predictors of BRCA mutations identified in 40.4% of breast cancer cases arising below 36 years, 42.5% of bilateral breast cancers and 71% of women affected by both breast and ovarian cancer. The number of affected relatives did not influence significantly the mutation detection rate. BRCA1 and 2 point mutations (128 and 66 deleterious, respectively) were distributed along the whole coding sequence of both genes: in BRCA1 as well as in BRCA2 most of the mutations identified were unique (71% and 77.5%, respectively) or recurrent in a few families. Beside BRCA1 recurrent mutations at exon 5 cysteine residues and 5382insC, there were only small founder effects. Of note, among the 220 mutations identified, 52 (24%) were missense mutations with known (19) or unproven biological effect. The latter were assayed for their biological impact by using the SIFT software: 17 missense mutations were identified which potentially affect protein function.

**Association between the occurrence of MPNST and subcutaneous and internal neurofibromas in NF1.** *T. Tucker<sup>1</sup>, P. Wolkenstein<sup>2</sup>, JM. Friedman<sup>1</sup>*. 1) Medical Genetics, Univ British Columbia, Vancouver, BC, Canada; 2) Service de Dermatologie, Hôpital Henri-Mondor, Créteil, France.

Neurofibromatosis 1 (NF1) is a fully penetrant autosomal dominant cancer predisposition disorder with variable expressivity, making it difficult to predict which patients will be severely affected. Individuals with NF1 have a lifetime risk of about 10% of developing malignant peripheral nerve sheath tumours (MPNST) and most develop from pre-existing plexiform neurofibromas. Benign neurofibromas of various types develop in almost all people with NF1, but the number, size, and type varies greatly among patients. It is not known if an individual's risk for developing MPNST bears any relationship to the burden of benign neurofibromas. The Henri-Mondor Database contains information on 476 probands with NF1 diagnosed by the NIH Criteria. The average age is 33; 68% were between 10 and 39 years of age at last exam. A semi-quantitative estimate of the number of cutaneous neurofibromas and information on the presence or absence of subcutaneous and internal neurofibromas and MPNSTs were recorded for each patient. Internal tumours were identified by abdominal ultrasound, CT or MRI and X-ray, CT or MRI of the thorax. MPNSTs were diagnosed by biopsy. We used logistic regression to determine the association between each of these features with age as a covariate. MPNSTs were 14.3 times (95% confidence interval [CI] 2.7-77.7) more likely to be present in individuals with internal neurofibromas than in patients without internal neurofibromas. Individuals with subcutaneous neurofibromas were 5.3 (95% CI 2.0-14.3) times as likely to have internal neurofibromas and 3.4 (95% CI 1.3-8.8) times as likely to have a MPNST as patients without subcutaneous neurofibromas. Patients with both subcutaneous and internal neurofibromas were 17.3 (95% CI 2.6-87.5) times more likely to have a MPNST than a patient with neither. Cutaneous neurofibromas were not associated with any of the above mentioned tumours. The observation that MPNSTs are associated with subcutaneous neurofibromas and internal neurofibromas suggests that individuals with such benign tumours may warrant increased surveillance for MPNST.

**Cancer Screening Adherence in Breast/Ovarian Cancer Families.** *M.E. Wood<sup>1</sup>, C.I. Grossman<sup>2</sup>, W.C. McKinnon<sup>1</sup>, B.M. Dausch<sup>2</sup>, A. Gray<sup>2</sup>, B.E. Compas<sup>3</sup>*. 1) Medicine, University of Vermont, Burlington, VT; 2) Psychology, University of Vermont, Burlington, VT; 3) Psychology, Vanderbilt University, Nashville, TN.

Women with strong family histories of breast and/or ovarian cancer have elevated ovarian cancer risk. This study evaluates adherence to ovarian cancer screening in high-risk women. Participants included women with a family history of breast and/or ovarian cancer who were recommended screening for ovarian cancer. Women were asked to complete questionnaires regarding medical and family history, health behaviors, cancer screening practices, psychological distress, adherence and barriers to ovarian cancer screening at study enrollment, 12 and 24 months. Forty-four women were enrolled, 5 had oophorectomy, 9 did not complete all time points and 1 patient expired; 29 women completed the study and are the focus of this report. The mean age of women in this study is 45 (range 29-71), 48% had breast cancer and 10 have BRCA mutations. We divided adherence into three groups; non-adherent (no exams over study period), minimally adherent (at least one CA125 or TVUS per year) and maximally adherent (exams every 6 months). Twenty eight percent of women did not adhere to any screening, 52% were minimally adherent and 20% were maximally adherent. Reasons for lack of adherence were most commonly related resources and estimation of risk. The most common barrier was the primary care providers failure to endorse screening. Variables associated with maximum adherence include intrusive thoughts and family history of ovarian cancer. Non-adherence was associated with avoidant thoughts related to cancer specific distress. Psychological distress in this group was comparable to a sample of women with newly diagnosed breast cancer, with greater levels of distress among unaffected women. We have shown a high-rate of adherence to ovarian cancer screening in this population in contrast to prior reports. Reasons for lack of adherence largely relate to PCP lack of recommendation. Having a family history of ovarian cancer was associated with some level of adherence to screening recommendations. Intrusive thoughts were associated with adherence while avoidant thoughts were associated with lack of adherence.

**The Protein Kinase A (PKA) Regulatory Subunit RI (PRKARIA) Alters MAP Kinase and Cell Cycle Entry in Transformed B-Lymphocytes.** *A.J. Robinson-White<sup>1</sup>, W. Leitner<sup>2</sup>, L. He<sup>3</sup>, D. Olson<sup>3</sup>, C.A. Stratakis<sup>1</sup>.* 1) UGEN/DEB, NICHD, NIH, Bethesda, MD; 2) DB, NCI, NIH, Bethesda, MD; 3) IRP AB, NIAMS, NIH, Bethesda, MD.

Carney complex (CNC) is associated with mutations in PRKAR1A, a gene that codes for the RI regulatory subunit of the cAMP-dependent protein kinase (PKA). A partial or complete loss of PRKAR1A apparently results in tumorigenicity, by an unknown mechanism. In many cells, RI inhibits the extracellular receptor kinase cascade (ERK1/2) of the MAP kinase (MAPK) signaling pathway causing decreased cell proliferation. In previous studies, we showed that upon stimulation of MAPK by lysophosphatidic acid (LPA, 0-150 nM), and PKA by isoproterenol and forskolin (0-100 uM), inhibition and stimulation of ERK1/2 phosphorylation occurred in normal and mutant cells, respectively. Isoproterenol and forskolin also inhibited LPA-induced cell proliferation and metabolism in normal cells, but caused stimulation in mutant cells. In the present studies, we asked whether the effects of PKA on ERK1/2 phosphorylation, cell proliferation and metabolism are via a decrease in cell cycle activity or by a stimulation of apoptosis. In normal cells, cell number decreased (2-60%) with isoproterenol, with no corresponding increase in cell death. Cell death was constant at 0-5% and no apoptosis was seen in normal or mutant cells (60-100 uM isoproterenol), as determined by TUNEL assay. In the same cell population, apoptosis could be induced by other stimuli (APO-1 and CH11, antiFAS/CD95 antibodies) showing 36-54% apoptosis. Phosphorylation of other components of the ERK1/2 cascade (c-Raf-1 and MEK1/2) was decreased by PKA stimulants in a similar manner to that of ERK1/2 in normal cells. Phosphorylation of the nuclear transcription factor c-Myc was also decreased in normal cells, but increased in mutant cells. We conclude: 1) PKA stimulation has opposite effects on ERK1/2 activity and cell growth and proliferation in mutant PRKAR1A vs normal transformed B-lymphocytes; 2) these changes are not associated with differences in apoptosis or in changes in DNA content of the cell cycle and 3) PKA may alter cell proliferation and metabolism in B-lymphocytes by altering the rate of entry of cells into the cell cycle.

**Colonoscopy utilization before and after HNPCC genetic testing.** *S.K. Peterson<sup>1</sup>, E.R. Gritz<sup>1</sup>, S.W. Vernon<sup>2</sup>, C.A. Perz<sup>3</sup>, S.K. Marani<sup>1</sup>, B.G. Watts<sup>1</sup>, C. Amos<sup>1</sup>, M. Frazier<sup>1</sup>, P.M. Lynch<sup>1</sup>.* 1) UT MD Anderson Cancer Center, Houston, TX; 2) UT Health Science Center School of Public Health, Houston, TX; 3) Univ Houston-Victoria, Victoria, TX.

Genetic testing can identify HNPCC-predisposing mutations in persons with a family cancer history suggestive of this syndrome. Mutation carriers have up to an 85% lifetime risk of developing colorectal cancer (CRC), and are advised to have annual or biannual colonoscopy usually beginning at age 25 years. In the absence of genetic testing, persons who are at increased risk for HNPCC by virtue of their family cancer history also are advised to follow the same cancer screening guidelines as mutation carriers. As part of a longitudinal study of psychosocial aspects of HNPCC genetic counseling and testing, we evaluated colonoscopy utilization before and after genetic testing. Participants were 79 adults who had no prior history of CRC and who were from families with a known HNPCC-predisposing mutation. Before pre-test genetic counseling, 53% (n=42) had ever had a colonoscopy. All participants underwent genetic testing, and 33% (n=26) were identified as carrying an HNPCC-predisposing mutation. There was no difference in baseline prevalence of colonoscopy use between mutation carriers and non-carriers (50% and 54%, respectively). Within 6 months of receiving test results, 76% of mutation carriers reported that they had undergone colonoscopy since receiving their results, a significantly greater proportion compared with baseline utilization and with non-carriers (F=18.87, p<0.001). Compared with baseline responses, mutation carriers also expressed significantly greater self-confidence in their ability to follow through with colonoscopy, a greater level of commitment to having colonoscopy, and fewer perceived barriers to CRC screening after test results disclosure. Undergoing HNPCC genetic counseling and testing may motivate mutation carriers to have a colonoscopy within a relatively short time period after disclosure of test results. HNPCC genetic counseling and testing also may positively influence mutation carriers' attitudes toward CRC screening.

**Cancer variation associated with the position of BRCA2 gene mutation.** *C.M. Phelan<sup>1</sup>, J. Lubinski<sup>2</sup>, P. Ghadirian<sup>3</sup>, H.T. Lynch<sup>4</sup>, J. Garber<sup>5</sup>, B. Weber<sup>6</sup>, D. Horsman<sup>7</sup>, J. Aube<sup>1</sup>, P. Sun<sup>1</sup>, S. Narod<sup>1</sup>.* 1) Center for Research in Womens' Health, 790 Bay St., Toronto, Ontario, Canada; 2) Hered Cancer Center, Pomeranian Academy of Medicine, Poland; 3) Unit de Recherche du CHUM, Htel Dieu, Montreal, Quebec; 4) Creighton University, Omaha, Nebraska; 5) Dana-Farber Cancer Institute, Boston, MA; 6) University of Pennsylvania, Philadelphia; 7) BC Cancer Agency, Vancouver, BC, Canada.

Inherited mutations of the BRCA2 gene give rise to a multi-site cancer phenotype which includes breast cancer, ovarian, pancreatic and prostate cancer, melanomas, laryngeal, colon and stomach cancers. Interpretation of test results and risk assessment is therefore complex. It has been proposed that families with mutations in the ovarian cancer cluster region (OCCR) of exon 11 (nucleotides 3035-6629) expressed a higher ratio of ovarian to breast cancer, than families with mutations elsewhere in the BRCA2 gene. In this study we have investigated the presence of seven types of cancer (ovary, male breast, pancreas, prostate, colon, stomach and melanoma) in 419 families with a BRCA2 mutation. Families with ovarian cancer were more likely to harbour mutations in the OCCR (nucleotides 3035-6629) compared to the remainder of the gene (OR = 2.20; p=0.0003). Ashkenazi Jewish families with the 6174delT founder mutation were more likely to have a family member with ovarian cancer (O.R. = 1.63, p=0.0018) and less likely to have a family member with prostate cancer (OR = 0.55; p=0.017) than were families of other ethnic origins. In contrast, a reduced presence of ovarian cancer was found with families of French-Canadian ancestry, compared to other ancestries (O.R. = 0.37, p=0.0026). Male breast cancer risk was observed with the French-Canadian founder mutation 6503delTT (OR = 15.0; p = 0.026). Families of Polish ancestry were associated with a reduced frequency of prostate cancer (OR = 0.29; p = 0.05) and of colon cancer (OR = 0.12; p=0.009) compared to families of other ethnic origins. In conclusion, both the position of mutation in BRCA2 and the ethnic background appear to contribute to the phenotypic variation observed in families with these mutations.

**Genetic polymorphism in the androgen receptor and prostate-specific antigen genes and prostate cancer risk.**

*C.A. Salinas<sup>1</sup>, M. Langlois<sup>2</sup>, L. Iwasaki<sup>1</sup>, E.A. Ostrander<sup>2</sup>, J.L. Stanford<sup>1</sup>.* 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA.

Prostate cancer is an androgen-dependent disease, with the androgen receptor (AR) regulating transcription of androgen-responsive genes in the prostate. Polymorphic CAG and GGN repeats in exon 1 of the AR may alter transcriptional activity, potentially influencing prostate cancer risk. A recent study suggests that short CAG alleles increase prostate cancer risk 5-fold in men homozygous for the G allele (-189) in the prostate-specific antigen (PSA) gene. To further evaluate the association of these polymorphisms with prostate cancer, we conducted a population-based study of Caucasian men. Germline DNA was collected from 553 newly diagnosed prostate cancer cases, aged 40 to 64 years, from King County, WA. 520 population-based controls were identified and frequency-matched to cases by age. Information on potential risk factors was collected by in-person interviews. Logistic regression was used to estimate odds ratios (OR) and assess statistical significance. Linear regression models were fit to estimate the effect of AR and PSA genotypes on serum PSA levels in controls. No association was detected between prostate cancer and having 22 compared with having 22 CAG repeats (OR=1.1; 95% CI 0.9-1.4), having other than 16 GGN repeats (OR<16 repeats =1.0; 95% CI 0.7-1.4; OR>16 repeats =0.9; 95% CI 0.7-1.3), or having the variant PSA AA at the PSA promoter compared with the PSA GG genotype (OR=1.0; 95% CI 0.7-1.4). Geometric mean serum PSA levels in men having 22 CAG repeats and PSA GG were 0.3% higher (95% CI -23% - +30%) than men with 22 repeats and PSA not GG genotype. No association was detected between disease aggressiveness and any of the AR or PSA genotypes. No evidence was found that risk of prostate cancer associated with CAG or GGN repeats varied within subgroups of the PSA genotype, family history of prostate cancer, or body mass index. The present study suggests that these AR and PSA genetic polymorphisms are not associated with risk of prostate cancer in middle-aged men.

**A paucity of identifiable mismatch repair gene mutations following a comprehensive screening of HNPCC-like families from Newfoundland.** *M.O. Woods<sup>1,2</sup>, J.S. Green<sup>2</sup>, D. Robb<sup>3</sup>, A. Pollett<sup>1</sup>, B. Younghusband<sup>2</sup>, J. McLaughlin<sup>4</sup>, P.S. Parfrey<sup>5</sup>, B. Bapat<sup>1</sup>.* 1) Lab Medicine & Pathobiology, Univ Toronto, Toronto, ON, Canada; 2) Genetics, Memorial University of Newfoundland, St. John's, NL, Canada; 3) Pathology, Memorial University of Newfoundland, St. John's, NL, Canada; 4) Public Health Sciences, Univ Toronto, Toronto, ON, Canada; 5) Nephrology, Memorial University of Newfoundland, St. John's, NL, Canada.

Colorectal cancer (CRC) is the second leading cause of cancer-related death in the United States. Hereditary Non-Polyposis Colorectal Cancer (HNPCC) is the most common form of hereditary colorectal cancer comprising between 1-10% of all CRC cases. Mutations in at least five mismatch repair genes are known to cause HNPCC. Approximately 95% of the disease causing alterations are found in MLH1, MSH2 and MSH6. Twenty-seven high risk Newfoundland HNPCC-like families were assessed to determine Mismatch Repair (MMR) alterations, cancer risks and possible genotype-phenotype correlations. In order to determine mismatch repair deficiencies, a comprehensive screening of probands was undertaken. When available, tumour tissue was assessed for MLH1, MSH2 and MSH6 presence/absence using immunohistochemistry. As well, microsatellite instability (MSI), a hallmark of HNPCC, was evaluated on all available tumours using markers BAT-25 and BAT-26. To assess genomic alterations, automated sequencing of all exons and intron/exon boundaries was performed for MLH1, MSH2 and MSH6 on every proband. Additionally, a relatively new technique called Multiplex Ligation-dependent Probe Amplification (MLPA), was used to identify genomic deletions in MLH1 and MSH2. Surprisingly, few disease-causing alterations were identified in our scan of these high risk families. Most notably, a deletion of MSH2 exon 8 was identified in four families from the same geographical area on the island. Also, two novel alterations of interest occurred in MLH1 (V49E and G22A); each in a single family. Due to the paucity of mutations thus far identified using a comprehensive screening procedure, some of these large kindreds could be valuable in mapping additional genes causing HNPCC-like disease.

**A novel technique for detecting genomic copy number changes combined with genotyping using oligo arrays.**

*G.R. Bignell<sup>1</sup>, J. Huang<sup>2</sup>, M.H. Shapero<sup>2</sup>, K.W. Jones<sup>2</sup>, W. Wei<sup>2</sup>, H. Zang<sup>2</sup>, A.P. Futreal<sup>1</sup>, M.R. Stratton<sup>1</sup>, R. Wooster<sup>1</sup>.*  
1) Cancer Genome Project, Sanger Ctr, Hinxton Cambridge, United Kingdom; 2) Genotyping Research, Affymetrix Inc, 3380 Central Expressway, Santa Clara CA95051, USA.

We carried out analysis using an oligo array to detect copy number changes in cancer cell lines, to date over 200 cancer cell-lines have been screened. Using the protocol developed we were able to detect homozygous deletions, gene amplifications and regions of reduced and elevated chromosomal copy number. The statistical significance (p-value) of any genomic alteration is given for each data point. The results from this type of analysis are similar to those of array CGH but have the added advantage of the associated genotype analysis for each data point allowing for a more thorough interpretation of the underlying alterations. Validation experiments to demonstrate the change in fluorescence in response to underlying changes in genomic copy number are also presented with the analysis of lines containing 1 to 5 copies of the X-chromosome, together with experiments where the copy number of 42 SNPs were increased up to 1000 fold by spiking with PCR products containing the relevant DNA sequence. These results indicate that at lower copy number (1 to 5 fold) the increase in fluorescence in response to increased copy number gives a linear response ( $R^2$  0.9967) which, although not directly proportional, is fairly good (5 copies gives an estimated value of 4.1), at higher copy number (up to 1000 fold) the relationship between copy number and fluorescence is linear although not directly proportional when plotted on a log-log scale. Further validation of the technique has been carried out confirming a selection of those genomic alterations detected, confirmation of genomic amplifications was carried out using real time PCR and homozygous deletions by PCR visualised by gel electrophoresis.

**No evidence of recurrent BRCA1/2 genomic rearrangement in high risk French-Canadian breast/ovarian cancer families.** *A.M Moisan, J. Fortin, M. Dumont, C. Samson, J. Simard, INHERIT BRCA's.* Cancer Genomics Laboratory, CHUL Research Center, Quebec, Canada.

The discovery of two genes, BRCA1 and BRCA2, which, when altered, confer markedly increased susceptibility to breast and ovarian cancer, has facilitated the identification of individuals at particularly high risk of these diseases. However, the literature shows wide variations in the prevalence of BRCA1/2 mutations and their related risk from one population to another and these estimates may not be extrapolated to Canadians, especially to founder populations, such as the French Canadians. The majority of these mutations were detected using PCR-based methods. These approaches do not allow the detection of large DNA rearrangements, which have been claimed to be involved in other populations in 5 to up to 36% of BRCA1 positive families, whereas there is very little, if any, information about the contribution of this type of mutations in BRCA2 positive families. To investigate if our available mutation spectrum of BRCA1 and BRCA2 in high risk French Canadian breast/ovarian cancer families has been biased by PCR-based direct sequencing method, DNA samples from 94 affected/obligate carrier individuals from 87 families (including 26 BRCA1/2 positive families as controls) were tested by Southern blot analysis. Moreover, the absence of rearrangement involving smaller exons have been verified by PCR using cDNA samples. Three RFLPs have been observed in BRCA1, whereas six were found in BRCA2. In BRCA1, a characterized polymorphism in exon 16 has been observed in 55 individuals, whereas 2 individuals has a supplementary bands with *AvaII* and *BglIII*, which is due to the high sequence similarity of exon 24 and a portion of chromosome 4. In BRCA2, a polymorphism have been observed in intron 16 abolishing a *AvaII* site in 25 individuals, whereas a new *TaqI* restriction site in the 3'UTR has been found in one sample. Based on our current extensive analysis, there is no evidence supporting the existence of any deleterious BRCA1/2 recurrent genomic rearrangement in the French-Canadian breast/ovarian population and we will validate these results for BRCA1 with the new Multiplex Ligation-dependent Probe Amplification technique.

**Whole Genome DNA Copy Number Changes Identified by Oligonucleotide Arrays.** *K.W. Jones<sup>1</sup>, J. Huang<sup>1</sup>, W. Wei<sup>1</sup>, H. Zhang<sup>1</sup>, G.R. Bignell<sup>2</sup>, A.P. Futreal<sup>2</sup>, M.R. Stratton<sup>2</sup>, R. Wooster<sup>2</sup>, M.H. Shapero<sup>1</sup>.* 1) Molecular Genetics, Affymetrix, Inc., Santa Clara, CA; 2) Cancer Genome Project, Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Genetic instability, such as changes in DNA copy number, is one of the hallmark features of most human cancers. We have developed a method termed whole genome analysis (WGA) which can genotype over 10,000 single nucleotide polymorphisms (SNPs) from human genomic DNA and can be used to identify DNA gains and losses across all chromosomes. This assay uses a single primer to amplify representative fractions of the genome followed by SNP genotyping via hybridization to high density oligonucleotide arrays. We have developed algorithms that jointly use PM intensity and discrimination ratios between paired perfect match (PM) and mismatch (MM) intensity values to identify and estimate genetic copy number change. A chip-wise normalization is performed to improve comparability across samples. SNP discrimination ratios and PM intensities from an experimental sample are then compared to distributions derived from a reference set containing over 100 normal individuals, allowing statistically significant regions of DNA copy number changes to be identified. Based on Taqman results from an established human breast cancer cell line, this approach shows good sensitivity and specificity. In addition, statistically significant genomic intervals showing loss of heterozygosity (LOH) can be identified by calculating the likelihood of a contiguous stretch of homozygous markers based on known allele frequencies using the same reference set of normal individuals. With mean and median inter-SNP distances of 241 kb and 115 kb respectively, this method affords resolution that is not easily achievable with alternative experimental approaches.

**Screening of 75 patients for 7 translocations by Multiplex RT-PCR.** *A.H. Taronchi, R. Karimi nejad, M. Zanganeh, H. Imanian, T. Nayeb bagher, S. Niazi, H. Najmabadi.* Karimi nejad Najmabadi Pathology & Genetics Center.

We have introduced a multiplex reverse transcription-Polymerase chain reaction (RT-PCR) method for diagnosis and screening of patients with 7 chromosomal translocations including: t(1;19)(q23;p13), t(12;21)(p13;q22), inv(16)(p13;q22), t(15;17)(q21;q22), t(9;22)(q34;q11), t(8;21)(q22;q22), t(4;11)(q21;q23). Many of these translocations are related to acute and chronic, myeloid and lymphoid leukemias. Multiplex RT-PCR detects hybrid mRNAs transcribed from the fusion genes produced by translocations. We have studied 75 patients with the following indications and results:

	Total number	Positive for translocation	Type of translocation
CML	43	21	t(9;22)
AML-M4 or M2	7	2	inv(16),t(8;21)
AML-M3	12	8	t(15;17)
ALL	10	1	t(9;22)
other	3	0	0

BCR/ABL b2a2 and b3a2 were the most frequently detected breakpoints in t(9;22)translocations.57 cases of 75 patients had cytogenetic analysis simultaneously. In 3 cases cytogenetic analysis failed in detection, because of insufficient metaphase cells but RT-PCR analysis revealed t(15;17) fusion gene RNAs. Also 3 case of inconclusive cytogenetic analysis were positive for t(9;22) in our method. Also cytogenetic analysis showed other numerical and structural aberrations in 3/57 of cases.

**Telomerase activation and telomere length in head and neck cancer in Western India (Gujarat): Institutional experience.** *R.M. Rakesh, R.N. Sainger RN,, P.M. Shah, P.S. Patel.* Biochemistry Research Division, Department of Cancer Biology, The Gujarat Cancer & Research Institute, Ahmedabad-380016, Gujarat, India.

During replication of the linear chromosomes, telomeres, i.e. the ends of the chromosomes, are not replicated completely by the conventional DNA polymerases. Therefore, normal somatic cells senesce after certain number of cell divisions. Telomerase is a special reverse transcriptase used by most eukaryotes to achieve immortalization. Telomerase activity has been determined in a variety of cancers. However, there are few reports on telomerase activity in head and neck cancer. The etiology of the disease in India is completely different from Western countries. Tobacco consumption is more prevalent in India and the mode of tobacco consumption (e.g. chewing, snuffing, bidi smoking, reverse smoking) is also different. Telomerase activation and telomere length alterations were studied in tumor and adjacent normal tissues in 110 patients with head and neck cancer and 40 patients with precancerous/benign conditions. Telomerase activity and telomere lengths were determined by Telomeric Repeat Amplification Protocol (TRAP assay) and Southern blot analysis, respectively. **RESULTS:** Telomerase activation was observed in 78.2% of the malignant tissues, 85% of the precancerous tissues, and 53.1% of the adjacent normal tissues. Peak terminal restriction fragment length (TRF) was observed to be significantly lower in malignant tissues compared with the adjacent normal tissues. No significant correlation could be observed between telomerase activation and clinicopathologic characteristics of the patients. Two-year disease-free survival analysis showed that patients showing telomerase activation in the adjacent normal tissues and patients showing higher telomere length in malignant tissues had poor disease-free survival. Our results demonstrate the significant clinical usefulness of telomerase activation and telomere length for head and neck cancer patients. These markers may be helpful in predicting the clinical course of the disease and thus in identifying the patients in need of a close follow-up and vigorous adjuvant treatment. Email: rakeshmrawal@yahoo.com.

**Comparing Familial Aggregation Study Designs: The Long Island Breast Cancer Study Project.** *R. Zimmerman<sup>1</sup>, H. Ahsan<sup>2</sup>, M. Gammon<sup>3</sup>, D. Greenberg<sup>1</sup>*. 1) Div.Statistical Genetics, Dept.Biostatistics, Columbia Univ., New York, NY; 2) Depart.Epidemiology, Columbia Univ, New York, NY; 3) Department of Epidemiology, School of Public Health, University of North Carolina at Chapel Hill, Chapel Hill, NC.

The Long Island Breast Cancer Study Project (LIBCSP) is a population-based case-control study of breast cancer on Long Island. The project data allow us to compare empirically two familial aggregation study designs, results of which reflect the genetic influence on a disease. These data also allow us to determine the familial risk of breast cancer on Long Island, New York. Over the last decade, investigators suggested that case-control derived effect estimates were biased compared to reconstructed cohort effect estimates. The perception was also wide-spread that confounding by family size and age further undermined the case-control design validity. However, our recent comparison of familial aggregation study designs demonstrated that the reconstructed cohort poses no benefit over the case-control design. Furthermore, we showed that the accuracy of estimates of genetic predisposition is a function of the family history measure used, as well as the prevalence of disease and the proportion of genetic disease in the populations. Based on the above work, we were able to estimate that effect estimates derived a first-degree relative family history measure (as used in the case-control design) would be slightly larger or comparable to a single relative family history measure (as used in the reconstructed cohort) when analyzing the LIBCSP breast cancer data. We found that the familial aggregation based on case-control suggested slightly more familiarity than that based on reconstructed cohort. Though family history is a poor measure of genetic risk, different measures of family history may provide more information about underlying genetic risk than previously understood.

**Missense mutations in cancer suppressor gene TP53 are associated with Exonic Splicing Enhancers (ESEs).** *I. Gorlov, O. Gorlova, M. Frazier, C. Amos. Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.*

We studied the association of exonic splicing enhancers (ESEs) with missense mutations in the tumor suppressor gene TP53 using the International Agency for Research on Cancer (IARC) mutation database. The goal of the study was to identify potentially functional ESE sites in the open reading frame (ORF) of the TP53. If a sequence functions as a splicing enhancer, then nucleotide substitutions in the site will disturb splicing, abrogate p53 function, and cause cancer. Therefore, functional ESE sites are expected to show increased number of missense mutations in affected individuals. Using several statistical tests, we found that missense mutations in TP53 strongly co-localize with ESEs, and that only a small fraction of ESE sites contributes to the association. There are usually 1 or 2 ESEs per exon showing a statistically significant association with missense mutations - so-called significant ESE sites. In many respects significant ESE sites are different from those that do not show association with missense mutations. In most exons, there are qualitative differences between significant and nonsignificant ESEs in the number of mutations. We also found that positions of significant ESE sites are codon-dependent - significant ESEs preferentially start from the first position of a codon. Individual significant ESEs show more consistent sequences compared to nonsignificant ESEs. These findings suggest that the ESE sites harboring significantly elevated number of missense mutations are functional splicing enhancers.

**CDKN2a Mutation Database.** *M. Greenblatt, J. Murphy, R. Barrantes-Reynolds, J. Bond.* Vermont Cancer Ctr, U Vermont, Burlington, VT.

Databases of gene variation can be valuable tools in studying the relationship of gene mutation to disease. In cancer genetics, database analysis can help clinicians and researchers interpret the significance of allelic variants. There are many databases of germline genetic variants that predispose to cancer, but few somatic mutation databases for cancer-related genes. We present a database of mutations in the CDKN2a gene (Ink4a, p16), available to the scientific community through the WWW ([www.biodesktop.uvm.edu/perl/p16](http://www.biodesktop.uvm.edu/perl/p16)). CDKN2a is mutated in many cancers and is responsible for some cases of Familial Melanoma. Our database improves upon existing resources by: 1) including somatic and germline variants, adding the perspective of somatic cell carcinogenesis to that of hereditary cancer predisposition; 2) annotation with information that may assist with the interpretation of allelic variants. This includes data regarding techniques of mutation analysis, intragenic evolutionary patterns, protein structure, and in vitro functional studies. We include correlation of these features with disease-associated mutations, statistical validation, and figures illustrating our findings and conclusions; 3) a format that allows a user to either download the database as an Excel file or to manipulate it online. Mutation and functional data were compiled by searching PubMed through Dec 2002. Functional, evolutionary and structural data are included from our recent paper (Greenblatt et al, *Oncogene* 22:1150-1163, 2003). We present the database through the UVM BioDesktop, a web infrastructure that combines features of a conventional desktop operating system, such as a graphical folder hierarchy, with those of a web-based biological database. The CDKN2a database is part of a larger project whose objectives are to develop and test a model for predicting the biological consequences and clinical relevance of CDKN2a missense variants by detailed study of gene evolution, disease-associated mutations, and protein structure and function. We hope to use CDKN2a as a prototype for integrating computational and laboratory data to help interpret variants in other cancer-related genes and single nucleotide polymorphisms (SNPs) found throughout the genome.

**The distribution of constitutional *NF2* mutations: results from an international *NF2* database.** *M.E. Baser*<sup>1</sup>, *A.J. Wallace*<sup>2</sup>, *S. Olschwang*<sup>3</sup>, *E. Bijlsma*<sup>4</sup>, *L. Papi*<sup>5</sup>, *D.M. Parry*<sup>6</sup>, *G.A. Rouleau*<sup>7</sup>, *D.G.R. Evans*<sup>2</sup>. 1) Los Angeles, CA, USA; 2) Department of Medical Genetics, St. Mary's Hospital, Manchester, UK; 3) INSERM U434, Fondation Jean-Dausset-CEPH, Paris, France; 4) Department of Clinical Genetics, Academic Medical Centre, University of Amsterdam, The Netherlands; 5) Department of Clinical Physiopathology, University of Florence, Italy; 6) Genetic Epidemiology Branch, National Cancer Institute, Bethesda, MD, USA; 7) Center for Research in Neuroscience, McGill University, Montreal, Canada.

A number of studies have suggested that *NF2* mutations are more common in exons 1-8 than in exons 9-15. We tested this hypothesis in an *NF2* database that has constitutional *NF2* mutations from published studies, from the United Kingdom *NF2* registry, and from unpublished data that are contributed by investigators. The study had 397 families with microdeletions in *NF2* coding sequences (excluding 134 families with splice-site mutations, 48 families with large deletions, and four families with chromosomal translocations). CpG dinucleotides are mutational hotspots in humans, and there are seven *NF2* codons where a CT transition would change an arginine codon (CGA) to a stop codon (TGA). One hundred twenty (58%) of the 205 nonsense mutations occurred in these codons. Mutations were more common in CGA codons 57, 196, 198, and 262 in exons 1-8 (N = 84) than in codons 341, 466, and 588 in exons 9-15 (N = 36). There were no reported mutations in codon 588. The seven *NF2* sites where GAG and GAA codons are preceded by a C also may be prone to transition to C:TAG and C:TAA due to a CpG on the opposite strand, but there were only six mutations at these sites, three of which were 1387 GT. After excluding CT transitions in CGA codons, the frequency of micro-lesions in the FERM domain (codons 1-302) was 0.51/bp (SE, 0.04/bp); in the -helical domain (codons 303-478), 0.47/bp (SE, 0.06/bp); and in exons 14 and 15 (codons 483-579) of the C-terminal domain, 0.34/bp (SE, 0.08/bp) (mutations have not been reported in exons 16 or 17). We conclude that the uneven distribution of micro-lesions in *NF2* coding sequences is due to CT transitions in CGA codons.

**Towards the definition of the cancer transcriptome.** *D.S. Gerhard<sup>1</sup>, R.L. Strausberg<sup>1</sup>, G.J. Riggins<sup>2</sup>, C.F. Schaefer<sup>3</sup>, L. Wagner<sup>4</sup>, V. Jongeneel<sup>5</sup>, A. Simpson<sup>6</sup>.* 1) Office of Cancer Genomics, NCI/NIH, Bethesda, MD; 2) Duke University, Durham, NC; 3) Center for Bioinformatics/NCI; 4) NCBI/NIH; 5) Ludwig Institute for Cancer Research, Louisanne, Switzerland; 6) Ludwig Institute, NY, NY.

Among the important questions still unanswered is the transcriptome size and composition of normal and transformed cells. We focus our efforts towards determining the answer by a number of ways. One is serial analysis of gene expression that was performed on 138 cells, normal and transformed tissues and cell lines to the depths of approx. 50,000 tags per cell as part of the Cancer Genome Anatomy Project (CGAP). More samples will be added within the next few months. From the data we can conclude that on the average ~19,000 genes are expressed in normal cells and that number does not change substantially in transformed cells. In general, the number of genes per sample increases somewhat with increased number of tags obtained. CGAP has a web viewer where the difference of expression levels for any known gene in normal and tumors cells can be determined visually as well as numerically. These data are found at <http://cgap.nci.nih.gov>. Recently, we used the massively parallel signature sequencing to generate tags and obtained greater than a million tags per cell line. The predicted size of the transcriptome was essentially unchanged. Another tool that provides cellular transcription information is the generation of full-length cDNAs. The Mammalian Gene Collection (MGC) generates tissue- and tumor-specific cDNA libraries and full length, sequenced clones for new and known genes for both the mouse and human. To date, there are clones for 11,276 non-redundant human and 7,940 mouse genes. Recently, we have added libraries from 5 different ES cell lines and expect to identify the ES-specific genes and isolate full length clones. All clones are accessible to the scientific community and can be viewed at the MGC web site <http://mgc.nci.nih.gov/>. The genes for which clones are available fall into many pathways, tissue types and transcription levels. The lists of member of the CGAP and MGC projects can be found on the web sites.

**Cancers as a complex phenotype.** *L.T. Amundadottir<sup>1</sup>, S. Thorvaldsson<sup>1</sup>, U. Thorsteinsdottir<sup>1</sup>, H. Sigurgeirsson<sup>1</sup>, S. Arnason<sup>1</sup>, K. Kristjansson<sup>1</sup>, A. Kong<sup>1</sup>, M. Frigge<sup>1</sup>, J. Bjornsson<sup>2</sup>, J.R. Gulcher<sup>1</sup>, K. Stefansson<sup>1</sup>.* 1) Department of Cancer Genetics, deCODE genetics, Reykjavik, ICELAND; 2) Department of Pathology, National University Hospital, Reykjavik, ICELAND.

Numerous linkage studies have unraveled genetic factors explaining cancer syndromes where highly penetrant mutations increase the risk of one or few types of cancers in families. However, these only explain a minority of all cancer cases. Inherited predisposition for the majority of cancer cases probably involves the interaction of multiple low risk genes where different combinations affect the site and severity of the disease. In an attempt to find evidence for cancer sites with shared genetic factors we have studied the familiarity of all cancer cases in Iceland. This was done by linking the entire Icelandic Cancer Registry containing all cancer patients diagnosed in Iceland from 1955-2002 to an extensive genealogical database containing all living Icelanders and most of their ancestors since the settlement of Iceland in the 9th century. This allowed us to estimate risk ratios (RR) and kinship coefficients (KC) both within and between all cancer sites. The completeness of the genealogical database furthermore allowed us to study relationships up to 5th degree making our approach unique in its ability to assess the effects of familiarity outside the nuclear family where individuals are less likely to share environmental factors but still share a substantial amount of their genetic makeup. Both risk and kinship calculations indicated that breast and prostate cancer have the highest level of extended familiarity and the most noticeable cluster of linked cancer sites included breast, prostate and kidney cancer. Other clustering will be presented. Our results indicate that not only are genetic factors involved in the etiology of cancers of specific sites but also that shared genetic factors are important in the context of cancers at combinations of specific sites. Furthermore, in some instances the difference between cancers at different sites may be explained by variation in expressivity rather than involvement of different susceptibility genes.

**Familial Risk of Lung Carcinoma in the Icelandic Population.** *U. Thorsteinsdottir<sup>1</sup>, S. Jonsson<sup>2</sup>, H.H. Jonsson<sup>1</sup>, A. Kong<sup>1</sup>, D.F. Gudbjartsson<sup>1</sup>, K. Kristjansson<sup>1</sup>, S. Arnason<sup>2</sup>, H.J. Isakson<sup>2</sup>, J. Hallgrimsson<sup>2</sup>, J.R. Gulcher<sup>1</sup>, K. Stefansson<sup>1</sup>.* 1) deCODE genetics, Reykjavik, Iceland; 2) Departments of Medicine and Pathology National University Hospital, Reykjavik, Iceland.

Lung carcinoma (LC) is the leading cause of death from cancer among males and females in many western countries. The dominant role of tobacco smoke as a causative factor in LC is well established while the effects of genetics are not. We investigated the contribution of genetic factors to the risk of developing LC by linking information on all 2756 LC patients diagnosed within the Icelandic population in the period of 1955-2002 to an extensive genealogical database containing all living Icelanders and most of their ancestors since the settlement of the country. This allowed us to estimate risk ratios (RR) for 1st, 2nd and 3rd degree relatives of LC patients. The RR for smoking was similarly estimated using a population of 10541 smokers who had smoked for over 10 years. We demonstrate here that a familial factor for LC extends beyond the nuclear family as evidenced by RRs significantly greater than 1 for 2nd(RR=1.40) and 3rd(RR=1.13) as well as 1st(RR=2.65) degree relatives of LC patients. This effect was strongest for relatives of early-onset LC patients (RR range 1.32-3.42). The hypothesis that this increased risk is solely due to the familiarity of smoking was rejected beyond the nuclear family with a single sided test on the RRs of LC versus the RR of smoking. These results underscore the importance of genetic predisposition in the development of LC, with its strongest effect in early-onset patients. The drop in RR between 1st, 2nd and 3rd degree relatives is consistent with multiple and/or interacting effects. However, shared environmental factors and/or assortative mating related to smoking are also important components as evident by a RR greater than one for spouses of LC patients.

Program Nr: 428 from 2003 ASHG Annual Meeting

**The Cancer Risk Assessment and Prevention Program Database enhances practical management and promotes clinical research of patient data within a cancer genetics program.** *J. S. Wilbur, M.K. McDonnell, B. Cady, R.D. Legare.* Program in Women's Oncology, Women & Infant's Hospital, Providence, RI.

With the increasing number of patients involved in cancer genetic programs, appropriate management of clinical as well as programmatic information is critical. For the accrual of data for clinical research, optimal patient care, effective risk reduction interventions and tracking program information, the use of database software becomes essential. A survey of cancer genetic specialists, via the National Society of Genetic Counselors cancer list-serve, identified that multiple institutions are using a variety of software products to manage cancer genetic clinic data. The Cancer Risk Assessment and Prevention Program (CRAPP) Database effectively organizes several levels of patient data into fields that can be easily defined using ACT! 6.0 database software. The CRAPP Database can be queried for research purposes in order to offer patients the most current testing, risk reducing and screening options. Specifically, follow-up questionnaires, patient satisfaction surveys and personalized reports allow for effective time management strategies in a growing clinic. The database also contains multiple template letters and reports designed to retrieve data field information for the verification of ancillary revenue sources. The CRAPP Database currently maintains up to 600 patients per site, operates in three separate institutions and is network enabled to accommodate cancer genetic outreach clinics. When used via a network, data entries made by multiple users at different sites simultaneously update a single database. To comply with HIPPA guidelines, the CRAPP Database is accessible only by an authorized username and password. This method of data management decreases the need for administrative staff thereby diminishing program expenses. In addition to providing structure and organization to cancer genetic programs, the CRAPP Database is an effective means for the management of medical information creating a powerful resource for clinical and translational research as well as documenting programmatic data vital for the continual growth of cancer genetic services.

**Do parents and grands-parents of peoples with achondroplasia have a higher cancer risk?** *C. Stoll*<sup>1</sup>, *J. Feingold*<sup>2</sup>.  
1) Service de Gntique Mdicale Strasbourg, France; 2) University Paris 7.

Several studies, performed according to hypotheses based on teratogenesis and cancerogenesis have tried to answer the question : do parents of children with congenital anomalies have a higher cancer risk ? If the general answer is no, however a higher risk for cancer was reported in the parents of children with cleft/lip palate. In achondroplasia the neo-mutations are from paternal origin raising the hypothesis of the existence of a mutator gene which may favored also the occurrence of cancer. A questionnaire was sent to members with non familial achondroplasia of two associations of little people, one french, and one from Quebec, we asked for cancer, lymphoma and leukemia in their parents and grandparents. In the hypothesis tested the maternal lineage was the control. Hundred forty eight answers were obtained from 76 males and 72 females with achondroplasia. Out of them 68 have parents and/or grandparents with cancer. Eight fathers and 2 mothers of patients with achondroplasia had cancer. Among the grandparents of achondroplastic dwarfs there were 36 cancers including 2 lymphomas in the paternal grandfathers, 20 cancers including 2 chronic myeloid leukemia (CML) in the paternal grandmothers, 22 cancers including 2 CML in the maternal grandfathers, and 4 cancers in the maternal grandmothers. Paternal grandfathers and grandmothers had significantly more cancers than maternal grandfathers and grandmothers ( $X=4.43$ ,  $p<0.05$ ). In conclusion this study showed that there were significantly more cancers in the paternal grandparents of patients with achondroplasia than in their maternal grandparents, the controls raising the question of the occurrence of a mutator phenotype not restricted to cancer cells, but also involving germ cells and being passed to the descendents.

**Clinical and Molecular Genetic Studies of Bilateral Adrenal Hyperplasias: Genomic Scale cDNA Microarrays Profiling, Molecular Analysis of the cyclic AMP-Dependent Protein Kinase Regulatory Subunit 1A (PRKAR1A) Gene and Evidence Suggested Multistep Adrenocortical Tumorigenesis.** I. Bourdeau<sup>1,2</sup>, D. Lorang<sup>3</sup>, S.K. Libutti<sup>3</sup>, A. Lacroix<sup>2</sup>, C.A. Stratakis<sup>1</sup>. 1) SEGEN/DEB/NICHD, NIH, Bethesda, MD; 2) Endocrinology, Hotel-Dieu, CHUM, Montreal, QC, Canada; 3) Surgery Branch, NCI, Bethesda, MD.

Molecular genetic alterations in most adrenal tumors remain unknown. Gs and regulatory subunit 1 alpha of the protein kinase A (*PRKARIA*) mutations may lead to bilateral adrenal hyperplasias and to unilateral adenomas. Genetic analysis of primary adrenocortical hyperplasia may be informative for the identification of events leading to adrenocortical tumor formation. We studied 20 patients with ACTH-independent macronodular adrenal hyperplasia (AIMAH) (n=8) and primary pigmented nodular adrenal disease (PPNAD)(n=12). Screening for *PRKARIA* mutation was negative in the AIMAH group however 8 out of 12 PPNAD patients were mutated. Using cDNA microarray we compared hyperplastic tissues to a pooled of 62 normal adrenal glands then the gene profile of the AIMAH and PPNAD groups were compared. Total RNAs were fluorescently labeled and hybridized on glass slides containing 10 000 cDNA clones. The PPNAD group included a woman carrying a new *PRKARIA* mutation [Exon7 IVS del(-5-107)] who underwent bilateral adrenalectomy. Both hyperplastic adrenals showed the wild type and the deleted alleles whereas only the deleted allele was found in a single adenoma rising from the right hyperplastic gland. Microarray analysis revealed several genes consistently expressed in both groups. Genes involved in adrenal steroidogenesis including *CYP11A* (Cholesterol side-chain cleavage) were downregulated. The common upregulated genes including ATP-binding cassette, DEAD/H box polypeptide 5 (*DDX5*), activator of S phase kinase (*ASK*) and catenin (cadherin-associated protein)-like 1 (*CTNNAL1*). This data is a novel description suggesting that multistep adrenocortical tumorigenesis may occur in PPNAD. The gene expression profile of both adrenal hyperplasia may provide clues for investigation of molecular pathways involved in adrenal tumorigenesis.

**Modification of *BRCA1*-Associated Breast Cancer Risk by Smoking and Metabolism Genes.** *S. Colilla*<sup>1</sup>, *M.A. Blackwood-Chirchir*<sup>1</sup>, *H.T. Lynch*<sup>2</sup>, *S.A. Narod*<sup>2</sup>, *J.E. Garber*<sup>2</sup>, *T. Wagner*<sup>2</sup>, *M.B. Daly*<sup>2</sup>, *O.I. Olopade*<sup>2</sup>, *C. Isaacs*<sup>2</sup>, *S. Neuhausen*<sup>2</sup>, *G. Tomlinson*<sup>2</sup>, *H. Anton-Culver*<sup>2</sup>, *S.E. Plon*<sup>2</sup>, *J. Schildkraut*<sup>2</sup>, *B.L. Weber*<sup>1</sup>, *T.R. Rebbeck*<sup>1</sup>. 1) University of Pennsylvania, Philadelphia, PA; 2) The MAGIC Consortium.

Cigarette smoke may influence breast cancer risk by mutagenesis or by modulating endogenous hormones. To explore the relationship of smoking and breast cancer in women with *BRCA1* mutations, we evaluated breast cancer risk modifying effects of smoking with *NAT2* or *AIB1* genotype. 1115 women with *BRCA1* mutations were evaluated for *NAT2* and *AIB1* genotypes and pre-diagnosis smoking habits. Cox proportional hazards models, accounting for birth year and reproductive history, was used to model the risk of developing breast cancer. Ever smoking (HR=0.99, 95% CI: 0.80,1.24) and 30 pack years of smoking (HR=1.08, 95%CI: 0.85-1.37) were not associated with breast cancer risk. However, breast cancer risk was reduced in women who smoked 30 pack years (HR=0.47, 95%CI: 0.23-0.95) compared to nonsmokers. Later age of smoking initiation was also associated with decreased breast cancer risk (HR=0.94; 95% CI: 0.91-0.98). Slow *NAT2* acetylators had increased breast cancer risk (HR=1.34, 95% CI: 1.0-1.78) but *NAT2* did not modify the smoking-breast cancer relationship. As shown previously, women with 29 *AIB1*-CAG repeats were at significantly increased breast cancer risk (HR=1.70, 95% CI: 1.16-2.49). Never smokers with 29 *AIB1*-CAG repeats were at highest breast cancer risk (HR=1.79, 95% CI: 1.07-3.00). Heavy smokers with 29 *AIB1*-CAG repeats and 30 pack years were at lowest breast cancer risk (HR=0.19, 95% CI: 0.07-0.48). No increased risk was conferred to heavy smokers with 29 *AIB1*-CAG repeats [HR=0.77, 95%CI: 0.28-2.11]. Therefore, *BRCA1*-associated breast cancer risk may depend in part on *AIB1* genotype and smoking. Since *AIB1* mediates endogenous hormone exposures and smoking depresses circulating hormone levels, these results present a biologically plausible pathway of hormone-mediated breast carcinogenesis in *BRCA1* mutation carriers.

**The relationship of allelic imbalance(AI)patterns in a MSS young onset(<50 year of age)colorectal cancer(CRC) compared to older onset(>65 years of age)CRC: predominance of rectal cancer in young onset CRC. L.**

*Boardman, R. Johnson, J. Slusser, M. de Andrade, B. Morlan, S. Schmidt, G. Petersen, S. Thibodeau.* Mayo Clinic, Rochester, MN.

**Introduction:**In the US, 15% of the CRC burden occurs in people <50 years of age. The cause for the majority of young onset CRC remains unknown. Discovery of genes responsible for CRC using AI has focused on sporadic, older onset CRC. **Methods:** Study subjects were selected from an IRB-approved protocol, Colorectal Risk Assessment (CRA), a prospective tumor collection of all CRC surgically treated at our institution from 1994-1997. 45 consented cases of MSS young onset CRC, excluding HNPCC or FAP, were identified. Ninety MSS older onset CRC with CRA consent were randomly selected on the sole criterion of age to serve as controls. We evaluated both the young and older onset CRC tumors for AI using 96 genome wide dinucleotide repeat markers from the ABI Prism Linkage Mapping set (Perkin-Elmer Corp., Foster City, CA). AI was assessed as positive if the calculated difference between the normal and tumor alleles was greater than or equal to 2. **Results:** Young onset patients were approximately three times more likely to present with rectal cancer than older onset patients ( $p=0.0015$ ). Of the young onset CRC cases, 51% (23/45) occurred in the rectum and 49% (22/45) developed in the colon proximal to the splenic flexure. Consistent with previous studies, AI on 17p, 18q, 5q, 20p, 21q and 15q occurred in at least one quarter of the study subjects. Within the young onset group, AI was detected on 6q in 18 to 21% of rectal and colon tumors, respectively, but in <1% of both older onset groups. AI was found in 30% of the older onset rectal tumors, 20% of young onset rectal cancer, and 13% of young and older onset colon tumors. **Conclusion:** MSS young onset CRC may arise more frequently in the rectum in young onset patients. Larger studies are required to confirm this age-related site difference. AI patterns in MSS young and older onset CRC indicate that further larger scale studies categorizing AI by age and site may be an efficient means to define genetic events unique to young onset CRC.

**The prevalence of Human Papilloma Virus Infection in cervical cancer patients from Reference Center-Iran.** *N. Kohannia*<sup>1,4</sup>, *E. Keyhani*<sup>1</sup>, *A. Hatami*<sup>1</sup>, *R. Amini*<sup>2</sup>, *N. Izadi*<sup>3</sup>, *L. Abbasi Moheb*<sup>1</sup>, *H. Najmabadi*<sup>1</sup>. 1) Genetics Research Center, USWR university, Tehran, Tehran, Iran; 2) Reference Laboratory of Iran Research Center- Tehran, Iran; 3) Tehran University-Mirzakouchakkhan Hospital- Tehran, Iran; 4) Islamic Azad University- Lahijan, Iran.

Human papiloma virus (HPV) is a well-known etiologic factor of cervical cancer in Western countries. However, despite a relatively high prevalence of cervical cancer in Iran, no studies are available on the relationship between HPV infection and cervical cancer. A retrospective study was performed on 110 cervical cancer paraffin-embedded histopathologic blocks. DNA extraction was performed through standard procedures followed by Multiplex Polymerase Chain Reaction amplification with two pairs of primers (one as internal control) which were designed to detect HPV in the related tissues. The products were run on 8% PAGE. HPV typing was done for the types 16 and 18 positive controls of which were available in Iran. In our study more than 70% of the malignant cervical lesions were contaminated with HPV. This finding confirms the previous reports on the significant association of HPV with cervical cancer.

**Analysis of paraffin embedded human breast cancer cell line xenografts by IS-RT-PCR reveals in vitro and in vivo differences MMP.** *L.M. Haupt<sup>1</sup>, E.W. Thompson<sup>2</sup>, A.E.O. Trezise<sup>3</sup>, R.E. Irving<sup>1</sup>, M.G. Irving<sup>4</sup>, L.R. Griffiths<sup>1</sup>.* 1) Genomics Research Center, School of Health Science, Griffith University Gold Coast, Southport, Queensland, Australia 4215; 2) VBCRC Invasion and Metastasis Unit, St. Vincent's Institute of Medical Research and University of Melbourne, Department of Surgery, Melbourne, Victoria, Australia 3065; 3) School of Biomedical Sciences, University of Queensland, St Lucia, Queensland 4072; 4) Institute of Health Sciences, Bond University, Queensland, Australia 4229.

**Purpose:** We applied the in situ-reverse transcription-polymerase chain reaction (IS-RT-PCR) method to examine MT1-MMP (MMP-14, membrane type-1-MMP), MMP-1 (interstitial collagenase) and MMP-3 (stromelysin-1) gene expression in human breast cancer (HBC) cell lines in vitro and in vivo. **Methods:** Combining the techniques of ISH and RT-PCR, IS-RT-PCR allows the detection and localisation of discrete low abundance mRNA sequences in situ. In vitro, MMP gene expression was examined following exposure to Con A. In vivo, we examined differences between the MMP-inductive effects using archival paraffin embedded xenografts derived from various HBC cell lines (MDA-MB-231, MDA-MB-435, MCF-7 and Hs578T). **Results:** In vitro, exposure to Con A caused increased MT1-MMP gene expression in MDA-MB-231 cells and decreased MT1-MMP gene expression in MCF-7 cells. MMP-1 and MMP-3 gene expression levels remained unchanged in both cell lines. In vivo, the stromal cells recruited into each xenograft demonstrated important differences. Estrogen treatment stimulated gene expression of MT1-MMP in the stromal cells around MCF-7 cells. No MMP gene expression was detected in the stroma of the MDA-MB-231 spleen metastasis or the MDA-MB-435 stroma. Hs578T cells elicited a strong stromal gene expression of MMP-3 compared to MT1-MMP and MMP-1. **Conclusion:** These results demonstrate potentially important differences in MMP expression between in vitro and in vivo model systems, and differential stromal induction in the xenograft setting. In addition, the data highlight the contribution of the stroma to MMP gene expression and the complexity of stromal-epithelial interactions within breast carcinoma.

**Prostate Cancer Cell Line PC-3 Lacks Expression Of The Cell Adhesion Molecule CEACAM1.** *O.A. Schirripa<sup>1</sup>, J.N. Weitzel<sup>1</sup>, J.E. Shively<sup>2</sup>.* 1) Clinical Cancer Genetics, City of Hope National Medical , Duarte, CA; 2) Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA.

Background: Cell-cell and cell-matrix interactions help to maintain a differentiated cell in a structurally and functionally balanced state. Carcinoembryonic antigen-related cell adhesion molecule 1 (CEACAM1), which is a subfamily in the immunoglobulin superfamily, is a cell-cell adhesion molecule with tumor-suppressive activity that has major influences on epithelial cell development, differentiation, and apoptosis. CEACAM1-4S, an isoform molecule of CEACAM-1 was found to mediate apoptosis and revert human mammary carcinoma cells to a normal morphogenic phenotype in a 3D Matrigel culture. It is our hypothesis that the molecular mechanisms that govern cell-cell and cell-matrix interactions in the mammary gland also are involved in the development and progression of prostate cancer. Using monoclonal antibodies, CEACAM1 has been shown to be down regulated in higher Gleason grades of prostate cancer. Method: Western blot analysis was performed on lysates of PC-3 cells for CEA, CEACAM1 and CEACAM6 using antibodies to the N extracellular domain (T84.1, monoclonal ), long cytoplasmic tail (22.9, polyclonal) and CEACAM1 extracellular domain (4D1C2, monoclonal). Monoclonal antibody 5F4 specific for CEACAM1 was used on PC-3 cells grown in Matrigel for 12 days Results: PC-3 cells are negative for CEACAM1 and CEACAM6 and CEA positive by Western blot. PC-3 cells grown in Matrigel for twelve days formed spheroids and were negative for CEACAM1 by immunohistochemistry. Conclusion: We report the absence of CEACAM1 expression on the PC-3 prostate cancer cell line. PC-3 cells grown as 3D spheroids in Matrigel may provide a model system to further elucidate the structure and function of specific CEACAM1 isoform expression patterns in human prostate cancer cells. Transfection experiments of PC-3 cells with different isoforms of CEACAM1 are currently underway to see if spheroids will revert to a normal morphology and form lumina in Matrigel. Supported in part by the NCI - Grant # 2R25 CA75131 and the California Cancer Research Program of the University of California - Grant # 99-86874.

**Association of ELAC2, MSR1, and RNASEL in the etiology and severity of prostate cancer.** *H. Rennert, K. Addya, C.M. Zeigler-Johnson, E.E. Spangler, A.H. Walker, S. Restine, S.B. Malkowicz, D.G.B. Leonard, T.R. Rebbeck.*  
University of Pennsylvania, Philadelphia, PA.

Family studies have identified three prostate cancer (PC) susceptibility genes, ELAC2/HPC2 (17p), RNASEL/HPC1 (1q25) and MSR1 (8p22). We evaluated the role of these genes in PC risk in a mixed ethnicity U.S. population. The frequency and association with PC of 14 putative susceptibility alleles in these three genes were studied in 827 incident PC cases and 714 controls. 26% of study participants were African American. Assays were performed using the ABI PRISM 7900HT Sequence Detection System. The ELAC2 E622V allele was observed only in Caucasians with a frequency of <0.3%. At MSR1, 4.4% of individuals carried S41Y, V113A, D174Y, R293X, or H441R. All variants studied were seen in Caucasians, while only V113A, D174Y, and H441R were seen in African Americans. No statistically significant effects were observed for rare MSR1 variants and PC risk, but these variants conferred increased risk of extracapsular extension (age- and race-adjusted odds ratio (OR)=2.7, 95%CI: 1.2-6.3). At RNASEL, 1.3% of Caucasians and no African Americans carried E265X or 354C>T. R462Q was carried by approximately 30% of individuals regardless of race. Individuals who inherited one or more of the RNASEL variants were at increased risk of PC (OR=3.5, 95%CI: 1.0-12.5), and more likely to have a family history of PC (OR=1.5, 95%CI=1.0-2.1), an earlier age at PC diagnosis ( $p=0.04$ ) and extracapsular extension (OR=4.0, 95%CI: 1.1-15.4). Carriage of rare variants at either RNASEL (E265X or 354C>T) or MSR1 (S41Y, V113A, D174Y, R293X, or H441R) was associated with an increased PC risk (OR=2.3, 95% CI: 1.1-4.7) and elevated probability of extracapsular extension (OR=2.8, 95% CI: 1.1-6.9). These results suggest that RNASEL and MSR1 are associated with PC etiology and tumor severity.

**Use of functional prediction models to evaluate the association of BRCA1 and 2 variants to breast cancer risk factors.** *D. Peel, A. Ziogas, H. Hoang, H. Anton-Culver.* Epidemiology Div, Univ of Calif, Irvine, Irvine, CA.

Limited data are available regarding the role of common variants in BRCA1 & 2 in breast cancer risk. We examined the relationship of variants in BRCA1 & 2 genes to early-onset (< age 35) breast cancer risk. To assign a level of significance to the variant proteins, we used 4 established Protein Structure and Activity Prediction Models (PSAPM): SIFT algorithm (emphasizes evolutionary conservation of protein sequence), PolyPhen algorithm (emphasizes aspects of the protein structure), % conservation (determines the level of conservation across species), and SSPRO (emphasizes secondary protein structure). We sequenced BRCA1 & 2 in 137 early-onset, population-based breast cancer cases to identify mutations and variants. For analysis of variants we included all 120 mutation negative cases. Using the 4 PSAPM, we determined scores for each of the variants for both the BRCA1 & 2 genes. We ranked the scores and calculated sum-scores across the variants for each sample. Statistical evaluation was performed to test possible associations between these scores and known breast cancer risk factors (family history of breast and ovarian cancer, reproductive history, and tumor characteristics) in the population under study. Although each of the PSAPM scores is independently assessed and partly based on different aspects of protein function/structure for each variant, significant correlation and agreement among the scores of the 4 PSAPM were found, indicating that the prediction potential of any one of these models can be used reliably in the identification of informative variants. Significantly higher PSAPM scores of BRCA1 but not BRCA2 were observed in nulliparous women compared to parous women. Positive family history of breast and ovarian cancer was significantly associated with high PSAPM scores in BRCA1 but not BRCA2. Significantly higher PSAPM scores of variants in both BRCA1 & 2 were associated with aggressive tumor behavior characteristics (tumor size and ER/PR negative tumors). This study demonstrates the use of PSAPM and indicates that non-mutation variants in the BRCA1 & 2 genes have a role in the characterization and evaluation of breast cancer risk.

**Comparative genomics of an evolutionary breakpoint region regularly deleted in human tumors.** *E.A. Darai, M. Kost-Alimova, H. Kiss, L. Fedorova, H. Kansoul, I. Kholodnyuk, G. Klein, S. Imreh.* Microbiology and Tumorbiology Center, Karolinska Institute, Stockholm, Sweden.

We developed a functional assay called the Elimination Test (Et) for identification and fine mapping of physically or functionally eliminated chromosomal regions containing tumor antagonizing genes. Et is based on the introduction of a normal human chromosome into murine or human tumor cells by microcell fusion. The resulting microcell hybrids are serially passaged through SCID mice, and the derived tumors are analyzed for regular eliminations of chromosomal segments by molecular and cytogenetic methods. The Et was focused on the short arm of chromosome 3 due to its frequent deletion in a large number of tumor types. A putative tumor suppressor region, CER1 at 3p21.3 was identified in the tumor panel derived from SCID mice. Large-scale comparison of genomic sequences between species allows characterizing important gene- or locus-specific regulatory elements. For characterization of our CER1 genes we compared 1.32 Mb of CER1 from human chromosome 3p21.3 to its orthologous regions on mouse chromosome 9F. The corresponding mouse region was found divided into two blocks, but their gene content and gene positions were highly conserved. We also recognized a large number of conserved elements that were neither exons, CpG islands nor repeats. We identified and characterized 5 novel orthologous mouse genes. Human CER1 belongs to two conserved chromosomal segments in mouse, containing a murine/human conservation breakpoint region. Several breaks occurred in tumors within the region surrounding CBR and this sequence has features that characterize unstable chromosomal regions: deletions in YAC clones, late replication, gene and segment duplications, pseudogene insertions. We extended our analysis of CER1 to other species: *C. elegans*, *Drosophila melanogaster*, *Fugu rubripes*. It was found that in all these organisms the genes from the telomeric part of CER1 are evolutionary conserved. The part of CER1 surrounding CBR contains genes, which are modified through evolution showing lower homology, duplications and changes of function. An evolutionary new gene TMEM7 was found in this region.

**Marsupial BRCA1: Conserved regions in mammals and the potential effect of missense changes.** *E.A. Ostrander<sup>1</sup>, C.J. Ramirez<sup>1</sup>, J.D. Potter<sup>2</sup>, M.A. Fleming<sup>1</sup>, G.K. Ostrander<sup>3</sup>*. 1) Clinical Div, Fred Hutchinson Cancer Res Ctr, Seattle, WA; 2) Division of Public Health Sciences, Fred Hutchinson Cancer Res Ctr, Seattle WA; 3) Departments of Biology and Comparative Medicine, Johns Hopkins University, Baltimore, MD.

More than half of reported missense changes in the breast cancer susceptibility protein BRCA1 occur in exon 11, but none has been clearly identified as disease-associated and only 28 are designated "probable" neutral polymorphisms. Previously, in a comparison of sequences from 57 eutherian mammal species, we found seven "highly conserved regions" between amino acids 282 and 1103 and identified 38 missense changes as likely to disrupt gene function. These conserved regions were also present in birds and amphibians and included only six of the mutations predicted to affect function. In this new analysis, we hypothesize that using 37 ancestral sequences derived from the 57 GenBank sequences and including three of eight newly cloned marsupial sequences would allow us to identify regions unique to mammals and refine our predictions of disease-associated missense changes. We identified 13 conserved regions, three of which appear to be unique to mammals, and 21 likely disease-associated missense changes, 11 of which occur in conserved regions. Seven regions identified in this analysis, including the three found only in mammalian sequences, and nine missense changes predicted to affect function are in the putative STAT1 interaction domain suggesting that the roll of STAT1 in immune response is important to mammary function. The reduction in the number of missense changes predicted to be disease-associated and the identification of conserved regions specific to mammals can facilitate the further study of the role of missense changes in BRCA1 associated breast cancers.

**Genome-wide linkage scan reveals evidence for hereditary prostate cancer gene on chromosome 17q. *E.M.***

*Lange*<sup>1</sup>, *E.M. Gillanders*<sup>2</sup>, *C.C. Davis*<sup>1</sup>, *W.M. Brown*<sup>1</sup>, *J.M. Trent*<sup>2</sup>, *J.E. Montie*<sup>3</sup>, *K.A. Cooney*<sup>3</sup>. 1) Public Health Sci, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 2) National Human Genome Res Inst, Bethesda, MD; 3) Internal Med and Urology, Univ of Michigan Sch Medicine, Ann Arbor, MI.

Previous linkage studies have suggested prostate cancer susceptibility genes located on chromosomes 1, 20, and X. Several putative prostate cancer candidate genes have also been identified including RNASEL, MSR1, and ELAC2/HPC2. Presently, these linkage regions and candidate genes appear to explain only a small proportion of hereditary prostate cancer cases suggesting the need for additional whole genome analyses. We conducted a genome-wide mode-of-inheritance-free linkage scan, using 405 genetic markers on 176 pedigrees from the University of Michigan Prostate Cancer Genetics Project (PCGP). Stratified linkage analyses were completed using previously established criteria. Results based on the entire set of 176 pedigrees showed strong suggestive evidence for linkage on chromosome 17q (LOD = 2.36), with the most significant evidence coming from the subset of pedigrees with four or more affected individuals (LOD = 3.27). Interestingly, these linkage peaks were centered directly over the BRCA1 gene. Race-specific analyses also revealed strong suggestive evidence for linkage in our African American pedigrees on chromosome 22q (LOD = 2.35). Given the linkage data, we are currently sequencing the BRCA1 gene from affected family members in chromosome 17q-linked families to better our understanding of the potential role of BRCA1 in hereditary prostate cancer.

**Recruitment of high-risk prostate cancer families in Southern Louisiana: challenges and successful strategies.**

*D.M. Mandal<sup>1</sup>, T.N. Turley-Stoulig<sup>1</sup>, S.L. Halton<sup>1</sup>, E.M. Gillanders<sup>2</sup>, J. Carpten<sup>2</sup>, J. Trent<sup>3</sup>, J.E. Bailey-Wilson<sup>2</sup>, W. Rayford<sup>4</sup>.* 1) Dept. of Genetics, LSU Health Sciences Ctr, New Orleans, LA; 2) NHGRI/NIH, Bethesda, MD; 3) Translational Genomics Research Institute, Phoenix, AZ; 4) Dept. of Urology, LSU Health Sciences Center, New Orleans, LA.

There is a trend of increasing risk in prostate cancer with increasing number of affected relatives and earlier age of onset in affected relatives. To date, three genes have been successfully cloned. However, more data are needed to confirm the suggested linkages and to identify and characterize specific mutations in diverse populations. We have initiated a study to ascertain families with history of 3 prostate cancer cases through the prostate cancer screening program at the LSUHSC Department of Urology, from participating local urologists and collaborative hospitals from Southern Louisiana. Entering participants into the study has been very challenging due to the raised concern of patient confidentiality and privacy issues but we have been able to build some successful collaboration through innovative approaches. Thus far, 224 individuals have been interviewed. Of those, nine reported a significant family history of prostate cancer. Biological sample collection and pathological confirmation are complete on three of those families, which are in the process of genome screening. Follow up is ongoing in the remaining six families. Description of the data resource will be presented and the critical issues involved in recruitment in a genetic study will be discussed, with particular emphasis on the challenges and innovative strategies in recruitment of families in a southern rural setting.

**Genome-wide search for novel breast cancer susceptibility genes in Australian multiple case kindreds.** *G.M. Pupo*<sup>1</sup>, *B. Newman*<sup>2</sup>, *D.J. Venter*<sup>3</sup>, *J.L. Hopper*<sup>4</sup>, *G. Chenevix-Trench*<sup>5</sup>, *kConFab*<sup>6</sup>, *G.J. Mann*<sup>1</sup>. 1) Westmead Institute for Cancer Research, University of Sydney at the Westmead Millennium Institute, Westmead, NSW 2145, Australia; 2) School Of Public Health, Queensland University of Technology, Kelvin Grove, QLD 4059 Australia; 3) Murdoch Children's Research Institute, Royal Children's Hospital, Parkville, VIC 3042, Australia; 4) Centre for Genetic Epidemiology, University of Melbourne, Carlton, VIC 3053, Australia; 5) Queensland Institute for Medical Research, Royal Brisbane Hospital, Herston, QLD 4029, Australia; 6) Kathleen Cuninghame Foundation Consortium for Research into Familial Breast Cancer.

Mutations in the known breast cancer susceptibility genes BRCA1, BRCA2 and ATM account for only part of the familial clustering of this disease and there is good evidence that further major susceptibility (BRCAX) loci remain to be found. We have been using the resources of the Kathleen Cuninghame Foundation Consortium for Research into Familial Breast Cancer (kConFab) and those of the Australian Breast Cancer Family Study (ABCFS) to identify kindreds suitable for mapping BRCAX loci. These were selected on the basis of having at least three genotypable individuals with female breast cancer, no cases of male breast cancer, and with few exceptions no cases of ovarian cancer. Clinic-based BRCA1 and BRCA2 mutation testing was negative, except for common population polymorphisms, and the probability of occult involvement of the BRCA1 and BRCA2 genes was reduced by exclusion of kindreds in which a haplotype of either BRCA1- or BRCA2-flanking markers was shared by all affected individuals. A 10cM genome-wide search was carried out in 40 such kindreds using the 400 marker ABI v2 panel. The highest LOD score under heterogeneity (HLOD) was 2.16 (non-parametric LOD 1.83,  $p=0.04$ ); several other regions with HLODs = 1.5-2.0 also merited investigation by further markers and/or fine mapping which is currently under way. Subsets based on age of onset and presence of other cancers correlated to some extent with particular linkage peaks, and this will also be discussed.

**Dietary factors and occurrence of microsatellite instability in sporadic colon carcinomas.** *B. Diergaarde*<sup>1,2</sup>, *H. Braam*<sup>3</sup>, *G. Van Muijen*<sup>3</sup>, *M. Ligtenberg*<sup>3</sup>, *F. Kok*<sup>2</sup>, *E. Kampman*<sup>2</sup>. 1) Public Health Sciences, Fred Hutchinson Cancer Res. C., Seattle, WA; 2) Human Nutrition & Epidemiology, Wageningen University, Wageningen, The Netherlands; 3) Pathology, UMC St Radboud, Nijmegen, The Netherlands.

Microsatellite instability (MSI) occurs in 10-20% of the sporadic colon carcinomas and appears to be primarily due to alterations in the mismatch repair genes *hMLH1* and *hMSH2*. Little is known about the role of diet in MSI-related colon carcinogenesis. We used data from a Dutch population-based case-control study (184 cases; 259 controls) on sporadic colon carcinomas to evaluate associations between dietary factors and occurrence of MSI, *hMLH1* expression and *hMLH1* promoter hypermethylation. Usual dietary habits were assessed by an interview-based questionnaire. Case-case and case-control comparisons were conducted. Odds ratios (OR) and the corresponding 95% confidence intervals (95% CI) were calculated using multiple logistic regression models. Red meat intake was significantly different related to MSI-H tumors than to MSI-L/MSS tumors (MSI-H vs. MSI-L/MSS, OR: 0.3, 95% CI: 0.1-0.9). A positive association was observed with MSI-L/MSS tumors (OR: 1.5, 95% CI: 0.9-2.6) when compared with the population-based controls, an inverse association with MSI-H tumors (OR: 0.5, 95% CI: 0.2-1.2). Fruit consumption was significantly different related to MSI-H tumors with hypermethylated *hMLH1* (Methyl<sup>+</sup> tumors) than to MSI-H tumors without hypermethylated *hMLH1* (Methyl<sup>-</sup> tumors) (Methyl<sup>+</sup> vs. Methyl<sup>-</sup>, OR: 0.2, 95% CI: 0.1-0.9; Methyl<sup>+</sup> vs. controls, OR: 0.4, 95% CI: 0.2-0.9; Methyl<sup>-</sup> vs. controls, OR: 1.2, 95% CI: 0.8-1.7). Vegetable consumption lowered the risk of MSI-H and MSI-L/MSS tumors but like most other evaluated dietary factors was not distinctively associated with a specific MSI or *hMLH1* promoter methylation status. Associations observed with tumors that showed absence of *hMLH1* expression (n=26) generally did not differ significantly from those observed with MSI-H tumors. Our data suggest that red meat consumption promotes the development of MSI-L/MSS carcinomas in particular, whereas fruit intake seems to especially decrease the risk of MSI-H carcinomas exhibiting epigenetically silenced *hMLH1*.

***Helicobacter pylori* infection in gastric carcinogenesis.** *S. Myllykangas*<sup>1</sup>, *O. Monni*<sup>3</sup>, *H. Rautelin*<sup>2</sup>, *S. Knuutila*<sup>1</sup>. 1) Department of Medical Genetics, Haartman Institute, University of Helsinki and Helsinki University Central Hospital Laboratory Diagnostics, Helsinki, Finland; 2) Department of Bacteriology and Immunology, Haartman Institute, University of Helsinki and Helsinki University Central Hospital Laboratory Diagnostics, Helsinki, Finland; 3) Biomedicum Biochip Center, University of Helsinki, Helsinki, Finland.

We studied human gene expression changes caused by *Helicobacter pylori* infection using an in vitro model and 13k cDNA microarrays. An AGS cell line was infected with *H. pylori* strain NCTC 11637. *H. pylori* infection was found to induce differential expression of genes located in chromosomal locations known to contain frequent chromosomal aberrations and gene mutations specific to gastric cancer. 17q11-q25 location comprised the most *H. pylori* infection responsive genes. 17q11-q25 is one of the most frequently amplified chromosomal locations associated with gastric cancer. Based on our time series experiments, the primary transcription target of the infection seemed to be *FOS*, the expression of which significantly increased quickly after *H. pylori* infection. Also *FOSL1* was overexpressed immediately after infection. *c-fos* and *Fra-1*, encoded by *FOS* and *FOSL1* genes, are part of the AP-1 transcription factor complex. *H. pylori* infection also activated transcription of several stress response genes. Genes encoding heat shock proteins HSP40 and HSP70 as well as genes activated in DNA damage and growth arrest, such as *GADD45A*, were upregulated. Our results suggest that *H. pylori* infection induced stress response might be connected with the emergence of DNA damage in the host genome. The open and active chromatin responding to *H. pylori* infection might be sensitive to injury, as it is not protected by the histones. This could explain the gene and structure aberrations frequently observed in the chromosomal locations specific to gastric cancer.

**Prospective risk of pancreatic cancer in familial pancreatic cancer kindreds.** *A.P. Klein<sup>1</sup>, K.A. Brune<sup>2</sup>, M. Goggins<sup>2,3,4</sup>, A.C. Tersmette<sup>5</sup>, J.A. Offerhaus<sup>5</sup>, G.M. Petersen<sup>6</sup>, S.E. Kern<sup>2,3</sup>, R.H. Hruban<sup>2,3</sup>.* 1) Statistical Genetics Section, NIH/NHGRI/IDRB, Baltimore; 2) Dept. of Pathology, Johns Hopkins School of Medicine, Baltimore; 3) Dept. of Oncology, Johns Hopkins School of Medicine, Baltimore; 4) Dept. of Medicine, Johns Hopkins School of Medicine, Baltimore; 5) Dept. of Pathology, Academic Medical Center, Amsterdam, The Netherlands; 6) Mayo Clinic, Rochester, MN.

**Background.** Pancreatic cancer is the 4th leading cause of cancer death in the United States, leading to an estimated 30,000 deaths in 2003. Numerous studies show that a family history of pancreatic cancer is a significant risk factor. The prospective risk of developing pancreatic cancer among those with a strong family history of the disease has not been well studied. The aim of this study was to quantify the prospective risk of developing pancreatic cancer among individuals with a family history of this disease. **Methods.** In a registry-based study, we estimated the risk of pancreatic cancer in individuals with a family history of pancreatic cancer. Person-years of follow-up were calculated for each individual from their time of enrollment in the registry until the date health information was last updated, date of pancreatic cancer diagnosis or death. Standardized incidence ratios (SIR) were calculated by comparing the observed number of incident pancreatic cancer cases among individuals enrolled in the National Familial Pancreas Tumor Registry (NFPTR) to those expected under SEER incidence rates. **Results.** 5,199 individuals over 1,000 kindreds were followed for a total of 13,910 person-years. 22 incident pancreatic cancers occurred in NFPTR kindreds, 19 of which were eligible to be included in this study. Risk was elevated in individuals with three (39.2, 95% C.I.=14.4-85.4), two (6.2, 95% C.I.=1.7-15.8), or one (2.7, 95% C.I.=0.7-6.9) first-degree relatives with pancreatic cancer. **Conclusions.** These results: a) demonstrate the existence of familial pancreatic cancer; b) provide a rational basis for cancer risk counseling; and c) emphasize the need for effective early-diagnosis screening techniques for at-risk family members.

**BRCA mutations and the risk of prostate and colorectal cancer in Ashkenazi Jews.** *T. Kirchhoff, N. Kauff, P. Kolachana, J. Satagopan, N. Mitra, H. Huang, J. Shia, C. Palmer, K. Nafa, N.A. Ellis, K. Offit.* Memorial Sloan-Kettering Cancer Center (MSKCC), New York, NY.

Germline mutations in the BRCA genes significantly increase the risk of developing breast or ovarian cancer. In the Ashkenazi Jewish (AJ) population, three founder mutations (185delAG and 5382insC in BRCA1 and 6174delT in BRCA2) account for >95% of the mutant alleles present in the population. Using a case-control design, we assessed the contribution of BRCA mutations to the risk of developing prostate cancer (PrC) or colorectal cancer (CRC). We genotyped 251 consecutive AJ PrC cases and 586 consecutive AJ CRC cases, ascertained at MSKCC from 2000-2003 and 1994-2002, respectively, for the three founder mutations using a modified restriction enzyme digestion analysis. Two groups of controls previously genotyped for the founder mutations were selected from volunteers participating in Washington Ashkenazi Study (WAS). For the PrC series, we selected all available PrC-free males (N=1472) and for CRC series we selected all available CRC-free persons (N=5012). A logistic regression model was used to estimate the relative risk for cancer due to BRCA mutations. We detected an elevated frequency of the three founder mutations in PrC cases (13/261=5.1%) versus controls (28/1472=1.9%). Of the three mutations, the BRCA2\*6174delT showed the largest increase (3.1% in cases vs. 1% in controls). After adjusting for age, we found the association was significant for PrC risk (OR=3.41; p=0.001; 95% CI: 1.64-7.06). However, there was not a significant increase in mutation carriers in PrC cases <50. An increased frequency of the founder mutations was not detected in CRC cases (6/586=1.02%) versus controls (118/5012=2.4%) and an increased risk was not observed (OR=0.50; p-value=0.10; 95% CI: 0.221.14). Our data suggest that BRCA mutations confer a three-fold increased risk of developing PrC but not of CRC. This case-control study design may be less biased than a family-based approach because the ascertainment was based on incident cancer cases.

**A frequent somatic mutation of the DOC-1 gene associated with microsatellite-unstable colorectal cancer. T.**

*Weber<sup>1</sup>, Z.Q. Yuan<sup>1</sup>, T.S. Kent<sup>1</sup>, Y. Wang<sup>2</sup>, A. Miller<sup>1</sup>, R. Hamelin<sup>3</sup>, W. Edelmann<sup>2</sup>, H.T. Lynch<sup>4</sup>.* 1) Surgery/Molec Gen, Ullmann1221, Albert Einstein Col Medicine, Bronx, NY; 2) Cell Biology, Albert Einstein College of Medicine, Bronx, NY; 3) INSERM, Paris, France; 4) Department of Preventive Medicine, Creighton University, Omaha, NE.

**Introduction:** p12DOC-1, a CDK2-associated protein, is a candidate cell growth suppressor. Previously, we demonstrated that absent or decreased expression of p12DOC-1 in microsatellite-unstable (MSI+) colorectal cancer (CRC) cell lines, or p12DOC-1 down-regulation, was associated with colorectal epithelial cell proliferation and decreased apoptosis. To further elucidate the relationship between decreased p12DOC-1 and MSI+ CRC, we screened the DOC-1 gene in MSI+ CRC samples. **Methods:** DNA from 50 CRC tissues and 21 CRC cell lines were obtained from several collaborating laboratories. Mismatch repair (MMR) status was assessed by MMR protein expression, MSI assay, and hypermutable assay. All samples were sequenced to look for mutations in the DOC-1 gene. p12DOC-1 mRNA and protein expression were assessed by real-time PCR and Western Blot assay. Cell proliferation and apoptosis status were determined by FACS assay. **Results:** A novel somatic mutation, delT at the 3' end of a poly (T)8 of the DOC-1 gene, was identified in 12% (5/41) of MSI+ CRC, but in none of the MSS samples (0/30). Interestingly, when wild-type MMR protein was induced in the in vitro recombinant system, the mutation was reversed and p12DOC-1 expression increased and colon epithelial cells proliferation was inhibited. **Discussion:** Because of the association between the DOC-1 mutation and MMR deficiency, our results strongly suggest that this mutation may be a pathologic mutation, leading to inactivation of DOC-1 and contributing to the development and progression of MSI+ CRC. Further investigation of the mutation status of DOC-1 in a larger number of MSI+ CRC samples are underway in our laboratory.

**Low expression of a novel gene TAF9L2, encoding a putative p53 binding domain, in neuroblastoma tumors.** C. Krona<sup>1</sup>, H. Carén<sup>1</sup>, F. Abel<sup>1</sup>, K. Ejeskär<sup>1,2</sup>, R.M. Sjöberg<sup>1</sup>, T. Martinsson<sup>1</sup>. 1) Dept. Clinical Genetics, Gothenburg Univ., Sahlgrenska Univ. Hosp. - East, S-41685 Gothenburg, Sweden; 2) Murdoch Childrens Research Institute, Melbourne, Australia.

Neuroblastoma is characterized by a lack of P53 mutations and no other tumor suppressor gene consistently inactivated has yet been identified in this childhood cancer form. Characterization of a new gene, denoted TAF9L2, in the neuroblastoma tumor suppressor candidate region in chromosome 1p36.22 reveals that TAF9L2 contains a predicted TFIID-31 domain, representing the TATA-binding-protein-associated factor, TAFII31, which is required for P53 mediated transcription activation. Two differential transcripts of this gene were shown to be ubiquitously expressed, one of them with an elevated expression in fetal tissues. Primary neuroblastoma tumors representing different stages of the disease showed either very weak or no measurable TAF9L2 expression, contrary to the level of expression observed in neuroblastoma cell lines. Furthermore, we determined the genomic organization of TAF9L2. Automated genomic DNA sequencing of the coding region of the gene as well as the promoter sequence in 42 neuroblastoma tumors did not reveal any loss-of-function mutations indicating that mutations in TAF9L2 is not a common abnormality of neuroblastoma tumors. We suggest that low expression of this gene, located in the neuroblastoma tumor suppressor candidate region in chromosome 1p, in embryonal cells impair the ability for apoptosis in defective cells through the P53-pathway.

**The Application of STS-QPCR for the High Resolution Physical Mapping of the Tumor Suppressor Locus *NRC1*.**

*K. Zhang*<sup>1</sup>, *L. Jin*<sup>1</sup>, *A.M. Killary*<sup>2</sup>. 1) Center for Genome Information, Department of Environmental Health, Univ Cincinnati, Cincinnati, OH 45267; 2) Department of Molecular Genetics, UT-MD Anderson Cancer Center, Houston, TX 77030.

A tumor suppressor locus *NRC1* (OMIM ID 604442) in renal cell carcinoma (RCC) has been previously defined within chromosome 3 by functional complementation experiments. The critical region of *NRC1* was further narrowed down to a 5-7cM region within 3p12 based on microsatellite analyses. The exact proximal and distal boundaries of the critical region have been ambiguous, however, because of the lack of informative markers, as well as the poor quality of chromosome 3p12 physical map before the NCBI Build 33 physical map was released. We have recently established a formal statistical framework for relative quantification using real-time quantitative PCR (QPCR). A SYBR Green I based QPCR method was also developed, which not only provides a sensitivity of detecting subtle DNA copy number changes as small as 25 percent, but also allows the use of any single tagged sites (STS) as a mapping marker. The improved technology (termed STS-QPCR) provides a theoretical mapping resolution as high as approximately 10-bp. Using the STS-QPCR method, we precisely define the *NRC1* critical interval to a 4.627-Mb region within chromosome 3p12. Furthermore, the distal boundary of *NRC1* was mapped to a 38-Kb interval between the exon 3 and exon 4 of the *DUTTI* gene, which was proposed as a candidate tumor suppressor gene partly because *NRC1* suppresses tumor growth in vivo. Further mutational screening and gene expression analyses indicate that *DUTTI* is not involved in the tumor suppressor activity of *NRC1*.

**TBX3 and TBX3+2a are Functionally Distinctive in Inhibition of Senescence and are Overexpressed in a Subset of Breast Cancer Cell Lines.** *T. Huang<sup>1</sup>, W. Fan<sup>1</sup>, X. Huang<sup>1</sup>, C. Chen<sup>2</sup>, L. Cai<sup>1</sup>, M. Gu<sup>3</sup>, L. Feutch<sup>1</sup>, J. Gray<sup>2</sup>.* 1) Div Human Genetics, Univ California, Irvine, Irvine, CA; 2) Laboratory Medicine and Radiation Oncology, Cancer Genetics and Breast Oncology, UCSF Comprehensive Cancer Center, University of San Francisco, San Francisco, CA; 3) Department of Pathology, University of California, Irvine, CA.

TBX3 is a transcription factor of the T-box gene family. Mutations of TBX3 cause Ulnar-Mammary syndrome (UMS) in humans, an autosomal dominant disorder characterized by the absence or underdevelopment of the mammary glands and other congenital anomalies. Recently, it was found that TBX3 was able to immortalize mouse embryo fibroblast cells. In addition, TBX2, a homologue of TBX3, is very active in preventing senescence in rodent cells and was found to be amplified in some human breast cancers. This study examined the roles of TBX3 and one of its isoforms, TBX3+2a, which differs in the DNA binding domain and has additional 20 amino acids, produced by alternative splicing, in the middle of the DNA binding domain. We first examined the tissue expression and alternative splicing patterns of these two isoforms. We found that TBX3 and TBX3+2a are widely expressed and that the ratio between them varies from tissue to tissue in human, suggesting that alternative splicing could be tissue-specific. In contrast, the ratio between *tbx3* and *tbx3+2a* is very consistent in mouse tissues. The replication-defective retrovirus carrying TBX3 (pFB-Neo-TBX3) is able to immortalize mouse embryo fibroblast cells, while TBX3+2a (pFB-Neo-TBX3+2a) shows an acceleration of senescence, a functional difference that may be explained by the fact that these two isoforms may have different downstream targets. TBX3, but not TBX3+2a, is able to bind to the previously identified T-box binding site in a nuclear extract gel shift assay. A subset of human breast cancer cell lines overexpresses TBX3 and TBX3+2a. Our results indicate that TBX3 and TBX3+2a are functionally distinctive in inhibition of senescence of mouse embryo fibroblast cells and may play an important role in breast cancer formation.

**Dye-primer chemistry reveals a cryptic mutation: A case report.** *J-A. Dolling<sup>1</sup>, M.D. Speevak<sup>1</sup>, N. Carson<sup>2</sup>, S. Taylor<sup>3</sup>, H. Feilotter<sup>3</sup>, R. Carter<sup>4</sup>.* 1) The Credit Valley Hosp, Mississauga, ON, Canada; 2) Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 3) Kingston General Hospital, Kingston, ON, Canada; 4) McMaster University Medical Centre, Hamilton, ON, Canada.

The BRCA2 mutation R2336P (G>C at 7235, NM\_000059) located at the end of exon 13 is predicted to adversely affect mRNA splicing and abrogate the generation of a full length, functional gene product. In the current study, we describe the testing parameters that led to the identification of this mutation in four family members and demonstrate a potential limitation of automated cycle sequencing using dye-terminated ddNTPs. Initial protein truncation test results showed an abnormal protein product derived from cDNA of exons 11-18. Automated cycle sequencing of genomic DNA using dye-terminator chemistry failed to identify the mutation. However, sequencing using dye-primer chemistry clearly detected the mutation in both the forward and reverse directions. The mutation was subsequently confirmed by allele-specific PCR. Reports in the literature have suggested that the context of the DNA sequence can affect electropherogram peak heights and ultimately detection of dye-terminated ddNTPs. With current dye-ddNTP terminator technology, suppression of peak heights has been minimized, and to our knowledge, there are no reports in which a dye-labeled ddNTP has gone completely undetected. For diagnostic purposes we therefore recommend further analysis of the genomic DNA sequence using dye-primer chemistry for cases in which the results of prescreening for mutations by another method are abnormal and reproducible.

**Mutational analysis of the MYH gene in familial adenomatous polyposis (FAP) patients negative for APC gene mutations.** *M.A. Blazo, M.R. Hegde, D.M. Odenbaugh, P.A. Ward, C.S. Richards.* Diagnostic Sequencing Laboratory, Molecular & Human Gen, Baylor College Medicine, Houston, TX.

Germline mutations in the APC gene are responsible for FAP and have been well characterized. The vast majority of mutations in the APC gene represent truncating mutations leading to frameshifts (small deletions, 46%; small insertions, 10%; nonsense mutations, 28%), although missense mutations (~3%) and gross alterations (~13%) have also been reported. Current technology is able to detect APC mutations in approximately 80% of the individuals who have received a clinical diagnosis of FAP. In our experience, approximately 65% of patients with a possible diagnosis of FAP are found to have an APC sequence variant that can be interpreted as a disease-causing mutation. Recently, two other genes, APC2 and MYH, have been investigated in patients with FAP phenotype. Germ-line mutations in the base-excision-repair gene MYH have been shown to be associated with recessive inheritance of multiple colorectal adenomas. Here we describe screening of 24 patients for mutations in the MYH gene who have a clinical diagnosis of FAP but have no identifiable mutation in the APC gene. The clinical presentation of these patients is typically presence of thousands of adenomatous polyps and in some cases extracolonic manifestations. We have evaluated the usefulness of denaturing high performance liquid chromatography (dHPLC) as a diagnostic tool for scanning the MYH gene for point mutations, small deletions, and insertions. The MYH gene was divided in 9 overlapping fragments to encompass the coding sequence and the splicing regions. All PCR reactions were amplified simultaneously using the same reaction conditions in a 96-well format and then analyzed by dHPLC, using empirically determined optimum temperatures for partial fragment denaturation. The assay was also performed and validated on dHPLC using 20 wild-type samples to scan for variants which were subsequently sequenced to identify SNPs.

**A high throughput, real-time PCR (TaqMan) method for detecting the heterozygous state for *GSTM1* and *GSTT1* deletion alleles.** *R. Welch*<sup>1</sup>, *S. Yadavalli*<sup>1</sup>, *V. Puri*<sup>1</sup>, *N. Rothman*<sup>2</sup>, *S.J. Chanock*<sup>3</sup>, *M. Yeager*<sup>1</sup>. 1) SAIC-Frederick, NCI-FCRDC, Frederick, MD at the Core Genotyping Facility, Department of Cancer Epidemiology and Genetics, NCI, NIH, Gaithersburg MD; 2) Occupational Epidemiology Branch, Department of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD; 3) Section on Genomic Variation, Pediatric Oncology Branch, NCI, NIH, Gaithersburg, MD.

Genes that are members of the glutathione-S- transferase family encode enzymes that are involved in the metabolism of a wide range of xenobiotics and carcinogens. Two of these genes, glutathione S-transferase M1 (*GSTM1*) and glutathione S-transferase theta 1 (*GSTT1*) have been implicated in the etiology of several cancers, including bladder and lung cancers. A characteristic of both of these genes is that they possess polymorphic gene deletions with significant heterozygosities. To date, the methods of genotyping these deletions has been by PCR or PCR-RFLP, which are not suitably sensitive to determine the heterozygous state, thus limiting the analysis to a strictly dominant model. We have developed separate, gene specific, high-throughput quantitative real-time PCR (TaqMan) assays that accurately and reliably produce genotypes for all three genotypic states (homozygous presence, heterozygous, and homozygous deletion). In the analyses of 16 CEPH family DNAs (N=232, performed in duplicate), and 102 CEPH unrelated individual DNAs of 4 self-described ethnicities (N=24 African/African Americans, N=31 Caucasians, N=23 Hispanics, N=24 Pacific Rim, all in duplicate) (<http://snp500cancer.nci.nih.gov>) there were no Mendelian inconsistencies in the family samples, no departure from Hardy Weinberg equilibrium in the unrelated individuals, and only a very small number of discordances in all duplicates (0.9 %). Further, we analyzed a SNP within *GSTT1* deleted region (UTR 101 bp 3 of STP), and all SNP/deletion combinations were as expected. Here, we present a novel method for genotyping two widely studied genes, including the determination of heterozygote state.

**DNA damage and repair in breast cancer.** *J. Blasiak*<sup>1</sup>, *M. Zadrozny*<sup>2</sup>, *K. Wozniak*<sup>1</sup>, *R. Krupa*<sup>1</sup>, *J. Drzewoski*<sup>3</sup>, *Z. Morawiec*<sup>4</sup>. 1) Dept. of Molecular Genetics, University of Lodz, Lodz, Poland; 2) Polish Mothers Memorial Hospital, Lodz, Poland; 3) Dept. of Clin. Pharmacol., Medical University of Lodz, Lodz, Poland; 4) N. Copernicus Hospital, Lodz, Poland.

Impaired DNA repair may fuel up malignant transformation due to accumulation of spontaneous mutations in target genes and increasing susceptibility to exogenous carcinogens. Moreover, the effectiveness of DNA repair may contribute to failure of chemotherapy and resistance of breast cancer cells to drugs and radiation. An individual ability to remove DNA damage may be, at least in part, determined by the genotype of DNA repair genes. It is generally accepted that the breast cancer susceptibility genes *BRCA1* and *BRCA2* are involved in DNA repair. To evaluate further the role of DNA repair in breast cancer we determined: 1) the kinetics of removal of DNA damage induced by UV light, gamma radiation, hydrogen peroxide and the anticancer drug idarubicin 2) the level of basal, oxidative and alkylative DNA damage before and after chemotherapy 3) polymorphisms of DNA repair genes: *ERCC1*, *RAD51*, *hOOG1*, *XRCC1*, *XRCC3*, *XPD* in the peripheral blood lymphocytes of breast cancer patients and healthy individuals. We observed slower kinetics of DNA repair after treatment by both kinds of radiation and idarubicin in lymphocytes of breast cancer patients compared to control individuals. The level of basal, oxidative and alkylative DNA damage was higher in breast cancer patients than in the control and the difference was more pronounced when patients after chemotherapy were enrolled. We found associations between the genotypes of *RAD51*, *hOOG1*, *XRCC1*, *XRCC3* repair genes and appearance of breast cancer. We did not find any link between genotypes of DNA repair genes and breast cancer progression. Our results indicate that polymorphisms in DNA repair genes may contribute to the appearance of breast cancer and the extent of DNA damage in breast cancer patients, especially those after chemotherapy, is significantly higher than in healthy individuals. The question whether decreased efficacy of DNA repair belongs to the reasons or is a consequence of breast cancer remains open.

**A new founder mutation (MSH2 deletion exon 8) in hereditary non-polyposis colorectal cancer families from Newfoundland with a distinct clinical phenotype.** *J. Green<sup>1</sup>, M. Woods<sup>1,2</sup>, D. Robb<sup>1</sup>, A. Pollett<sup>2</sup>, S. Gallinger<sup>2</sup>, B. Bapat<sup>2</sup>, J. McLaughlin<sup>2</sup>, P. Parfrey<sup>1</sup>, B. Younghusband<sup>1</sup>.* 1) Dept Medical Genetics, Memorial Univ Newfoundland, St John's, NF, Canada; 2) Mt. Sinai Hospital, Toronto, ON, Canada.

Hereditary non-polyposis colorectal cancer (HNPCC) is the most common form of hereditary colon cancer. Mutations in at least five known susceptibility genes involved in mismatch repair (MMR) have been identified in HNPCC families, the majority of these mutations being in MLH1, MSH2, and MSH6. The island of Newfoundland has a unique genetic structure because of historic and geographic factors. The majority of ancestors were from the southwest of England or the south of Ireland. Because of settlement in isolated coastal communities, large family size, and descendants living in neighboring areas, there are multiple genetic isolates with founder effect for many genetic disorders identified. Four HNPCC families with ancestors from a common geographic area, have a unique clinical phenotype with frequent transitional cancers of the renal pelvis, ureter, and bladder, as well as the more common HNPCC cancers including colorectal, gastric, endometrial, and ovarian cancers. A mutation was not identified by sequencing MLH1, MSH2, and MSH6, however a tumour from one affected individual was MSH2-deficient on immunohistochemistry. RT-PCR identified a deletion of MSH2 exon 8 which was confirmed as a genomic deletion by MLPA (Multiplex Ligation-Dependent Probe Amplification). This was confirmed in 11 affected members from the four families with the common phenotype from the same genetic isolate. A previous founder mutation (MSH2, 943+3 A to T) was identified in another cluster of 13 families from a distinct genetic isolate. In this previous founder cluster with greater than 150 affected individuals, colorectal, endometrial, and ovarian cancers were frequent but transitional cell cancers of the urogenital system were not identified.

**The influence of modifier genes on the disease phenotype in South African families with hereditary nonpolyposis colorectal cancer (HNPCC).** *R. Felix<sup>1</sup>, N. Fearnhead<sup>2</sup>, R. Ramesar<sup>1</sup>, W. Bodmer<sup>2</sup>.* 1) Division of Human Genetics, University of Cape Town Medical School, Cape Town, South Africa; 2) ICRF Cancer and Immunogenetics Laboratory, Weatherall Institute of Molecular Medicine, Oxford University, United Kingdom.

It is becoming increasingly apparent, in the field of human genetics that few diseases are caused exclusively by a mutation in a single gene. Cancer development and progression is a multiplex process involving numerous primary and modifier genes. A modifier is an inherited variation that leads to a qualitative or quantitative difference in the disease phenotype. As the knowledge of the influence and involvement of these primary and secondary cancer genes increases, it should be possible to accurately predict an individual's risk of developing the disorder as a function of both severity of the disorder and the age of onset. Individuals from HNPCC families with identical mutations in the hMLH1 and hMSH2 genes do not all exhibit the disease phenotype in the same manner. Differences exist in the age of onset of disease symptoms, the site of the cancer in the colon and the re-occurrence of cancer after treatment. It is postulated that polymorphisms and mutations within modifier genes could contribute to variability in the disease phenotype observed within these HNPCC families. Recently, several modifier genes have been shown to have a modifying role in colorectal cancers (CRCs). A cohort of 96 HNPCC individuals was investigated in the current study. These individuals harbour the same nonsense mutation (C1528T) in exon 13 of the hMLH1 gene and belong to 13 different families. Forty-three percent of these individuals had cancer of the proximal colon and eighty-six percent were diagnosed with CRC under 50 years of age. These subjects were screened for modifying DNA alterations in the CDH1, APC, ATM, CCND1, MTHFR, GSTT1, GSTM1 and the NAT2 genes. Statistical analyses were performed to identify any significant associations between these polymorphisms and the various phenotypes described in an attempt to explain the clinical variability observed in these subjects.

**Germline *Bcl-2* SNPs, haplotypes, and inherited predisposition to prostate cancer.** A. Coulibaly<sup>1</sup>, L. Long<sup>1</sup>, W. Chen<sup>1</sup>, R. Panguluri<sup>1</sup>, T. Lewis-Smith<sup>1</sup>, C. Bonilla<sup>1</sup>, W. Isaacs<sup>2</sup>, R.A. Kittles<sup>1</sup>. 1) National Human Genome Center, Howard University, Washington, DC; 2) Dept. of Urology, Johns Hopkins University, Baltimore, MD.

The expression of the anti-apoptotic protein Bcl-2 is strongly correlated with increased prostate tumor progression. The *Bcl-2* gene promoter consists of several transcription regulatory elements which may affect Bcl-2 expression. In order to determine if sequence variation of the *Bcl-2* promoter region affects prostate cancer risk we screened approximately 1.5 kb of the *Bcl-2* gene promoter and its two exons (total 717 bp) in 50 African American men using denaturing high performance liquid chromatography. Four single nucleotide polymorphisms (SNPs), -938C/A, -758 delT, -40C/T and +20A/G, were detected and confirmed by DNA sequencing. The -938C/A, -40C/T and +20A/G SNPs were genotyped using Pyrosequencing in three clinical populations consisting of African American (N=390), Jamaicans (N=205), and European American (N=210) prostate cancer cases and age and ethnicity matched controls. Haplotypes were generated using the EM algorithm. Association analyses were performed by contingency and regression analyses using single markers and haplotypes. Pairwise linkage disequilibrium (LD) was estimated for each population. We observed a reduced risk for prostate cancer among European-Americans for -938 AA genotypes (OR=0.25; 95%CI=0.09-0.64). Since the three SNPs were highly correlated (strong LD) in all populations (P<0.001), haplotype analysis was warranted. Haplotype analysis revealed the ACG haplotype to be significantly more frequent in European-American controls than in the cases implying that individuals with this haplotypes were at less risk for prostate cancer (OR=0.66, CI=0.44-0.98). African-American men with the CCA haplotype had an increased risk for prostate cancer (OR=1.39; CI=1.02-1.89). These data suggest that association analyses on closely linked SNPs are not independent and that combining the data into a haplotype analyses is a more powerful approach. Our haplotype analyses provide strong evidence that germ-line polymorphisms of the *Bcl-2* gene likely contribute to a prostate cancer risk.

**Multigene Combinations to Estimate Individual Risk for Breast Cancer.** *C. Aston*<sup>1,3</sup>, *D. Ralph*<sup>2</sup>, *E. Jupe*<sup>2</sup>, *C. Shimasaki*<sup>2</sup>, *J.J. Mulvihill*<sup>3</sup>. 1) Dept Arthritis & Immunology, Oklahoma Med Res Foundation, Oklahoma City, OK; 2) InterGenetics Inc, Oklahoma City, OK; 3) Oklahoma Univ Health Sci Ctr, Oklahoma City, OK.

In addition to BRCA1/2, variants of many other genes alter the risk for human breast cancer (BrCa), as seen in case-control studies. OMIM (20 June 2003) had 321 entries that mention BrCa. Against this background Pharoah et al (Nat Genet 2002;31:33) theorized that a panel of approx. 13 genes, acting without interaction, would be able to predict high risk individuals. We posit that there are interactions between genes that result in alterations in BrCa risk not predicted by the individual effects of the genes. To put form to theory, we developed SNP assays for polymorphisms in 9 genes that, individually, have been associated with increased relative risks of BrCa, such as prohibitin, cyclin D1, CYP17, and XPD. Polymorphisms were selected to have been replicated independently, have physiological consequences, and involve pathways of tumorigenesis. From a group of 1190 cases and 2584 controls, we report results for the Caucasian subsample. DNA from 770 women with incident BrCa diagnosed at ages 19 to 86 years was collected in Oklahoma, as well as from 1943 controls (21% with a 1st- or 2nd-degree relative with BrCa), ages 15 to 92 years. Allele frequencies at individual loci were verified to be in Hardy-Weinberg equilibrium in controls. For proof of principle and computational ease, all combinations of the 9 genes taken 3 at a time were assayed. Whereas the relative risks for individual genes ranged from 0.6 to 1.8; estimates for predisposing triads of markers were as high as 5.6 for the triad CYP17,COMT,SULT1A1 in pre-menopausal, and 5.1 for the triad VDR/ApaI,CYC D1,XPD 751 in post-menopausal women, and as low (protective) as 0.4 for a different allele triad for VDR/ApaI,CYC D1,XPD 751 in pre-menopausal women. Based on the individual gene effects and the non-interaction approach of Pharoah et al, the predicted relative risk for the triad CYP17,COMT,SULT1A1 in pre-menopausal women is 1.5 compared to the observed 5.6. These findings will enable stratification of BrCa risk across a wide spectrum, improving clinical risk assessment for all women.

**Inactivation patterns of *NF2* and *DAL-1* in sporadic meningioma.** *F.P. Nunes*<sup>1</sup>, *Y. Niida*<sup>2</sup>, *R. Beauchamp*<sup>2</sup>, *A.O. Stemmer-Rachamimov*<sup>3</sup>, *V. Ramesh*<sup>2</sup>, *J. Gusella*<sup>2</sup>, *M. MacCollin*<sup>1</sup>. 1) Neurology Department, MGH, Charlestown, MA; 2) Molecular Neurogenetics Unit, MGH, Charlestown, MA; 3) Neuropathology Department, MGH, Charlestown, MA.

Meningiomas are common neoplasms of the brain and spinal cord, accounting for 15-20% of all sporadic tumors of the human nervous system. The molecular genetic basis of the genesis and progression of sporadic meningioma remains unclear. We studied 63 sporadic meningiomas from adult patients. Intragenic and flanking markers at the *NF2* locus on chromosome 22 and the related cytoskeletal element *DAL-1* on chromosome 18 were used to detect loss of heterozygosity (LOH). We further sought to correlate the molecular genetic events with tumor pathology and grade. Forty-one of 62 informative tumors showed LOH at the *NF2* locus (67%) while only 12 of 60 informative tumors showed loss at the *DAL-1* locus (20%). Eleven of 12 tumors with *DAL-1* LOH also had *NF2* LOH. LOH of *NF2* and *DAL-1* was more common in malignant tumors than in atypical tumors, and was least common in benign tumors. This correlation was true when markers were analysed separately or together. *NF2* LOH was present in 100% of tumors classified as fibroblastic, 26% classified as transitional and 33% classified as meningothelial. In conclusion, we found the *DAL-1* locus to be less commonly involved in sporadic meningiomas than previously suggested. Ninety one percent of tumors with *DAL-1* loss also had *NF2* LOH, suggesting that *DAL-1* LOH may be a progression event rather than an early event in meningioma formation. Another tumor suppressor gene responsible for genesis of sporadic meningioma is yet to be identified.

**Apolipoprotein E gene polymorphisms in patients with breast cancer.** A. Sazci<sup>1</sup>, E. Ergul<sup>1</sup>, Z. Canturk<sup>2</sup>, Z. Utkan<sup>2</sup>.  
1) Dept Medical Biol & Genetics, Fac Med, Kocaeli Univ, Kocaeli, Turkey; 2) Dept Gen Surgery, Fac Med, Kocaeli Uni, Kocaeli, Turkey.

To investigate the role of apolipoprotein E (APOE) gene polymorphisms in breast cancer patients, we analysed the APOE genotypes of 107 patients and 193 controls. The results of a Chi-square analysis showed that APOE alleles were significantly distributed ( $\chi^2=11.526$ ;  $P=0.042$ ) between breast cancer cases and controls. The APOE 3 allele was statistically significant ( $OR=8.933$ ;  $95\% CI=1.163/68.592$ ;  $\chi^2=6.374$ ;  $P=0.012$ ). Nevertheless the APOE 4 allele had a protective effect towards breast cancer ( $OR=0.330$ ;  $95\% CI=0.148-0.736$ ;  $\chi^2=7.908$ ;  $P=0.005$ ). On the basis of genotypes, the APOE 33 genotype was 2.080-fold increased risk for breast cancer ( $OR=2.080$ ;  $95\% CI=1.185/3.651$ ;  $\chi^2=6.648$ ;  $P=0.010$ ). However the APOE24 genotype was protective against breast cancer ( $OR=0.938$ ;  $95\% CI=0.904/0.973$ ;  $\chi^2=6.930$ ;  $P=0.008$ ). The allelic frequencies of APOE 2, 3, 4 alleles were 10.36%, 79.27% and 10.36% in the controls and 6.07%, 89.72% and 4.21% in the breast cancer cases respectively. In conclusion, we observed an association among APOE alleles and genotypes and breast cancer.

**The role of *CHEK2* and *MSR1* genes in prostate cancer predisposition in Finland.** *E.H. Seppälä<sup>1</sup>, T. Ikonen<sup>1</sup>, V. Autio<sup>2</sup>, N. Mononen<sup>1</sup>, A. Rökman<sup>1</sup>, M.P. Matikainen<sup>3</sup>, T.L.J. Tammela<sup>3</sup>, J. Schleutker<sup>1</sup>.* 1) Laboratory of Cancer Genetics, Institute of Medical Technology, University of Tampere and Tampere University Hospital, Tampere, Finland; 2) Tampere School of Public Health, University of Tampere, Tampere, Finland; 3) Department of Urology, Tampere University Hospital and Medical School, University of Tampere, Tampere, Finland.

Recently, mutations in *CHEK2* (22q12.1) and *MSR1* (8p22-23) genes have been reported to associate with prostate cancer (PRCA) risk. In the present study from Finland, five sequence variants were identified in the SSCP analysis from the both genes in 120 index patients from Finnish families with hereditary prostate cancer (HPC). We found that the frequency of *CHEK2* 1100delC, a truncating variant that abrogates the kinase activity, was significantly elevated among 120 patients with HPC (4/120 [3.3%]; odds ratio [OR] 8.24; 95% confidence interval [CI] 1.49-45.54; P = 0.02) compared to 480 population controls. Suggestive evidence of segregation between the 1100delC mutation and prostate cancer was seen in all positive families. In addition, *CHEK2* I157T variant had significantly higher frequency among HPC patients (13/120 [10.8%]; OR = 2.12; 95% CI 1.06-4.27; P = 0.04) than the frequency 5.4% seen in the population controls. In contrast, when the carrier frequencies of the *MSR1* R293X, P275A, and -14743A>G variants were compared between the probands with HPC, unselected PRCA cases, and healthy male blood donors, no significant differences were observed. However, the mean age at diagnosis of the R293X mutation carriers among HPC probands was significantly lower compared to non-carriers (55.4 vs. 65.4 years; P = 0.04). The same trend was observed among unselected PRCA cases (65.7 vs. 68.7 years; P = 0.37). The results indicate that *CHEK2* variants are low-penetrance PRCA predisposition alleles that contribute significantly to familial clustering of PRCA at the population level. For the *MSR1* gene no major role in the causation of hereditary or unselected PRCAs is supported, but a possible modifying role in cancer predisposition is suggested.

**Oncogenic pathway of nasal NK/T cell lymphoma with novel germ line missense mutation in the *IGF2R* gene.**  
*H.S. Sun*<sup>1,2</sup>, *S.-M. Lin*<sup>1</sup>, *J.-S. Chen*<sup>2</sup>. 1) Inst Molecular Medicine, National Cheng Kung Univ, Tainan, Taiwan; 2) Inst Basic Medical Sciences, National Cheng Kung Univ, Tainan, Taiwan.

The human mannose 6-phosphate / insulin-like growth factor 2 receptor (M6P/IGF2R) gene encodes a multifunctional protein involved in lysosomal enzyme trafficking, fetal organogenesis, latent TGF- activation, and cytotoxic T cell-induced apoptosis. IGF2R gene contains 48 exons and spans 137kb genomic region on chromosome 6q25-27. Previous studies suggested that IGF2R acts as a tumor suppressor (TS) gene and sequence mutations have been identified in 60% of dysplastic liver lesions and HCCs, also in the early stage of breast cancer development. Furthermore, a poly-G region of the IGF2R gene was commonly mutated in colon, gastric and endometrial tumors with mismatch repair deficiencies and microsatellite instability. Result from our previous work has mapped potential TS gene containing region of nasal NK/T cell lymphoma to chromosome 6q25. IGF2R is a good candidate gene within this region thus it merits further investigation. This study aims to investigate if sequence variant of IGF2R gene plays a role in tumorigenesis for human nasal NK/T cell lymphoma. Ten exons of the IGF2R gene, which has been previously reported containing mutation hot spots, were selected for screening sequence variant. We have sequenced DNAs from 7 paired tumor and normal tissues of patients with the nasal NK/T cell lymphoma. One point mutation as well as several polymorphisms have been identified. The novel exon38 G5716A point mutation changes amino acid sequence from cysteine to tyrosine (Cys1856Tyr). Prediction of this protein sequence alteration has demonstrated a structural modification thus it can lead to functional change of the IGF2R protein. Extensive biochemical and molecular biological studies are currently undertaken to illustrate the potential role of this novel missense mutation on tumorigenesis of nasal NK/T cell lymphoma.

**Identifying novel homozygous deletions by microsatellite analysis and characterization of a putative tumor suppressor gene, TSG-9, on chromosome 9p in human lung cancer.** *Z. Shan, P. Tracy, J. Wiest.* Laboratory of Cellular Carcinogenesis and Tumor Promotion, CCR/NCI, Bethesda, USA.

Lung cancer is a worldwide medical problem and the leading cause of cancer-related mortality in the United States. Loss of heterozygosity studies show that genetic alterations of chromosome 9p occur in a variety of tumor types, suggesting the presence of tumor suppressor genes (TSGs) critical in the development of cancer. The p16/CDKN2 locus is located on 9p21 and is a major TSG inactivated in various cancers. We previously identified a region of homozygous deletion (HD) on chromosome 9p in lung cancer at D9S126, a locus distinct from the p16/CDKN2A gene. This finding led us to propose that chromosome 9p may harbor other TSGs important in lung tumorigenesis. To this end, 42 lung cancer cell lines were screened with 42 STS markers to search for new regions of homozygous on chromosome 9p. Four novel HD regions were identified in three lung cancer lines. The sizes of deleted regions vary from 980 Kb to 4.4 Mb. One gene identified in a HD, TSG-9, is a novel intronless gene. The deletion of TSG-9 was confirmed by PCR and Southern blot. Northern blot analysis of TSG 9 demonstrated two transcripts of approximately 2 kb (TSG-9L) and 1.5 kb (TSG-9S) that are ubiquitously expressed in various human tissues. Sequence analyses of TSG-9 identified alternative polyadenylation signals generating the two transcripts. However, both transcripts encode a peptide of 209 amino acids. Analysis of cDNAs from tumor cell lines demonstrated that TSG-9 is down regulated in lung cancer cell lines and hepatocellular carcinoma with/without homozygous deletion of the region, suggesting that TSG-9 may play the role in lung and liver tumorigenesis. To further address its function as a TSG, an expression vector containing TSG-9 will be transfected into the cell lines lacking expression of TSG-9 to study its effect on cell growth and tumorigenicity. The results will provide detailed information as to the function of TSG-9 as a tumor suppressor gene. Taken together, our results demonstrate several novel regions of HD and at least one gene within these regions may function as a TSG in lung and liver cancer.

**Mutation and segregation analysis of ATM alleles in 192 Australian breast cancer families.** *T. Wayne<sup>1</sup>, G. Chenevix-Trench<sup>5</sup>, M. Jenkins<sup>2</sup>, T. Bachrich<sup>3</sup>, D. Muhr<sup>3</sup>, R. Davis<sup>1</sup>, N. Albert<sup>4</sup>, P. Oefner<sup>1</sup>, Y. Thorstenson<sup>1</sup>.* 1) Stanford Genome Technology Center, Palo Alto, CA; 2) University of Melbourne, Australia; 3) University of Vienna, Austria; 4) University of Kiel, Germany; 5) Queensland Institute of Medical Research, Australia.

Mutations in the two major breast cancer susceptibility genes, BRCA1 and BRCA2, account for only 20 to 50% of families at high risk for the disease. The ATM gene is a third candidate for breast cancer susceptibility based on previous epidemiological studies. Although some reports failed to find a link between ATM mutations and breast cancer, studies with new, more sensitive technologies such as DHPLC cast doubt on those negative results. In our previous study of 270 Austrian families with Hereditary Breast and Ovarian Cancer (HBOC), 3.7% had deleterious ATM mutations. However, it was not possible to measure the penetrance of these alleles without further family data. Here, we report on the mutation analysis of 192 Australian families with an average of 5 samples per family. With about 50% of the gene analyzed to date, two mutations were observed in five families (2.5%). In addition, the most common missense variant previously observed in breast cancer families, L1420F, was observed in four families. Pedigree analyses will be performed to determine if these alleles segregate with breast cancer.

**Results of a genome-wide linkage analysis in prostate cancer families ascertained through the ACTANE Consortium.** *D. Easton.* CR UK Genetic Epidemiology, Univ Cambridge, Cambridge, United Kingdom.

THE INTERNATIONAL ACTANE CONSORTIUM Familial aggregation of prostate cancer suggests an inherited component. We performed a genome-wide linkage search in 64 families, 63 with at least 3 prostate cancer cases, from 5 countries. Most cases had clinically detected disease. 397 polymorphic markers were typed. Multipoint heterogeneity analysis was conducted under 3 genetic models and non-parametric analyses were undertaken. Weak evidence of linkage, under at least one model, was seen on chromosomes 2 (HLOD=1.15,  $\alpha=0.31$ ), 3 (HLOD=1.25,  $\alpha=0.36$ ), 4 (HLOD=1.28,  $\alpha=0.41$ ), 5 (HLOD=1.20,  $\alpha=0.29$ ), 6 (HLOD=1.41,  $\alpha=0.35$ ) and 11 (HLOD=1.21,  $\alpha=0.32$ ) and in two regions on chromosome 18 (HLOD=1.40,  $\alpha=0.30$  and HLOD=1.31,  $\alpha=0.32$ ). No HLOD scores were greater than 1.5 under any model, and no locus explains more than half of the genetic effect. There was no evidence in previously reported linkage regions on chromosomes 1, 8, 17, 20 or X. Genetic susceptibility to prostate cancer is likely to be controlled by many loci, with no single gene explaining a large fraction of the familial risk. Pooling of results from all available genome scans is likely to be required to obtain definitive linkage results. **Linkage and association studies localize prostate cancer aggressiveness gene on 7q32.** *J.S. Witte<sup>1</sup>, P. Curran<sup>2</sup>, M. Cicek<sup>2</sup>, B.K. Suarez<sup>3</sup>, J.K. Burmester<sup>4</sup>, W.J. Catalona<sup>5</sup>, G. Casey<sup>2</sup>.* 1) Dept of Epidemiology and Biostatistics, UC San Francisco, CA; 2) Dept of Cancer Biology, Cleveland Clinic Foundation, OH; 3) Depts of Psychiatry and Genetics, Wash Univ, St Louis, MO; 4) Center for Personalized Medicine, Marshfield Clinic Res Found, WI; 5) Dept of Urology, Northwestern University, Chicago, IL.

The severity of prostate cancer varies widely: some tumors progress to invasive life-threatening disease while others remain indolent for many years. Genetic factors may underlie this variability, and previous studies have detected linkage between 7q32 and Gleason score (a measure of tumor aggressiveness). We have further investigated this with linkage and association studies. In particular, we first undertook a new genome-wide linkage study of Gleason score (N=259 affected brothers). Second, we genotyped and analyzed an additional 101 finely spaced markers in the 259 men, and in 594 previously studied brothers, allowing for a pooled genome-wide analysis of 853 affected brothers. We detected linkage to chromosome 7q32 in the new study ( $p=0.0009$ ), and in our pooled analysis ( $p=0.0002$ ), confirming previous results. A biologically plausible candidate gene for tumor aggressiveness at this locus is podocalyxin-like protein (*PODXL*), a transmembrane sialomucin. Others have implicated *PODXL* as a down stream target of Ets-1, a positive regulator of angiogenesis, and suggest that *PODXL* is regulated by the tumor suppressor gene *WT1*. Therefore, we next searched for mutations in *PODXL* among 17 men exhibiting linkage, and detected an in-frame deletion. We then evaluated the association between the deletion and prostate cancer aggressiveness with a sibling-based case-control study (N=920). In comparison with carrying no deletions, men with one or two deletions had a 2.2- or 4.7-fold increased risk of aggressive prostate cancer, respectively ( $p=0.004$ ). This suggests that *PODXL* may be the aggressiveness gene linked to 7q32. Using information about such genes to distinguish tumor aggressiveness will provide valuable information about the most appropriate course of treatment among men diagnosed with prostate cancer.

**Enhancing minority recruitment into a national genetics registry: Data from the Cancer Genetics Network.** *D. Bowen, T. Vu.* Cancer Genetics Network, Minority Recruitment Committee, Seattle, WA.

The Cancer Genetics Network (CGN) is a national collaboration at 8 sites in the US, all focused on the conduct of studies on genetic influences on cancer incidence and mortality. The majority of the CGN participants (n=18,000) are Caucasian (90%), with small proportions of Hispanic (4%), African American (3%), Asian (1%) and other ethnicities (2%). To enhance the recruitment of minority individuals and families into the CGN, the investigators have designed four protocols to test new strategies of recruitment. Cluster 1 focused on testing a culturally tailored brochure in African American families in a randomized trial. Cluster 2 is testing the use of genetic risk assessment as an incentive to participate, also in African American participants. Cluster 3 is testing a Spanish language, culturally targeted magazine, Buena Vida, as a novel communication strategy for Hispanic participants in a randomized trial. Cluster 4 tests two incentives, a pan-Asian welcome letter and the provision of a telephone card, to enhance recruitment from the federally funded cancer registry into the CGN.

To date, these efforts have resulted in over one thousand new minority contacts for the CGN. Participants have come from medical, community, and registry settings. All four studies are in their final stages and will be completed in August, 2003. These studies will inform the scientific community about the best ways to recruit minority individuals into cancer genetics studies.

**Microfluidic analysis of multiplex reverse transcription-PCR Assays for semi-quantitative gene expression screening.** *R. Salowsky<sup>1</sup>, R. Wittig<sup>2</sup>, J.S. Maa<sup>3</sup>, M.J. Su<sup>3</sup>, S. Blaich<sup>2</sup>, J. Mollenhauer<sup>2</sup>, A. Poustka<sup>2</sup>, O. Mueller<sup>1</sup>.* 1) Agilent Technologies, Waldbronn, Germany; 2) Department of Molecular Genome Analysis, German Cancer Research Center, Heidelberg, Germany; 3) Maxim Biotech, San Francisco, CA.

During the last decade, micro-array analysis led to the identification of a large number of genes that are differentially expressed in disease processes. After target validation, identified marker genes can be used for screening of different samples (e.g. biopsies, cell lines, blood) in clinical research. Multiplex PCR (mPCR), including the amplification of different DNA fragments in one single reaction, has become a versatile experimental tool for the gene expression screening via reverse transcription-PCR (RT-PCR). For the analysis of multiple bands of an mPCR experiment, the data acquisition from slab gels is often inconvenient in terms of sizing resolution and data accuracy. To advance the analytical parameters of mPCR studies, a microfluidic based analytical platform using Lab-on-a-chip technology was tested to replace slab gels as the tool for the electrophoretic separation of the mPCR products. For the semi-quantitative monitoring of expression variances in different cancer cell lines, an mRT-PCR assay including 12 out of 266 target genes for cancer drug resistance was developed. These target genes were formerly identified by cDNA-array based expression analysis. Lab-on-a-chip technology was applied for the quality control and quantitation of RNA samples as well as for the electrophoretic separation, sizing and quantitation of the mRT-PCR products. All 12 amplicons ranging from 116 582 bp could be separated and quantified. The results of this study clearly demonstrate the improved sizing resolution and data accuracy of this technology compared to slab gels, thereby expanding the application areas for mPCR assays.

**Methylation of p15 tumor-suppressor gene in familial and sporadic malignant melanoma.** *G.A. Molfetta*<sup>1,2</sup>, *P.S.P. Lima*<sup>1,2,3</sup>, *M.V.S. Passos*<sup>1</sup>, *W.A. Silva-Jr*<sup>1,2</sup>. 1) Centro de Terapia Celular-Hemocentro de Ribeirao Preto-Brasil; 2) Depto. Genetica-FMRP-USP-Brasil; 3) Depto. Ciencias Naturais-UESB-BA-Brasil.

The malignant melanoma has its origin in abnormal melanocytes and, it is the worst type of cancer due to its high probability of metastasis. The malignant melanoma is mostly spread among white individuals with an important increase of its incidence worldwide. However, there are few data on the molecular basis of its origin. Hypermethylation of the CpG islands in the promoter region is the only mechanism for the loss of function of many tumours. Additionally, there are many tumor-suppressor genes that are silenced by promoter hypermethylation in cancer. With the objective of evaluating the p15 methylation in familial and sporadic malignant melanoma we have studied the p15 methylation status in 10 patients with familial melanoma and in other 10 patients with sporadic melanoma. To assess the p15 methylation status we used methylation-specific PCR technique. We have observed that 90% of the patients with familial melanoma showed unmethylated p15 pattern and, 80% of the patients with sporadic melanoma showed both methylated and unmethylated p15 patterns. It has been reported that p15 mutations play a role in the origin of sporadic melanoma; our results show that p15 methylation is also related to sporadic melanoma. In addition, we have observed that p15 methylation may occur in late stages of melanoma tumorigenesis. When comparing the p15 methylation status in familial and sporadic malignant melanoma, we concluded that the type of abnormality causing sporadic melanoma seems to involve more complex mechanisms. It seems that the abnormalities causing familial cases of melanoma are mutations in specific genes, while in the sporadic cases there is an accumulation of abnormalities in one or more genes, which act in conjunction for the regulation of the gene expression. Hypermethylation in sporadic melanoma is a consequence of other initial abnormalities in genes which control the normal pattern of methylation. P15 methylation is observed with a higher frequency in patients with sporadic melanoma in later stages, which reinforces our hypothesis. Financial support: FAEPA, FUNDHERP.

**EXPRESSION OF BREAST CANCER RESISTANCE PROTEIN DEPENDS ON THE METHYLATION STATUS OF ITS PROMOTER REGION IN LUNG CANCER CELLS.** *K. Tsukamoto<sup>1</sup>, M. Kamikatahira<sup>1</sup>, S.*

*Sado<sup>1</sup>, K. Yanagihara<sup>1</sup>, T. Kishino<sup>2</sup>, M. Oka<sup>3</sup>, S. Kohno<sup>3</sup>, I. Murata<sup>3</sup>.* 1) Div Pharmacotherapeutics, Dept Clin Pharm, Course Pharmaceutical Sci, Grad Sch Biomed Sci, Nagasaki Univ, Nagasaki, Jpn; 2) Nagasaki Univ Gene Res Center, Nagasaki, Jpn; 3) Div Mol & Clin Microbiol, Dept Mol Microbiol & Immunol, Grad Sch Biomed Sci, Nagasaki Univ, Nagasaki, Jpn.

Breast cancer resistant protein (BCRP) functions as a drug efflux transporter that causes resistance to certain anticancer drugs when expressed in cancer cells. Methylation of the CpG sites in the promoter region of the certain genes has been shown to cause their transcriptional silencing. SN-38 substrate used in this study is an active metabolite of irinotecan. Since the mechanism underlying expression of the BCRP gene during acquisition of drug resistance remains unclear, the aim of this study was to determine the methylation status of the BCRP promoter region in both small cell lung cancer cell line, PC-6 and its SN-38-resistant cell line, PC-6/SN2-5H. We screened the methylation status of the promoter region (spanning from nt -1381 to nt +261 with respect to the transcription initiation site) of the BCRP gene (GenBank accession No.: AF151530), compared to DNA sequences with or without bisulfite modification treatment for each cell line. We found that all of the CpG sites in this whole region examined were completely methylated in SN-38-sensitive cells, PC-6. On the other hand, in SN-38-resistant cells, PC-6/SN2-5H, some of the CpG sites in the limited region (nt -721 to nt -109) were unmethylated at both alleles. Our results indicate that the hypomethylation status of the BCRP promoter region might be necessary for BCRP expression, leading to drug resistance in this lung cancer cells. Furthermore, we have designed methylation-specific PCR (MSP) primer set in the hypomethylated region in order to determine the methylation status of the BCRP promoter region easily. At the next step, we will screen methylation status of the biopsy specimens of lung cancer before chemotherapy with irinotecan by MSP, implicating the possibility to predict irinotecan responsibility before chemotherapy.

***FANCF* Promoter is Methylated in Human Sporadic Breast Cancers.** M.J. Wei<sup>1</sup>, J. Dignam<sup>2</sup>, L. Sveen<sup>1</sup>, J. Fackenthal<sup>1</sup>, T. Taniguchi<sup>3</sup>, F. Hagos<sup>1</sup>, A.D. D'Andrea<sup>3</sup>, O.I. Olopade<sup>1</sup>. 1) Department of Medicine, The University of Chicago, Chicago, IL 60637; 2) Department of Health Studies, University of Chicago, Chicago, IL 60637; 3) Department of Pediatric Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA 02115.

*FANCF*, a gene of Fanconi anemia (FA), encodes a protein required for DNA damage-inducible monoubiquitination of FANCD2 and for targeting of FANCD2 to DNA repair complexes that include the BRCA1 and BRCA2 proteins. A previous study suggested that methylation of CpG islands in the *FANCF* promoter regions in ovarian tumors results in *FANCF* gene silencing and cisplatin resistance. Previous work from our lab has shown that several cancer-related genes may be simultaneously silenced by methylation in breast tumors, including *BRCA1* and *ER*. We therefore sought to analyze the *FANCF* methylation status and to determine its relationship with *ER* and *BRCA1* promoters methylation, in primary breast cancers. Methylation patterns in the *FANCF*, *BRCA1* and *ER* promoter were assessed in breast cancer cell lines and primary breast tissues by methylation-specific PCR (MSP). *FANCF* RNA expression was determined in cell lines by reverse transcription PCR. To date, we have analyzed 5 breast cancer cell lines and 75 invasive breast cancers. The results show that CpG islands in the 5' region of the *FANCF* are methylated in 13 of 75 (17.3 %) of the primary breast cancers while *BRCA1* was methylated in 20 and *ER* in 33 of the same samples. Interestingly, *FANCF* methylation status was strongly correlated with *BRCA1* promoter methylation (50.0 % of *BRCA1* methylated tumors were *FANCF* methylated vs. 5.5 % *FANCF* methylation in *BRCA1* unmethylated tumors,  $P < 0.001$ ). There was no association between *FANCF* methylation status and *ER* methylation ( $P = 0.54$ ). Of the cultured human breast cancer cell lines, MDA-MB-231 cells exhibited methylated *FANCF*; *FANCF* mRNA was expressed, at a relatively low level. These data suggest that epigenetic mechanisms resulting in disruption of the Fanconi Anemia-BRCA pathway contribute to tumor progression in a significant proportion of primary breast tumors, and could be targeted for novel treatment and chemoprevention approaches.

**The Human Mitochip: A High-throughput Sequencing Microarray for Mitochondrial Mutation Detection. A.**

*MAITRA*<sup>1</sup>, *Y. COHEN*<sup>1</sup>, *S. GILLESPIE*<sup>1</sup>, *E. MAMBO*<sup>1</sup>, *N. SHAH*<sup>2</sup>, *D. SIDRANSKY*<sup>1</sup>, *A. CHAKRAVARTI*<sup>1</sup>. 1) PATHOLOGY, ONCOLOGY, AND GENETIC MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD; 2) AFFYMETRIX, INC., SANTA CLARA, CA.

Somatic mitochondrial mutations are common in human cancers, and can be used as a tool for early detection of cancer. We have developed a mitochondrial Custom Reseq microarray as an array-based sequencing platform for rapid and high-throughput analysis of mitochondrial DNA. The MitoChip contains tiled oligonucleotide sequencing probes synthesized using standard photolithography and solid-phase synthesis, and is able to sequence >29kb of double stranded DNA in a single assay. Both strands of the entire human mitochondrial coding sequence (15,451bp) are arrayed on the MitoChip; both strands of an additional 12,935bp (84% of coding DNA) are arrayed in duplicate, providing internal validation of sequence data. We used 300ng of genomic DNA to amplify the mitochondrial coding sequence in three overlapping long PCR fragments. We then sequenced >1.6 million base pairs of mitochondrial DNA, and successfully assigned base calls at 96.54% of nucleotide positions. Replicate experiments demonstrated >99.99% reproducibility. In serial dilution experiments using mixed normal and tumor DNA, the MitoChip was able to detect an aberrant clonal population in 50-fold diluted samples. Consequently, the MitoChip is a high-throughput sequencing tool for the reliable identification of mitochondrial DNA mutations from primary tumors in clinical samples.

**Mitochondrial DNA mutations and aging in human colonic crypts and stem cells.** *R.W. Taylor<sup>1</sup>, M.J. Barron<sup>1</sup>, G.M. Borthwick<sup>1</sup>, A. Gospel<sup>1</sup>, P.F. Chinnery<sup>1</sup>, D.C. Samuels<sup>2</sup>, G.A. Taylor<sup>1</sup>, S.M. Plusa<sup>3</sup>, S.J. Needham<sup>4</sup>, L.C. Greaves<sup>1</sup>, T.B.L. Kirkwood<sup>5</sup>, D.M. Turnbull<sup>1</sup>.* 1) Department of Neurology, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom; 2) Department of Mathematics, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom; 3) Department of Surgery, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom; 4) Department of Pathology, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom; 5) Department of Gerontology, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom.

Oxidative stress plays a major role in the build-up of molecular damage underlying the aging process. The main source of oxidative stress within cells is mitochondrial respiration, which generates reactive oxygen species (ROS) as by-products. Because mitochondrial DNA (mtDNA) is close to the site of ROS production and has limited repair capacity, it is especially vulnerable to stress-induced mutation. Several studies have reported age-related accumulation of mtDNA mutations in post-mitotic tissues such as muscle and brain. These mutations impair cellular energy generation, thereby contributing to degenerative processes in these tissues. To date, age-related pathogenic mtDNA mutations have not been described in actively dividing tissues.

Here we present data from human colonic epithelium showing a marked increase with aging of respiratory deficient colonic crypts. Within these crypts are pathogenic mtDNA mutations, which because of the unique crypt structure must originate in the stem cells. These observations highlight the potential impact of mitochondrial DNA mutations on aging of human stem cells. Our observations explain a recently reported association between mtDNA mutations and colon cancer, a late-onset condition for which age is the major risk factor, suggesting a connection between mitochondrial genome instability, aging, stem cells, and cancer.

**High throughput mitochondrial genome screen in non-melanoma skin cancer (NMSC) using temperature capillary gradient gel electrophoresis (TGCE).** *J.E. Sligh, W. Giraldo-Rosa.* Division of Dermatology, Vanderbilt University Medical Center, and VA TN Valley Healthcare System, Nashville, TN.

Mitochondrial DNA (mtDNA) mutations have been observed in a variety of human malignancies. Surprisingly, these mutations were often homoplasmic within the tumors. Theories to explain the role of these mtDNA changes in tumorigenesis have included a possible selective growth advantage or that they arise by stochastic segregation. We explored the utility of TGCE as a screening tool to identify mutations in human NMSC. TGCE is a high throughput method for detection of DNA sequence variation using capillary gel electrophoresis in a parallel array run through a controlled temporal temperature gradient and paired with laser-induced fluorescence detection. We obtained paired tissue specimens of NMSC tumors and adjacent tumor-free margin skin from excisions. DNA was isolated from the specimens for screening of the entire mtDNA by multiplexed TGCE. We amplified the entire mtDNA in 17 overlapping amplicons averaging 1.1 kb in size (range 418 bp to 2 kb) using a high fidelity DNA polymerase. Larger amplicons were digested with restriction endonucleases to generate up to five smaller fragments (as large as 588 bp). The PCR-amplified segments of the mtDNA from the tumors were annealed with the PCR products amplified from the margin skin, allowing for the formation of heteroduplexes in regions of DNA mismatch. Regions of the mtDNA that formed heteroduplexes were detected by the Reveal system (SpectruMedix) and compared to our sequencing data of the mtDNA. We identified a variety of polymorphisms as well as homoplasmic point mutations in the mtDNA including protein synthesis mutations affecting the mtDNA-encoded rRNA subunits and mutations affecting specific subunits of complex I and complex IV. The TGCE system was highly sensitive in detecting mutations present in amplicons less than 800 bp in both singlet reactions and in multiplexed assays. A mutation was also detected by TGCE in a 2 kb amplicon, although not in all amplicons of this size. We conclude that multiplexed TCGE is a sensitive and rapid screening tool for identifying mtDNA variation.

**NCI Mouse Models of Human Cancers Consortium - Resources for Discovery.** *C.L. Marks.* Division of Cancer Biology, National Cancer Institute, Bethesda, MD.

Mouse models are invaluable for exploring many aspects of the natural history and clinical course of human cancers. The development of new genetically engineered strains promises to provide increasingly accurate models for cancer researchers engaged in basic, translational, clinical, and epidemiological investigations. To accelerate the pace at which well-designed, appropriate mouse models are available for application to human cancer research, the NCI established the **Mouse Models of Human Cancers Consortium (MMHCC)**. The Consortium works cooperatively with the NCI to evolve an integrative program of human/mouse cancer research, convene community-based meetings to promote state-of-the-art mouse cancer science, and identify resources and infrastructure for cancer model development and application to basic and translational cancer research.

The **NCI Center for Bioinformatics** (<http://ncicb.nci.nih.gov>) provides the necessary infrastructure to integrate descriptive cancer models information with that from comparable human diseases. Enabling this information system to function are the **Cancer Models Database** and the **Cancer Images Database**; their data reflect broad experience with how well cancer models inform human therapy, prevention, early detection, imaging, and population science. The interface to the NCI's preclinical models programs is the **MMHCC Website** (<http://emice.nci.nih.gov>), an expanding resource of cancer models information and useful links.

The NCI deploys models to the research community from the **Mouse Models Repository**. The Repository maintains and distributes fully developed cancer models, as well as strains that may be used to derive models. The Repository, in Frederick, Maryland, serves the worldwide scientific community through its website at <http://mouse.ncifcrf.gov>. The site has descriptions of available strains and information about obtaining or submitting mouse models. The Repository monitors the genetic quality of both the mutated allele(s) and backgrounds for all strains, and cryopreserves sperm, and occasionally embryos or ovaries, from each strain. Breeding pairs are available from the Repository at no charge except for the cost of shipping.

**PUMA (P53 Upregulated Modulator of Apoptosis) induces free radicals generation in cancer cell death.** *H. Lu<sup>1</sup>, Z. Liu<sup>1</sup>, H. Shi<sup>2</sup>, J. Yu<sup>3</sup>, K. Liu<sup>2</sup>, C.A. HU<sup>1</sup>.* 1) Dept. Biochem. and Molecular Biol.; 2) Toxicology Program, Univ. New Mexico Health Sciences Center, Albuquerque, NM; 3) Dept. Pathology, Univ. Pittsburgh Cancer Institute, Pittsburgh, PA.

Many cancer cells exhibit aberrations in the genetic and biochemical pathways of apoptosis (programmed cell death). Apoptosis, which is defective in most cancers, is regulated by reactive oxygen species (ROS). Disturbances of ROS homeostasis are involved in the pathophysiology of cancer and other diseases such as stroke and atherosclerosis. Many chemotherapeutic drugs with diverse structures and acting on distinct primary targets induce cancer cell death through P53-mediated apoptosis. The tumor suppressor gene, p53, is mutated in >50% of all cancers and induces apoptosis, mainly through the generation of ROS. The Bcl-2 protein, an oncogene product possessing anti-apoptotic activity, may itself have significant antioxidant activity. In order to better understand the mechanisms underlying ROS generation and homeostasis in cancer cell death, we investigated functions of PUMA (P53 Upregulated Mediator of Apoptosis) in the induction of ROS generation in a Tet-Off inducible cancer cellular model, DLD-1.PUMA. PUMA, a novel mitochondrial Bcl2-homology domain 3 (BH3)-only protein and a potent p53 downstream pro-apoptotic effector, induces rapid apoptosis through a mitochondria-dependent pathway. Utilizing ROS scavengers, electron paramagnetic resonance (EPR) techniques and ROS-sensitive fluorescence dye analysis, we found that: (i) PUMA-induced apoptosis in DLD-1, a colorectal cancer cell line, is specific and is PUMA-dose-dependent; (ii) PUMA-induced apoptosis is directly related to ROS generation because ROS can be detected in apoptotic DLD-1.PUMA cells by EPR and fluorescence dye analysis; (iii) Diphenyleneiodonium chloride (DPI), a ROS scavenger, slows down apoptosis in DLD-1.PUMA cells; and (iv) Quantitative RT-PCR study shows that overexpression of PUMA in DLD-1.PUMA cells induces oxidative stress-responsive genes (e.g., Wild type p53-induced Gene 1, or Wig-1/PAG608, was induced >4X). In summary, we showed that PUMA induces apoptosis, in part, through the generation of ROS and oxidative stress.

**Germ-line mutations in multiple primary melanomas.** *C. Badenas*<sup>1,3</sup>, *J. Malvey*<sup>2</sup>, *M. Mila*<sup>1,3</sup>, *C. Herrero*<sup>2</sup>, *S. Puig*<sup>2,3</sup>, *The Melanoma Genetic Consortium*. 1) Genetics, Hospital Clinic, Barcelona, Barcelona, Spain; 2) Dermatology Service. Hospital Clinic. Barcelona. Spain; 3) IDIBAPS (Institut d'Investigacions Biomediques Agusti Pi i Sunyer). Hospital Clinic. Barcelona. Spain.

Cutaneous malignant melanoma (CMM) is a potential fatal type of skin cancer from melanocytes. Ten to 26% multiple primary melanoma patients (MPM) have been reported to carry mutations in the CDKN2A irrespective of family history. Approximately 5% of melanoma patients will develop more than one primary melanoma. We report the screening of 60 MPM patients (46 with 2 melanomas, 10 with 3 melanomas, 3 with 4 melanomas and 1 with 6 melanomas) for germ-line mutations in CDKN2A, p14ARF and CDK4 exon2. We have detected 7 different mutations in 13 cases (21.7%). Five mutations affect CDKN2A exon 2, 1 affects CDKN2A exon 1 and one affects p14ARF exon 1. No mutation has been detected in CDK4 exon 2. Two mutations are recurrent: G101W and R87W that are found in 6 and 2 patients, respectively. The only remarkable item is age at onset. Dysplastic nevi or family history does not show statistical differences between mutation and non-mutation groups. The mean age at diagnosis of the first melanoma in the mutation group is 31.4 years (range 19-66), while in the non-mutation group is 43.8 years (range 20-83). The results presented in this study show that more than 20% of MPM individuals carry CDKN2A mutations in the Spanish population. ***In vivo* loss of heterozygosity in splenic T cells accumulates with age.** L. Deng<sup>1</sup>, L. Liang<sup>1</sup>, M. Kim<sup>1</sup>, C. Shao<sup>1</sup>, P. Stambrook<sup>2</sup>, J. Tischfield<sup>1</sup>. 1) Dept of Genetics, Rutgers Univ, Piscataway, NJ; 2) Dept of Cell Biology, Neurobiology, and Anatomy, Univ of Cincinnati, Cincinnati, OH.

The age-related increase in cancer is hypothesized to be the result of accumulation of mutations in somatic cells. Such mutations may lead to loss of function of heterozygous tumor suppressor genes. There are several mechanisms that produce this loss of heterozygosity (LOH), resulting in loss of cellular growth control and, ultimately, carcinogenesis. To test whether or not LOH accumulates with age, we have measured the mutant frequency at the *Aprt* (adenine phosphoribosyltransferase) locus and examined mechanisms of LOH in normal T cells of "old" (12-months-old, n = 19) and "young" (4-months-old, n = 47) *Aprt* heterozygous mice. T cell variants that arose *in vivo* as a consequence of genetic or epigenetic alterations abolishing APRT function were selected and expanded *in vitro* by virtue of their resistance to 2,6-diaminopurine. The *Aprt* mutant frequency increased significantly with age, from a median frequency of  $17 \times 10^{-6}$  in young mice to  $41 \times 10^{-6}$  in old mice. This 2.4-fold increase was caused by accumulation of mutants showing physical loss of the *Aprt* wild-type allele (class I mutants) as well as mutants that did not exhibit loss of the *Aprt* wild-type allele (class II mutants). Microsatellite marker and cytogenetic analyses of class I mutants indicated that mutational events, such as mitotic recombination, chromosome loss, and gene conversion/interstitial deletion, were increased in older mice. DNA sequencing analysis of class II variants showed that intragenic point mutations, predominantly base substitutions, increased during aging. Interestingly, epigenetic allelic inactivation also significantly increased, by about 4-fold, in older mice. Taken together, the data indicate that several different types of mutations resulting in LOH accumulate with age. This study improves our understanding of how accumulation of somatic mutations can contribute to various age-related diseases, including cancers.

**Mitotic Instability of Rare *HRAS1* Minisatellite Alleles in *S. cerevisiae*.** S. Ding<sup>1</sup>, G.P. Larson<sup>1</sup>, A.M. Bailis<sup>2</sup>, T.G. Krontiris<sup>1</sup>. 1) Divisions of Molecular Medicine; 2) Divisions of Molecular Biology; City of Hope Beckman Research Institute, Duarte, CA.

The human *HRAS1* minisatellite is located at 11p15.5 and is composed of 30-100 units of a polymorphic 28-bp repeat. Several dozen rare alleles, which arise from four common alleles as a consequence of both replication errors and gene conversion events, demonstrate a significant association with breast, colon, lung, and prostate cancer. To explore the pathways controlling the stability of the *HRAS1* minisatellite, we designed a plasmid-based assay to investigate and compare the alleles' spontaneous mitotic mutational events in *S. cerevisiae*. The primary transformation efficiency of 80 rare alleles was lower than that of 50 common alleles in a wild-type strain; but there was only a marginally significant difference ( $2.831.67 \times 10^3$  vs.  $3.512.24 \times 10^3$ ,  $p=0.049$ ). However, the length alteration of rare alleles was significantly higher than that of common alleles when genotyping individual colonies (28.1624.28% vs. 20.2716.65%,  $p=0.007$ ). Also, this ratio was increased dramatically after incubation of full-length allele clones in nonselective YPD media for 24 hours (62.7626.34% vs. 40.8120.05%,  $p=0.0001$ ). We also sequenced 30-50 randomly selected clones from each of wild type, *rad51* mutant, *dnl4* mutant, *rad1* mutant, and *rad51/dnl4* double mutant strains after YPD incubation. The DNA double-strand breaks repair consequences, such as crossovers and complex conversions, were observed after co-transformation of two rare alleles; but no such events were identified after co-transformation of one rare allele with one common allele. Compared with wild type, the mutation frequencies were slightly lower in *dnl4* (-4%,  $p=0.681$ ) and *rad1* (-18%,  $p=0.079$ ), but significantly dropped in *rad51* (-35%,  $p=0.0003$ ) and *rad51/dnl4* (-36%,  $p=0.004$ ) mutant strains. Therefore, Rad51 mediated strand exchange for homologous recombination repair initiated by spontaneous DNA double-strand breaks, which play a major role in the instability of rare *HRAS1* minisatellite alleles.

**Assessment of hMSH2/hMLH1 genomic rearrangements in individuals at risk for Hereditary Nonpolyposis Colorectal Cancer.** *P.J. Ainsworth, D. Koscinski, B.P. Fraser, J.A. Stuart.* Molecular Diagnostic Lab, London Hth Sci/Univ Western On, London, ON, Canada.

Hereditary Nonpolyposis Colorectal Cancer (HNPCC) results from inactivating germline mutations in a set of DNA mis-match repair genes, of which the most clinically relevant are hMSH2 and hMLH1. The calculation of an individual's likelihood of carrying such a deleterious mutation is typically carried out by assessment of the relevant pedigree, with attention to the number of related cancer-affected individuals, the type of HNPCC-associated cancers, and the age at diagnosis. More recently computer assisted risk assessment tools have become available to facilitate this type of risk analysis. One such tool, the CancerGene program obtained from Dr D. Euhus, University of Texas, SouthWestern, was used to assess the risk of colon cancer in a panel of 39 individuals referred to the LRCC Cancer Genetics Clinic because of their family history of HNPCC-related cancers. Of this panel, 22 individuals were calculated to have a >10% risk of colon cancer by the CancerGene method. DNA isolated from each member of the panel of 39 was screened for genomic re-arrangements in the hMSH2 and hMLH1 genes by the Multiplex Ligation-dependent Probe Amplification (MLPA) method that has recently become available as a kit from MRC-Holland. Individuals from 7 distinct families were determined to carry a genomic rearrangement in either hMSH2 (hMSH2del ex1\_8, (2)hMSH2del ex8, hMSH2del ex12\_16) or in hMLH1 (hMLH1del ex2\_6, (2)hMLH1del ex12). Six of the individuals with genomic rearrangements were calculated by CancerGene to have a colon cancer risk of >50%, the 7th individual being calculated to have a risk of >25%. Though the numbers in this pilot study are small, the trend is unmistakable. The proportion of hMSH2/hMLH1 inactivating genomic re-arrangements in individuals with a colon cancer risk of >10% (as calculated by CancerGene) is >30 %, a number consistent with the current literature. Furthermore genomic rearrangements invariably resulted in a more severe familial pattern of HNPCC. We suggest that the MLPA assay be utilised as an economical primary screen of probands calculated to be at risk for HNPCC.

**Fluorescent DHPLC assay for deletion screening: a preliminary study.** C. Dehainault, A. Laug, V. Caux-Moncoutier, S. Pags-Berhouet, F. Doz, L. Desjardins, J. Couturier, M. Gauthier-Villars, D. Stoppa-Lyonnet, C. Houdayer. Institut Curie, Paris, France.

Gene rearrangement tests are of special importance for the molecular diagnosis of diseases caused by either deletion or duplication of a specific DNA region. One example of disease caused by such gene deletions is retinoblastoma, a malignant tumor of retina that arises predominantly in children. Germ-line mutations of the *RB1* gene are associated with a predisposition to retinoblastoma. It has been demonstrated that an average 20% of the mutations found in *RB1* are large deletions of the gene. FISH or quantitative multiplex fluorescent PCR (e.g. QMPSF) are currently used to identify gene rearrangements in *RB1*. These methods are easy to use but remain costly. Moreover it is of good practice to confirm gene mutations by two different methods in routine molecular diagnosis. Therefore we evaluated the performance of a fluorescent DHPLC system for gene deletion analysis. DNAs from 5 normal controls and from 5 retinoblastoma patients with complete deletion of the gene were extracted using a perchlorate/chloroform procedure. DNA quantity was determined using a picogreen assay (Interchim) and a Genios microplate reader (Tecan), then adjusted to 25ng/l working solutions. Exons 25 and 26 of *RB1* were PCR-amplified using 50ng of DNA and standard cycling condition, except for cycle number which was set to 22. PCR products were then injected on a 3500 Wave system using non denaturing conditions and an elution gradient as predicted by WaveNavigator software, and following fluorescent detection with High Sensitivity Detection system using a double strand staining solution (Transgenomic). All samples were matched and deletions were unambiguously detected by an approximately two-fold decrease in peak area and intensity. Samples were amplified and analyzed 2 times with identical results. These preliminary results showed that a fluorescent DHPLC system could be used for deletion screening and probably allele quantification. However, it must now be tested and validated on large series to draw definite conclusions.

**Analysis of the Birt-Hogg-Dubé (BHD) tumour suppressor gene in sporadic renal cell carcinoma and colorectal cancer.** *N.F. da Silva<sup>1</sup>, D. Gentle<sup>1</sup>, L.B. Hesson<sup>2</sup>, D.G. Morton<sup>3</sup>, F. Latif<sup>1, 2</sup>, E.R. Maher<sup>1, 2</sup>.* 1) Cancer Research UK Renal Molecular Oncology Research Group, University of Birmingham, The Medical School, Edgbaston, Birmingham, B15 2TT, U.K; 2) Section of Medical and Molecular Genetics, Department of Paediatrics and Child Health, University of Birmingham, The Medical School, Edgbaston, Birmingham, B15 2TT, U.K; 3) Department of Surgery, University of Birmingham, Birmingham B15 2TT, UK.

Germline mutations in the BHD gene cause the dominantly inherited cancer susceptibility disorder, Birt-Hogg-Dubé (BHD) syndrome. Individuals with BHD are reported to have an increased risk of renal cell carcinoma and colorectal polyps and cancer. The BHD gene maps to 17p11.2 and to investigate whether somatic inactivation of the BHD gene region is implicated in the pathogenesis of sporadic RCC and colorectal cancer, we performed mutation analysis in 30 RCC primary tumours and cell lines and 35 colorectal cancers and cell lines. A somatic missense mutation (A444S) with loss of the wild type allele (consistent with Knudson's two-hit hypothesis) was detected in a primary clear cell RCC and a further missense mutation (A238V) was identified in clear cell RCC cell line for which matched normal DNA was not available. A somatic missense substitution (R392G) was identified in a primary colorectal cancer and the same change was detected in 3/6 oncocytomas tested for which matched normal DNA was not available. A germline R320Q missense variant detected in a primary colorectal cancer was not detected in 40 control individuals. However AA homozygotes for an intronic SNP (c.1517+6 G>A) were under-represented in familial cases compared to controls ( $p=0.03$ ). For some TSGs, epigenetic silencing is a more common mechanism of inactivation. No evidence of epigenetic silencing of BHD was detected in 19 colorectal cancer and RCC cell lines, and BHD promoter region hypermethylation was not detected in 20 primary RCC. These findings suggest that BHD inactivation occurs in a subset of clear cell RCC and colorectal cancer.

**Screening for genomic rearrangements of the mismatch repair genes must be included in the routine diagnosis of HNPCC.** *F. Di Fiore*<sup>1</sup>, *F. Charbonnier*<sup>1</sup>, *C. Martin*<sup>1</sup>, *S. Frerot*<sup>1</sup>, *S. Olschwang*<sup>2</sup>, *Q. Wang*<sup>3</sup>, *C. Boisson*<sup>2</sup>, *M.P. Buisine*<sup>4</sup>, *M. Nilbert*<sup>5</sup>, *A. Lindblom*<sup>6</sup>, *T. Frebourg*<sup>1</sup>. 1) Department of Genetics and INSERM EMI 9906, CHU and Faculty of Medicine, Rouen, France; 2) INSERM U434 and Hôpital Saint Antoine, Paris, France; 3) Unité d'Oncologie Moléculaire, Centre Léon Bérard, Lyon, France; 4) Laboratoire de Biochimie et Biologie Moléculaire, CHU de Lille, Lille, France; 5) Department of Oncology, University Hospital, Lund, Sweden; 6) Department of Clinical Genetics, Karolinska Hospital, Stockholm, Sweden.

We recently showed, using QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments) that genomic rearrangements of *MSH2* are involved in 20% of the HNPCC families fulfilling the Amsterdam (AMS) criteria, without detectable point mutations. We have now integrated the QMPSF into the routine diagnosis of HNPCC and have analyzed a total of 332 HNPCC families, without detectable point mutations and corresponding to 123 AMS+ and 209 AMS- families. We identified in 37 families, corresponding respectively to 24 AMS+ (20%) and 13 AMS- (6%) families, 21 distinct exonic rearrangements of *MSH2*, removing exon(s) 1, 1-2, 1-4, 1-6, 1-7, 1-8, 1-11, 1-15, 2, 3, 4-6, 5, 5-6, 7, 7-10, 8, 9-10, 12-13, 13-15 and two cases of duplication involving exons 9-10 and 7-8. Analysis by QMPSF of 50 Kb of genomic sequences upstream the *MSH2* transcription initiation site revealed 8 distinct 5'breakpoints. QMPSF analysis of the *MSH2* promoter region in 90 AMS+, without exonic deletion, allowed us to detect a deletion removing 1.7 kb of the promoter. Analysis of *MLH1* in 182 families led us to identify, in 6/82 AMS+ (7 %) and 3/100 AMS- (3%) families, 8 exonic rearrangements of *MLH1*, removing exon(s) 1-19, 2, 4-6, 6, 7-9, 11, 13-16 and 14. We found that the selective extinction of the MMR protein was highly predictive of a *MMR* rearrangement. We conclude that *MSH2* rearrangements are involved in at least 10% of the AMS+ families, which justifies to include their search in the routine diagnosis of HNPCC. Even if genomic rearrangements of *MLH1* appear less frequent, their presence should be considered in HNPCC patients, when the immunostaining of the tumours reveals an absence of MLH1 expression.

**Broadening the WT1 mutation associated phenotype.** *H. Druker<sup>1</sup>, R. Weksberg<sup>1,2</sup>, S. O'Neill<sup>1</sup>, D. Malkin<sup>1,3</sup>, A. Khoury<sup>4</sup>, R. Grant<sup>3</sup>.* 1) Cancer Genetics Program, The Hospital for Sick Children, Toronto, ON, Canada; 2) Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 3) Haematology/Oncology, The Hospital for Sick Children, Toronto, ON, Canada; 4) Urology, The Hospital for Sick Children, Toronto, ON, Canada.

WT1 is required for the normal development and function of the urogenital tract and gonads. Constitutional mutations (MIM#194070) are associated with familial Wilms tumour and syndromes such as Denys-Drash syndrome (DDS) characterized by nephropathy (mesangial sclerosis), genital anomalies often including ambiguous genitalia or pseudohermaphroditism in XY individuals, and often a predisposition to Wilms tumour. Incomplete DDS has been defined as nephropathy with genital anomalies or Wilms tumours (Little, 1997). We report a case of a 46,XY male with a constitutional WT1 mutation with bilateral triphasic Wilms tumour with heterologous rhabdomyomatous component involving the right kidney at 10 months of age. Present in biopsies of the right and left kidneys were areas of focal segmental cystic dysplasia, and focal parenchymal atrophy and fibrosis, although no renal dysfunction was noted. At 3 years 10 months of age, triphasic Wilms occurred in the left kidney. Our patient also had hypospadias, deficient proximal urethra, cryptorchidism and chordee, all of which have been surgically corrected. Our patient did not have mesangial sclerosis, and therefore did not meet the classical DDS definition. Constitutional DNA was obtained from this patient which revealed a de novo truncating mutation R362X in exon 8 of the WT1 gene. This mutation has been reported in patients with variable expressivity from the classical DDS phenotype to a normal phenotype. Twelve patients with this mutation have been reviewed in the literature to date (Little, 1993; Kaplinsky, 1996; Heathcott, 2002). However, our patient was reported to have cystic dysplasia, a deficient proximal urethra and chordee, which are findings not yet described in patients with this mutation. This patient extends the range and variation of phenotypes that may arise from a specific germline mutation in WT1.

**Conversion technology increases the sensitivity of genetic testing in hereditary non-polyposis colorectal cancer.**

Background: Identification of germline mutations is a challenge. In Hereditary Non-Polyposis Colorectal Cancer (HNPCC), the mutation spectrum of MLH1 and MSH2 genes is diverse. Large deletions or promoter mutations and mutations close to splice-sites may be missed by genomic sequencing or be difficult to interpret. Methods: 93 individuals were selected from the Cooperative Family Registry for Colon Cancer Studies. Each had a colorectal cancer with high level of microsatellite instability, 84 were from families meeting the classical Amsterdam I criteria for HNPCC. From EBV transformed cell lines, the chromosomes containing alleles for MLH1 and MSH2 genes were separated in somatic cell hybrids by Conversion Technology followed by analysis of cDNA expression and cDNA sequencing of MLH1 and MSH2. Results were compared to data obtained from traditional mutation analysis of genomic DNA by sequencing of all exons and splice-sites of MLH1 and MSH2. Results: All 39 exon mutations were identified by both conversion technology and exon scanning methods. However, conversion technology was also able to identify 13 large genomic deletions, one exon duplication and 2 loss of expression mutations not identified by exon scanning. Conversion technology was also able to confirm that 16 of 20 splice site mutations resulted in altered splicing. Conclusions: Mutation analysis on haploid templates increases the sensitivity of genetic testing. Acknowledgements to the Cooperative Family Registry for Colon Cancer Studies. This study was supported in part by NCI award U01CA74799.

**Total murine mitochondrial genome screening of cutaneous tumors.** *A. Eshaghian, J.E. Sligh.* Division of Dermatology and Department of Cell and Developmental Biology, Vanderbilt University Medical Center and VA Tennessee Valley Health Care System, Nashville, TN.

The mouse mitochondrial genome is a 16,295 bp circular DNA molecule encoding 13 polypeptides involved in oxidative phosphorylation, two rRNAs, and 22 tRNAs. The accumulation of homoplasmic mitochondrial DNA (mtDNA) point mutations has been observed in various malignancies in humans. We sought to identify the potential role of mtDNA point mutations in the pathogenesis of cutaneous tumors in an animal model. We isolated total genomic DNA from ultraviolet-induced cutaneous tumors as well as from minimally-exposed skin on the ventral surface of hairless mice. The entire mouse mitochondrial genome was PCR-amplified with high-fidelity Optimase polymerase (Transgenomic) using 51 primers pairs whose products are 400-500 bp in length each with a minimum of 15% overlap. The PCR products amplified from tumor DNA were then mixed with PCR products amplified from non-tumor DNA. Denaturation of these DNAs followed by slow cool down allows for wild type DNA to re-anneal with potentially mutated DNA (tumor), forming heteroduplexes. Heteroduplexes were detected using either the WAVE denaturing high performance liquid chromatography (DHPLC) system (Transgenomic) or the Reveal temperature gradient capillary electrophoresis (TGCE) system (SpectruMedix). In an initial screen, we have identified a heteroplasmic mutation (A8875G) in the mtCOX3 gene affecting codon 90 (E90G). We have also designed a multiplex system in which multiple larger PCR products are simultaneously amplified in the same tube. The products are then digested with a restriction enzyme forming multiple smaller fragments, whose sizes vary sufficiently such that all fragments in each tube can be screened simultaneously using TGCE. This multiplex method allows for high-throughput screening of the entire mitochondrial genome for SNPs conveniently in eight tubes. We found that TGCE is as sensitive as DHPLC in mutation detection and we are screening more tumors using these methods.

**Prevalence results for five recurrent *BRCA1* rearrangement mutations in 7570 analyses.** *B. Hendrickson, A.M. Deffenbaugh, C.A. Gaglio, T. Judkins, S. Chen, B.E. Ward, T. Scholl.* Myriad Genetic Laboratories, Salt Lake City, UT.

Using an automated high-throughput, multiplexed assay, 7570 patients at risk for hereditary breast and ovarian cancer were tested for five recurrent *BRCA1* rearrangement mutations as part of the comprehensive analysis of the *BRCA1* and *BRCA2* genes. The rearrangements detected in this panel include previously characterized deletions of exons 8-9, 13, 14-20, 22 and a duplication of exon 13. From a total of 1036 patients identified with deleterious mutations, 31 (3.0%) were positive for one of these rearrangement mutations. The exon 13 duplication was the most common rearrangement and was identified in 26 patients, representing 83.9% of the rearrangement mutations and 2.5% of the total mutations. The frequency of this mutation makes this the most prevalent non-Ashkenazi *BRCA1* mutation in our test population. Also, two patients were positive for the deletion of exons 14-20 and three had the deletion of exon 22. The deletion of exon 13 and the deletion of exons 8-9 did not occur in this sample set. Over 90% of the patients with the exon 13 duplication claimed European ancestry. All instances of the exon 22 deletion and the deletion of exons 14-20 occurred in individuals of Western or Northern European ancestry.

A review of SNP haplotypes obtained from the sequencing data revealed that the exon 13 duplication and deletions of exon 14-20 and 22 reside on the consensus allele. Interestingly, because the 14-20 deletion occurs in a region that contains SNPs used to define these haplotypes, its presence can often be inferred from sequencing data when the mutant allele occurs in a context with common non-consensus alleles. This circumstance allowed us to identify four additional occurrences of this mutation.

This assay has proven to be a highly effective method to detect rearrangement mutations and improves the sensitivity of clinical genetic tests.

**Comprehensive screening for germ-line *RBI* mutations by DHPLC and QMPSF.** *S. Pagès-Berhouet, A. Laugé, C. Dehainault, V. Caux-Moncoutier, P. Karczynski, F. Doz, L. Desjardins, J. Couturier, M. Gauthier-Villars, C. Houdayer, D. Stoppa-Lyonnet.* Institut Curie, Paris, France.

Germ-line mutations of the *RBI* gene are associated with a predisposition to retinoblastoma. It is essential to identify these mutations in order to provide appropriate genetic counseling in retinoblastoma patients, but this represents an extremely challenging task, as the vast majority of mutations are unique and spread over the entire coding sequence. Since 2001, we have implemented *RBI* testing on a routine basis as part of the clinical management of retinoblastoma. As most screening techniques do not meet the requirements for efficient *RBI* testing, we have devised a semi-automated DHPLC (Denaturing High-Performance Liquid Chromatography) method for point mutation detection combined with a QMPSF (Quantitative Multiplex PCR of Short fluorescent Fragments) approach to screen for gene rearrangements. We report the results of this comprehensive screening of all exons and promoter of *RBI* in 192 unrelated patients, mostly of French origin. Among 102 bilateral and/or familial cases and 90 unilateral sporadic probands, mutations were identified in 83 (81.5%) and 5 (5.5%) cases, respectively. One half of these mutations have not been previously reported. The mutational spectrum was found to be significantly different from previous published series, displaying an astonishing amount of splice mutations and large deletions. This study demonstrates the reliability of DHPLC for *RBI* analysis, but also illustrates the need for a deletion scanning approach and the successful adaptation of QMPSF to *RBI*. Finally, considering the benefits to retinoblastoma patients, *RBI* testing should be widely implemented in routine healthcare since our study clearly illustrates its feasibility.

**A simple DHPLC-based method for quantitative analysis of allele-specific expression of the *MLH1* gene.** *M. Tosi<sup>1</sup>, G. Raux<sup>1</sup>, I. Tournier<sup>1</sup>, F. Di Fiore<sup>1</sup>, C. Martin<sup>1</sup>, I. Maréchal<sup>2</sup>, C. Leclerc<sup>2</sup>, T. Frébourg<sup>1</sup>.* 1) INSERM EMI 9906, Faculty of Medicine, Rouen, France; 2) EFS de Normandie, Rouen, France.

Quantitative measurements of allele-specific gene expression open the way to indirect detection of mutations within regulatory elements or in deep intronic regions that may result in significant physiological or pathological changes of gene expression, but can hardly be detected by the current methods of genetic analysis. Since most methods for the analysis of allele-specific gene expression are either imprecise or expensive, we have devised a simple method, based on RT-PCR and single nucleotide primer extension (SNuPE) using unlabelled dideoxy-nucleotides. Extension products were separated on a 3.0 x 75mm Helix DNA column (Varian). As a first test of this method, we genotyped 99 French unrelated control individuals for the frequent I219V polymorphism in exon 8 of *MLH1* and found 40 heterozygous subjects. We then measured the allele-specific *MLH1* expression in these heterozygous controls, using ARNs extracted from fresh blood samples taken under strictly identical conditions. Triplicates of PCR and primer extension performed on each of these 40 heterozygotes showed that this method produces allele-specific UV absorbance peaks that provide reliable measurements of allele-specific expression. No significant deviation from the expected 50% contribution of each allele was found in these controls (standard deviation 3.5%, including biological variability and measurement error). We then measured the allele-specific gene expression in 10 hereditary nonpolyposis colorectal cancer patients with different stop or frame-shift mutations or in-frame microdeletions, in order to determine which of these defects induce nonsense-mediated mRNA decay (NMD). Comparison of the allelic expression levels in these 10 patient samples with the normal range defined above allowed us to identify unambiguously the defects that induce mRNA instability, with results consistent with the current models of NMD. This study provides a sensitive tool to identify indirectly any type of *MLH1* defect that may escape detection in genomic DNA screenings but results in a quantitative change at the mRNA level.

**Molecular analysis of familial cases of renal cell cancer.** *D. Bodmer, A. Bonn , M. Eleveld, F. van Erp, E. Schoenmakers, A. Geurts van Kessel.* Department of Human Genetics, University Hospital Nijmegen, P.O. Box 9101, 6500 HB Nijmegen, The Netherlands.

To date, eight families have been described in literature in which constitutional chromosome 3 translocations co-segregate with a predisposition to the development of renal cell cancer (RCC). Through a multi-center study we have identified several additional families with RCC and chromosome 3 translocations. Previously, we found that loss of the derivative chromosome carrying the 3p arm and subsequent VHL mutations constitute critical steps in the development and progression of these RCCs. In addition, we hypothesized that genes located at or near the translocation breakpoints may be related to tumor initiation (Bodmer et al., 2002). In order to test this hypothesis, we have set out to positionally clone the translocation breakpoints and to characterize them in detail. Using this approach we identified two novel breakpoint-spanning genes in one of our RCC families with a t(2;3)(q35;q21) translocation. The breakpoint-spanning gene on chromosome 3, named DIRC2, encodes a putative membrane-spanning protein belonging to the major facilitator super family (MFS) of transporters. The gene disrupted by the breakpoint on chromosome 2, named DIRC3, forms fusion transcripts with HSPBAP1, a JmjC-Hsp domain gene that maps proximal to the breakpoint on chromosome 3. Currently, we are characterizing these (fusion) genes in detail at the cell biological and functional level. Together with known and novel genes to be identified by others, and us, these studies might eventually lead to a unified model for hereditary RCC development in families with constitutional chromosome 3 translocations. Bodmer et al., Human Molecular Genetics 11: 2489-2498 (2002).

**Gene expression based classification of malignant gliomas provides more accurate prediction of survival than histologic grading.** *W.A. Freije, F.E. Castro-Vargas, Z. Fang, S. Horvath, P. Mischel, L. Liau, T. Cloughesy, S. Nelson.* Human Genetics, UCLA, Los Angeles, CA.

Although histologic grading of malignant gliomas correlates strongly with survival, it is subjective and applied differently by different pathologists creating variability between treatment centers in diagnostic categories. Histology provides little insight into the underlying biology of gliomas. Large scale gene expression studies provide an attractive alternative to tumor classification schemes that can be applied uniformly and provide robust predictors. We have performed genome-wide analysis of gene expression of malignant gliomas to identify groupings of tumors which are divided into distinct prognostic groups. 59 glioblastoma multiforme(GBM), 2 grade II astrocytoma, 9 anaplastic astrocytoma, 8 grade II oligodendroglioma, 11 grade III oligodendroglioma, and 9 mixed grade III oligo-astrocytoma samples (total N=98) were analyzed for approximately 31,000 different transcripts using the Affymetrix U133A/B microarrays. Using a partial least squares supervised dimension reduction technique, 8 linear components were defined which accounted for 96.7% of the power to predict survival. Using these 8 components the unsupervised classification model of partition around the medoids was used to classify the glioma samples. This yielded two groups, GBM-like and NonGBM-like. The GBM-like group contained 51 GBM, 5 oligodendroglioma, and 1 mixed oligo-astrocytoma samples. The NonGBM-like group contained 8 GBM, 11 astrocytoma, 14 oligodendroglioma, and 8 mixed astro-oligodendroglioma samples. Kaplan-Meier survival analysis of these two groups were significantly different, and significantly more predictive than histologic grading, with a 50% survival time of approximately 250 days for the GBM-like group, and greater than 2500 days for the NonGBM-like group ( $P=3.3e-11$ ). To test the robustness of the model, the results were validated on an independent set of malignant glioma data which used the U95Av2 arrays( $p=0.00013$ ) (Nutt et al, Cancer Research 2003 63:1602-7). Such classification schemes may be used in the future to supplant the current system of prognostication through histopathology.

**Synergistic effects of Aurora-A and p53 in liver regeneration and pathogenesis.** *H.Y. Chu*<sup>1</sup>, *H.J. Chen*<sup>2</sup>, *Y.R. Chen*<sup>3</sup>, *C.K. Chou*<sup>2,3,5</sup>, *C.W. Chi*<sup>4,5</sup>, *T.F. Tsai*<sup>1,2,3,5</sup>. 1) Institute of Genetics, National Yang-Ming University, Taipei, Taiwan; 2) Division of Molecular and Genomic Medicine, National Health Research Institute, Taipei, Taiwan; 3) Department of Life Science, National Yang-Ming University, Taipei, Taiwan; 4) Institute of Pharmacology, Natl Yang-Ming Univ, Taipei, Taiwan; 5) Department of Medical Research and Education, Veterans General Hospital, Taipei, Taiwan.

Hepatocellular carcinoma (HCC) is one of the most common forms of human cancers. The formation of HCC is a multi-step process involving the occurrence of somatic mutations, loss of tumor suppressor gene(s), and activation of oncogenes. Our goal is to establish an *in vivo* mouse model of HCC. Aurora-A has been suggested as an oncogene in cultured cells, and overexpression of Aurora-A has been found in HCC. We have successfully developed transgenic lines with human Aurora-A cDNA over-expressed from the PEPCK promoter. The effect of Aurora-A overexpression on cell cycle progression was analyzed in liver regeneration induced by two-third partial hepatectomy (PHx). Abnormal cell cycle progression was detected based on expression profile of the cell cycle marker, BrdU labeling and mitotic index. Prolonged S phase and decreased mitotic figures were observed in the regenerated livers of the Aurora-A transgenic mice. Several foci of cell death in transgenic livers were detected at day 1, 3, 4, and 7 after PHx. The pathological abnormality may due to arresting of G2/M progression. The data also suggest a negative regulation in the Aurora-A transgenic livers under physiological condition. Previous report indicated that Aurora-A directly interact with p53 in cell culture system. It was also suggested that overexpression of Aurora-A in p53 knockout (p53<sup>-/-</sup>) mouse embryonic fibroblasts (MEF) favor centrosome amplification. To delineate their roles in relationship to cell cycle progression and pathogenesis, the Aurora-A transgenic mice with p53 knockout (p53<sup>-/-</sup>) background were studied. Our data suggest that there are synergistic effects of Aurora-A deregulation and p53 deficiency in liver regeneration and carcinogenesis process.

**Analysis of *CHEK2* for ovarian cancer susceptibility.** *B.E. Baysal*<sup>1</sup>, *J.A. DeLoia*<sup>1</sup>, *M.T. Goodman*<sup>2</sup>, *J.E. Willett-Brozick*<sup>1</sup>, *P. Watson*<sup>3</sup>, *M.J. Birrer*<sup>4</sup>, *H.H. Gallion*<sup>1</sup>. 1) Ob/Gyn&Reproductive Sci., Univ. Pittsburgh Sch. of Med., Pittsburgh, PA; 2) Cancer Res. Ctr. of Hawaii, Univ. Hawaii, Honolulu, HI; 3) Creighton Univ., Omaha, NE; 4) Natl. Cancer Inst. (NCI) Mol. Mech. Section, Rockville, MD.

Ovarian cancer (OvCa), with a lifetime incidence of approximately 1%, is the fifth leading cause of death from cancer among women. Familial predisposition has been observed in up to 20% of the OvCa cases. It has been estimated that up to 10% of all OvCas result from an inherited mutation in the *BRCA1* or *BRCA2* genes. However, the genetic factors that may contribute to the etiology in up to 50% of the familial and in the nonfamilial cases are largely unknown. Recently, germline mutations in *CHEK2* have been identified as a low-penetrance risk factor for familial breast cancer. However, the role of *CHEK2* in OvCa is unknown. Because of the commonality of genetic risk factors between breast and OvCas, we are investigating the role of *CHEK2* for OvCa susceptibility in a large number of subjects ascertained throughout the United States.

The subjects were recruited through the Gynecologic Oncology Group (GOG) protocols 143, 144, 172, 182; the University of Hawaii Cancer Res. Ctr.; and Creighton University. GOG is a premier NCI Sponsored Cancer Cooperative Clinical Trials Research Group. First, we have tested a common deletion variant, del1100C that has been observed in approximately 1% of the general population, by Pyrosequencing and found this deletion in only 2 of 345 (~0.6%) unselected OvCa subjects. Both deletion carriers were from a subgroup with a positive family history for breast or OvCas but no *BRCA1* mutations (n=40). Initial sequencing of the fourteen exons of the *CHEK2* gene in 15 subjects with a positive family history did not identify further mutations, only a previously identified silent variant (E84E). These findings suggest that the *CHEK2* gene del1100C variant does not play a role in predisposition to sporadic OvCa, but may be involved in familial OvCa. The rarity of the deletion variant in the patient population may limit its practical value in the clinical management of OvCa patients.

**Transcriptional deregulation by adenovirus E1A in human tumor cells: reprogramming of tumor cells to less malignant phenotypes.** *J. Dorsman*<sup>1, 4</sup>, *A. Teunisse*<sup>2</sup>, *B. Pepers*<sup>1</sup>, *T. van Laar*<sup>5</sup>, *G. van Ommen*<sup>1</sup>, *A. Zantema*<sup>2</sup>, *A. van der Eb*<sup>3</sup>. 1) HCG, LUMC, Leiden, Netherlands; 2) MCB1, LUMC, Leiden, Netherlands; 3) TG, LUMC, Leiden, Netherlands; 4) O&G, VUmc, Amsterdam, Netherlands; 5) MC, NKI, Amsterdam, Netherlands.

The adenovirus 5 (Ad5) E1A protein can reverse the transformed phenotype in a wide range of human tumor cells and can suppress primary human tumor growth. E1A apparently interferes with oncogenic pathways by its ability to reprogram transcription in human tumor cells. To get more insight which genes are deregulated by E1A in human tumor cells, Affymetrix expression array studies were performed analysing two different model systems. Firstly, human osteosarcoma U-2 OS cells were transfected with constructs expressing the 12S Ad5 E1A protein, in parallel with the transfection of a control vector. Two independent experiments showed the down-regulation of various genes involved in stress responses including, GADD45, GADD153 and ATF3. In agreement with previous studies, an up-regulation of genes involved in the heat shock response was observed. The Affymetrix array data were validated by Northern blot. To study the long term effects of E1A, glioblastoma T98G cell lines which stably express the 12S Ad5 E1A gene were compared with cell lines generated by transfection of the same vector lacking the E1A gene. The E1A-expressing cell lines do not give rise to any colony formation in soft agar, whereas the control cell lines efficiently form colonies under the same conditions. Also in these stable cell lines the expression of genes involved in the heat shock response are up-regulated, including HSP40 and HSP110. In addition, other groups of co-regulated genes are found, including the down-regulation of a group of genes coding for metalloproteases and of genes involved in xenobiotics metabolism. The implications of these findings are discussed.

**Transcription Factor Profiling of Endometrial Cancers.** *I. DASKALAKIS<sup>1</sup>, N. SACCONI<sup>1</sup>, D. MUTCH<sup>2</sup>, P. GOODFELLOW<sup>2</sup>, M. LOVETT<sup>1</sup>, A.M. BOWCOCK<sup>1</sup>.* 1) DEPARTMENT OF GENETICS, WASHINGTON UNIVERSITY, ST. LOUIS, MO; 2) DEPARTMENT OF SURGERY, WASHINGTON UNIVERSITY, ST. LOUIS, MO.

Endometrial cancer is the most common form of pelvic malignancy representing 7-10% of all invasive cancers in women. One molecular classification of endometrial cancers is based on the presence of Microsatellite Instability (MSI). MSI- tumors are associated with major chromosomal instability or aneuploidy while MSI+ tumors harbor alterations in the length of short repeat tracts and an increase in mutation rate. Approximately 25% of endometrial cancers are MSI+. In some cases, MSI+ tumors are due to mutations in mismatch repair genes eg. MSH2, MLH1 and MSH6. The objectives of this study are to understand the molecular basis of endometrial cancer and to identify the tumorigenic targets in the MSI+ tumors. Gene expression profiles of four well characterized MSI+ and MSI tumor samples, matched on the basis of age and stage were compared by hybridization to a unique custom microarray comprised of 1700 transcription factors (Tfs). Statistical validation of the results was performed using the method of Wolfinger et al. 9 Tfs were downregulated in MSI+ tumors ( $p < 0.0001$ ). At a cut-off p value of 0.05, 30 Tfs were downregulated MSI+ tumors. Many of the altered Tfs previously shown to be involved in tumor formation were downregulated in the MSI- tumors and included p53 and MYCL1. However, a number of novel Tfs were also down-regulated in MSI- tumors and included ZNF73 and KIAA0478. TaqMan RT PCR is being used to confirm these findings in larger numbers of samples. 9 Tfs downregulated in MSI- tumors and mapping to tumor suppressor loci are being mutationally analyzed with denaturing high performance liquid chromatography. The ability to interrogate large numbers of tumors with a comprehensive set of transcription factors is potentially a valuable resource for the identification of novel tumor suppressors.

**Complementary analysis of clear cell renal carcinoma by array-based CGH and expression profiling:**

**Identification of relevant genomic aberrations.** *E. Lausch*<sup>1</sup>, *B. Fritz*<sup>2</sup>, *D. Reutzel*<sup>1</sup>, *B. Radlwimmer*<sup>2</sup>, *C. Spangenberg*<sup>1</sup>, *W. Brenner*<sup>3</sup>, *H. Decker*<sup>4</sup>, *P. Lichter*<sup>2</sup>, *B. Zabel*<sup>1</sup>. 1) Children's Hospital, Mainz; 2) DKFZ, Heidelberg; 3) Department of Urology, Mainz; 4) Bioscientia Institut, Ingelheim.

Renal cell carcinoma (RCC) is the most common type of renal cancer accounting for 3% of all malignancies in men. The clinical manifestation of RCC is highly variable. More than 1/3 of patients with RCC present with metastatic disease at the time of diagnosis, an additional 20% develop metastasis within 5 years after nephrectomy. The prognosis of patients with metastatic disease remains poor. Tumor biology is partly related to the histopathological subtypes of RCC which in turn are associated with a broad spectrum of genetic alterations and morphological signs of differentiation. The most common subtype, clear cell RCC is strongly associated with somatic deletions of the short arm of chromosome 3 coupled with inactivation of the *VHL* gene. Other common chromosomal alterations in progressing clear cell RCC include deletions of 6q, 8p, 9, and 14q, and duplication of 5q. Although some of these genomic aberrations appear to be linked to clinical outcome, specific genes have not yet been identified. In order to understand the underlying molecular mechanisms causing different biological behaviour of RCC we performed a parallel analysis of 19 clear cell RCC specimens and patient-matched normal tissue by array-based comparative genomic hybridization and expression profiling. The genomic microarray contained 2300 BAC elements allowing to detect copy number changes with an average resolution of 1.5 Mbp. Expression profiling was carried out using microarrays consisting of 3600 nonredundant sequence-validated human cDNAs selected on their putative involvement in tumorigenesis. Differentially expressed genes were confirmed by reverse quantitative PCR. Classification of tumors based on their genomic and expression profile was achieved by cluster analysis. Profiles were used to stratify tumors according to clinical behaviour. Congruent changes in genomic loci and gene expression were correlated and are the basis for further functional analysis. Candidate 'progression suppressor' genes will be discussed.

**Genome-wide analysis of genetic alterations in tumor cell lines by Ccap BAC microarray.** *H. He<sup>1</sup>, A. Roschke<sup>1</sup>, R. Yonescu<sup>1</sup>, E. Hatchwell<sup>2</sup>, T. Ried<sup>1</sup>, I. Kirsch<sup>1</sup>.* 1) Genetic Branch, CCR, NCI, NIH Bethesda, MD; 2) Genome Research Center, Cold Spring Harbor Laboratory, Woodbury, NY.

Recently, the first Ccap BAC microarray has been developed and printed by the NCI and the Cold Spring Harbor Laboratory. This array contains over 1,300 Ccap BAC clones and all of these BAC clones have been mapped by high-resolution fluorescence-in-situ-hybridization (FISH) to single sites on chromosomes. The Ccap BAC set is also physically mapped and can be localized by alignment of BAC end sequences to the finished HGP contig. Ccap BAC clones are localized at 12-Mb intervals across the entire genome. Information about those clones is available on a publicly accessible web site <http://www.ncbi.nlm.nih.gov/CCAP> BAC clones were amplified by DOP-PCR and printed onto glass slides. Using this Ccap BAC array, several tumor cell lines have been analyzed. The CGH microarray data have been validated by chromosomal CGH and SKY on the same cell lines. Copy number changes of small regions (microdeletions and duplications) were confirmed by interphase FISH. Our data demonstrated that Ccap BAC arrays were able to define copy number changes of whole chromosome or chromosome regions in cancer cell lines. The Ccap BAC array provides a valuable tool, which not only allows definition of a target area of gain or loss from cancer samples, but also leads seamlessly from a cytogenetic band to the primary DNA sequence allowing integration of molecular cytogenetics and genomics.

**Recombinant Protein encoded by Esophageal Cancer Related Gene-1 (ECRG-1) inhibits the proliferation of the Esophageal carcinoma cell line *in vitro*.** *Y. Wang*<sup>1, 2</sup>, *H. Tang*<sup>2</sup>, *S. Lu*<sup>2</sup>, *T.-J. Chen*<sup>1</sup>. 1) Dept Medical Genetics, Univ South Alabama, Mobile, AL; 2) Cancer Institute (Hospital), Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing 100021.

The ECRG-1 gene was isolated and characterized by our group from the differential display studies of esophageal cancer and normal esophageal epithelia cells. The ECRG-1 gene is expressed in several human tissues, including the normal esophageal epithelia cells. The expression of ECRG-1 gene is down regulated in esophageal cancer tissue. To study the function of this gene on the esophageal carcinoma cells (NEC), the ECRG-1 cDNA was cloned and over-expressed as a fusion protein with GST. The recombinant protein was purified and confirmed with Western blot. Different concentrations of ECRG-1 protein were incubated with NEC cells. The cell numbers of NEC were determined by the MTT method. The results shown that the proliferation of the NEC cells was inhibited by the ECRG-1 protein starting at a concentration of 50g/ml. With increasing the ECRG-1 protein concentration, the inhibition rate increased. After incubation with 400g/ml ECRG-1protein for 24, 48, 72, and 96 hours, the inhibition rates were 12%, 60%, 62% and 65%, respectively. These inhibition rates were significantly different from those on the control groups ( $P < 0.001$ ), including GST protein alone. Cell cycle analysis using flow cytometry indicated that the percentage of NEC cells on G2/M phase increased from less than 15% on control groups to 30% on ECRG-1 protein treated NEC cells. These results suggested that the ECRG-1 gene might play an important role on the control of esophageal carcinoma proliferation. The possible inhibition mechanism may involve the regulation of cell cycle, particularly on the G2/M phase checkpoints.

**Identification and pathway mapping of brain tumor progression associated genes.** *C. Tso<sup>1</sup>, R. Shai<sup>1</sup>, W. Freije<sup>1</sup>, E. Castro<sup>1</sup>, K. Mitsouras<sup>1</sup>, Z. Chen<sup>1</sup>, B. Merriman<sup>1</sup>, L. Liau<sup>3</sup>, P. Mischel<sup>2</sup>, S. Horvath<sup>1</sup>, S. Nelson<sup>1</sup>.* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Pathology, UCLA, Los Angeles, CA; 3) Surgery, UCLA, Los Angeles, CA.

In order to elucidate the molecular mechanisms underlying brain tumor progression, we have established an oligonucleotide microarray-based transcription database for malignant brain tumors with defined pathological grading, as well as survival and treatment data. The database contains over 200 individual tumors as well as 15 normal brain tissue samples. We have identified 67 genes which have a likely oncogenic effect due to overexpression and 33 whose effect is mediated by loss of expression. These include genes which encode proteins involved in cell cycle/growth, signaling, apoptosis, metabolism, structure, motility, RNA processing, transport and traffic, angiogenesis and DNA and protein repair. A subset of these 100 genes have been screened in unrelated types of high-grade tumor cell lines, derived from cancers of the prostate, bladder, kidney, lung, and breast as well as melanoma. Most of the genes tested were also highly expressed in these cell lines, indicating an existing common pathway(s) operating in most high-grade tumors. In order to elucidate the pathway link of our identified high-grade tumor associated factors, we have compared the gene expression levels in U87 GBM cell line treated with and without inhibitors for PI3 kinase (Ly294002), MEK1/2 (U0126), EGFR (AG1478), and IGFR (AG1024), respectively or combined. Among 26 genes screened, 16 genes are altered (2-10 fold changes) by at least one of these treatments. Based on the gene regulation profile, a pathologic network is proposed.

**Molecular analyses examining the consequences of reversible ERBB2-expression in breast carcinoma cells. C.**

*Spangenberg*<sup>1</sup>, *T. Trost*<sup>1</sup>, *E. Lausch*<sup>1</sup>, *S. Fees*<sup>1</sup>, *D. Prawitt*<sup>1</sup>, *J.G. Hengstler*<sup>2</sup>, *U. Sahin*<sup>3</sup>, *O. Türeci*<sup>3</sup>, *B. Zabel*<sup>1</sup>. 1) Children's Hospital, Univ Mainz, Germany; 2) Institute of Toxicology, Univ Mainz, Germany; 3) Department of Medicine III, Univ Mainz, Germany.

Members of the *EGFR* gene family encode type I receptor tyrosine kinases involved in the transmission of proliferative as well as differentiating signals in a variety of cells. The level of expression of the ERBB2 protooncogene is directly correlated with the prognosis of several human malignant neoplasias, like breast and ovarian carcinoma. Upregulation of ERBB2-expression which leads to aberrant signaling can frequently be attributed to genomic amplification of the *ERBB2*-locus on chromosome 17q21. A different mechanism known to cause inadequate ERBB2-activation is based on shedding large parts of the extracellular portion of the receptor. Both processes lead to ligand-independent activation of ERBB2 signaling cascades that ultimately result in the cellular changes associated with malignant transformation. To examine the cellular processes associated with ectopic ERBB2-signaling we reversibly overexpressed a mutant version of the ERBB2-protein (NeuNT; the homologous rat-protein constitutively activated by a point-mutation) in human MCF7 breast carcinoma cells using the Tetracycline regulatory system. NeuNT-expression resulted in prominent phenotypic alterations 16-48h after NeuNT-induction in several independent MCF7/Tet-NeuT clones. Initially, these morphologic changes resemble the epithel-to-mesenchyme transition that has been described for the process of carcinogenesis (cellular protrusions, spindle-morphology) whereas at later time points the cells flattened and displayed a "senescent" phenotype. When NeuNT was expressed transiently, complete reversibility of the phenotypic alterations could be observed. In order to correlate the phenotypic response with intracellular signaling pathways, inhibitors for different signal transduction cascades known to be engaged in ERBB2-signaling (PI3K/AKT, P42/P44 MAPK, JNK, P38 MAPK) were applied. Using this approach we could attribute the NeuNT-mediated phenotypic epithelial-mesenchymal transition of MCF7-cells to the activation of the p38 MAPK-pathway.

**Elucidation of ependymoma-associated oncogenic pathways by comparative SAGE analysis.** *B. Schmucker, H. Steinhart, H. Iro.* Molecular Genetics, Friedrich-Alexander-University of Erlangen-Nuremberg, Erlangen, Germany.

To gain insight into molecular basis of ependymomas, we first generated a SAGE library of normal hippocampus pooled of 19 Caucasians and then compared global gene expression profiles of 5 SAGE ependymoma libraries to control SAGE libraries from normal hippocampus and normal total brain. The sequence analysis of 16,605 tags of the hippocampus SAGE library revealed 9,829 unique transcripts corresponding to known genes, ESTs or novel transcripts. 4 of the top-10 transcripts representing the highest expression levels in hippocampus did not have any EST or GenBank entry. Comparison of the transcriptomes of the ependymomas to normal brain included more than 360,000 tags and provided a dataset of 40,387 transcripts including their abundance. To generate a profile of genes significantly overexpressed in ependymomas, the significance filter was set to  $p < 0.001$  and the expression factor to at least 4-fold in each of the ependymoma libraries. These very stringent criteria were fulfilled by 26 genes. Filamin A (overexpressed) is involved in the Rho pathway. It binds GTPases, including Rac1, cdc42, RhoA, and to the p21-activated kinase 1 (pak1). Pak1 is an effector of Rac/cdc42 implicated in proliferation and cell survival. Interestingly, pak1 was found to be significantly downregulated in ependymoma. pak1 was reported to phosphorylate histone H3 (here), which are linked to transcription activation. Filamin A participates in TNF- signal transduction by activation of the SAPK pathway and has a negative role in MAPK-mediated Elk-1 transcription in response to insulin by direct binding to the insulin receptor. We found alteration of the RAS/MAPK pathway further by: MAP2K1, MAP2K4, MAPKAPK3, MAPK8IP2. IGF signaling cascade may be involved in pathogenesis of ependymoma since: IGF2 splice form 1 and 2, SPARC, IGFBP-7. Mediators of the RAS/RHO pathway are dysregulated: MARCKS, calmodulin-3, S100-calcium binding protein-A10. So far, no data about pathways in ependymoma are available and strikingly, the identified signaling cascades are distinct from those of gliomas (p53-, RB-, PTEN-pathways and PDGF-, EGF- growth factor pathways).

**The regulatory role of THY-1 on other putative ovarian tumor suppressor genes (PTSG).** *N. Wang<sup>1</sup>, L. Li<sup>1</sup>, R. Miller<sup>2</sup>, J. Xu<sup>1</sup>, H. Abeysinghe<sup>1</sup>.* 1) Dept Pathology, Univ Rochester Sch Medicine, Rochester, NY; 2) Dept OB/GYN, Univ Rochester Sch Medicine, Rochester, NY.

We have previously reported that the introduction of chromosome 11 into ovarian cancer cell line, SKOV-3, leads to the suppression of tumorigenicity and the up-regulation of 7 chromosome 11 genes which include: CRYAB, LDHA, Thy-1, and Thy-1-co-transcribed genes and 4 non-chromosome 11 PTSG's: CAV1, HPAC3, IGFBP7, and SPARC. Also using transfection studies, we have demonstrated previously the tumor suppressing nature of Thy-1. In the present study, using cDNA microarray combined with RT-PCR, we demonstrated that by abolishing the Thy-1 expression in one of the non-tumorigenic clone 11(c)9-8 through the transfection of Thy-1 antisense results in a significant suppression of 4 putative tumor suppressor genes: CAV1, HAAC3, IGFBP7 and CDH6 as well as CRYAB and the THY-1-co-transcribed gene. In contrast, the expression of SPARC is not affected by the abolishing of THY-1 expression which indicates a SPARC regulating gene, not Thy-1, is located on chromosome 11. In conclusion, our data suggests the crucial role of Thy-1 in ovarian tumor suppression through its regulatory effect on other putative tumor suppressor genes.

**Molecular Genetic Profiling of Normal Prostate, Benign Prostatic Hyperplasia, Dysplasia, Gleason Grade 3 and 4/5 Prostate Cancer.** Z. Zhang<sup>1</sup>, M. Mahadevappa<sup>1</sup>, MC. Caldwell<sup>2</sup>, Z. Chen<sup>2</sup>, Z. Fan<sup>2</sup>, JE. McNeal<sup>2</sup>, R. Nolley<sup>2</sup>, TA. Stamey<sup>2</sup>, JA. Palma<sup>1</sup>, WA. Warrington<sup>1</sup>. 1) Clinical Applications R&D, Affymetrix Inc., Santa Clara, CA.95051; 2) Department of Urology, Stanford University School of Medicine, Stanford, CA 94305.

Prostate cancer (PC) is one of the most common causes of cancer death among American men and is by far the most prevalent of all human malignancies with the exception of skin cancer. Serum prostate-specific antigen (PSA) between 2-10 ng/ml has been widely used in the U.S. as a marker for PC, but in this range serum PSA is largely related to benign prostatic hyperplasia (BPH), and correlates poorly with PC curative outcome. In this study we compared gene expression activity in the normal prostate, BPH, dysplasia of prostate and prostate cancer in an attempt to better understand the etiology of PC and to aid in the development of new PC serum markers and/or an array-based diagnostic. More than 80 labeled targets from prostate central zone (CZ), BPH, dysplasia, Gleason grade 3 (GG3) and Gleason grade 4/5 (GG4/5) were hybridized to high-density oligo nucleotide microarrays containing probes representing ~22,000 full-length human genes. Using a number of analysis methods, genes differentially expressed between tissues were identified and functionally annotated. Clustering using differentially expressed candidates grouped the samples distinctly. A minimal set of genes was identified for class prediction. A number of candidates were validated by QRT-PCR. The candidates include genes previously associated with PC, including racemase, as well as genes associated with oncogenesis, transcription, signal transduction and apoptosis. New candidates involved in pathways of interest were identified and will be discussed.

**Caspase 8 is Associated with Granules in Normal but not Malignant Prostate Tissue as Detected by Tissue Microarray Analysis.** *Y. Elshimali, S. Hanna, B. Bonavida, D. Chia, D. Seligson, L. Goodglick.* Department of Pathology and laboratory Medicine, and Human Genetics. David Geffen School of Medicine, UCLA. Los Angeles, CA 90095.

Caspase 8 is a cysteine protease which is important in the initiation and execution of receptor-triggered apoptosis. Caspase 8 is synthesized in an inactive, pro-protein form. However, upon induction of the apoptotic pathway, caspase 8, along with caspase 10, are recruited to the death-induced signaling complex where upon both proteins are cleaved to form active effector enzymes. Because of the central role of this and other caspases in apoptosis signaling, we have started to explore the expression of these proteins in various malignancies using tissue microarray analysis. We hypothesized that malignancies would be dysfunctional in one or more steps of the apoptotic pathway. A prostate tissue microarray was constructed consisting of 1364 tissue cores representing 246 patients. The microarray was stained with an anti-caspase 8 Ab and scored based on signal intensity, percentage of cellular staining, and intracellular localization. Both malignant and benign glandular cells demonstrated cytoplasmic caspase 8 staining. Interestingly, caspase 8 also was associated with relatively large (~0.1-3.0um) intracellular granular complexes seen in both basal and epithelial cells, predominantly in the normal cells. We have started to examine the nature of these granules, and their correlative and/or functional relationship to malignancy. First, we observed that most other proteins examined, did not colocalize to these granules. Second, granular caspase 8 staining did not co-localize with CD59 nor PSA, thus suggesting that caspase 8 was not present in the 'prostosome granules' or the prostate secretory granules (PSG), respectively. Third, caspase 8 was associated with similar granule structures in normal colonic epithelium. In conclusion, our results suggest a unique granule-association of caspase 8 in epithelium undergoing normal cellular turnover. That the granule-associated caspase 8 is decreased in prostate cancer epithelium is an intriguing observation which is currently being studied in our laboratory.

Program Nr: 505 from 2003 ASHG Annual Meeting

**A survey of receptor tyrosine kinases FLT3, c-KIT, and CSF1R polymorphisms in AML patients.** *A.A. Chen, C.M. Sullivan, N. Iartchouk, A. Parker, N.A. Giese, N.A. Lokker.* Millennium Pharmaceuticals, Cambridge, MA.

Mutations in FLT3 (fms-related tyrosine kinase, a type III receptor tyrosine kinase) have been associated with acute myeloid leukemia (AML). Specifically, an internal tandem duplication (ITD) in the juxtamembrane region, seen in 21-40% of AML patients, has been shown to constitutively activate this receptor and to associate with poor prognosis. We have sequenced DNA from the bone marrow of 18 patients to determine if there exist additional mutations in FLT3 that are predictive of prognosis. We additionally sequenced two related receptor tyrosine kinases, KIT (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) and CSF1R (colony stimulating factor 1 receptor) to determine if there are additional activating mutations present in these genes, both of which are thought to play a role in AML. The FLT3 ITD mutation was the only non-synonymous mutation found in FLT3. There was one non-synonymous mutation found in each of the other two genes, KIT and CSF1R. Additionally, three patients appear to exhibit loss of heterozygosity at the FLT3 locus. Our data indicate polymorphisms in the FLT3, KIT, and CSF1R genes in AML blast cells, which may have utility as biomarkers for response to tyrosine kinase inhibitors.

**Polymorphisms in CYP3A5 may not be associated with levels of tamoxifen and its metabolites in breast cancer patients.** *A. Deigert, L. Lewis, K. Tkaczuk, J. Flaws.* Univ Maryland, Baltimore, MD.

Tamoxifen (TAM) is a widely used antiestrogen in women with breast cancer and in women at high risk of developing breast cancer. TAM is metabolized by the cytochrome P450 (CYP450) family of enzymes into two major metabolites, 4-hydroxytamoxifen (4-OHT) and N-desmethyltamoxifen (N-DMT). Recent studies show that CYP3A5 is a major enzyme involved in the metabolism of TAM. Although this enzyme has been shown to have two polymorphisms (CYP3A5\*3 and CYP3A5\*6), the impacts of the polymorphisms on TAM metabolism are not known. We hypothesized that polymorphic status in CYP3A5 affects the rate of metabolism of TAM to 4-OHT and N-DMT. To test this hypothesis, we recruited 63 women with breast cancer from a single clinic at the University of Maryland who had been taking TAM for at least 30 days. A survey was completed by each patient to obtain information on age, race, potential confounding factors, and adverse side effects. Blood samples were obtained from each patient and were subjected to genomic DNA extraction followed by polymerase chain reaction for CYP3A5\*3 and CYP3A5\*6. The associations between polymorphic status and TAM, 4-OHT and N-DMT levels were assessed using t-tests and logistic regression models. Our data indicate that 40.7% of the women had the CYP3A5\*3 polymorphism and 9.1% had the CYP3A5\*6 polymorphism. Our data also show that Caucasian women are 2.5 times more likely to carry the CYP3A5\*3 polymorphism than African-American women. The CYP3A5\*6 polymorphism was seen only in African-American patients. No significant differences were seen in TAM, N-DMT and 4-OHT levels by polymorphic status. For example, levels of TAM were 68.79.3ng/ml in women without CYP3A5\*3, and 73.14.7ng/ml in women with CYP3A5\*3. Levels of N-DMT were 117.429.2ng/ml in women without CYP3A5\*3, and 110.811.7ng/ml in women with CYP3A5\*3. These data suggest that two known polymorphisms in CYP3A5 (CYP3A5\*3 and CYP3A5\*6) are not associated with levels of TAM or its metabolites. However, there may be a racial distribution of CYP3A5\*3 and CYP3A5\*6 among breast cancer patients. Supported by DOD grant DAMD 17-00-1-0321 and the University of Maryland, Maryland Statewide Health Network.

**CHEK2:1100delC mutation and elevated breast cancer risk.** *L.H.M. Pereira<sup>1</sup>, A.J. Sigurdson<sup>2</sup>, M.M. Doody<sup>2</sup>, M.A. Pineda<sup>1</sup>, B.H. Alexander<sup>4</sup>, M.H. Greene<sup>3</sup>, J.P. Struewing<sup>1</sup>.* 1) Laboratory of Population Genetics; 2) Radiation Epidemiology Branch; 3) Clinical Genetics Branch, DHHS/NIH/NCI, Bethesda, MD; 4) Division of Environmental and Occupational Health, University of Minnesota, Minneapolis, MN.

The 1100delC mutation in *CHEK2*, a cell cycle checkpoint gene, was initially identified as a rare cause of Li-Fraumeni Syndrome. It has been associated with familial breast cancer, predominantly among European subjects, being present in 1 - 1.5% of controls, ~ 2% of unselected breast cancer cases, and in 3 - 5% of familial breast cancer patients. We evaluated this mutation in 2 settings: a nested breast cancer case-control study within a prospective cohort study of U.S. radiologic technologists, and in 21 probands from *BRCA1/2* mutation-negative breast/ovarian cancer families (mean of 4 cases per family). Case-control subjects included 829 prevalent breast cancer cases and 859 controls without breast cancer, frequency matched on age. The mutation was detected using a Taqman 5'-nuclease assay, and confirmed by dHPLC. The mutation was present in 9 (1.1%) cases and 4 controls (0.5%). Using logistic regression analysis, the unadjusted odds ratio was 2.3 (95% C.L. 0.7 8, P=0.16), and was unchanged after adjustment for other risk factors. The small number of carriers precluded occupational radiation risk analyses stratified on mutation status. Mutations were more common in breast cancer cases diagnosed with a second primary other than breast cancer (2.6%) and when diagnosed before age 41 (2.5%). Cases with an affected first degree relative were only slightly more likely to be mutation positive (1.2%) while controls were more than three times as likely to be positive (1.6%). Two of 21 (9.5%) probands were positive (1 proband had breast, ovarian, and thyroid primaries), and 3 of 3 affected sisters with DNA available from the families were also positive, although a daughter with osteosarcoma tested negative for the mutation. Our results suggest that the *CHEK2:1100delC* mutation may be a risk factor for both sporadic and familial breast cancer in the U.S. population. Because of its low frequency, even if it is causal, the attributable fraction of breast cancer due to the mutation is only approximately 0.6%.

**Allele frequencies of single nucleotide polymorphisms (SNPs) in 38 candidate genes for gene-environment studies on cancer: data from population-based Japanese random samples.** *K. Yoshimura*<sup>1</sup>, *T. Hanaoka*<sup>2</sup>, *S. Ohnami*<sup>3</sup>, *S. Ohnami*<sup>3</sup>, *T. Kohno*<sup>4</sup>, *Y. Liu*<sup>1</sup>, *T. Yoshida*<sup>3</sup>, *H. Sakamoto*<sup>3</sup>, *S. Tsugane*<sup>2</sup>. 1) Cancer Information and Epidemiology Division; 2) Epidemiology and Biostatistics Division; 3) Genetics Division; 4) Genetics Division, National Cancer Center Research Institute, Tokyo, JAPAN.

Knowledge of genetic polymorphisms in gene-environment studies may contribute to more accurate identification of avoidable risks, and to developing tailor-made preventative measures. The aim of this study is to describe the allele frequencies of single nucleotide polymorphisms (SNPs) of select genes, which may be included in future gene-environment studies on cancer in Japan. SNP typing was performed on middle-aged Japanese male subjects randomly selected from the general population in five areas of Japan. We genotyped and calculated allele frequencies of 152 SNPs located on 38 genes: CYP1A1, CYP1B1, CYP2C19, CYP2E1, CYP17, AHR, ESR1, ESR2, ERRRG, PGR, EPHX1, EPHX2, HSD17B2, HSD17B3, GSTM2, GSTM3, GSTT2, GSTP1, NAT1, NAT2, COMT, ADH1A, ADH1B, ADH1C, ALDH2, NOS2A, NOS3, IL1A, IL1B, OGG1, NUDT1 (MTH1), DRD2, DRD3, DRD4, SLC6A4, NR3C1 (GCCR), MTHFR, and NQO1. In the present study, the Japanese allele frequencies were verified by using nation-wide population samples.

**Identification of sequence variants in the 17-hydroxysteroid dehydrogenase type 2 gene in French-Canadian high-risk breast cancer families.** *M. Plourde<sup>1</sup>, C. Manhes<sup>1</sup>, G. Leblanc<sup>1</sup>, F. Durocher<sup>1</sup>, M. Dumont<sup>1</sup>, INHERIT BRCA<sub>s</sub> collaborators<sup>1</sup>, J. Simard<sup>1,2</sup>.* 1) Cancer Genomics Laboratory and; 2) Cancer Research Chair in Oncogenetics, CHUL Research Center, CHUQ, Laval University, Quebec, Quebec, Canada.

The 17-hydroxysteroid dehydrogenase (17-HSD) type 2 enzyme is the key enzyme in the inactivation of active estrogens and androgens. Experiments have well documented the important contribution of estrogen in breast cancer etiology. This study was designed to identify sequence variants in the *HSD17B2* gene and in order to verify their potential association with an elevated risk of breast cancer and/or modify the impact of *BRCA1/2* mutations. Then, the nucleotidic sequence of exons, intron-exon boundaries and the 5 and 3 non-coding regions of *HSD17B2* gene have been analysed among 63 breast cancer French-Canadian cases having strong family history of breast cancer. Twenty-six among them are carriers of a mutation in *BRCA1/2* gene. In the coding regions, three variants lead to a single amino acid substitution : Ala111Asp, Gly160Arg, Leu204Phe and three other are silent sequence variants : 318CT, 390GA, 936GA, all have been found in one individual. Moreover, we have also found six variants in the non-coding regions which are in strong linkage disequilibrium (D : 0.76 to 1) : -1287CG, -1047GC, -525TC, -400TC, -132CT, IVS6-57CG, with respective allele frequency of : 0.8%, 1.3%, 2.5%, 1.1%, 32.2%, 32.5%. There is also a CA repeat, designated -328(CA)<sub>4-9</sub>. By *in vitro* expression, the kinetic properties of the Gly160Arg mutant enzyme was similar to the wild-type enzyme, Leu204Phe mutant caused a partial loss of activity, whereas the mutant carrying Ala111Asp exhibit no detectable activity. In contrast to the Gly160Arg and Leu204Phe mutant proteins, no protein product could be detected by immunoblot analysis in cell extracts transfected with the Ala111Asp mutant vector. It is important to note that both Leu204Phe and Ala111Asp were not segregating with breast cancer, and the Leu204Phe mutation have been found in a *BRCA2* positive family, thus not supporting their potential association with breast cancer risk.

**Inducible Gene Expression Models for MEN2A and MEN 2B forms of RET.** *J.L.V. Shaw, S.D. Andrew, D.S. Richardson, S.M. Myers, J.L. Yome, L.M. Mulligan.* Pathology, Queen's University, Kingston, ON, Canada.

*RET* is a proto-oncogene, encoding a receptor tyrosine kinase with three C-terminal variants, RET 9, RET 43, and RET 51, each with its own unique carboxy-terminus, allowing for potentially distinct signaling properties. Germline mutations of *RET* are implicated in the cancer syndrome, Multiple Endocrine Neoplasia type 2 (MEN 2), which has two main subtypes, MEN 2A, and MEN 2B. Mutations in the extracellular domain of *RET*, usually involving cysteine residues, cause MEN 2A. A single point mutation in the tyrosine kinase domain of *RET*, causes MEN 2B, a more aggressive form of the disease. MEN 2A and MEN 2B mutations both result in altered *RET* activation, albeit by different mechanisms, which are not completely understood. In order to characterize these differences in MEN 2A and MEN 2B forms of all three *RET* isoforms, we have developed a two tiered, inducible model for *RET* expression. The first tier of control is transcription based, in which expression of the *RET* gene is controlled using a tetracycline inducible system. The second tier of the system allows for control of *RET* protein dimerization and subsequent phosphorylation and activation. We have created human embryonic kidney HEK derived 293 cells, which stably express these *RET* proteins upon induction. We have used this model to confirm the abilities of the induced proteins to bind several PTB domain containing, adaptor proteins, such as SHC and DOK1, which are known to bind to *RET*, by immunoprecipitation and GST pull down experiments. We are currently using these cell lines to evaluate differences in functions and interactions of the three *RET* isoforms, and the impact on these, of the MEN 2A and MEN 2B mutations. Our model represents a valuable tool to evaluate the underlying molecular events responsible for the genotype-phenotype correlations in the MEN 2A and MEN 2B forms of *RET*, in each of the *RET* isoforms.

**Increased genetic instability near rare HRAS1 minisatellite alleles in murine embryonic stem (ES) cells. G.**

Zhang, M. Isomura, A. Franck, G. Larson, L. Hsu, S. Ding, T. Krontiris. Dept Molecular Medicine, City Hope Beckman Res Inst, Duarte, CA.

Rare alleles of the HRAS1 minisatellite have been linked to a 2-fold increase in cancer risk. To examine potential pathogenic effects of rare alleles, we analyzed instability of human minisatellites in mouse ES cells. Targeting by homologous recombination, we placed three minisatellites the common progenitor, a1, and two rare alleles one repeat unit (a0.29) and two repeat units (a0.28) shorter than a1 downstream of the murine homologue, hras1. Heterozygotes were obtained by double targeting. Resulting clones were then subcloned under various conditions and genotyped to determine minisatellite allele status. No allele change was observed in a1(-neo)/wt, a0.29(-neo)/wt and a0.28(+neo)/wt ES cells. However, allele loss was observed in a1/a0.29(+neo) or a1/a0.28 (+neo) ES cells, which shown 16/96 a0.28 and 5/96 a0.29 alleles lost. In contrast, a1(+neo)/a0.29 ES cells didn't show any allele loss. In summary, hemizygous alleles were stable, regardless of the presence or absence of a neo gene in cis and regardless of mutation-inducing treatment such as irradiation or heat shock. When heterozygotes were examined, a very high rate of allele loss (7-17%) was observed. In every instance (21/21) the rare allele was lost. If the neo gene was instead on the progenitor a1 allele, the genotype remained stable. Selection with G418 also maintained the parental clone genotype. We concluded that the a0.28 and a0.29 alleles destabilized nearby regions if these regions had some nonhomologous sequences. Allele loss required the presence of a minisatellite on the homologue, implicating perhaps a recombinational intermediate. Possible implications for carcinogenesis will be discussed.

**Collagen type I gene mutations of alpha 1 chain (Col1A1) in Czech patients with Osteogenesis Imperfecta**

**Syndrome.** *O. Marikova*<sup>1, 2, 3</sup>, *I. Mazura*<sup>1, 3</sup>, *I. Marik*<sup>2</sup>, *D. Zemkova*<sup>2, 4</sup>, *M. Kuklik*<sup>2, 4</sup>, *S. Mazurova*<sup>1, 3</sup>, *D. Leznarova*<sup>5</sup>, *P. Capek*<sup>1, 3</sup>. 1) Anthropology and Human Genetics, Faculty of Science, Charles University, Prague 2, Czech Republic; 2) Ambulant Centre for Defects of Locomotor Apparatus, Prague, Czech Republic; 3) EuroMISE Cardio, Prague, Czech Republic; 4) 2nd Paed. Dept., University Hospital Motol, Charles University, Prague; 5) Institute of Forensic Medicine, Brno, Czech Republic.

The Ambulant Centre for Defects of Locomotor Apparatus is one of the places in Czech Republic where patients with various bone dysplasias are centralized. The authors would like to share more than 10 years experience with comprehensive treatment of severe cases of osteogenesis imperfecta (caused by mutations of genes coding chains of collagen type I on the chromosomes 7 (Col1A2) and 17 (Col1A1)). A group of 50 living patients with osteogenesis imperfecta syndrome (OI) is followed up in this centre. DNA bank (since 1998) contains 35 isolated DNA samples from patients with OI type IA, IB, III and IVB according to Sillence classification. Sequencing analysis was done in 23 samples for exons 17, 27, 30, 31 of COL1A1 gene and their side introns in our pilot molecular genetic study. Mutations were found in 14 patients of the studied group (10 females, 4 males). Most common were substitutions in exons, substitutions in introns No. 26 and 27 were on the second place. In one case was discovered insertion of 4 nucleotides in exon 30. We can't include mutations in other exons and introns. The molecular genetic results were confronted to clinical and anthropometric findings. We verify that more mutations in one genotype area in one patient are not in correlation with clinical severity of the disease. We didn't find any characteristics between compared patients with the same mutation. We share the idea of G. Cetta (Italy) that other genes, besides collagen genes, could interact the collagen production and become responsible for the severity of the outcome. DNA analysis of col1A1 gene exons is going on. Supported by grant of The Ministry of Education of Czech Republic EuroMISE - Cardio No. LN00B107.

**GLUTEN AND DAIRY RESTRICTED DIETS ALTER PLASMA AMINO ACIDS AND NEUROTRANSMITTER PRECURSORS IN AUTISM.** *G.L. Arnold, S.L. Hyman, L. Delucia, R.A. Mooney.*  
Department of Pediatrics and Pathology, University of Rochester School Medicine and Dentistry, Rochester, NY.

One popular alternative therapy for autism spectrum disorders (ASD) is the gluten-free/casein-free (GF/CF) diet, a regimen that eliminates milk and most grain products. It is hypothesized that natural opiate-like peptides found in these foods alter behavior in children predisposed to autism. Appropriately designed studies have not been published to confirm this hypothesis or demonstrate efficacy or long term nutritional safety of the diet. Prior pilot data have suggested that this diet might affect neurotransmitter precursors (of interest since altered tryptophan metabolism has been implicated in symptoms of ASD) or result in essential amino acid deficiencies. We studied 96 children aged 17 mos to 10 yrs diagnosed with ASD. Essential amino acids and the ratio of tryptophan to the sum of the other large neutral amino acids (tryp/LNAA - a measure of serotonin precursor availability) were reviewed. There were no significant differences between the control group of children (who had developmental delay without ASD) and the children with ASD on regular diets in essential amino acids. However, children on the GF/CF diet had significantly lower levels of isoleucine and leucine ( $p < 0.04$ ). There was also no significant difference in plasma alanine between the control group and the children with autism. The tryp/LNAA ratio was similar in controls and children with ASD on regular diets (0.11 and 0.12, respectively), but was significantly lower in the children with ASD on the GF/CF diet (0.096,  $p < 0.009$ ). The amino acid levels raise concern about the long term nutritional impact of the diet as practiced. The altered tryp/LNAA ratio merits further study in relation to how diet may alter neurochemistry and behavior or brain development in these children.

**A novel Frataxin mutation and unusual heterozygote expansion associated with a very late onset of FA. D.**  
*McDaniel, C. Woodley, L. Langford, S. Subromany.* Dept Surgery/Neurology, Univ Mississippi Medical Ctr, Jackson, MS.

Great majorities(98%) of patients with Friedreich's ataxia (FA) are homozygous for GAA repeat expansion in the first intron of the frataxin gene. The expansion is associated with disease presentation and a decrease in frataxin expression. Patients with smaller expansions have a later onset and lower rates of disease presentation. The remaining small population of FA patients are compound heterozygotes, with a GAA repeats on one allele and a point mutation on the other allele. Here we described a 51 year old male patient with clinical characteristics consistent with a very late onset of FA but with an unusual feature of heterozygote expansion of GAA repeats. The relationship of the expanded gene sequence to the severity of disease and age of onset presented here was not previously described. A Friedreich mutation analysis revealed normal allele with a GAA size of approximately 40 and the abnormal allele with an expansion size of approximately 800 repeats. CAG repeat sizes for SCA-1, -2, -3, -6, and 7 were normal. Sequence-based analysis of the frataxin gene found a single base substitution (A to G) on exon 4, causing a glutamine to arginine change at amino acid 148. Structurally, this change would result in the loss of a H-bond between the amide carbonyl of Gln148 in the beta-sheet spanning amino acids 142-148 and the backbone N of Gln153 in the beta-sheet from amino acid 153-158. The highly basic Arg would likely rotate away from Lys147, between Trp155 and into the protein surface. This would result in a looser structure and would add a positive charge in place of the neutral Gln. These changes may alter frataxin interactions with other proteins and diminish its role in Fe metabolism. In conclusion, it is not clear yet if substitution of arginine for glutamine would reduce the level of frataxin production. However, the confirmation of the FA gene mutation in this atypical case, broadens the clinical spectrum of FA and supports the use of molecular approaches for a definitive diagnosis and interpretation of unusual cases.

**Superficial Siderosis as a Cause for Progressive Late Onset Hearing.** *K.M. Dodson<sup>1</sup>, A. Sismanis<sup>1</sup>, W.E. Nance<sup>2</sup>.* 1) Otolaryngology, Virginia Commonwealth University, Richmond, VA; 2) Human Genetics, Virginia Commonwealth University, Richmond, VA.

Superficial siderosis is an important cause for progressive late onset hearing loss that is largely unrecognized by the genetics community. Hemosiderin deposition in the leptomeninges was first described as an incidental autopsy finding in 1908, but not until 1940 was its association with subarachnoid hemorrhage recognized, and subsequently confirmed by animal studies. The advent of T2 weighted MRI, which is sensitive to the paramagnetic properties of ferritin, has permitted the diagnosis in living patients by demonstration of the characteristic rim of hypointensity surrounding the brain stem and cerebellum. The 1st and 8th cranial nerves are especially vulnerable, because only short segments of these nerves are protected by a sheath of Schwann cells. Hearing loss is the most common clinical finding, along with anosmia, ataxia, pyramidal signs and dementia. Depending on the cause for the hemorrhage, focal neurologic signs including paralysis and seizures may be seen. Typically, a high frequency loss is noted initially, doubtless reflecting the tonotopic organization of axons within the 8th nerve. A remarkable feature of the syndrome is its long latent period. Our awareness of this condition was prompted by a 36 year old man with a 10 year history of progressive hearing loss who had a history of a craniotomy for a cerebellar cyst at four years of age with the subsequent development of radiologic findings of superficial siderosis. Isolated cases have been reported in patients with Marfan Syndrome and NF1, and multiple cases have been observed in families with cerebral cavernous malformation and hereditary transthyretin amyloidosis. Superficial siderosis should be considered as a pathogenic mechanism for any form of late onset progressive deafness especially those such as Alport, the Muckle Wells, Fehntner and Epstein Syndromes that can be plausibly linked to subarachnoid hemorrhage. Clearly, the deafness could be caused by genes that are not even expressed in the cochlea and would be missed by positional candidate screening strategies that rely exclusively on this property.

**Missense changes in USH1C in a Type 1 Usher patient?** *D.C. Blaydon<sup>1</sup>, B. Leroy<sup>2</sup>, S. Bhattacharya<sup>2</sup>, M. Bitner-Glindzicz<sup>1</sup>*. 1) Clinical and Molecular Genetics Unit, Institute of Child Health, London WC1N 1EH, UK; 2) Institute of Ophthalmology, London, EC1V 9EL, UK.

Usher syndrome type 1 is an autosomal recessive condition in which profound, congenital sensorineural deafness is found in association with vestibular hypofunction and childhood onset retinitis pigmentosa. The gene responsible for Usher type 1C, USH1C, encodes a protein containing three PDZ domains and mutations in this gene have also been shown to cause the nonsyndromic recessive deafness, DFNB18. There appears to be a genotype-phenotype correlation whereby frameshift, nonsense or splicing mutations in the 5' end of the gene give rise to Usher syndrome type 1C, while missense mutations affecting cochlea-specific exons and a splice site mutation leading to reduced levels of wild-type mRNA have been found in DFNB18 patients.

Here we report two sisters of Zulu Somalian descent diagnosed with Usher syndrome type 1 who have two novel missense changes in the USH1C gene. These changes are predicted to lead to conservative amino acid changes in the first and third PDZ domains of the USH1C protein, but they were not found in 100 normal controls. Haplotype analysis excluded linkage to CDH23 and PCDH15, the two genes in which mutations are the second most common cause of Usher type 1. However, linkage to both MYO7A, the gene responsible for 70% of Usher syndrome type 1 cases, and USH1C could not be excluded. Since the parents are dead, we explored a number of other strategies to try and determine whether the mutations in exon 5 and 18, 26.5kb apart in genomic DNA, were in cis or trans.

**WILDERVANCK SYNDROME . CLINICAL AND RADIOLOGICAL FINDING.** *M. Diaz-Garcia<sup>1</sup>, G. Garcia-Sanchez<sup>1</sup>, E. Martinez-Coria<sup>2</sup>, C.G. Santillan-Chapa<sup>3</sup>, C.F. Martinez-Cruz<sup>4</sup>, J. Moreno-Aguirre<sup>1</sup>.* 1) Depto. de Genetica.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion(CNR), Mexico, D.F; 2) Departamento de Tomografia.CNR; 3) Depto. de Rehabilitacion Pediatrica. CNR; 4) Servicio de Comunicacion Humana, Depto. de Seguimiento Pediatrico.Instituto Nacional de Perinatologia, Mexico, D.F.

The Wildervanck syndrome or Cervico-oculo-acoustic (COA) is a rare disorder characterized by a triad of features including congenital deafness (sensorineural, conductive, or mixed); fused cervical vertebrae (Klippel-Feil anomaly), and abducens palsy with retractio bulbi (Duane syndrome). Occasional abnormalities include mental retardation, occipital meningocele, pseudopapilledema, hydrocephalus, growth deficiency, cleft palate, ear abnormalities, cardiac defects, cervical ribs, absent kidney and cholelithiasis. This syndrome may be responsible for at least 1% of deafness among females, the deafness has been shown by radiologic studies to be due to a bony malformation of the inner ear and/or anomalies of the ossicular chain. The etiology is unknown. The disorder is limited, or almost completely limited, to females, raising the question of sex-linked dominance with lethality in the hemizygous male. An environmental etiology, due to a vascular disruption sequence during embryonic development, has been noted in Klippel-Feil, as in Moebius and Poland sequences. A combination of defects (Klippel-Feil and Moebius) could induce the more complex phenotype observed in COA syndrome. We present a 7-year-old male child with sporadic COA syndrome with right hemifacial microsomia, right microtia, low occipital hairline, limitation of ocular movement, abduction with retraction in both eyes (Duane type I), nystagmus, uvula bifida, submucous cleft palate, short neck, mirror movement of the upper extremities. Audiometry showed bilateral hearing impairment sensorineural profound. Ear CT scan, revealed a Mondini dysplasia. Radiography of the entire spine revealed a congenital fusion of C2 and C3 vertebrae, thoracic hemivertebrae, scoliosis, and spina bifida occulta (Klippel-Feil type III). MRI of cervical spine showed continuity of the vertebral body of C2 and C3.

**Palmoplantar hyperkeratosis with short stature, facial dysmorphism, and hypodontia: a case report.** *F. Castillo-Lorca<sup>1</sup>, G. Garcia-Sanchez<sup>1</sup>, M. Diaz-Garcia<sup>1</sup>, S.G. Juarez-Garcia<sup>1</sup>, C.F. Martinez-Cruz<sup>2</sup>, A.L. Torres-Rodriguez<sup>1</sup>.* 1) Departamento de Genetica, Instituto de la Comunicacion Humana, Centro Nacional de Rehabilitacion. Mexico, D.F; 2) Servicio de Comunicacion Humana, Departamento de Seguimiento Pediatrico, Instituto Nacional de Perinatologia. Mexico, D.F.

Seow in 1989 described 18 members of a family with a syndrome comprising palmoplantar hyperkeratosis, proportionate short stature, facial dysmorphism, clinodactyly, epilepsy, deafness, and hypodontia. This syndrome is inherited in an autosomal dominant manner with a high degree of penetrance but variable expressivity. This syndrome differs from the autosomal recessive types of palmoplantar hyperkeratosis such as Papillon-Lefevre syndrome which shows premature loss of both dentitions. It is also distinct from Unna-Thost syndrome in that it presents short stature, facial dysmorphism, and hypodontia. Seow suggest that these features found in the family that he studied may be a new syndrome. Case report: 23 years old female with moderate diffuse hyperkeratosis of the palms and soles, proportionate short stature, frontal bossing, ocular hypertelorism, clinodactyly of the fifth fingers, sensorineural bilateral hearing loss, and hypodontia. She has a family history of epilepsy and deafness. However she has not family history of the others features found by Seow.

**KEARNS-SAYRE SYNDROME.** *G. Garcia-Sanchez<sup>1</sup>, L.A. Ruano-Calderon<sup>2</sup>, C.F. Martinez-Cruz<sup>3</sup>, L. Hernandez-Gomez<sup>4</sup>, M. Diaz-Garcia<sup>1</sup>, A.L. Torres-Rodriguez<sup>1</sup>.* 1) Departamento de Genetica, Instituto de la Comunicacion-Centro Nacional de Rehabilitacion. Mexico, D.F; 2) Clinica de Enfermedades Neuromusculares.Instituto Nacional de Neurologia y Neurocirugia. Mexico, D.F; 3) Servicio de Comunicacion Humana, Departamento. de Seguimiento Pediatrico.Instituto Nacional de Perinatologia, Mexico, D.F; 4) Departamento de Audiologia.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion, Mexico, D.F.

Kearns-Sayre syndrome (KSS) is a mitochondrial rare disorder characterized by a triad of features including (1) onset in persons younger than 20 years; (2) chronic, progressive, external ophthalmoplegia; and (3) pigmentary degeneration of the retina. In addition, KSS may include cardiac conduction defects, cerebellar ataxia, and raised cerebrospinal fluid (CSF) Additional features associated with KSS may include myopathy, dystonia, endocrine abnormalities (eg, diabetes, growth retardation/short stature, hypoparathyroidism), bilateral sensorineural deafness, dementia, cataracts, and proximal renal tubular acidosis. Thus, KSS may affect many organ systems. KSS occurs secondary to deletions in mitochondrial DNA (mtDNA) that cause a particular phenotype. The gene in which deletions occur is identified as Online Mendelian Inheritance in Man number 530000. We describe a 27-year-old woman . She onset at 11-years-old with right ocular ptosis followed by right progressive external ophthalmoplegia. Muscular weakness. Onset at 26 years old. It has improved with Carnitina and Coenzina Q10 (CoQ10) administration. Progressive hearing loss onset at 24-years-old. At 27-year-old the audiogram shows sensorineural bilateral severe hearing loss and the ABR show bilateral no response at 100dB. Secondary amenorhea onset at 23 years old.It responding to hormonal administration. ECG at 26 year-old was referred as normal. Skeletal muscle biopsy shows ragged-red fibers.Squeletal muscular molecular test reported deletion in mitochondrial DNA (mtDNA).Pedigree. Her sister began at 19-years-old (2 months ago) with muscular weakness.

**WAARDENBURG SYNDROME. AUDIOMETRIC MANIFESTATIONS.** *L. Acosta-Ramos<sup>1</sup>, G. Garcia-Sanchez<sup>1</sup>, M. Diaz-Garcia<sup>1</sup>, C.F. Martinez-Cruz<sup>2</sup>, A.J. Moreno-Aguirre<sup>1</sup>, L. Hernandez-Gomez<sup>3</sup>.* 1) Departamento de Genetica.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion, Mexico, D.F; 2) Servicio de Comunicacin Humana, Departamento. de Seguimiento Pediatrico.Instituto Nacional de Perinatologia, Mexico, D.F; 3) Departamento de Audiologia.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion, Mexico, D.F.

Waardenburg syndrome (WS) is an inherited autosomal disorder. It was first described in 1951 as a new genetic entity characterized by: congenital sensorineural hearing loss, and pigmentary disturbances of the skin, hair and eyes. WS is classified as one of two types, according to the presence (type I) or absence (type II) of dystopia canthorum. La penetrance of the congenital hearing impairment (HI), the most significant clinical finding in patients with this syndrome, has been reported to 35 to 70%; in type I and 55 to 85%; in type II. When it occurs, the HI can be either complete or partial and bilateral or unilateral. Unilateral HL has been reported to be 4 to 13%;. Symmetrical HI 25%; of type I and 50%; of type II. A significant number of patients with WS have U-shaped audiograms. WS is inherited in dominant fashion. World-wide, approximately 1 in 42,000 infants is affected by WS. We studied 40 patients who had WS with HI, 14 male and 26 female. All of them were bigger than 3 years of age (mean 16 years). The patients were evaluated by conventional audiometric methods to determine the penetrance and the degree, type, symmetric, of HI. Ten (25%) of the patients had the type I of the syndrome and 30 (75%;) had type II. We found sensorineural profound HI in 90%; of type I and 83.3%; of type II. The symmetry was present in 60%; both type I and type II. The progression was only detected in one patient type II. Slowly descending configuration in 67.5%; for both types. Progression was only present in type II . Regarding the sex predominance the type I was only observed in the women. No significant statistical difference was found between patients type I and type II. We do not find significant statistical differences  $\chi^2=P>0.05$  in the audiometric manifestations between type I and type II of WS.

**JOHNSON McMILLIN SYNDROME: REPORT OF A NEW CASE.** *S.G. Juarez-Garcia<sup>1</sup>, G. Garcia-Sanchez<sup>1</sup>, M. Diaz-Garcia<sup>1</sup>, C.F. Martinez-Cruz<sup>2</sup>, L. Acosta-Ramos<sup>1</sup>.* 1) Departamento de Genetica, Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion. Mexico, D.F; 2) Departamento de Seguimiento Pediatrico, Servicio de Comunicacion Humana.Instituto Nacional de Perinatologia, Mexico, D.F.

Alternative titles; symbols: Johnson-McMillin syndrome. Alopecia-Anosmia-Deafness-Hypogonadism syndrome. AADH syndrome. In 1983, Johnson described a 'new' autosomal dominant neuroectodermal syndrome in which anosmia and hypogonadotropic hypogonadism were combined with conductive deafness, alopecia, and other anomalies. In 3 generations, 16 persons were affected. Deafness was associated with protruding ears, microtia, and/or atresia of the external auditory canal. Variable features included congenital heart defect, cleft palate, mild facial asymmetry, facial nerve palsy, mental retardation, multiple truncal cafe-au-lait spots, hypohidrosis, tendency to caries and growth retardation. Inherited in an autosomal dominant pattern and with variable expressivity. We present a new case of Johnson McMillin Syndrome in a 2-year-old child, Mexican, gestational product III, with widespread alopecia, asymmetric ears: left microtia-atresia aural and right prominent ear, facial asymmetry, and red stains, his mother thinks that the child has anosmia or hiposmia, mild dental caries. ABR performed at 18 months of age reported bilateral hearing loss.

**Okhiro Syndrome: clinical features ; two cases in a Mexican Family.** *A.J. Moreno-Aguirre<sup>1</sup>, G. Garcia -Sanchez<sup>1</sup>, M. Diaz-Garcia<sup>1</sup>, L. Acosta-Ramos<sup>1</sup>, F. Castillo-Lorca<sup>1</sup>, C.F. Martinez-Cruz<sup>2</sup>.* 1) Departamento de Genetica.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion, Mexico, D.F; 2) Servicio de Comunicacin Humana, Departamento. de Seguimiento Pediatrico.Instituto Nacional de Perinatologia, Mexico, D.F.

Okhiro syndrome is an autosomal dominant inherited disease. The main features consists of Duane anomaly, radial ray defects and deafness. Deafness is congenital and usually sensorineural , polydactyly , hemifacial microsomia with skin tags, cardiac defects, and Hirschsprung disease have also reported.. Less frecuently reported anomalies are cervical vertebral anomalies, spinal and other skeletal abnormalities, palatal clefts and renal anomalies. Case A: The female proband 4 years old is the first child of young parents. She was an under diagnosed cause of deafness and squint.She presented as a neonate with bilateral hypoplasia external ear, with absent both thumbs, hypoplasia right radial and thenar, ventricular septum defect and Hirshchsprung disease. She has presented chronic middle otitis, courses with asymetrical hearing impairment (mild left and severale right conductive hearing loss) and right Duanes anomaly type I.Case B. Female 27 years old, probands mother . She was opered of bilateral syndactyly and courses with Bilateral Duanes anomaly.Mother and daughter, both have 46,XX, karyotype and molecular biology test in process.Okhiro syndrome must be differentiated with acro-renal-ocular syndrome, Fanconi syndrome, Holt-Oram syndrome, Wildervanck syndrome, 22q partial duplication and 22q11.2 deletion syndrome.

**Correlations Between Otovestibular Findings and Family History in Mexican Otosclerotic Patients. L.**

*Hernandez-Gomez<sup>1</sup>, S.G. Juarez-Garcia<sup>2</sup>, G. Garcia-Sanchez<sup>2</sup>, C.F. Martinez-Cruz<sup>3</sup>, M. Diaz-Garcia<sup>1</sup>, D.O. Gomez-Torres<sup>4</sup>.* 1) Departamento de Audiologia.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion, Mexico, D.F; 2) Departamento de Genetica.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion, Mexico, D.F; 3) Servicio de Comunicacin Humana, Depto. de Seguimiento Pediatrico.Instituto Nacional de Perinatologia, Mexico, D.F; 4) Departamento de Investigacion.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion, Mexico, D.F.

Background: Otosclerosis due to abnormal bone homeostasis of the otic capsule is a frequent cause of hearing loss in adults. Usually , the hearing loss is conductive, resulting from fixation of the stapedial footplate. And additional type of sensorineural hearing loss may be caused by otosclerotic damage to the cochlea. The etiology of the disease is unknown , and both environmental and genetic factors have been implicated. Objective: The goals of this study were to assess the prevalence of sporadic and familial forms of otosclerosis in a population of otosclerotic patients and to compare the findings between groups.Study Design and Setting: This retrospective/prospective study was conducted in a single institution.Patients: This study included 32 patients with diagnosis for otosclerosis.Main Outcome Measures: Clinical data, including pure tone audiograms ,tympanogram vestibular tests, computed tomography, were available in all the patients with otesclerosis. A letter was mailed to 100 patients to invite them to come to our Genetics Department for the realization of the pedigree. Results: A family history of otosclerosis was found in 21.87% of the patients. The otovestibular findings no differed between patients with a sporadic form and those patients with a familial form of otosclerosis (  $X^2=p > 0.05$ ).Conclusion:The variable expresivity in the OTSC could be due to the time of evolution and /or genetic heterogeneity.

**Fraser's "Northamptonshire Syndrome" - a distinct entity which mimics Pendred syndrome.** *W. Reardon<sup>1</sup>, D. Stephens<sup>2</sup>*. 1) Dept Clin Gen, Ctr Medical Gen, Our Lady's Hosp Sick Children, Dublin, Ireland; 2) Welsh Hearing Institute, University Hospital of Wales, Heath Park, Cardiff CF4 4XN, Wales.

The association of deafness and goitre in any patient rightly prompts consideration of Pendred syndrome as the likely diagnosis. There are occasional exceptions among which is the little known condition first alluded to by Fraser in his PhD thesis as the "Northamptonshire family." Fraser presented details of a six generation family, several individuals manifesting deafness. Reanalysis of the pedigree presented by Fraser shows several differences from the classical Pendred situation - 1) goitre and deafness occurred both separately and together, 2) affected individuals are seen in successive generations, 3) deafness was not congenital, 4) audiogram characteristics show a uniform loss across all frequencies, contrasting with the mainly high frequency loss seen in most cases of Pendred syndrome, 5) perchlorate test was normal in the 3 cases tested. In the course of identifying patients with Pendred syndrome we encountered 2 further families who present features consistent with the description of Fraser's "Northamptonshire Family." These observations have led us to conclude that there is a distinct clinical entity, largely unrecognised, which masquerades as Pendred syndrome. Initial molecular studies confirm neither evidence of mutation at the PDS locus nor linkage to that region of chromosome 7.

**ALOPECIA AREATA AND TURNER SYNDROME: AN UNCOMMON ASSOCIATION.** *H. Turki<sup>1</sup>, N.B. Abdelmoula<sup>2</sup>, M.F. Portnoi<sup>3</sup>, A. Saad<sup>5</sup>, A. Amouri<sup>4</sup>, T. Rebai<sup>1</sup>.* 1) service de dermatologie, CHU H. Chaker, Sfax, Tunisia; 2) laboratoire d'histologie, facult de mdecine de sfax, Tunisia; 3) laboratoire de cytogntique, hopital saint-antoine paris, France; 4) laboratoire de cytogntique, institut pasteur de tunis, Tunisia; 5) laboratoire de cytogntique, CHU f. Hached sousse, Tunisia.

Alopecia areata (AA) is a common form of non-scarring alopecia that appears equally in males and females of any age, although children and adolescents are more commonly affected. The vast majority of patients with AA are in excellent health and have no associated clinical conditions but a number of diseases have been reported showing increased prevalence in conjunction with AA for a minority of people such as Down's syndrome. We describe a 10-year-old female who was referred for a cytogenetic analysis because she developed an alopecia universalis. She had been found to have a mosaic 45,X/46,X,+r. Molecular cytogenetic analysis using sex chromosome probes permitted to identify the very small ring as a ring X chromosome which was detected in 90% of cells and appeared to be formed almost totally of alphoid sequences with breakpoints in the juxtacentromeric region. Using XIST probe at Xq13.2 the r(X) does not include the XIST locus and therefore, may not be subject to X-inactivation. The simultaneous occurrence of alopecia areata and Turner's syndrome has been reported by 4 authors (see references). As Turner's syndrome are frequently associated with autoimmune diseases or with serological markers for autoimmune diseases, an autoimmune origin has been suggested for alopecia areata. But, this uncommon association may indicate some genetic relationship between the two entities. Hypothesis of "skin mosaicism" can be also suggested to explain the association of the two entities in our patient.

**Prenatal diagnosis of Smith-Lemli-Opitz syndrome by triple screen of maternal serum.** *B.S. Reddy<sup>1</sup>, S.S. Reddy<sup>2</sup>.*

1) Department of Genetics, St. Joseph Medical Clinic, Detroit, MI; 2) Department of Internal Medicine, St. Joseph Medical Clinic, Detroit, MI.

Smith-Lemli-Opitz (SLO) is an autosomal recessive disorder. It has been known a defect in cholesterol biosynthesis is probable cause of this syndrome. VT was a 36 year old G3P2, referred at 16.2 weeks gestation for possible risk of having a fetus with Down's syndrome. The triple screen revealed that MSAFP was 0.41 MOM; unconjugated estriol 0.40 MOM and HCG 0.32. The patient was referred for amniocentesis. Karyotype revealed 46,XY. Biochemical analysis of amniotic fluid revealed that 7-dehydrocholesterol was greatly elevated when compared to control. Suspicion of early IUGR led the perinatologist to suggest elective termination of pregnancy. VT consulted for genetic counselling and she was explained about the biochemical and sonographic evidence taht was suggestive of SLO. The patient elected for termination of prgnancy. Autopsy revealed dolichocephaly, ambiguous genitalia with micropenis, hypospadias. Partial syndactyly the third and fourth toes bilaterally. Internal examination revealed VSD, ASD and bilateral unilobular lungs. This report demonstrates the role and importance of triple screen of maternal serum in the detection of fetus at risk for SLO.

**Characterizing genetic disorders: NF1 as a model for distinguishing between features, consequences and complications.** *E. Pivnick*<sup>1</sup>, *V. Riccardi*<sup>2</sup>. 1) Dept Ped, Div Clinical Gen, Univ Tennessee, Memphis, TN; 2) The Neurofibromatosis Institute.

In depicting a disorder, all too often, the specification, feature, is used without qualification, often subsuming primary, secondary and tertiary elements as simply features. We report here a system that distinguishes features as primary elements, consequences as secondary elements, and complications as tertiary elements. We have reviewed the clinical and radiological data from over 1,200 patients in the combined Baylor NF Program and The Neurofibromatosis Institute databases to identify anatomic and functional characteristics of the disorder, NF1. For example, vertebral dysplasia is a feature of NF1, while dystrophic scoliosis is a consequence of the vertebral dysplasia and spinal cord compression is a complication of the scoliosis. Distinguishing between these three levels is critical for understanding pathogenesis and for devising treatment strategies. For example, is the treatment directed at the feature, the consequence or a complication? For each of the many anatomic and functional elements of NF1 we will provide a table showing assignments to the feature, consequence and complication levels of involvement. This same line of reasoning obviously relates to a wide variety of genetic disorders and its delineation for NF1 therefore has wide application.

**INHERITANCE AND OSSEOUS DAMAGE BETWEEN OSTEOGENESIS IMPERFECTA TYPE III AND OSTEOPETROSIS IN TWO MEXICAN FAMILIES.** *J.M.R. Aparicio<sup>1,5</sup>, C.O. Gil<sup>2,5</sup>, M.P. Barrientos<sup>3</sup>, W.B. San Martin<sup>2</sup>, M.V.C. Mendez<sup>2</sup>, E.M. Landini<sup>4</sup>, J.A.R. Cao<sup>4</sup>, M.A.J. Enciso<sup>5</sup>, E.M. Huitzil<sup>5</sup>, C.F. Salinas<sup>6</sup>.* 1) Genetics; 2) Estomatology; 3) Endocrinology; 4) Ortopedics, Hospital para el Nino Poblano, Mexico; 5) Estomatology, Benemerita Universidad de Puebla, Mexico; 6) Oral genetics, medical University South Carolina, Charleston, usa.

**INTRODUCTION.** Are osseous dysplasia with dental aberrations due to an alteration of the conjuntive tissue. **OSTEOPETROSIS:** It is a rare genetic disease with both inheritance patterns, dominant ( 1:20 000) and recessive ( 1:200 000), characterized mainly due to a deficient metabolic reabsorption into the bone and cartilage. In relation to sex predisposition is 1;1. In relation to this disease, a defect in the bone shape and a high fracture incidence has been observed. As clinical features short size, anemia, microcefaly, fontocraneal bone increase and exoftalmos has also been documented, slow dental eruption, malformation and a high caries incidence was observed. Infections in this patients may give rise to osteomelitis. **CLINICAL CASE.** It is a seven years old female patient with multiple bone fractures in both legs, short size, exoftalmos, frequent headaches. **OSTEOGENESIS IMPERFECTA:** It is also a rare genetic disease (1:40 000 nb) due to a bone alteration within the collagen tipe I metabolism. In relation to the disease bone fragility, blue escleras, hipoacusia, opalescents dental color and articular hyper flexibility, prognatism, slow dental eruption, pulpar obliteration has been described. Osteogenesis type III is associated to dentinogenesis imperfecta. **CLINICAL CASE.** It is an eight years old female patient diagnosed with OI III. caries. **DISCUSION.** It is nowadays possible to find a major variability type of aberrations or syndromes with craniofacial alterations in relation to genetics. It may be important then to consider it as one of the primary cause of estomatologic and ortpedic diseases. In this study bone dysplasia was considered the most important eiologic factors in both studied patients. However, although both osseous diseases in this study have multiple fractures, the bone damage was totally different if compared the fractures type.

**Risk factors in limb reduction defects.** *Y. Alembik, B. Dott, M.P. Roth, C. Stoll.* Dept Genetique Medicale, Hosp de Hautepierre, Strasbourg, France.

**Objectives :** The aim of this study was to describe the prevalence at birth of limb reduction defects (LRD) and to identify possible etiologic factors. **Material and Methods :** The LRD came from 293,923 consecutive births of known outcome registered in the registry of congenital malformations of Strasbourg for the period 1979 to 2000. Request information on the child, the pregnancy, the parents, and the family was obtained. For each case a control was studied. The LRD was localised and classified according to the EUROCAT guide for the description and classification of limb defect. **Results :** The prevalence of LRD was 9.9 per 10,000 (291 cases). Non isolated malformations were present in 52.8% of the cases, 19 fetuses with LRD had an abnormal karyotype and 35 had a recognisable syndrome, association or an unspecified malformation pattern. Antenatal ultrasound examination was able to detect 101 cases (34.7%). The proportion of males was 0.55. The most common malformations in the 51.2% of children who had at least one other anomaly than LRD were cardiac, digestive and renal anomalies. Weight, length, and head circumference (HC) at birth of infants with LRD were less than those of controls. The weight of placenta of infants with LRD was less than the weight of placenta of controls. Pregnancies with LRD were more often complicated by threatened abortion, oligohydramnios and polyhydramnios but there were no differences in parental characteristics. However mothers of children with LRD took more often medications during pregnancy than mothers of controls and parental consanguinity was higher in parents of infants with LRD than in controls. First degree relatives also had more non-limb malformations than did those of controls. **Conclusions :** Weight, length, HC and weight of placenta of infants with LRD were less than those of controls. Pregnancies of infants with LRD were more often complicated by threatened abortion, oligohydramnios and polyhydramnios. Mothers of children with LRD took more often medications during pregnancy than mothers of controls. Parental consanguinity was higher than in controls and first-degree relatives of cases had more non-limb malformations than controls.

Program Nr: 530 from 2003 ASHG Annual Meeting

**The Hemi-3 syndrome, another case report.** *W.M. Eyaid.* Pediatrics, king Fahad Hospital, Riyadh, central region, Saudi Arabia.

The hemi-3 syndrome is a developmental syndrome that consists of hemihypertrophy, hemihypereasthesia, hemiareflexia, and scoliosis. We report on a 16 years old girl who was born with meningomyelocele. Physical examination revealed left sided hemihypertrophy, loss of pain sensation, decreased deep tendon reflexes and scoliosis. she had chronic left foot ulcer because of repeated trauma. Also, she had chronic urinary tract infection and required extensive urological operations. Neurophysiological studies revealed abnormal sympathetic skin response on the left side, slow sensory and normal motor nerve conduction velocities. Also, she had increased sensory threshold for the left-sided extremities compared to the right. The hemi-3 syndrome should be looked for in patients presenting with hemi hypertrophy to avoid the complications resulting from loss of pain and temperature sensation as in our patient.

**Generalized osteopenia in Neurofibromatosis Type I patients points to an underlying disorder of skeletal homeostasis and mineralization.** *N. Brunetti-Pierri<sup>1</sup>, K. Phan<sup>1</sup>, S. Carter<sup>1,3</sup>, R.A. Lewis<sup>1,2</sup>, S. Plon<sup>1,4</sup>, K.J. Ellis<sup>5</sup>, S.E. O'Brian<sup>5</sup>, B. Lee<sup>1,3</sup>.* 1) Dept Genetics, Baylor College of Medicine, Houston, TX; 2) Dept Ophthalmology, Baylor College of Medicine, Houston, TX; 3) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX; 4) Dept Pediatrics, Baylor College of Medicine, Houston, TX; 5) Children's Nutrition Research Center, Baylor College of Medicine Houston, TX.

Neurofibromatosis type 1 (NF1) is the most common autosomal dominant human disorder. Skeletal complications include macrocephaly, scoliosis, pseudoarthrosis, and short stature. However, bone mass in NF1 children and adults has not been systematically investigated. In a prospective observational study of NF1 subjects, we measured bone mineral status by dual energy X-ray absorbiometry (DXA). The cohort included 27 males [age 3.1 to 39.1 yrs] and 46 females [age 2.8 to 58.9 yrs] seen in an NF clinic and unselected for skeletal problems. The mean lumbar bone mineral density z score and the whole body bone mineral content z score were both significantly reduced [-1.381.05 and -0.611.19 respectively] ( $p < .001$ ). In a subgroup of 16 osteoporotic and osteopenic subjects, we evaluated the mechanism of osteopenia/osteoporosis with intact parathyroid hormone (PTH), 25(OH)vitamin D, calcium, phosphate, alkaline phosphatase, and markers of bone turnover. All markers were within the normal range except PTH, which was significantly increased from age-matched controls (mean PTH 58.325.6 ng/l) in 9 subjects. In those subjects, after conventional therapy with calcium and vitamin D, PTH decreased into the normal range for age (30.422.6 ng/l). Our data imply that NF1 patients are at risk for previously unrecognized osteopenia and osteoporosis without evidence of dietary vitamin D deficiency. Metabolic parameters and the therapy response in a subgroup of severely affected subjects suggest the presence of secondary hyperparathyroidism, perhaps due to underlying osteomalacia. A generalized defect in osteoblast and/or osteoclast function may be present in NF1, and additional longitudinal studies will determine long-term health inferences of these findings in older NF1 individuals.

**A new syndrome with skeletal dysplasia and mental retardation in two sisters.** *D. Genevieve*<sup>1,2</sup>, *D. Heron*<sup>2</sup>, *M. Le Merrer*<sup>1</sup>, *A. Jacquette*<sup>2</sup>, *D. Sanlaville*<sup>1</sup>, *F. Pinton*<sup>3</sup>, *N. Villeneuve*<sup>3</sup>, *G. Khalifa*<sup>4</sup>, *A. Munnich*<sup>1</sup>, *V. Cormier-Daire*<sup>1</sup>. 1) Department de Genetique, Hopital Necker-Enfants Malades, Paris, France; 2) Departement de genetique, Hopital de la Pitie-Salpetriere, Paris, France; 3) Service de Neuropediatrie, Hopital Saint Vincent de Paul, Paris, France; 4) Service de Radiologie, Hopital Saint Vincent de Paul, Paris, France.

Spondyloepimetaphyseal dysplasias (SEMD) are an heterogeneous group of conditions comprising at least 14 entities defined by clinical and radiological features. Here, we report on a new form of SEMD with mental retardation (MR) in two Pakistani sisters born to first cousin parents. The clinical phenotype is characterized by MR, ataxia and facial dysmorphism including coarse face, low anterior and posterior hairline, brachycephaly, simple and flat ears, synophrys, bilateral epicanthal folds, broad nose, full lips with eversion of the lower lip, short neck, and hirsutism on back and legs. Skeletal findings include flat vertebral bodies with irregular vertebral plates, irregular and flared metaphyses with vertical striations, small and irregular epiphyses, small carpal bones and narrow iliac wings without lacy pelvis iliac crest. Mental retardation in association with SEMD is observed in lysosomal storage disorder and Dyggve-Melchior-Clausen (DMC) syndrome. Extensive blood and urine metabolic screening was normal. Moreover, molecular studies of the Dymeclin gene responsible for DMC are currently performed. This combination of features observed in two sisters does not correspond to any reported case of SEMD and represents therefore a new autosomal recessive form of SEMD with MR.

**Aspondylodysostosis : delineation of a probably recessive spinal dysostosis with absent ossification of all vertebral bodies.** *M. Gonzales<sup>1</sup>, A. Verloes<sup>2</sup>, N. Joyé<sup>3</sup>, J.L. Taillemite<sup>3</sup>, P. Maroteaux<sup>4</sup>.* 1) Fetal Pathology Unit, Hôpital Saint Antoine, Paris, France; 2) Clinical Genetic Unit and INSERM E9935, Hôpital Robert Debré, Paris; 3) Embryology & Cytogenetics dept, Hôpital Saint Antoine, Paris; 4) Genetic Department, Hôpital Necker-Enfants Malades, Paris.

We report here 4 patients from 3 families with a striking and easily recognizable spinal anomaly characterized by total absence of the vertebral bodies, for which we suggest the name aspondylodysostosis. The first two patients were sibs born to consanguineous Maghrebian parents. Pregnancy of patient 1, a girl, was terminated after prenatal diagnosis of MCA. She had short trunk, short and wide thorax, spina bifida, and nephroblastomatous kidneys. Her younger sib had the same physical appearance, large kidneys, but no NTD. X rays were identical in both: total absence of vertebral bodies and sacrum associated with anarchic position of the vertebral pedicles, reduced number of ribs, narrow pelvis, with an upward widening of the iliac wings and unusual tilt of the the ischiopubic rami explained by pelvic anteversion. Appendicular skeleton was normal, as was the shoulder girdle. Patient 3 and 4 come to the term and died soon afterwards of respiratory insufficiency. Both had a radiological pattern similar to the former cases. Moreover, patient 3 had a cleft palate and patient 4 hypoplastic nails. Macroscopic examination at necropsy of case 1 indicated that the spine was not missing but rather replaced by a dense structure. These 4 patients appear to show the same vertebral dysostosis. They share similarities with the "polytopic anomalies with agenesis of the lower vertebral column" recently reported by Bohring, but differs by the extend of the vertebral defect, which goes higher than the thoracolumbar junction, and may thus represent a new dysostosis with possible AR inheritance.

**Genetics and periodontal health study in a four Iranian consanguineous families with Papillon-Lefevre Syndrome, Mashhad, North East of Iran.** *K. Ghodsi<sup>1</sup>, S. Banihashem Rad<sup>2</sup>, M. Tamizy<sup>2</sup>, R. Akbarzadeh<sup>1</sup>, M. Gorji Nejad<sup>1</sup>, M. Radvar<sup>2</sup>, A. Lotf Azar<sup>3</sup>.* 1) Dept Medical Genetics, Mashhad Univ Medical Sch, Khorasan, Iran; 2) Department of Periodontology 2, Dental School; 3) Department of Periodontology3, Dental School, Shiraz University of Medical Sciences, Iran.

**Introduction:**Papillon-Lefevre Syndrome (PLS) is an autosomal recessive palmoplantar keratodermal disorder which is characterized by hyperkeratosis of the palms, soles and severe early onset periodontitis. The frequency of PLS is approximately 1 to 4 per million. Genetic basis for most PLS appears to be mutations affecting both alleles of the cathepsin C gene (CTSC), located on chromosome 11q14.**Materials and Methods:**All families' members were clinically examined. A diagnosis of PLS was made in subjects with severe early onset periodontitis and the clinical appearance of hyperkeratosis on the palmar and plantar surfaces. Pedigrees were drawn and peripheral blood samples were taken. Lymphocytes were cultured and cells were harvested. GTG bandings chromosomes were analyzed. **Results:**Five cases of PLS in four families with almost 200 individuals in three generation diagnosed who were between 4.5 and 12 years of age. Parents were consanguineous. The pathological findings involve severe inflammation and destruction of the gingival as well as hyperkeratosis of the skin from palmar, plantar, and knee sites. Periapical radiographs showing severe alveolar bone loss affecting erupting permanent teeth. Atrophic changes of the nails, and a radiographic deformity of the fingers. None of the members of this family showed evidence of other systemic disorders and no other abnormality was detected. Chromosomal analysis of peripheral blood was performed after high resolution banding showed an apparently normal. **Conclusion:**The most PLS patients in Iran are from Mashhad and Shiraz so joining projects to study clinic and genetics were planned. First cousin marriages may suggest recessive inheritance for PLS in these families. Although cytogenetics did show any chromosomal abnormalities, to study molecular genetics DNA from patients and families were extracted.

**Dominant distal arthrogryposis in a 2 generation family: clinical and genetic analysis.** *P. Bitoun*<sup>1</sup>, *E. Pipiras*<sup>2</sup>, *B. Benzacken*<sup>2</sup>, *J. Gaudelus*<sup>3</sup>. 1) Genet Medic, CHU Paris-Nord, Hosp Jean Verdier, Bondy, France; 2) Embryo-Cytogenetics and Reproductive Biology Dept; 3) Pediatrics Dept.

Arthrogryposis has been defined as limitation of joint motion of 2 or more joints and results from multiple causes from uterine mechanical constraint, oligohydramnios to iatrogenic, ligamentous, neurogenic atrophy or myopathic pathology. Dominant distal arthrogryposis has been reported in several families. We report a 2 generation family. Purpose: to describe and search for the genetic etiology of dominant distal arthrogryposis. Material and methods: Family with distal arthrogryposis was examined and photographs, radiographic studies and blood samples were taken for lymphoblastic cell lines and informed consent was granted for molecular genetic research. We present the case of a mother with congenital distal arthrogryposis with surgically corrected club feet, limited range of motion of hands (camptodactyly and ulnar deviation) and elbows, scoliosis, hypertelorism and short stature. She gave birth to 2 affected sons with normal intelligence who presented with oligohydramnios, club feet and club hands with clino and camptodactyly and hypertelorism. The 5 year old has had surgical correction for the club feet and the 1 year old is treated with strapping pending surgical correction. They both have hypertelorism but no scoliosis and are responding well to physical therapy. The more severe affection of the mother suggests dominant inheritance; there is no microstomia suggestive of Freeman-Sheldon syndrome. Results: We describe the clinical and radiologic phenotype of 3 affected members of a Dominant distal arthrogryposis family. Molecular analysis by Sung et al have recently identified genes encoding fast-twitch contractile proteins TNNI2 and TNNI3 involved with DA2B and TPM2 with DA1. Mutation analysis will be performed in this family to try to identify the genetic etiology.

**Spontaneous cerebrospinal fluid leaks: Part of the Marfan spectrum, or a new entity?** *O. Gordon*<sup>1</sup>, *J. Tourje*<sup>3</sup>, *W. Schievink*<sup>2</sup>. 1) GenRISK Program, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Maxine Dunitz Neurosurgical Insitute, Cedars-Sinai Medical center, Los Angeles, CA; 3) Imaging Medical Group, Cedars-Sinai Medical center, Los Angeles, CA.

Spontaneous spinal cerebrospinal fluid (CSF) leaks are the most common cause of spontaneous intracranial hypotension and postural headaches. The exact cause of spontaneous spinal CSF leaks is unknown, but a structural dural weakness predisposes to the formation of fragile menigeal diverticula or dural rents that allow CSF to leak out. Previous case reports and a retrospective study have found evidence for a systemic connective tissue disorder in some patients. We prospectively evaluated a group of patients with CSF leaks for evidence of a generalized connective tissue disorder. **Methods:** 18 consecutive patients referred for surgical repair of a spontaneous CSF leak were evaluated via comprehensive physical examination, echocardiography, skin biopsy and CT myelogram. **Results:** The mean age of the 15 women and 3 men was 38 years (22 to 55). Three patients demonstrated a Marfanoid habitus (height >95%, U/L ratio <.8, and arachnodactyly), and mild to moderate hypermobility. Imaging revealed no vertebral column deformities, dural ectasia or pulmonary blebs. All had multiple menigeal diverticula. None had myopia or lens dislocation, and echocardiogram was normal. Two patients had normal stature but marked hypermobility of large and small joints and were found to have markedly attenuated dorsal muscular fascia at the time of surgical repair, precluding proper wound closure. MRI revealed dural holes or rents. Echocardiography revealed mitral valve prolapse in one patient. Five patients had isolated moderate to marked small joint hypermobility, and the remaining six had no associated findings. **Conclusions:** Dural ectasia is a common and highly sensitive diagnostic finding in Marfan syndrome, but spontaneous CSF leaks have not been described. Our study reveals a broad spectrum of connective tissue abnormalities associated with the development of spontaneous CSF leaks. Further research is warranted to investigate possible fibrillin or collagen abnormalities in this group of patients.

**Achondroplasia-hypocondroplasia complex in a Mexican patient.** *A. Gonzalez-del Angel<sup>1</sup>, E. Spector<sup>2</sup>, MA. Alcantara<sup>1</sup>, V. del Castillo<sup>1</sup>.* 1) Departamento de Investigacion en Genetica Humana, Instituto Nacional de Pediatria, Mexico City, Mexico; 2) Department of Pediatrics, University of Colorado Health Sciences Center, USA.

Achondroplasia (ACH) is the most common short-limb skeletal dysplasia with an autosomal dominant inheritance. Most of the cases result from a de novo mutation in the fibroblast growth factor receptor 3 gene (FGFR3) that causes a substitution of an arginine for a glycine at position 380 (G380R/G1138A). The most frequent clinical manifestations are rhizomelic limb shortness, enlarged head with frontal bossing, midface hypoplasia, and short, broad hands with a trident configuration. Hypocondroplasia (HCH) is considered an allelic disease of ACH with a less severe phenotype. The mutation observed in about 70% of HCH patients is a transversion at nucleotide 1620 (C1620A or C1620G). The phenotype of patients with the achondroplasia-hypocondroplasia complex (ACH-HCH complex) is not well defined, because there are only three patients reported in the literature with a confirmed diagnosis by molecular studies. We report a Mexican patient whose mother has ACH and the father HCH, neither had genetic counseling or molecular testing prior to when the patient was born. The index case was studied at the National Institute of Pediatrics when he was 11 months of age, he had a phenotype of ACH patients but he also had important respiratory difficulties and he required surgical management due to an abnormal size and shape of the foramen magnum. He has been hospitalized 11 times due to bronchopneumonias and in one occasion he had a cardiac arrest. He is now 4 years old and has a severe developmental psychomotor delay. The clinical manifestations and the evolution of the patient suggest that he could have the ACH-HCH complex, and was confirmed by molecular studies that showed he is a compound heterozygous (G1138A/C1620G). The clinical evolution of the patient indicates that the phenotype of the ACH-HCH is more severe with important neurological and respiratory complications than observed in ACH or HCH patients.

Program Nr: 538 from 2003 ASHG Annual Meeting

**Wolcott-Rallison syndrome in a Bedouin boy: a brief clinical report.** *M.J. MARAFIE, A.R. Mary, R.L. Alnaggar.*  
Obstetric&Gynecology, Kuwait Medical Genetics Center, Kuwait.

We present a 7-year old Bedouin boy with short stature due to epiphyseo-metaphyseal dysplasia, infancy onset insulin-dependant diabetes mellitus, osteoporosis, recurrent hepatitis, seizures and developmental delay. He had additional manifestations such as microcephaly, mental retardation, hypothyroidism and skin/teeth changes. His karyotype was 46,XY. The clinical and radiological findings are consistent with the autosomal recessive mode of inheritance. This syndrome might be underestimated in the population of Arab peninsula, possibly due to early death of diabetic infants and the late expression of the full clinical picture.

**Comparison of Height and Thoracic Circumference Measurements of 20 Spondylothoracic Dysplasia Patients with the General Population.** *J.M. Massanet<sup>1</sup>, S.E. Carlo<sup>1</sup>, N. Ramirez<sup>2</sup>, A.A. Reis<sup>1</sup>, H. Rivera<sup>1</sup>, J.R. Acevedo<sup>3</sup>, V. Franceschini<sup>1</sup>, A.S. Cornier<sup>1</sup>.* 1) Genetic Division, Ponce School of Medicine, Ponce, PR; 2) Department of Orthopedics, Mayaguez Medical Center, Mayaguez, PR; 3) Dept. of Nursing, Univ. of PR at Arecibo, Arecibo, PR.

Spondylothoracic dysplasia (STD; MIM#277300) is a genetic disorder with autosomal recessive inheritance. Findings include segmentation and formation defects throughout cervical, thoracic and lumbar spine such as hemivertebrae, block vertebrae, and unsegmented bars with fusion of all the ribs at the costo-vertebral junction (crab-like chest configuration). We have followed 20 patients, of which 11 were male and 9 were females, ranging from 1 day to 13 years old, in our genetics clinic. We measured the thoracic circumference and the height, later correlating the values with their percentiles for the respective ages. Both the average chest circumference and the average height were lower than the general population with values in the 30.85th and 2.33th percentiles respectively for the entire group. These values were statistically significant with a p value of 0.008 for chest circumference and 0.001 for the height. The average female measurements were the 33.89th percentile for the chest circumference Vs 28.36th percentile for males, and 3.11th percentile for height Vs 1.27th percentile for males. These results show that these patients are well below the average height for their age. Their chest circumference measurements were also below average. However, it falls within less than one standard deviation below the general populations mean, whereas the height percentile falls more than 2 standard deviations below the general populations mean. This leads us to conclude that the chest circumference is less affected than the height in this syndrome, and that clinically the patients appear to have a large chest circumference for their height.

**A novel missense mutation in the FGFR3 gene causing hypochondroplasia.** *S. Heuertz<sup>1</sup>, M. Le Merrer<sup>1</sup>, V. Cormier-Daire<sup>1</sup>, L. Legeai-Mallet<sup>1</sup>, E. Flori<sup>2</sup>, A. Munnich<sup>1</sup>, J. Bonaventure<sup>1</sup>.* 1) Medical Genetics, INSERM U 393, Paris, France; 2) CHU Strasbourg, Hopital Hautepierre, 67098 Strasbourg cedex.

Hypochondroplasia (HCH) belongs to a clinical spectrum of skeletal dysplasias comprising HCH, achondroplasia (ACH), Severe Achondroplasia with Developmental Delay and Acanthosis Nigricans (SADDAN) and thanatophoric dysplasia (TD). All these dysplasias are accounted for by recurrent missense mutations in the FGFR3 gene. While FGFR3 mutations are routinely identified in more than 98% of ACH and TD patients, this percentage is much lower in the case of HCH owing to the difficulty to accurately diagnose this condition. Screening a large series of HCH patients including 65 sporadic cases and 18 familial forms for FGFR3 mutations, we identified the most common N540K mutation in 47 patients (57%). One patient carried the K650Q mutation in the tyrosine kinase 2 (TK2) domain of the receptor and a novel V381E mutation in the transmembrane domain was identified in one case. Interestingly, this mutation is adjacent to the G380R achondroplasia mutation and equivalent to the V644E mutation that occurs in the transmembrane part of the tyrosine kinase receptor Neu, causing its constitutive activation into an oncogene. Clinically, the V381E substitution was associated with a relatively mild phenotype characterized by normal size (52 cm) at birth and an absence of macrocephaly. Later on, statural retardation was moderate (-1.5 SD). Radiographs at eight years showed mild flaring of the metaphyses and slightly reduced interpedicular distances between lumbar vertebrae whereas phalanxes had a normal size. Since the K650Q mutation was also associated with a moderate phenotype, we suggest that HCH mutations outside the TK1 domain could result in milder phenotypes than the N540K mutation. This work was supported by the European Skeletal Dysplasia Network (ESDN).

**Agenesis of the parietal bones: Cleidocranial dysplasia or unique skeletal dysplasia.** A. Hing<sup>1</sup>, K. Leppig<sup>2</sup>, M. Seto<sup>1</sup>, M. Cunningham<sup>1</sup>. 1) Division of Genetics and Development, Univ Washington, Seattle, WA; 2) Genetic Services, Group Health Cooperative, Seattle, WA.

Congenital defects in cranial ossification can be observed in metabolic bone disease, parietal foramina permanga, and skeletal dysplasias such as Cleidocranial dysplasia. Congenital absence of the parietal bones is a rare anomaly that can be seen in isolation or in association with multiple birth defects or generalized bone dysplasia. We present clinical, radiographic, and molecular findings in a male child born with agenesis of the parietal bones and progressive skeletal deformity. The proband was delivered by Cesarean section due to fetal distress at term to a healthy female. Pregnancy was complicated by in utero demise of a twin fetus at 8-10 weeks gestation. At birth he was noted to have absence of skull bone by palpation. Radiographs showed minimal frontal and occipital bone ossification, normal clavicles, and undermineralization of the pubic symphysis. Laboratory studies showed normal calcium and thyroid studies with transient low alkaline phosphatase. A high-resolution CT scan at two months of age showed complete absence of the parietal bones with abnormal occipital bone formation. CT images at 8 months of life showed symmetric islands of parietal bone formation, multiple small ossific island of occipital bone formation, and absent nasal bones. Repeat alkaline phosphatase levels were elevated. Clinical examination was significant for progressive hypertelorism and chest wall deformity with increased anterior-posterior dimension. Linear growth and neurologic development were normal. Chest radiograph showed poorly mineralized bones with broad ribs. Family history was notable for short stature and a late-closing anterior fontanelle in the father and other paternal relatives. We present serial radiographic evidence of a skeletal dysplasia and progressive symmetric membranous bone ossification in a child born with complete agenesis of the parietal bones. We compare radiograph findings in this child with those seen in individuals with Cleidocranial dysplasia and parietal foramina permanga, and discuss results of *Msx2*, *Alx4*, and *Cbfa1* mutational analysis.

**Clinical Genetic, Radiological, & Molecular Analysis of Congenital Scoliosis and Kyphosis.** *M.K. Maisenbacher*<sup>1</sup>, *J.-S. Han*<sup>1</sup>, *E.H. Zackai*<sup>1,3</sup>, *J.P. Dormans*<sup>2,4</sup>, *B. Erol*<sup>2</sup>, *M.R. Tracy*<sup>1,2</sup>, *P.D. Turnpenny*<sup>5</sup>, *K. Kusumi*<sup>1,2,3,4</sup>. 1) Div Hum Genet & Mol Biol; 2) Div Orthop Surg, Children's Hosp of Philadelphia, PA; 3) Dept Ped; 4) Dept Orthop Surg, Univ of Penn School of Med, Philadelphia, PA; 5) Royal Devon & Exeter Hosp, Exeter, UK.

Congenital vertebral malformations occur in the context of genetic syndromes such as VATER association and Goldenhar syndrome, as well as non-syndromic congenital scoliosis and kyphosis. The genetic etiology of congenital scoliosis is largely unknown. Recently, mutations in the notch ligand *DLL3* have been identified in the vertebral disorder, spondylocostal dysostosis, and studies in the mouse have identified that notch pathway disruptions lead to vertebral defects.

To identify diagnostic subgroups, we analyzed radiological, clinical genetic, and molecular data from 74 infants and children with congenital vertebral malformations, divided into 32 syndromic (including VATER, Goldenhar) and 42 nonsyndromic (congenital scoliosis and kyphosis) cases. Radiologically, cases were analyzed by the extent of segmental defect, into vertebral dysostosis type 1 (global), type 2 (multiple vertebrae affected in 1 region), and type 3 (single). In 8 syndromic cases, we identified 6 type 2 (75%) and 2 type 3 (25%) defects. In 29 non-syndromic cases, we identified 17 type 2 (59%) and 12 type 3 (41%) defects. Clinical genetic analysis of the 42 nonsyndromic congenital scoliosis patients identified a high rate of nonskeletal associations, including genitourinary (14%), cardiovascular (10%), and neurological (17%) systems.

Molecular sequence analysis of notch pathway genes was carried out for 18 syndromic patients, and sequence polymorphisms were identified: *DLL3* (8 cases with synonymous and 4 with amino acid changes), and *HES7* (8 cases with synonymous changes). Molecular analysis of 27 nonsyndromic patients identified polymorphisms: *DLL3* (13 cases with synonymous and 4 with amino acid changes), and *HES7* (5 cases with synonymous and 1 with amino acid changes). Comparison with the general population and identification of multiplex families is underway, to elucidate the significance of these findings.

**Bone dysplasias in spontaneous abortions: Thanatophoric Dysplasia (TD) with unusual anomalies.** *V. Moran<sup>1</sup>, I. Garcia Pelaez<sup>1, 2, 4</sup>, C. Ortiz<sup>1, 3</sup>, H. Perez<sup>1, 2</sup>, O. Aguirre<sup>2</sup>, L.R. Cornejo-Roldan<sup>2</sup>, D. Saavedra<sup>2</sup>, M. Arteaga<sup>1, 2, 4</sup>.* 1) School of Medicine, Univ Panamericana, Mexico City, Mexico; 2) Hospital Infantil de Mexico; 3) Hospital ABC; 4) Faculty of Medicine, National Autonomous University of Mexico.

**INTRODUCTION:** Bone dysplasias have wide phenotypic expression that complicates its diagnosis specially in embryos and fetuses as some times few cases have been reported and some may be lethal varieties not usually seen. We present the case of a fetus with a probable TD with unusual anomalies. **CASE DESCRIPTION:** The fetus was product of the 5th gestation of young, non-related parents. The mother suffered previously from diabetes mellitus and hypertension and had vaginal and urinary infections during the pregnancy; while pregnant, she took prescribed drugs for chronicle and acute illnesses. The 2 previous pregnancies ended in spontaneous abortions. Pregnancy weeks are unknown, the last menstrual period date coincided with the last abortion, the mother was seen in consultation 6 months after it. The case was a male, 14 wks of gestational age by measures, with macrocephaly, turri-dolicocephaly, left ablepharon, right eyelid coloboma, anteverted nostrils, mild syndactyly, hypoplastic pelvis and legs, a discrete outlined sacral tail and hypertrophic left parotide region. Karyotype analysis was not available. The radiology showed a turri-dolicocephaly skull, abnormal ribs and severely bowed femura. Necropsy showed a liquid collection in parotid region, hypoplastic aortic arch, thymus hypoplasia, ectopic left kidney and Meckel diverticulum. The femur histology showed an irregular growth plate, big transversal blood vessels, fibrous ring and clusters of osteoblast without bone matrix formation. **DISCUSSION.** The diagnosis considered was a bone dysplasia probably of a TD type I but this case shows other characteristics not usually seen. The bone histology is shared with other bone dysplasias, and there is also a lethal variety of achondroplasia with thymus hypoplasia and bowing of the femura, however our case has also other anomalies. We consider that the mother illnesses or the drugs treatment do not support a teratogenic effect.

**BLAU SYNDROME AND THE COMPLEXITIES OF PROPER DIAGNOSIS AND TREATMENT.** *S. Kleppe*<sup>1</sup>, *D. Metry*<sup>2</sup>, *C. Bacino*<sup>1</sup>. 1) Dept Genetics, Baylor Col Medicine, Houston, TX; 2) Dept dermatology, Baylor Col Medicine, Houston, TX.

Blau syndrome is an autosomal dominant condition characterized by multi-systemic non-caseating granulomatous inflammation. Clinically Blau syndrome is manifested by arthritis, uveitis and a maculo-erythematous skin rash. This disorder can be easily confused with sarcoidosis or juvenile reumathoid arthritis (JRA). Blau syndrome is caused by mutations in the NOD2/CARD15 gene (caspase recruitment domain containing protein 15) that has recently been mapped to 16q12. Blau syndrome is a rare disorder and to this date there are very few reported families with Blau syndrome. Because of that, very little is known about treatment approaches to this disease. We report a mother with her two sons affected with Blau syndrome that were mis-diagnosed and treated for JRA with steroids and methotrexate with no response to the treatment and multiple adverse reactions to the drugs used. On further evaluation, a skin biopsy done in one of the affected children showed non-caseating granulomatous lesions. The possible diagnosis of sarcoidosis was raised, but could not be proved due to unknown etiology and the absence of a specific diagnostic test. Given the clinical presentation Blau syndrome was suspected and mutation analysis of the NOD2/CARD15 gene was undertaken. Mutaton studies showed a previously reported Arg334Gln heterozygous missense mutation in the centrally located nucleotide-binding domain, where most of the Blau syndrome mutations where found in the past. In contrast with CARD15 alleles associated with Crohn disease that affect the leucine rich domain (LRR) that interacts with bacterial peptidoglycan (PGN) to form the inflammatory granulomas, alleles associated with Blau syndrome promote PGN-independent Nuclear factor Kappa B (NFkB) activation, a finding that explains the affected organs in each condition. Tumor Necrosing Factor (TNF)-alpha is a direct regulator of NFkB. The treatment with Etanercept, a TNF antagonist, showed immediate relief of multiple symptoms in the affected individuals. This case illustrates the importance about knowing the gene defect and its function to tailor an appropriate treatment.

**Multiple exostoses, mental retardation, dysmorphic facies in a girl with no detectable mutation in**

**EXT1,EXT2,and TRPS1.** A. Shanske<sup>1</sup>, H.-J. Ludecke<sup>2</sup>. 1) Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY; 2) Institut für Humangenetik, Universitätsklinikum, Essen,Germany.

Multiple exostoses is a genetically heterogeneous disorder. *EXT1* on 8q24.1 and *EXT2* on 11p11-12, have been identified and a third locus, *EXT3*, has been assigned to 19p. Multiple exostoses are also observed in two contiguous disorders: the Langer-Giedion syndrome or TRPS II caused by the simultaneous deletion of the *EXT1* and *TRPS1* genes and the proximal 11p deletion syndrome (P11pDS) associated with the deletion of *EXT2* and *ALX4*. Here we report on a 10 and 2/12 year old girl with multiple exostoses, mild mental retardation and dysmorphic features. She was the 2.7 kg product of a term uneventful pregnancy. Her height, weight and head circumference were all 2-4 SD's beneath the mean. She had brachycephaly and a low anterior hair-line, thick brows with a synophrys and a bulbous nasal tip. The eyes were deep-set and the ears were large. She had a slight levoscoliosis, winging of the right scapula and hyperextensibility of all small and large joints. She had syndactyly of the 3rd and 4th fingers of both hands and the 2nd and 3rd toes bilaterally and brachydactyly of both 5th metacarpals. The bone age was greatly delayed between 6 and 7 SD's below the mean and cone-shaped epiphyses were present at multiple sites, predominantly in the middle phalanges. She had multiple exostoses of both humeri, left femoral neck and the left scapula. High resolution karyotyping revealed normal chromosomes and in situ hybridization showed ish 8q24.1(*EXT1*x2,*TRPS1*x2), 11p11.2(*EXT2*x2), and the patient was heterozygous for three *TRPS1* intragenic polymorphisms. These results exclude the deletions typically found in TRPS II or P11pDS. We could not detect any mutation by sequencing the entire *TRPS1* protein coding region. Because the patient's appearance resembles neither the TRPS nor the P11pDS closely, we must consider several alternative etiologies: 1) one mutation in one of the EXT genes and one mutation in the promoter or non-coding region of *TRPS1*, or in an unknown gene that results in a TRPS-like phenotype. 2) an undetectable paracentric inversion of 8q24 effecting *EXT1* and *TRPS1*. 3) a contiguous gene syndrome involving *EXT3* on 19p.

**Chondrodysplasia punctata and maternal autoimmune disease: a new case and review of the literature.** *N. Shur, R. Marion, C. Vega-Rich, A. Shanske.* Center for Congenital Disorders, Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, New York.

Chondrodysplasia punctata (CDP) is a rare but well-known skeletal abnormality characterized by irregular punctate calcifications. It is seen in a heterogeneous group of disorders including disorders of cholesterol or plasmalogen metabolism. It is also seen following maternal exposure to warfarin, dilantin, phenytoin, and alcohol as well as in rubella embryopathy and deficiency of vitamin K. There have been three previous reports of a direct association with a maternal autoimmune disease. We report a new case and review the literature. A male infant was the second child born of healthy unrelated parents. There was a history of 3 spontaneous abortions at 4 months gestation and he was delivered by SVD after a 36 week gestation with a birthweight of 2176 gm and length of 42 cm and HC of 33 cm. He had midfacial hypoplasia, an upward obliquity of the palpebral fissures, and bilateral epicanthal folds. There were no skin lesions. He had rhizomelic shortening of the arms and legs and brachydactyly of the fingers. A skeletal survey demonstrated stippling of all of the vertebrae, carpal bones, phalanges, knees, hips and tarsal bones. Biochemical studies revealed no abnormalities associated with CDP with normal plasmalogen, 8(9)cholestenol, and very long chain fatty acid levels. When last seen at 22 months, he was in good health and demonstrating mild developmental delays. However, his mother was noted to have a butterfly rash and dermatitis of the dorsum of both hands. Serologic investigation and dermatopathology were consistent with discoid lupus erythematosus. The 3 previous reports described either stillborns or a newborn with features of neonatal lupus all born to mothers with SLE. Further investigation of the mother may give further insights into this unusual pathogenetic mechanism of CDP.

**Differences of Anthropomorphic Measurements in the Survival Probability of 20 Patients with Spondylothoracic Dysplasia.** *A.A. Reis<sup>1</sup>, J.M. Massanet<sup>1</sup>, S.E. Carlo<sup>1</sup>, N. Ramirez<sup>2</sup>, V. Franceschini<sup>1</sup>, H. Rivera<sup>1</sup>, J. Acevedo<sup>1</sup>, A.S. Cornier<sup>1</sup>.* 1) Genetic Division, Ponce School of Medicine, Ponce, PR; 2) Department of Orthopedics, Mayaguez Medical Center, Mayaguez, PR.

Spondylothoracic dysplasia (STD; MIM#277300) is a pleiotropic genetic disorder with autosomal recessive inheritance. Findings include segmentation defects throughout cervical, thoracic and lumbar spine such as hemivertebrae, block vertebrae, and unsegmented bars with fusion of all the ribs at the costo-vertebral junction (crab-like chest configuration). It was generally regarded as a lethal condition in the neonatal period. However, we have followed 20 patients from birth, of which 8 died within the first 6 months of life. This group consisted of 5 males and 3 females, with an average age of death of 58 days. The group that survived consisted of 6 males and 6 females, ranging from 6 months to 13 years old, and with an average age of 5 years old. We measured the thoracic circumference at the nipple level and the height, later correlating the values with their percentiles for the respective ages, which is available in the literature for children up to 14 years old. Both the average chest circumference and the average height were lower than the general population with values in the 30.85th and 2.33th percentiles respectively. These values were statistically significant with a p value of 0.008 for chest circumference and 0.001 for the height. The average measurements for the group that did not survive were the 35.38th percentile for the chest circumference Vs 28.83th percentile for survivors, and 1.13th percentile for height Vs 2.75th percentile for survivors. These differences were not statistically significant (p value of 0.539 for chest circumference and 0.209 for the height), probably due to the small size of our sample. This data demonstrate that the non-survivor group was more disproportionate with a shorter height and a larger chest circumference. The shorter height does not allow for diaphragmatic descent, which may be compensated by a increase in the thoracic circumference. However, the fusion of the ribs may not permit a sufficient chest expansion to be compatible with survival.

**Sequential Pulmonary Function Tests in 5 Spondylothoracic Dysplasia Patients.** *N. Ramirez<sup>1</sup>, J.R. Acevedo<sup>3</sup>, S.E. Carlo<sup>2</sup>, J.M. Massanet<sup>2</sup>, A.A. Reis<sup>2</sup>, H. Rivera<sup>2</sup>, V. Franceschini<sup>2</sup>, A.S. Cornier<sup>2</sup>.* 1) Departemtn of Orthopedics, Mayaguez Medical Center, Mayaguez, PR; 2) Division of Genetics, Ponce School of Medicine, Ponce, PR; 3) Dept. of Nursing, Univ of PR at Arecibo, Arecibo, PR.

Spondylothoracic dysplasia (STD; MIM#277300) is a rare autosomal recessive pleotropic disorder with high prevalence in the Puerto Rican population. Typical findings include segmentation and formation defects throughout cervical, thoracic and lumbar spine such as hemivertebrae, block vertebrae, and unsegmented bars with fusion of all the ribs at the costo-vertebral junction (crab-like chest configuration). It was generally regarded as a lethal condition in the neonatal period due to pneumonia and respiratory failure. Pulmonary hypertension has been documented as well in some patients with STD. We have followed 5 patients, of which 2 was male and 3 were females, ranging from 10 to 22 years old, in our genetics clinic. Pulmonary function tests were performed by a respiratory care technician and supervised by a respiratory medicine specialist and repeated after an interval of 2 to 3 years. The pulmonary function tests showed a severe restrictive pattern with an average FEV1/FVC ratio of 0.98 and 0.90, for the first and second measurements respectively. The average first measurements were: FVC: 23.72 %, FEV1: 26.09 %, PEF: 36.33 %, and the average for the second measurements were: FVC: 27.65 %, FEV1: 28.92 %, PEF: 48.28 %, of the predicted values for the group. Even tough these values tend to be slightly higher in the second series, statistical analysis has not shown the differences to be significant (p values of 0.452 for FVC, 0.618 for FEV1, and 0.351 for PEF). There appears to be some improvement in the pulmonary function of these patients with a decrease in the FEV1/FVC ratio and increased FVC, FEV1, and PEF. Even though these results are not statistically significant, this is probably due to the small sample. However, individually these patients pulmonary function either improved or remained clinically stable as they grew older.

**Long survival in a case of opsismodysplasia.** *P. Strisciuglio<sup>1</sup>, G. Scarano<sup>2</sup>, G.R. Vega<sup>1</sup>, G. Muzzi<sup>1</sup>, M.T. Moricca<sup>1</sup>, R. De Marco<sup>1</sup>, D. Concolino<sup>1</sup>.* 1) Dept Pediatrics, Univ Catanzaro, Catanzaro, Italy; 2) Med. Genet.Division, Hospital of Benevento, Italy.

Opsismodysplasia is a rare chondrodysplasia, first described in 1977 by Zonana et al and designated opsismodysplasia only in 1984 by Maroteaux. This disorder is characterised clinically by micromelia with extremely short hands and feet. Respiratory distress is responsible for death in the first years of life. The main radiological features include severe platyspondyly, delayed skeletal ossification, and metaphyseal cupping. The inheritance seems to be autosomal recessive. We describe the first Italian case of opsismodysplasia with pulmonary hypoplasia and a long survival. S.S. female, at the age of 3 years and 3 months, presented recurrent respiratory infections, and low disharmonic stature. Her weight was of Kg 11,800 (< 5 Centile), the length of 79 cm (<< 5 Centile) , and cranial circumference of 47.3 cm (< 5 Centile). Other important features included large anterior fontanel, short nose with depressed nasal bridge and short hands and feet, coxa vara and metaphyseal cupping of the knees. Molecular analysis of FGFR3 gene did not show mutations in 7,9,10,13, 15 and 19 exons. Until now in literature 13 patients have been described: two of them showed pulmonary hypoplasia and died during the first years of life for respiratory insufficiency. Our patient also has a pulmonary hypoplasia, but he is still in good conditions at the age of 3 years and 7 months. We report this patient with a rare disease, suggesting to take in account the diagnosis of opsismodysplasia in all patients with achondroplasia-like signs and negative molecular analysis and recurrent respiratory infections. Finally the diagnosis of opsismodysplasia is also important for genetic counselling because this syndrome is inherited with autosomal recessive mechanism.

**Hypochondroplasia: Clinical and FGFR3 gene mutation analysis in an Indian pedigree.** *V.K Patel<sup>1</sup>, R. Meda<sup>1</sup>, M.R. Memon<sup>2</sup>, J.V. Solanki<sup>3</sup>, U. Ratnamala<sup>1</sup>, U. Radhakrishna<sup>1</sup>.* 1) RIA Laboratory, Green Cross Voluntary Blood Bank & Genetic centre; 2) Department of Zoology, Gujarat University, Ahmedabad; 3) Department of Animal Genetics & Breeding, Veterinary college, Gujarat Agriculture University, Anand, India.

Hypochondroplasia (HCH; OMIM 146000) in humans is an autosomal dominant skeletal dysplasia characterized by short stature, micromelia, lumbar lordosis, short and broad bones. The skeletal features of hypochondroplasia are similar to that of achondroplasia but milder, and these phenotypes are considered to be allelic. The gene responsible for HCH has been mapped to chromosome 4p16.3 and mutations in the fibroblast growth factor receptor 3 (FGFR3) gene have been identified in patients with the disorder (Nat Genet. 1995 10:357-9). Over 95% of reported cases are accounted by a single Gly380Arg mutation. Some reports suggested HCH is clinically and genetically heterogeneous (J. Med. Genet. 33: 749-752, 1996; J. Med. Genet. 32: 492-493, 1995). We studied a large family from the Western part of India with HCH. The pedigree consists of 42 individuals including 9 affecteds. Clinical findings were recorded for all affecteds and radiographic findings were analyzed in selected individuals. Short stature, micromelia, macrocephaly, short hands and small fingers, shortening of the long bones characterize the phenotype in this family. Genomic DNAs of two affecteds and one normal individual were screened for mutations in the coding region of FGFR3. No mutation was found. Thus this study supports previous data suggesting that HCH be genetically heterogeneous. Systematic genome-wide linkage analyses, using HCH families that are excluded FGFR3 gene mutations may reveal different chromosomal loci for the phenotype. Email: u\_c\_rao@hotmail.com.

**Anatomical and functional brain imaging evidence of lenticulo-insular anomalies in Smith Magenis syndrome.** *N. Boddaert*<sup>1, 2</sup>, *M. Zilbovicius*<sup>2</sup>, *A. Munnich*<sup>3</sup>, *F. Brunelle*<sup>1</sup>, *H. De Leersnyder*<sup>3</sup>. 1) Dept Radiology, Hosp Necker, Paris, France; 2) ERM 0205 INSERM-CEA, Hosp Frederic Joliot, Orsay, France; 3) Dept Ped Genetics, Hosp Necker, Paris, France.

Smith Magenis syndrome (SMS) is a clinically recognizable contiguous gene syndrome ascribed to an interstitial deletion of chromosome 17p11.2. The neurobehavioral phenotype of SMS includes mental retardation, speech delay, hyperactivity, attention deficit, decreased sensitivity to pain, self-injury, aggressive behavior and sleep disturbance. This peculiar phenotype suggests that SMS could be associated with still unknown brain anomalies. Therefore, we performed anatomical and functional brain imaging studies in 5 SMS boys. Anatomical MRI were analyzed using optimized voxel-based morphometry. This method can detect structural anomalies not apparent on visual inspection of the scans. Two comparisons groups were studied: 12 age-matched healthy control children and 5 age-matched children with idiopathic mental retardation. In addition, positron emission tomography and water-labeled method were used to investigate a putative localized brain dysfunction in SMS. The same age-matched mental retarded children composed the control group. A significant bilateral decrease of grey matter concentration was detected in the insula and lenticular nucleus ( $p < 0.0001$ ,  $p < 0.05$  corrected height threshold,  $df = 15$ ) in SMS patients compared to normal children using MRI and optimized voxel-based morphometry. In addition, a significant hypoperfusion was found in the same regions ( $p < 0.001$ ,  $df = 9$ ) detected with PET in SMS patients compared to mentally retarded children. This anatomo-functional evidence of bilateral insulo-lenticular anomalies in SMS should be relevant to neurobehavioral symptoms. In fact, several lines of evidence support the involvement of insula in the complex processes associated with pain and thermosensory control and lenticular nucleus was shown to be involved in attention-deficit/hyperactivity disorder (ADHD). The identification of localized brain anomalies in SMS will hopefully help understanding how this well defined genetic entity can lead to a relatively specific severe neurobehavioral syndrome.

**A clinical study of Mast syndrome, an autosomal recessive form of hereditary spastic paraplegia with dementia.**

*A.H. Crosby<sup>1</sup>, C. Proukakis<sup>1</sup>, M. Simpson<sup>1</sup>, M.A. Patton<sup>1</sup>, H. Cross<sup>2</sup>.* 1) Dept Medical Genetics, St George's Hospital Med Sch, London, United Kingdom SW17 0RE; 2) Dept Ophthalmology, University of Arizona School of Medicine, 655 N. Alveron Way, Tuscon, USA.

Mast syndrome, originally described in 1967, is an autosomal recessive complicated form of hereditary spastic paraplegia (HSP) with dementia present at high frequency amongst the Old Order Amish. We have studied 14 affected individuals with ages ranging from 31 to 62, with a consequent great variation in disease severity. Milestones were sometimes delayed, and mild motor and learning difficulties were often noted in childhood. Several patients were married and had children. Decline in walking and mental function started in early adulthood, although age of onset was difficult to define. The volume of speech also declined and swallowing difficulties arose later. The condition was clearly progressive in all, leading to akinetic mutism in the most severe. Mini mental test scores ranged from 0 to 14. All had clear pyramidal signs which were much more severe in the lower limbs. Mild cerebellar abnormalities were seen, and the most advanced cases also had extrapyramidal movements. MRI scans in 3 patients revealed a thin corpus callosum, cerebral atrophy and white matter abnormalities. The Mast syndrome is thus an example of HSP associated with adult-onset dementia and a thin corpus callosum. Parallel genetic studies have led to the identification of a causative mutation in the polypeptide product of SPG21, designated maspardin (Mast syndrome, spastic paraplegia, autosomal recessive with dementia).

**Fetal brain malformation with pseudo-infectious features in three successive pregnancies.** *R.J.M. Gardner, S.M. White.* Genetic Health Services Victoria, Monash Medical Centre and Royal Children's Hospital, Melbourne, Australia.

Aicardi-Goutieres and Pseudo-TORCH syndromes are recessively inherited disorders of brain malformation in which the appearance somewhat resembles an intrauterine infection. We have seen a condition which may also warrant inclusion in this category, in which the brain malformation is more severe than with either of these two diagnoses. All three pregnancies (one female, two male) of a nonconsanguineous Anglo-Celtic couple were identified on ultrasonography with severe underdevelopment of the brain by 17-19 weeks (earlier scans having been apparently normal), with terminations done at 18-19 weeks. In the third pregnancy, fetal MRI demonstrated the anatomy of the defect with clarity at 19 weeks gestation. Pathology studies showed severe thinning of the parenchyma of the cerebral hemispheres (3-4 mm), and hypoplasia of the cerebellar hemispheres and deficiency of the vermis. On histology, severe cerebral leukomalacia, and multiple foci of calcification but without inflammatory infiltration, were noted. We propose that these cases represent a new recessively inherited syndrome of global brain maldevelopment with a pseudo-infectious histopathology.

**Familial isolated congenital anosmia with morphologically normal olfactory bulb in two unrelated Iranian families.** *M. Ghadami*<sup>1,4,5</sup>, *K. Majidzadeh-A*<sup>6</sup>, *K.S. Morovvati*<sup>6</sup>, *E. Damavandi*<sup>2</sup>, *G. Nishimura*<sup>3</sup>, *N. Niikawa*<sup>1,4</sup>, *K.I. Yoshiura*<sup>1,4</sup>, *Mohsen Ghadami*. 1) Dept Human Genetics, Nagasaki Univ Sch Med, Nagasaki, Japan; 2) Department of Cell Biology and Histology, Nagasaki University; 3) Tokyo Metropolitan Kiyose Children's Hospital; 4) Japan Science and Technology Corporation, Japan; 5) Department of Medical Genetics, Tehran University of Medical Sciences, Iran; 6) Jihad Research Center, Tehran University of Medical Sciences, Iran.

Congenital total loss of the sense of smell occurs as a part of a syndrome, e.g., Kallmann syndrome or an isolated form. Congenital isolated anosmia (MIM 107200) is very rare, and only a few families with the disease have been reported to date. It appears to be due to a change in the olfactory epithelium or aplasia of the olfactory nerve, bulb and tract. Here we report two unrelated Iranian families with isolated congenital anosmia. One family consisted of a total of 9 affected members, and the other family contained 3 affected members. Anosmia in each affected member was confirmed by clinical history, physical examinations and smell testing by intravenous injection of combined vitamins (Arinamin<sup>TM</sup>, Takeda Pharmaceutical Co. Ltd., Japan). No signs of hypogonadism or other neurological disorders was observed in any affected members. Family analysis with the complete ascertainment method under assumption of the same condition in the two families suggested that the disease is not inconsistent with an autosomal dominant mode with incomplete penetrance. The inheritance in one family appears unusual, as if it shows a reverse anticipation pattern, i.e., the lower generation the less number of affected persons. When only the upper two generations in the family are concerned, the segregation ratio was 0.39 0.11. Male-to-male transmissions and affectedness of both sexes were observed in both families. Magnetic resonance imaging (MRI) of the olfactory bulb and sulcus revealed no evidence of morphological changes in affected members, suggesting that these patients have a functional defect in the olfactory system, and the condition in the two families is a new type of anosmia.

**Hypocalcemia and the neuropsychiatric phenotype of 22q11.2 Deletion Syndrome.** *A.S. Bassett<sup>1,2</sup>, O. Caluseriu<sup>2,3</sup>, V. Wong<sup>2</sup>, M. Gheroghiu<sup>2</sup>, R. Weksberg<sup>1,3</sup>, E.W.C. Chow<sup>1,2</sup>.* 1) University of Toronto, Toronto, ON, Canada; 2) Centre for Addiction & Mental Health; 3) Hospital for Sick Children.

22q11.2 Deletion Syndrome (22qDS) is associated with a microdeletion on chromosome 22q11.2 and variable multisystem features. The central nervous system (CNS) is commonly involved with learning disabilities and psychiatric illness like schizophrenia presenting over time. Hypocalcemia and hypoparathyroidism are reported in infants and children with 22qDS, usually as transient conditions. We investigated rates of lifetime hypocalcemia in 63 (27 M; 36 F) adults with 22qDS and its association with major CNS features. 46 (73.0%) 22qDS subjects (median age 28 y) had a history of hypocalcemia, first detected in infancy (n=10), at paediatric surgery (n=2), later in childhood (n=7) or on systematic testing as adults through our clinic (n=27, median age 27). Parathyroid hormone levels were inappropriately low in all but 4 subjects with hypocalcemia. There was a high risk of seizures in subjects with hypocalcemia. Rates of hypocalcemia were similar in 33 subjects with schizophrenia (22qDS-SZ; 75.8%) and 30 with no psychosis (22qDS-NP; 70.0%) (p=0.61). Hypocalcemia had no effect on IQ or age at onset of schizophrenia in the 22qDS-SZ group. However, subjects with a history of hypocalcemia in the 22qDS-NP group had significantly lower mean full scale IQ than those without hypocalcemia (n=17, 68.5 SD 9.4 vs. N=7, 78.3 SD 6.1, p=0.02). Hypocalcemia is prevalent in adults with 22qDS and may be associated with significant CNS morbidity. Aggressive monitoring for and treatment of hypocalcemia in 22qDS is warranted across the lifespan.

**Neuroaxonal dystrophy in partial trisomy 5 and monosomy 15q of maternal origin.** *D. McFadden, P. MacLeod, G. Jevon, K. Neuert, M. Parslow, G. Hendson.* Dept Pathology and Medical Genetics, University of British Columbia, Vancouver, BC.

An unbalanced translocation, 46, XX, der(5)t(5;15)(q13;q13)mat, resulting in trisomy for the short arm and proximal long arm of chromosome 5 and monosomy for the proximal long arm of chromosome 15 was diagnosed prenatally after detection of growth restriction. FISH with a SNRPN probe showed no hybridization to der(5), indicating monosomy for SNRPN, with loss of the maternal allele as seen in Angelman syndrome (AS). The child was dysmorphic and had a laryngeal web, tracheomalacia, and an atrial septal defect (ASD). She died at 9 weeks of respiratory failure.

At autopsy, dysmorphic features included cranial asymmetry, broad nasal bridge, anteverted nares, short upslanting palpebral fissures, prominent infraorbital creases, large fontanelles, and an ASD.

The most striking finding was of neuroaxonal dystrophy with axonal spheroids throughout the grey matter of the central nervous system (CNS). These were not associated with iron deposition and the cerebellum was of normal size. Mild ventriculomegaly and changes of hypoxic-ischemic encephalopathy were present.

Trisomy 5p is characterized by macrocephaly, facial dysmorphisms, cardiac and renal anomalies, and abnormal CNS with ventriculomegaly and periventricular heterotopic neuroglial tissue. Duplications of proximal 5q are uncommon; the phenotype is characterized by developmental delay without other anomalies. The phenotype of AS is well known. Neuropathologic study is reported in two cases of AS and has documented cerebral atrophy and variable cerebellar hypoplasia.

Neuroaxonal dystrophy is characteristic of inherited neuroaxonal dystrophies. This case differs from these in that the spheroids were not associated with cerebellar atrophy or iron deposition. CNS neuroaxonal dystrophy is uncommon outside the setting of the primary neuroaxonal dystrophies and has not been previously reported in chromosome abnormalities. This may represent a new finding associated with deletion of proximal 15q of maternal origin.

**Down syndrome mouse models Ts65Dn, Ts1Cje, and Ms1Cje/Ts65Dn exhibit variable severity of cerebellar phenotypes.** *L.E. Olson<sup>1</sup>, L.L. Baxter<sup>2</sup>, E.J. Carlson<sup>3</sup>, C.J. Epstein<sup>3</sup>, R.H. Reeves<sup>1</sup>*. 1) Department of Physiology, Johns Hopkins School of Medicine, Baltimore, MD; 2) National Institutes of Health, National Human Genome Research Institute, Bethesda, MD; 3) Department of Pediatrics, University of California, San Francisco, CA.

The mechanisms by which trisomy 21 causes specific traits of Down syndrome (DS) are unknown. One qualitative hypothesis proposes that small regions of chromosome 21 are sufficient to cause specific phenotypes of DS, while the quantitative hypothesis asserts that defects occur due to small effects of many genes. We evaluated the cerebellar phenotype of DS using mouse models that are trisomic for different regions orthologous to human chromosome 21. The Ts65Dn mouse is trisomic for approximately 113 genes; complementary subsets of 89 and 23 of these genes are trisomic in the Ts1Cje and Ms1Cje/Ts65Dn mouse models, respectively. Using high-resolution 3D MRI and histological analyses, we calculated total cerebellar volume and cell densities of granule cells and Purkinje cells in Ts1Cje and Ms1Cje/Ts65Dn mice. By comparing our analysis to a previous study of the Ts65Dn mouse (Baxter et al., *Hum Mol Genet*, 2000), we show that cerebellar volume was reduced to the same extent in Ts65Dn and Ts1Cje mice but not reduced at all in the Ms1Cje/Ts65Dn model. Granule cell density was equally affected in both Ts1Cje model and Ms1Cje/Ts65Dn, but to a lesser degree than in Ts65Dn. Purkinje cell density, which is significantly reduced in Ts65Dn mice, was unaffected in either Ts1Cje or Ms1Cje/Ts65Dn mice. Neither the qualitative nor the quantitative hypothesis makes a prediction to cover the various outcomes seen here. A more useful description, therefore, is whether a region of trisomy is necessary and/or sufficient to cause a phenotype. The region of trisomy sufficient to cause cerebellar reduction has been narrowed to the Ts1Cje region; the Ts1Cje and the Ms1Cje/Ts65Dn segments may have an additive affect to produce the degree of granule cell deficiency seen in Ts65Dn; and neither of these regions is sufficient to cause Purkinje cell density reduction.

**The Floating-Harbor syndrome: Is it really that rare?** *C. Morel<sup>1,2</sup>, L. Tidmarsh<sup>3</sup>, C. Poulin<sup>4</sup>, M. Sufrategui<sup>5</sup>, V. Der Kaloustian<sup>1,2</sup>*. 1) Dept of Human Genetics, McGill University, Montreal, QC, Canada; 2) Dept of Medical Genetics, Montreal Children's Hospital, Montreal, QC, Canada; 3) Dept of Psychiatry, Montreal Children's Hospital, Montreal, QC, Canada; 4) Dept of Neurology and Neurosurgery, Montreal Children's Hospital, Montreal, QC, Canada; 5) Dept of Psychology, Montreal Children's Hospital, Montreal, QC, Canada.

The Floating-Harbour Syndrome is a rare condition presenting with short stature, delayed bone age and expressive language delay. The facial features characteristic for this syndrome are a triangular face with a broad nasal bridge and deep-set eyes. We present a 6-year-old boy with the clinical picture of the Floating-Harbour syndrome, but with cerebral MRI findings previously undescribed in the literature. Our patient was born after a normal pregnancy and by induced vaginal delivery. Up until the age of 3, he had irregular sleeping patterns. Acquisition of developmental milestones was globally delayed. His cognitive development was evaluated and revealed mild mental deficiency at the age of 5. The sphere of development the most severely impaired was that of language, with expressive language problems predominating. In addition, he presented with severe oppositional behaviour. Physical examination revealed a height, weight and head circumference within normal limits. He has a triangular face, long eyelashes, a broad-based nose, wide columella, broad mouth, thin lips, low-set and posteriorly-angulated ears. His voice is high-pitched and nasal, and he also has 5th finger clinodactyly. The following examinations revealed normal results: Fragile-X test, blood karyotype, EKG and echocardiogram. Audiologic examination suggested a mild conductive hearing loss. EEG showed occasional epileptiform activity during wakefulness, drowsiness and sleep. Cerebral MRI studies revealed asymmetry of the lateral ventricles with a larger left ventricle and mildly abnormal development of the left cerebral hemisphere. Bone age was delayed by 1.5 years. Our patient represents the 31st case described with the diagnosis of Floating-Harbour syndrome. The results of some of his neurological testing may help to better delineate this rare syndrome.

**Central nervous system malformations in a child with Knobloch (encephalocele-myopia-retinal detachment) syndrome.** *B. Keren*<sup>1</sup>, *A. Monnier*<sup>2</sup>, *N. Blanc*<sup>2</sup>, *M. Elmaleh*<sup>3</sup>, *D. Bremond*<sup>4</sup>, *C. Baumann*<sup>1</sup>, *A. Verloes*<sup>1,5</sup>. 1) Clinical Genetic Unit; 2) Pediatric Neurology Dept; 3) Medical Imaging Dept; 4) Ophthalmology Dept; 5) INSERM E9935, Hôpital Robert Debré Paris, France.

Knobloch syndrome is a combination of posterior midline encephalocele, macular abnormalities, high grade myopia, vitreoretinal degeneration with retinal detachment and normal intelligence, suggesting alterations during early neuroectodermal morphogenesis. 28 cases have been reported insofar. It has been shown to be due to mutations in COL18A1 gene, mapped to 21q22.3. It leads to abnormal expression of collagen XVIII and endostatin. Endostatin is the non triplehelical C-terminal NC1 globular domain of collagen XVIII. This proteolytically derived component is located in almost all epithelial basement membranes of capillaries and blood vessels, and in basement membranes of all major developing organs. Endostatin controls neuronal guidance in *Caenorhabditis. elegans*. Abnormal neuronal migration has been very recently reported in Knobloch syndrome by Kliemann et al. (*Am J Med Genet.* 2003, 119A:15-9). We report a 3 year-old girl born to consanguineous Maghrebian parents with high grade myopia (-15d), perimacular retinal coloboma, septo-optic dysplasia (septal agenesis and optic nerve hypoplasia), symmetric frontal micropolygyria, occipital meningocele and subnormal psychomotor development. This patient expand the range of CNS malformations observed with Knobloch syndrome and confirms the implication of endostatin in neuronal migration and CNS organization in higher vertebrates. Screening for mutations in COL18A1 is pending.

**Idiopathic Seizures In Patients With A 22q11.2 Deletion.** A. Kao, D.M. McDonald-McGinn, J. Mariani, M.K. Maisenbacher, E.H. Zackai, D.R. Lynch. The Children's Hosp of Phila Philadelphia, PA.

Brain anomalies have been described in the 22q11.2 deletion including underopercularization & polymicrogyria(Bingham, 1997 & 1998), cerebellar hypoplasia(Lynch 1995), atrophy(Eliez 2000) & agenesis of the corpus callosum(Ryan 1997 & McDonald-McGinn 1999). Other neurologic/cognitive features include: hypotonia, microcephaly, asymmetric crying facies, ADD, & nonverbal learning disability(Moss 1999). Further there are isolated reports of recurrent unprovoked seizures. Whether these are coincidental, secondary or primary is unclear. We therefore reviewed the records of 348 deleted CHOP patients for documentation of seizures including EEG findings & causal events (hypocalcemia, fever, recent surgery). 94% were 20y or younger (mean 9.5y & median 8y). 81(23%) had seizures including 55(16%) with provoked seizures (hypocalcemia, post-op complications, hypoxic/ishemic events, fever). However, 26(7.5%) had unprovoked seizures w/o clear precipitating events, 19 with focal & 7 with primary generalized seizures (PGS). Most focal patients had onset by 4y. PGS patients had onset as neonates(2) or as adolescence(5). 5 PGS patients had MRIs-all normal. 10 focal patients had MRI abnormalities such as polymicrogyria(2), focal cortical dysplasia, unspecified cortical nodules, cerebellar degeneration, hypomyelination, temporal edema, & diffuse cortical atrophy suggestive of epilepsy due to a brain lesion. So excluding these 10 patients, 16(4.6%) deleted patients had idiopathic or generalized seizures, in contrast to the general population incidence of 2.8 to 20.7/1000 (Hauser 2001). In addition we found that cardiac disease, family history, & prematurity were not risk factors for the development of unprovoked seizures (Fishers exact test). Of note, recent linkage studies have mapped an epilepsy locus to 22q11-12 (Xiong 1999). Thus our findings suggest that the idiopathic seizures found in our cohort represent a primary manifestation of the deletion. Furthermore, these results have implications for consideration of the 22q11.2 deletion in patients presenting primarily for epilepsy and for the identification of potential genetic loci responsible for idiopathic epilepsy.

**Fragile X-associated tremor/ataxia syndrome (FXTAS) involvement in females.** *R.J. Hagerman<sup>1</sup>, S. Jacquemont<sup>1</sup>, F. Tassone<sup>2</sup>, C. Greco<sup>3</sup>, J. Brunberg<sup>4</sup>, D. Hessel<sup>1</sup>, S. Harris<sup>1</sup>, L. Zhang<sup>5</sup>, T. Jardini<sup>1</sup>, L. Ruiz<sup>1</sup>, L. Gane<sup>1</sup>, P.J. Hagerman<sup>2</sup>.* 1) MIND Institute, Univ. of California Davis Med. Center, Sacramento, CA; 2) Biological Chemistry, Univ. of California Davis School of Med., Davis, CA; 3) Pathology, Univ. of California Davis Med. Center, Sacramento, CA; 4) Radiology, Univ. of California Davis Med. Center, Sacramento, CA; 5) Neurology, Univ. of California Davis Med. Center, Sacramento, CA.

FXTAS is a progressive neurological disorder that affects some older male carriers (50 yo) of premutation alleles of the *FMR1* gene. Presentation typically involves intention tremor and/or gait ataxia, parkinsonism, autonomic dysfunction; often accompanied by cognitive deficits and subsequent dementia. MRI findings include symmetric hyperintensities in the middle cerebellar peduncles (MCP sign). Neuropathologic changes include intranuclear (neuronal and astrocytic) inclusions. Previous published reports have not identified FXTAS in females. We report 3 females with premutation alleles who present with clinical features of FXTAS, yet none shows cognitive involvement seen in males with FXTAS. Case 1 is a 67 yo female [full scale IQ, 126; 90 CGG repeats; mRNA level, 3.250.55, FMRP level, 89%; activation ratio (AR), 0.5], with gradually progressive intention tremor (35 yrs) and ataxia (12 yrs). T2-weighted MRI demonstrates mild atrophy with symmetric hyperintensities of the MCPs. Case 2 is the 62yo sister of Case 1 with a history of intention tremor (10 yrs) and ataxia with frequent falling (2 yrs), but no executive function deficits [full scale IQ, 111; 90 CGG repeats; mRNA level, 2.520.27; AR, 0.50; FMRP, 70%]. Case 3 is deceased an 85 yo female [87 repeats; AR 0.6] who had mild tremor (3 yrs), and mild ataxia complicated by hip surgery, eventually leading to cane use at 79y. She had significant anxiety without cognitive impairment (full scale IQ of 100). Upon autopsy, neuropathologic examination revealed mild atrophy of the posterior frontal region and intranuclear inclusions in the hippocampus. FXTAS occurs infrequently in females, who also appear to be relatively protected from the cognitive deficits associated with FXTAS.

### **Structural Neuroimaging and Molecular Correlates of Psychopathology in Adult Males with the FMR1**

**Premutation.** D. Hessl<sup>1</sup>, C. Cohen<sup>1</sup>, C. DeCarlie<sup>3</sup>, R. Tong-Turnbeaugh<sup>3</sup>, S. Jacquemont<sup>1</sup>, L. Gane<sup>1</sup>, T. Jardini<sup>1</sup>, J. Wegelin<sup>4</sup>, F. Tassone<sup>2</sup>, P.J. Hagerman<sup>2</sup>, R.J. Hagerman<sup>1</sup>. 1) M.I.N.D. Institute, U.C. Davis, Sacramento, CA; 2) Biological Chemistry, U.C. Davis, Davis, CA; 3) Neurology, U.C. Davis, Sacramento, CA; 4) Epidemiology, U.C. Davis, Davis, CA.

**BACKGROUND:** Fragile X associated tremor/ataxia syndrome (FXTAS) is a recently described disorder in of male carriers of premutation alleles of the fragile X mental retardation 1 (*FMR1*) gene. FXTAS is characterized by gait ataxia and/or intention tremor and Parkinsonism. Brain MRI has revealed white matter signal hyperintensity in the middle cerebellar peduncles, cerebellar atrophy, and intranuclear inclusions throughout the cortex and brain stem, with highest concentration in the hippocampus. Psychopathology associated with FXTAS has not been previously described.

**METHOD:** Sixteen premutation males ( $M = 61$  yrs) and male controls ( $M = 67$  yrs) underwent brain MRI, FMR1 protein and mRNA analysis, neurological examination, and psychological assessment (SCL-90-R). Cerebellar and hippocampal volumes, corrected for cranial size, were compared and correlated with SCL-90-R scores and *FMR1* molecular measures. **RESULTS:** MRI analysis showed reduced cerebellar volume in premutation subjects compared to controls that approached significance ( $t = 1.87$ ,  $p = .07$ ), but no significant differences in hippocampal or cerebral volume were found. Within the premutation group only, reduced hippocampal volume was significantly associated with increased psychopathology,  $r = -.81$ ,  $p = .005$ , especially symptoms of depression, interpersonal sensitivity, and psychoticism. This association remained significant after adjusting for severity of neurological impairment through standardized measures of tremor and ataxia. Increased FMR1 mRNA and *FMR1* protein were positively correlated with psychopathology,  $r_s = .70$  and  $.77$  respectively,  $p < .05$ , such that increased message and protein were associated with increased psychopathology. **CONCLUSION:** Molecular alterations due to the *FMR1* premutation in those affected by FXTAS may lead to increased psychological symptoms as a result of neuropathology in the hippocampus that are independent of tremor and ataxia.

**Trisomy 2p and monosomy 8p in a patient with DiGeorge syndrome.** *R. Stephane<sup>1</sup>, D. Genevieve<sup>1</sup>, D. Sanlaville<sup>1</sup>, A. Maltret<sup>1</sup>, S. Sererro<sup>2</sup>, C. Beyler<sup>3</sup>, V. Cormier-Daire<sup>1</sup>, M. Vekemans<sup>1</sup>, A. Munnich<sup>1</sup>, S. Lyonnet<sup>1</sup>, D. Bonnet<sup>3</sup>.* 1) Department of genetics, Hopital Necker-Enfants Malades, Paris; 2) Cytogenetics Unit, Evreux; 3) Cardiology Unit, Hopital Necker-Enfants Malades, Paris, France.

Microdeletion 22q11.23 is the most frequent chromosomal anomaly in syndromic conotruncal heart defect (CTHD). However, other cytogenetic anomalies have been reported in CTHD including deletion of chromosome 10p13-14 and 4q34.2. Here, we report on a patient with pulmonary atresia and ventricular septal defect with partial trisomy 2p22-pter and partial monosomy 8p23-pter. The balanced 46,XY, t (2;8)(p22; p23) translocation, was found to be carried by the healthy father. Clinical features were consistent with DiGeorge syndrome namely facial dysmorphism, arachnodactyly, thymic hypoplasia and hypocalcemia. In addition, skeletal X-rays showed absent distal phalanges on both feet, sacral agenesis and calcaneal punctuations. Abdominal CT scan showed a right adrenal gland mass which was diagnosed as a neuroblastoma. FISH analysis ruled out chromosome 22q11.2 deletion. So far, 85% of patients reported with a terminal deletion 8p presented with heart defects, of which 27% were CTHD. Other features were minor facial dysmorphic features, growth retardation, microcephaly, developmental delay and genitourinary anomalies. On the other hand, patients with trisomy 2p present with facial dysmorphism including small palpebral fissures, enlarged nasal bones, small mouth, arachnodactyly, psychomotor delay and congenital heart defect. Interestingly, these patients also show a predisposition to neuroblastoma. Therefore, the facial features observed in our patient could be the result of the combination of the overlapping features ascribed to monosomy 8p and trisomy 2p. On the other hand, we suggest that neuroblastoma may result from the duplication of either the proto-oncogene N-myc or the NAG gene mapping to 2p23.4 and 2p25.1 respectively. We propose that all patients with atypical DiGeorge phenotype and normal 22q11.2 FISH should be carefully investigated for both deletion of 8p23.1 and trisomy of 2p, especially as a predisposition to neuroblastoma may be involved.

**X-inactivation Analysis in female carriers of ATR-X (X-linked -thalassemia/mental retardation syndrome).** T. Wada<sup>1</sup>, A. Sudo<sup>2</sup>, Y. Fukushima<sup>1</sup>, S. Saitoh<sup>2</sup>. 1) Shinshu Univ Sch of Medicine, Matsumoto, Japan; 2) Hokkaido Univ Sch of Medicine, Sapporo, Japan.

**Introduction** ATR-X (MIM#301040) is among syndromic forms of X-linked mental retardation, and is characterized with severe mental retardation, mild HbH disease, dysmorphic facies, genital abnormalities, skeletal abnormalities, and behavioral abnormalities. Mutations of *ATRX* give rise to ATR-X. Thus far, 26 patients from 23 families in Japan have been diagnosed as ATR-X. We reported here the X-inactivation analysis in female families of ATR-X patients.

**Subjects and Methods** Twenty HbH positive cases from 18 families and 14 HbH negative cases from 14 families who demonstrated characteristic features for ATR-X were examined for *ATRX* mutations. We performed the X-inactivation analysis for female family members whose DNA was available. *ATRX* mutations were screened by RT-PCR and direct sequencing using lymphoblastoid cells, and confirmed using genomic DNA. For X-inactivation analysis, genomic DNA was digested with a methylation-sensitive restriction enzyme, and subsequently the polymorphic CAG repeats in the *HUMARA* gene were PCR amplified. **Results** We detected *ATRX* mutations in 18 HbH positive cases from 16 families and 7 HbH negative cases from 7 families. Nine out of 11 mothers (81.8%) of the ATR-X patients were carriers. We analyzed the X-inactivation pattern for 9 females from 7 families. Three out of nine females were excluded, because their CAG repeats of *HUMARA* gene were homozygous and we could not differentiate two alleles. In 4 female carriers who had a mutation, three showed a skewed pattern but one showed a not-skewed pattern (70: 30), and she had mild mental retardation. Two females without mutations showed a random pattern. **Discussion** Females carriers with *ATRX* mutations have been reported to have no mental retardation, because the X chromosome with an *ATRX* mutation is selectively inactivated. Our case of the female with mild MR may indicate that an *ATRX* mutation could cause mental retardation in female, if skewed X-inactivation is not strictly maintained. We should study more families to confirm this hypothesis, and we are analyzing another family with a mild MR female.

**Baraitser-Winter (coloboma-ptosis-pachygyria) syndrome.** A. Verloes<sup>1,2</sup>, C. Baumann<sup>1</sup>, P. Blanchet<sup>3</sup>, A. David<sup>4</sup>, J. Roume<sup>5</sup>, C. Rusu<sup>6</sup>, P. Sarda<sup>3</sup>, M. Till<sup>7</sup>, D. Pilz<sup>8</sup>. 1) Clinical Genetics Unit; 2) and INSERM E9935, Hosp Robert DEBRE, Paris; 3) Genetic dept, Hosp A. de Villeneuve, Montpellier; 4) Genetic Dept, University Hospital, Nantes; 5) Genetic Unit, CH Intercommunal, Clinical Genetics Unit, CH Intercommunal, Poissy - Saint Germain-en-Laye, France; 6) Genetic Dept, Iasi University Hospital, Romania; 7) Genetic Dept, Hpital Debrousse, Lyon, France; 8) Genetic Dept, University Hospital of Wales, Cardiff, UK.

Baraitser-Winter syndrome (BW) is an exceptional disorder (5 patients reported) characterized by short stature, hypertelorism, broad epicanthus, bilateral ptosis, coloboma, metopic ridge and pachygyria. Fryns-Aftimos syndrome (FA), reported in 9 patients, is defined by hypertelorism, ptosis, large nose, neck webbing, low posterior hairline, broad thorax, frontal pachygyria, preaxial anomalies and seizures. An unusual body habitus is present, with truncal obesity, tip-toe walking, limited extension of knees and shoulder propulsion. Both disorders are reminiscent of Noonan syndrome and both are associated with mild to severe mental retardation. We report a series of 8 patients (some followed for more than 10 years) with a phenotype overlapping BW syndrome and FA syndrome, suggesting that both disorders are identical (but reported at different ages : youngsters in BW, teen-agers in FA), and possibly less exceptional than previously thought. PTPN11 screen was negative in 3 of our cases, and telomere screen in several of them. Facial Gestalt of BW seems the most reliable clue for diagnosis. Predominantly frontal pachygyria and coloboma are common but inconstant. Mental retardation is variable and may be influenced by epilepsy. Contrasting with Noonan syndrome, heart is not a target. Most cases are sporadic. Based on this new series, we propose a renewed definition of Baraitser-Winter syndrome and will review the earlier literature.

**Two distinct mutations are responsible for the higher prevalence of Hereditary Sensory and Autonomic Neuropathy Type II (HSAN II) in French Canadians.** *K. Roddier<sup>1</sup>, T. Thomas<sup>1</sup>, G. Marleau<sup>1</sup>, A.M. Gagnon<sup>1</sup>, M.J. Dicaire<sup>1</sup>, A. Saint-Denis<sup>1</sup>, A.M. Sarrazin<sup>2</sup>, A. Larbrisseau<sup>3</sup>, M. Lambert<sup>3</sup>, M. Vanasse<sup>3</sup>, M. Samuels<sup>4</sup>, G.A. Rouleau<sup>4</sup>, B. Brais<sup>1</sup>.* 1) CHUM, Université de Montréal, Montreal, Quebec, Canada; 2) 2. Centre Hospitalier Régional de Lanaudière, Joliette, Quebec, Canada; 3) 3. Hôpital Ste-Justine, Montréal, Quebec, Canada; 4) 4. Xenon Genetics Inc., Burnaby, B.C. Canada.

Hereditary sensory and autonomic neuropathy type II (HSAN II, OMIM 201300) is a rare childhood recessive neuropathy. It was first clearly described in 1973 in a French-Canadian (FC) kinship. The HSANII locus and the *HSN2* mutated gene have been uncovered. Purpose. Establish that a higher prevalence of this condition exists in the FC population. Fine-map the candidate interval using linkage disequilibrium analysis. Uncover the number of mutations responsible for FC HSANII cases. Methods. We recruited all cases that were evaluated in pediatric and neurological clinics during the past 30 years. Haplotypes were constructed for all carrier chromosomes by genotyping nine polymorphic markers. The *HSN2* gene was sequenced. Results. We have uncovered the largest cluster ever described of 17 HSANII cases belonging to 12 families. They all originated from southern Quebec. Haplotype analysis determined that two distinct mutations were responsible for HSANII in FC. Linkage disequilibrium analysis fine-mapped the candidate region to a 1cM (225Kbp) interval. Two distinct loss-of-function *HSN2* mutations were identified. The higher prevalence of this condition in Quebec appears to be due to a relatively high carrier frequencies for both mutations. The following genotypes were uncovered in the different families: seven (58.3%) cases were homozygote for mutation 1, one (8.3%) was homozygote for mutation 2 and four (33.3%) were compound heterozygotes for the two mutations. 75% of chromosomes carried mutation 1 and 25% mutation 2. Conclusion. HSANII is more frequent in the FC population due to higher carrier rates for two distinct *HSN2* mutations. This is the first example of a FC recessive disease where the most common mutation is responsible for less than 90% of causal mutations.

**Keratosis Palmaris et Plantaris with Plagiocephaly.** *J.C. Prieto<sup>1,2</sup>, H. Velasco<sup>1</sup>*. 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Cundinamarca, Colombia; 2) Hospital la Victoria, SDS, Bogota, Colombia.

The inherited palmoplantar keratodermas are an extremely heterogeneous group of skin diseases that can be subclassified on the basis of the pattern and age of onset of hyperkeratosis on the palm and sole and on whether they fall into clinical syndromes and, much more recently, by their inherited genetic defect. Keratosis palmaris et plantaris is an autosomal dominant disorder in which hyperkeratosis confined to the palms and soles is characterized histologically by cytolysis of suprabasal keratinocytes which usually becomes evident between the ages of 3 and 12 months. The underlying defects of some genodermatoses of the epidermis that involve mutations of the keratin proteins have been found. Mutations in the keratin 9 gene (KRT9), a type I keratin expressed exclusively in the suprabasal keratinocytes of palmoplantar epidermis, have previously been demonstrated in this disorder. Others forms the keratosis palmaris can include clinodactyly or deafness. Here we report on 2 year old boy with normal stature, plagiocephaly, hyperkeratosis palmo-plantar, rocker-bottom feet, and vertical talus. The cytogenetic analysis was normal 46,XY. The CT images showed plagiocephaly. We present this case of Keratosis palmaris et plantaris with thirteen affect family members in which is demonstrated the autosomal dominant inheritance pattern and intrafamilial phenotypic variability. To our knowledge, not other reports have described patients with this disease and plagiocephaly and rocker-bottom feet. This new case contributes with new clinic and radiological findings that have not been reported on previous cases.

**The spectrum of conditions with the molar tooth sign: more than just Joubert syndrome.** *M.A. Parisi<sup>1</sup>, C.L. Bennett<sup>1</sup>, W.B. Dobyns<sup>2</sup>, B.L. Maria<sup>3</sup>, P.F. Chance<sup>1</sup>, I.A. Glass<sup>1</sup>.* 1) Dept of Pediatrics, Univ of Washington, Seattle, WA; 2) Dept of Human Genetics, Univ of Chicago, Chicago, IL; 3) Dept of Child Health, Univ of Missouri, Columbia, MO.

Joubert syndrome (JS) is an autosomal recessive condition characterized by hypotonia, neonatal breathing abnormalities, ataxia, developmental delays, and abnormal eye movements known as oculomotor apraxia. MRI changes in JS include cerebellar vermis hypoplasia with distinctive brainstem abnormalities comprising the molar tooth sign (MTS), proposed to be pathognomonic for JS. Variable features include postaxial polydactyly, retinal dystrophy, ocular colobomas, renal complications that include cystic dysplastic kidneys (CDK) or nephronophthisis (NPHP), and hepatic fibrosis. The MTS has been identified in individuals with Arima, Senior-Loken, and COACH syndromes in the past. Here we summarize our experience with 74 JS pedigrees and describe the clinical features in the probands. We extend the spectrum of conditions with the MTS to include individuals with Oral-Facial-Digital syndrome type VI (OFD VI), and provide further evidence of the heterogeneity of conditions with the MTS. Of the 74 pedigrees, 96% have cerebellar vermis hypoplasia while 65% have a documented MTS. 73% have abnormal eye movements, and 68% have a history of breathing abnormalities. In contrast to previous reports of a low incidence of polydactyly, 20% of our families have this feature. Of the 22% with kidney involvement, 4 have CDK and 2 have NPHP. Four are reported to have liver involvement, with one demonstrating the features of COACH syndrome. Two siblings have mesaxial polydactyly and lingual papules suggestive of OFD VI. Although the genetic causes of JS have not been identified, two consanguineous Arab pedigrees showed linkage to 9q34. This locus has been excluded in several families, establishing the genetic heterogeneity of JS. We suggest that clinical delineation of the findings in the MTS syndromes will allow subcategorization to aid in genetic linkage studies. We propose the term Joubert syndrome and related disorders to encompass these conditions that share the MTS but have significant clinical differences.

**Four neurofibroma phenotypes in NF1: The intersection of clinical acumen, natural history and histopathology.**  
*V. Riccardi.* The Neurofibromatosis Institute, La Crescenta, CA.

There are at least four types of neurofibromas appreciated from clinical and natural history vantage points, while histopathologists simply refer to neurofibroma, as though there were not multiple types. These differences in terms of clinical acumen and natural history on the one hand and histopathology, on the other, are critical to devising studies to test treatment strategies and investigate pathogenesis. Analyses of neurofibromas from over 1,000 patients with NF1 in the combined Baylor NF Program and Neurofibromatosis Institute data sets indicate that there are four types of neurofibromas in NF1 in terms of their topography and gross anatomy, time of appearance, rate of growth and associated consequences and complications, including overall severity and mortality. **Cutaneous neurofibroma:** Located in the skin with sparing of certain areas (shin, glans penis), derived from minor nerves; soft, blend into adjacent tissue and non-tender; non-congenital; slow-growing, but may number in the thousands; cosmesis, excessive itching and compromised wearing of clothing. **Subcutaneous neurofibroma:** Located under the skin, derived from medium-sized nerves; firm, discrete and tender; non-congenital; moderate rate of growth; early onset is harbinger of serious nodular plexiform neurofibromas and their attendant compromises. **Nodular plexiform neurofibroma:** Located on dorsal nerve roots, plexuses and large nerves; firm, twisted-rope appearance, confined by perineurium, painful and tender; non-congenital; moderate to fast rate of growth, with spinal cord and peripheral nerve compromises including paralysis, severe pain, neurofibrosarcoma and premature death. **Diffuse plexiform neurofibroma:** Located in the skin and/or internally (eg, mediastinum), soft and fleshy, may have overlying hyper pigmentation and hypertrichosis, invades local tissue beyond perineurium, generally not tender or painful; congenital; slow, erratic rate of growth, with potential of massive size leading to crowding out of local viscera, loss of extremity use and neurofibrosarcoma development and premature death.

**An autosomal dominant hidradenitis suppurativa in a large Indian family.** *U. Radhakrishna<sup>1</sup>, T.Y. Mehta<sup>2</sup>, J.V. Solanki<sup>3</sup>, U.C. Rao<sup>1</sup>.* 1) GeneHealth, Green Cross Blood Bank & Genetics centre, Paldi, Ahmedabad; 2) Samarpan Medical & Research Organization, Modasa; 3) Department of Animal Genetics & Breeding, Veterinary college, Gujarat Agriculture University, Anand, India.

Hidradenitis suppurativa (HS) (OMIM 142690) is considered a chronic disease of apocrine glands. It usually develops in the groin and sometimes under the arms and under the breasts. The risk of developing any cancer with patients with HS is high as compared with others (*Arch Dermatol* 137:730-73, 2001). Several small and moderate families with autosomal dominant mode of inheritance have been reported (*Br J Dermatol* 142(5): 947-53, 2000), however the genes responsible for HS have yet to be identified. We have studied a large four generation Indian pedigree with autosomal dominant HS. The pedigree consists of 68 individuals including twenty affecteds (12 males/8 females). The age of onset was during puberty and the phenotype appeared to be 100% penetrant in this family. The expression of the phenotype was variable and ranged from very severe to moderate with typical features of HS. Detailed pathologic examinations were performed including histopathological studies in selected affecteds. The majority of the examined individuals were severely affected and their findings included cutaneous scars, folliculitis, GI polyps, familial gall stones, sinuses axillae, polymorph function defects, pilosebaceous abscesses and folliculitis. Hirsutism was observed in affected females. Skin grafting was performed in some of these individuals and two affecteds died due to squamous cell carcinoma. To our knowledge, this may be the biggest family with several affecteds. Blood DNA samples have been collected from selected individuals for future research. [u\\_c\\_rao@hotmail.com](mailto:u_c_rao@hotmail.com).

**The Azorean population: A genetic resource for the study of Congenital Heart Defects.** *R. Anjos<sup>1</sup>, T. Cymbron<sup>2</sup>, C. Macedo<sup>3</sup>, C.P. Duarte<sup>3</sup>, L. Mota-Vieira<sup>2</sup>.* 1) Pediatric Cardiology Dept., Hosp. Santa Cruz, Lisbon,; 2) Genetics & Molec Pathol Unit,; 3) Pediatric Dept. Hosp. Divino Espirito Santo (HDES), Azores Islands, Portugal.

Congenital heart defects (CHD) are the clinical manifestation of anomalies in embryonic cardiac development and constitute the most common form of clinically significant birth defects. This project aims to study CHD in the Azorean population. Located in the Atlantic Ocean, the Azores was first settled during the 15th century mainly by native Portuguese. The current population of 241,763 inhabitants grew over 22 generations almost entirely through reproduction, as immigration subsequent to founding was minimal. Azoreans live mostly in small rural localities, showing great similarity in life style and eating habits. Recently, we showed that this population is relatively homogeneous and has the highest value of consanguinity in Portugal. This project is based on the Azorean Register of CHD, established in 1992 at the HDES, the central Hospital of the archipelago. Our strategy includes a database with clinical data and detailed pedigree information, and a biobank of DNA, RNA, serum and frozen cells. Special attention will be taken in the reconstruction of extended multigenerational pedigrees, which greatly improves the statistical power of genetic analysis. This resource is a valuable tool to investigate the epidemiology of CHD, to characterize mutations present in candidate genes associated with CHD sub-phenotypes and to assess the effect of consanguinity in the CHD families. To date, 383 patients were clinically evaluated and classified according to the predominant cardiac lesion. Cardiac malformations affect 11 per 1,000 live births in Azores, a frequency 40% higher than in the general population. We are currently analysing the geographic distribution of CHD per island, the pedigree size and the family structure. With the exception of Corvo, all islands present CHD cases. The highest frequency was found in Santa Maria island and the lowest in Flores island. Moreover, we have evidence for familial aggregation in some rural localities, mainly in S. Miguel island. Funded by DRCT. (tcymbron@hdes.pt).

**A Rare Cause of Congestive Heart Failure in an Infant: First Reported Case of Infantile Marfan Syndrome in the Philippines.** *D.D. Cheng<sup>2</sup>, E. Cutiongco<sup>1</sup>, J. del Rosario<sup>2</sup>.* 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila; 2) Section of Cardiology, Department of Pediatrics, College of Medicine, University of the Philippines Manila.

A 2-month old boy presented with difficulty of breathing, irritability and feeding intolerance. Physical examination showed a poorly nourished infant in severe cardiorespiratory distress with associated tachycardia, poor pulses, holosystolic murmur at the apex and gallop. Extracardiac findings included hepatomegaly, pectus excavatum, arachnodactyly and dolichostenomelia. Chest radiograph revealed cardiomegaly with left pleural effusion. Electrocardiogram results showed sinus rhythm with normal axis for age with right and left atrial, and right ventricular hypertrophy. Echocardiography showed tricuspid and mitral valve prolapse with severe regurgitation, aortic root dilation and biatrial enlargement. Anti-congestive heart failure treatment was instituted with some improvement. Genetic and ophthalmologic consultations confirmed the clinical diagnosis of Marfan syndrome. Cardiac manifestations of Infantile Marfan syndrome in contrast to Classic Marfan syndrome are discussed.

**Chromosomal 22q11 deletion in conotruncal heart defects.** *YS. Choy<sup>1</sup>, HA. Latiff<sup>2</sup>, SK. Tan<sup>3</sup>, M. Alwi<sup>2</sup>, H. Samion<sup>2</sup>, G. Kandhavello<sup>2</sup>, LH. Ngu<sup>1</sup>, Azizion<sup>3</sup>.* 1) Genetics Unit, Pediatric Institute, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia; 2) National Heart Institute, Kuala Lumpur, Malaysia; 3) Cytogenetic Unit, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia.

Conotruncal heart defects are the commonest cardiac lesions found in chromosomal 22q11 deletion with significant implications in cardiac management beside overall management of the patient. A prospective randomized study was designed to study 22q11 deletion in patients with conotruncal heart defects. A total of 197 patients with conotruncal heart defects were tested for 22q11 deletion by FISH from July 2002 to Mac 2003. Patients with a known syndrome were excluded. The primary diagnosis were Tetralogy of Fallot (n=84), pulmonary atresia with VSD (n=52), truncus arteriosus (n=14), interrupted aortic arch (n=14), VSD with posterior malalignment of ventricular septum (n=7), simple TGA (n=12), and complex TGA (n=14). Dysmorphic features characteristic of 22q11 deletion were found in 33 patients (16.7%) and 27 patients (13.7%) had hypocalcemia. 22q11 deletion was found in 29 patients (14.7%). The deletion was positive in 28.8% of patients with PAVSD, 28.6% of patients with truncus arteriosus and 28% of interrupted aortic arch (75% of interrupted aortic arch type B) and 5.9% of patients with Tetralogy of Fallot. None of the patient with TGA or VSD and posterior malaligned ventricular septum was 22q11 deleted. Univariate analysis showed PAVSD, truncus arteriosus, interrupted aortic arch (particularly type B), right sided aortic arch, the presence of multiple aortopulmonary collaterals, hypocalcemia, presence of characteristic dysmorphic features to be significant predictors for 22q11 deletions. On multivariate analysis however, only PAVSD, truncus arteriosus, interrupted aortic arch and hypocalcemia were significant predictors for the deletion. In conclusion, testing for 22q11 deletion should be carried out for patients with isolated PAVSD or truncus arteriosus or interrupted aortic arch or any patients with conotruncal heart defects and hypocalcemia. The test should only be done in other patients with conotruncal heart defects after a careful clinical genetic evaluation.

**Abnormal mitochondria in arrhythmogenic right ventricle disease (ARVD).** *C. Friedrich, C. Gaymes.* Div Med Gen and Pediatric Cardiology, U Mississippi Medical Ctr, Jackson, MS.

A 15-year-old girl in excellent health developed a headache with facial flushing and died while bathing. She had no history of cardiac or neurologic symptoms. Her autopsy revealed an enlarged, markedly dilated, flabby, thin-walled right ventricle. The free wall was thin with adipose tissue extending to the endocardium with patchy fibrosis, with a 3.5 cm white-tan patch. There was pulmonary and generalized visceral congestion with herniation of unci and the cerebellar tonsils. Her psoas muscle showed Type 1 predominance, lipid deposition, scattered ragged red myofibers, and decreased cytochrome oxidase staining. On EM the mitochondria were large and exhibited rigid needle-like paracrystalline structures. Cristae were irregular and overlapping and some showed focally rounded distensions. Many had rounded osmiophilic condensations. She had hepatomegaly with marked microsteatosis. On EM her hepatocytes showed lipid and lipofuscin deposition, numerous large mitochondria, some expanded with flocculent material, some with swollen cristae, some with rounded osmiophilic condensations, and some mitochondria had fine cristae that overlap each other. Her father died at 53 of an MI. There were no other premature deaths. Her 17-year-old brother is in excellent health, with normal cardiac and neurological examinations. His skin, hair and nails were normal. His EKG, echocardiogram and exercise stress test were normal. His CPK was 4772 u/L (normal: 24-195). Aldolase was 43.2 u/L (normal: <8.3). His lactate, pyruvate, and the L/P ratio were normal. His ESR was zero. His urine organic acids, plasma carnitine levels and acylcarnitine profile were normal. A cardiac MRI is pending. Seven loci for familial ARVD have been mapped and two genes (*RYR2* and *DSP*) identified. Elevations of CPK and aldolase are not typical in ARVD. Mitochondrial abnormalities have not been reported. How myocardium is replaced by adipose tissue and fibrosis is unclear, although the arrhythmias may be due to disturbances of calcium homeostasis. The novel mitochondrial abnormalities seen on autopsy in this case may be a clue to the pathophysiology seen in this group of disorders.

**Autonomic Dysregulation in 22q Deletion Syndrome.** *O. Caluseriu<sup>1, 2</sup>, T. Tayyeb<sup>1</sup>, E.W.C. Chow<sup>1, 3</sup>, A.S. Bassett<sup>1, 3</sup>.*  
1) Centre for Addiction & Mental Health, Toronto, ON, Canada; 2) Hospital for Sick Children; 3) University of Toronto.

22q Deletion Syndrome (22qDS) is a microdeletion syndrome, commonly presenting with learning disabilities and congenital heart defects (CHD). Mortality in infants with 22qDS is often associated with major CHD but a recent study suggested that abnormal autonomic regulation of the vascular system may sometimes be responsible (Shashi et al, 2003). We comprehensively reviewed lifetime medical records for 72 adults with 22qDS for evidence of autonomic abnormalities such as severe hypotension or body temperature dysregulation. Three subjects had a history of unexplained hypotension that did not respond to sympathomimetics (inotropes). Subject 1 had tetralogy of Fallot (TOF) and on three separate occasions (at 2 months of age and twice at 2.5 years) presented an unexplained low cardiac output which responded poorly to inotropic agents. One of these events was accompanied by unexplained hyperthermia to 40.5 C with no identifiable focus of infection and negative blood cultures. Subject 2 during a second corrective surgery for TOF at age 6 years had a crisis on induction of anaesthesia with severe persistent hypotension (mean blood pressure of 20 mm Hg systolic) and tachycardia that did not respond to inotropes. Subject 3 had renal agenesis, recurrent hypocalcemia with aberrant subclavian artery. At age 18 years she developed pancreatitis after elective ERCP procedure; no signs of infection or necrosis of pancreas on CT were found. She developed persistent fever (38.9 C) but 48-hour cultures were negative. She became acutely unstable with blood pressure falling to a mean of 50 mm Hg. Increasing doses of inotropes were started but a second episode of refractory hypotension lead to cardiac arrest. Our data indicate it is possible (subjects 1 and 2) to survive autonomic system regulatory abnormalities in 22qDS but that death may occur (subject 3) even in the absence of major CHD. These data support previous case reports of 22qDS patients with abnormal autonomic regulation. This is a rare but important feature that can have dramatic consequences for 22qDS patients in view of their frequent need for invasive procedures and surgeries.

**Case report: jaundice due to biliary atresia with cardiac malformation and, umbilical and inguinal hernia. L.**

*Cornejo*<sup>1,2</sup>, *A. Molina*<sup>1</sup>, *I. Luna*<sup>1</sup>, *A. Noriega*<sup>1</sup>, *D. Harappe*<sup>1</sup>. 1) Genetics, Hospital del Niño DIF, Pachuca de Soto, Hidalgo, Mexico; 2) Area Academica de Medicina, Instituto de Ciencias de la Salud, Universidad Autonoma del Estado de Hidalgo.

**INTRODUCTION:** Biliary atresia and cardiac anomaly could be manifested as isolated malformations, or, they have been present as part of a syndromic disease. Differential diagnostic should be done with: biliary atresia, extrahepatic (OMIM 210500), Cat Eye Syndrome (OMIM 157450), Kabuki Syndrome (OMIM 147920), and, Alagille syndrome (OMIM 118450). **OBJETIVE:** To describe a patient with biliary atresia, extrahepatic, cardiac malformation and, umbilical and inguinal hernia. **CLINICAL DATA:** Male patient who was 5 months old when he was attended at the Hospital del Nio due to jaundice and fever. He was the first product gestation from a mother who was 27ys old and a father being 30ys old at conception time. Apparently, the gestation process was normal, spontaneous abortus and teratogenic data were negative. Delivery was done through cesarean section after forty weeks of gestation. Consanguinity was negative. His mother died when he was 3 months old. After clinical evaluation, he showed: microcephaly, none facial dismorphism; neck and thorax were normal; umbilical hernia; lefted inguinal hernia, male genitals; both, superior and lower extremities were normal. He also showed: severe mental retardation; ophthalmologically normal; atrial septal defect; normal hepatic function; biliary atresia, extrahepatic from hepatic biopsy; cervical and lumbar x-ray were normal; cerebral CT-Scan with cortical-subcortical atrophy. **DISCUSSION:** Infectologic test was not done. It was not recorded data for Cat Eye Syndrome, or, Kabuki Syndrome. It was thought in biliary atresia, extrahepatic, and, Alagille syndrome as differential diagnostics, last one was negative also. **CONCLUSION:** The present case report represent an biliary atresia, extrahepatic associated to cardiac malformation, and, hernial anomalies, last ones not previously reported. Counseling will be given as multifactorial disease.

**Phenotype of a 66 year old man with the 22q11 deletion syndrome.** *T. Ohki*<sup>2</sup>, *M. Wolfson*<sup>3</sup>, *A. Shanske*<sup>1</sup>. 1) Center for Craniofacial Disorders, Children's Hospital at Montefiore, and; 2) Vascular and Endovascular Surgery, Department of Surgery, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; 3) Institute for Basic Research, George A. Jervis Clinic, Staten Island, New York.

The chromosome 22q11 deletion syndrome includes the velocardiofacial syndrome (Shprintzen), Di George syndrome and conotruncal anomaly face syndrome. The prevalence is estimated to be 1/4500. The phenotype is highly variable and includes at least 150 associated anomalies. Most phenotypic studies are of children ascertained as a result of craniofacial or cardiac anomalies. We describe the phenotypic and, in particular, the vascular findings in a 66 year old man. S.O. is a 66 year old man referred by psychiatry with the deletion 22q11 syndrome. A cleft palate was repaired as a child and he now has low-frequency sensorineural hearing loss and bilateral cataracts. There is no cardiac history. He has unilateral renal agenesis and recently had surgery for prostatic hypertrophy. He had a seizure disorder many years ago and is being treated for hypothyroidism and hypoparathyroidism and has thrombocytopenia without giant platelets or a bleeding diathesis. He has a history of chronic candidiasis and basal ganglia calcifications. He has resided in a group home since his teenage years because of mental illness and retardation. His first psychiatric hospitalization was at 16 years. His psychiatric diagnosis is schizoaffective disorder and moderate mental retardation. His physical examination revealed a short well-nourished bald adult male with a blunt affect and euthymic mood and unclear speech. The pinna were normal, the palate was intact except for a bifid uvula, and the nasal tip was bulbous. Bilateral carotid bruits were audible and he had extensive varicosities of both lower extremities. Additional studies of adults with the 22q11 deletion syndrome are necessary to delineate the phenotype in adults and to better understand the natural history of the syndrome. The most comprehensive review of the subject to date (Cohen, 1999) reported on only a single adult over 50 years of age. Our patient has fewer major anomalies and different vascular findings than patients ascertained through a pediatric clinic.

**Arrhythmogenic right ventricular cardiomyopathy linked to 3p25: ventricular dysrhythmias and early sudden death, prevented in males with implantable cardioverter defibrillator therapy.** *K. Hodgkinson<sup>1</sup>, P. Parfrey<sup>1</sup>, S. Stuckless<sup>1</sup>, L. Thierfelder<sup>2</sup>, E. Dicks<sup>1</sup>, A. Bassett<sup>3</sup>, S. Connors<sup>4</sup>.* 1) Patient Research Centre, Health Science Centre, St John's, NL Canada; 2) Max-Delbruck Centre, Berlin, Germany; 3) Clinical Genetics Research, University of Toronto, On, Canada; 4) Division of Cardiology, Health Science Centre, St. John's, NL Canada.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) in Newfoundland is an autosomal dominant disorder, linked to a founder haplotype at 3p25, with high morbidity and mortality. In 11 large well ascertained families 367 subjects at 50% risk were identified: 197 were at high-risk (HR; based on haplotype data, obligate carrier status or early sudden death), 91 at low-risk (LR; based on haplotype), and the remainder were unknown. 24-hour Holter monitoring was done to assess number of premature ventricular complexes (PVCs) in 136 subjects (91HR: 44M, 47F, and 45LR; 21M, 24F). Forty eight HR subjects (30M, median age 32y, 18F, median age 41y) received an implantable cardioverter defibrillator (ICD) and were compared to controls with no ICD (matched on sex, age, family and risk status). We hypothesized that increased numbers of PVCs may be diagnostic in ARVC. Using 1000 PVCs in 24 hours in the age group 25-39, 100% M (n=21) and 41% F (7/17) with a first Holter fell above the cut-off. No LR subject (21M, 24F) had more than 1000 PVCs. These figures remain the same if a cut-off of 200 PVCs in 24 hours is used. Median age of death is 41 y (95% CI 38-44y) for males and 71 y (95% CI 64 -79y) for females: a relative risk of death M: F of 4.8 (95% CI 2.9 8.1). To date, the 5-year male mortality rate following ICD is zero vs. 28% in controls (p=0.009). The same (non-significant) trends were observed for females. Males are 100% penetrant for multiple PVCs by age 40y, have a higher prevalence of multiple PVCs at a younger age, and a much higher risk of early sudden death than females, which can be prevented by ICD therapy.

**Inheritance analysis of congenital left ventricular outflow tract obstruction (LVOTO).** *K. McBride<sup>1</sup>, M. Lewin<sup>2</sup>, R. Pignatelli<sup>2</sup>, S.D. Fernbach<sup>1</sup>, P. Schliekelman<sup>3</sup>, A. Combes<sup>1</sup>, A. Menesses<sup>1</sup>, W. Lam<sup>1</sup>, L.I. Bezold<sup>2</sup>, N. Kaplan<sup>4</sup>, J.A. Towbin<sup>2</sup>, J.W. Belmont<sup>1</sup>.* 1) Mol and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Cardiology, Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Statistics Department, University of Georgia, Athens, Georgia; 4) Environmental Diseases & Medicine Program, Biostatistics Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC.

**INTRODUCTION:** Left ventricular outflow tract obstruction malformations (prevalence 8/10,000), are suspected to have a substantial genetic component. In a large echocardiography study, we demonstrated a relative risk for bicuspid aortic valve (BAV) of  $>5$  and a heritability of 0.50 for first-degree relatives of children with aortic valve stenosis (AVS), BAV, aortic coarctation (CoA), or hypoplastic left heart syndrome (HLHS). To further define the inheritance pattern, we performed formal segregation analysis on this echocardiography study group. **METHODS:** We sequentially ascertained 95 probands with AVS, BAV, CoA, or HLHS and their families, for a total of 331 individuals. The symptomatic probands and all asymptomatic relatives with BAV were collapsed into a binary trait. Segregation analysis was performed under S.A.G.E. version 4.3, which utilizes a regressive multivariate logistic model for binary traits. Five models of inheritance were constructed, consisting of recessive, codominant, dominant, dominant with reduced penetrance, and no major gene. Multiple relative risk (MRR) was used to estimate the number of loci. **RESULTS:** All of the Mendelian inheritance models were significantly different from the general model, and thus rejected. The MRR analysis indicated a high likelihood for a limited number of loci, highest for 1-2 loci with a decline of likelihood dropping below the support level at 10 loci. **CONCLUSION:** A specific Mendelian inheritance pattern could not be supported with our family data. MRR analysis showed a high likelihood for a small number of loci. This data suggests linkage analysis could be fruitful in identifying the causative gene or genes in LVOTO malformations.

**Noonan syndrome and cardiomyopathy: outcome indicators.** *B.A. Salbert<sup>1</sup>, A. Lowe<sup>2</sup>, D. Connuck<sup>1</sup>, J. Towbin<sup>3</sup>, S. Colan<sup>4</sup>, G. Cox<sup>5,6</sup>, L. Sleeper<sup>2</sup>, E. Cadregari<sup>1</sup>, S. Clunie<sup>3</sup>, J. Messere<sup>6</sup>, S. Lipshultz<sup>1</sup>.* 1) University of Rochester and The Golisano Children's Hospital at Strong, Rochester, NY; 2) New England Research Institutes, Watertown, MA; 3) Baylor College of Medicine, Texas Children's Hospital, Houston, TX; 4) Harvard Medical School, Children's Hospital of Boston, Boston, MA; 5) Genzyme Corporation, Cambridge, MA; 6) Children's Hospital of Boston, Boston, MA.

In an effort to provide counseling for families, we reviewed long term data on patients with Noonan syndrome(NS) and cardiomyopathy(CM) focusing on the association between survival and age at diagnosis, congestive heart failure (CHF) at CM diagnosis, gender, and race/ethnicity. The Pediatric Cardiomyopathy Registry (PCMR), sponsored by a grant from the NHLBI, has 62 patients with NS diagnosed with CM between 1990 and 2002. All had hypertrophic CM. Annual followup data was collected from the time of diagnosis until death, transplant, transfer to a non-participating institution or discharge from followup. Of the 62 cases, 39% were retrospective(diagnosed 1990-1995) and 61% were prospective(1996-2002). Forty-seven(76%)had an etiology of NS at the time of diagnosis. Half of the NS patients were diagnosed with CM at <6 mo. of age, 27% had CM at the time of diagnosis, and 52% were male. The racial/ethnic breakdown was 64% white, 11% black, 20% hispanic, 5% other. The median followup time for these patients was 3.7 yrs. with 15 deceased(24%). Of the deceased, 93% were diagnosed with CM at <6 mo. of age as compared to 36% of those alive. One-year survival since the diagnosis of CM was lower in those diagnosed at <6 mo. of age than those diagnosed at >6 mo. of age(59% vs. 95% respectively, log-rank p-value<0.001). If CHF was present at the time of diagnosis of CM, one-year survival was lower than if CHF was not present(39% vs. 87%, log-rank p-value<0.001). One-year survival was similar between males and females(74% vs. 76%, log-rank p-value=0.767). One-year survival also did not differ by race(white 80%, Black 71%, Hispanic=50%, other=100%, log-rank p-value=0.181). Age of <6 mo. and CHF at the time of diagnosis are associated with poor outcome in patients with NS and CM.

**The phenotypic expression of poor-R wave progression on ECG in arrhythmogenic right ventricular**

**cardiomyopathy linked to 3p25.** *S. Stuckless<sup>1</sup>, K. Hodgkinson<sup>1</sup>, M. Norman<sup>2</sup>, A. Healey<sup>3</sup>, A.M. Whalen<sup>3</sup>, L. Thierfelder<sup>4</sup>, E. Dicks<sup>1</sup>, A. Bassett<sup>5</sup>, P. Parfrey<sup>1</sup>, S. Connors<sup>3</sup>.* 1) Patient Res Ctr, Health Sciences Ctr, St Johns, NL, Canada; 2) Finley Park Hospital, London, England; 3) Division of Cardiology, Health Sciences Ctr, St Johns, NL, Canada; 4) Max-Delbruck Centre, Berlin, Germany; 5) Clinical Genetics Research, University of Toronto, Ontario, Canada.

Eleven families with autosomal dominant arrhythmogenic right ventricular cardiomyopathy (ARVC) linked to a founder haplotype at 3p25 are ascertained in Newfoundland. Five additional families cannot be defined by DNA haplotype analysis due to the death of all affected individuals. Clinical diagnosis for ARVC in the absence of a genetic test is important. We examined the diagnostic utility of poor R-wave progression (PRWP:in the absence of septal myocardial infarction) in leads V1-V3 in 191 well-ascertained subjects from the 11 families. Risk status was determined as high (HR; n=110; 54M, 56F) based on haplotype data, obligate carrier status or early sudden death, or low (LR; n=81; 40M, 41F) based on haplotype. Of 43M under 40y with a first ECG, 47% had PRWP vs. 80% (8/10) over 40y. No LR M (n=31) under 40y had PRWP vs. 1/8 (12.5%) over 40y. Of 36 F under 40y with a first ECG, 11/36 (30%) had PRWP vs. 17/20 (85%) over 40y. Of 29 LR female under 40y, 1 (3%) had PRWP vs. no female over 40y. Specificity and positive predictive value are 100% for males in the age group 25-54y. Of 29 HR males who did not have PRWP on first ECG, 7 went on to develop this feature and 15/28 HR females developed PRWP. The median age of onset is 46y for both males and females. The development of PRWP on ECG is age dependant but not gender dependant. When account is taken of age, PRWP is a good diagnostic, inexpensive, accessible test for ARVC in these families, when genotyping is not possible.

**PHENOTIPICAL GENETIC VARIABILITY OF ECTODERMIC DYSPLASIA IN A PEDIATRIC HOSPITAL.**

**STUDY OF FIVE DIFFERENT MEXICAN FAMILIES.** *C.N. Gil<sup>1,7</sup>, J.M.R. Aparicio<sup>2,7</sup>, M.P. Barrientos<sup>3</sup>, W.B. San Martin<sup>4</sup>, M.V.C. Mendez<sup>2</sup>, L.H. Hurtado<sup>5</sup>, E.R. Balbuena<sup>6</sup>, L.A.S. Gonzalez<sup>7</sup>, R.T. Tenorio<sup>7</sup>, F.C. Salinas<sup>8</sup>.* 1) Estomatology; 2) Genetics; 3) Endocrinology; 4) Maxilofacial Surgery; 5) Cytogenetics; 6) Dermatology, Hospital para el Nino Poblano, Puebla, Mexico; 7) Estomatology, Benemerita Universidad de Puebla, Mexico; 8) Oral genetics, Medical University South Carolina, USAg.

**INTRODUCTION:** Ectodermic dysplasias form a heterogenic group characterized by the involvement of embryo-ectodermic tissue: teeth, nails, ophthalmologic signs, labial-palatinum grooves sweat glands, and hair. **CLINICAL CASES:** Although all 5 syndromes in this study had different grade of phenotypic variability, the most common clinical characteristics were: anhidrotic ectodermic dysplasia (AED), the most frequent form and characterized by hypo- or anodontia, unguis dysplasia, varying alopecia, more or less severe dysmorphia (forehead bumps, rings under the eyes, etc.), and notably a hypo- or anhidrosis, including one patient without saliva production. All patients showed discrete hyperpigmented dermatological lesions, variability in alopecia manifestations. In one case the father was also diagnosed as ectodermic dysplasia with few saliva production. One case was diagnosed as cardiofacio cutaneous syndrome that has no dental alterations. **GENETICS:** For this same phenotype, several transmission modes have been published: recessive related to the X chromosome, and less frequently autosomal dominant or recessive. Two genes have been identified before: EDA1 for the X-related form and EDA3 localized on the 2q13 chromosome. EDA3 is implied in the AED transmitted in the autosomal dominant and recessive forms. A fourth gene incriminated in autosomal recessive AED has recently been identified. The gene, EDARADD, is located on chromosome 1. The protein it encodes is associated with the Edar intracellular domain and consequently in the Ectodysplasin-Edar. **CONCLUSIONS:** It is important for special third level diseased patients with congenital or genetic disorders to work in a multidisciplinary way in order to offer the best rehabilitation therapy for a better quality of life.

**Hyperactivity in individuals with Autistic Disorder.** *R.K. Abramson<sup>1</sup>, A.V. Hall<sup>1</sup>, S.A. Ravan<sup>1</sup>, M.L. Cuccaro<sup>2</sup>, C.M. Wolpert<sup>2</sup>, M.A. Pericak-Vance<sup>2</sup>, H.H. Wright<sup>1</sup>.* 1) Dept Neuropsychiatry & Behav, Wm S Hall Psychiatric Inst, Columbia, SC; 2) Duke University Center for Human Genetics, Durham, NC.

Hyperactivity is reported in a subset of probands with Autistic Disorder (AD). AD individuals are often characterized by their level of adaptive functioning. This study compares AD males and females with high adaptive functioning (AD-H) to those with low adaptive functioning (AD-L) to see if hyperactivity will discriminate between the two groups. Subjects (82 male and 30 female) came from a pool of 150 AD participants [125 Caucasian (C) and 25 African-American (AA)] in the Duke/USC collaborative study. Diagnoses were confirmed by the Autism Diagnostic Interview-Revised (ADI-R) (Lord, 1995). Hyperactivity was measured by the Aberrant Behavior Checklist Community subscale for hyperactivity (ABC-H) (Aman, 1985) and by the SNAP-IV (Swanson, 2001). ABC-H scores were not significantly different for AA versus C probands ( $F=0.013$ ,  $p=0.987$ ,  $df=2$ ). Using Vineland Adaptive Behavior Scale supplemental norms (Carter, 1998), AD-H was defined as 60th percentile or greater and AD-L as below the 60th percentile. Males and females were represented differentially in the high and low groups (Chi square = 3.69, z score = 1.92, which exceeded the critical value of  $z = 1.67$ ). ABC-H scores did not differentiate the 44 AD-L probands from the 68 AD-H probands. A significant gender by group interaction effect showed that AD-L males had higher ABC-H scores than any other group ( $F=5.99$ ,  $p=0.016$ ,  $df=1$ ). AD-L males had higher SNAP IV scores than AD-H males ( $t=2.137$ ,  $p=0.038$ ,  $df=48$ ). AD-L females had the lowest ABC-H scores of any group but there was no difference between AD-L and AD-H female ABC-H scores. This study supports previous findings that females as a group had lower functioning than males. However, ADHD symptoms may discriminate low and high functioning males with autism. This pattern did not hold true for the female participants.

**A novel mutation in the Caveolin-3 gene causing familial isolated hyperckemia.** *P. Gallano<sup>1</sup>, L. Alías<sup>1</sup>, I. Ferrer<sup>2</sup>, A. Freixas<sup>1</sup>, M.J. Rodríguez<sup>1</sup>, M. Baiget<sup>1</sup>, M. Olivé<sup>2</sup>.* 1) Dept Genetics, Hosp Sant Pau, Barcelona, Spain; 2) Dept Neuropathology, Hosp Bellvitge, Barcelona, Spain.

Caveolin-3 is the skeletal and cardiac muscle-specific protein of the caveolin gene family and the major component of the caveolae complex. Mutations in the CAV-3 gene cause Limb girdle muscular dystrophy type 1C (LGMD1C), Rippling muscle disease (RMD), Distal myopathy and Hyperckemia. We report a family suffering from isolated hyperckemia originated by a novel mutation in the CAV-3 gene. The evaluation of the patient (22-year-old, good sportsman and without muscular weakness) showed mild bilateral calf hypertrophy, normal EMG and elevated serum CK levels. His mother presented identical features. Caveolin-3 was reduced in the muscle biopsy analyzed by immunohistochemical and Western blot studies. Dysferlin was reduced in immunohistochemical analysis but normal in Western blot. A C->A transition in 169 nucleotide position, causing Valine to Methionine change in 57 codon of the polypeptide, was detected in exon 2 of CAV-3 gene. This change was confirmed as a novel missense mutation after the analysis of 50 normal individuals, 10 calpainopathies, 10 sarcoglycanopathies, 5 dysferlinopathies, 15 dystrophinopathies and 10 spinal muscular atrophies. This V57M mutation is the second one described in the CAV-3 gene associated to familial hyperckemia. The fact of the existence of clinical heterogeneity associated to CAV-3 gene mutations could be due to the specific altered protein domain. Nevertheless, there are a few mutations described in that gene to conclude about phenotype-genotype correlations. We consider suitable the study of CAV-3 gene in isolated hyperckemia cases in whose dystrophin involvement was excluded.

**Neurofibromatosis type 1 (NF1): phenotypical variability in patients with scoliosis or pseudoarthrosis of the tibia.**

*E. Bonioli<sup>1</sup>, M. Russo<sup>1</sup>, G. Morcaldi<sup>1</sup>, C. Bellini<sup>1</sup>, M. Baldi<sup>1</sup>, S. Boero<sup>2</sup>, G. Stella<sup>2</sup>.* 1) Paediatric Department State University of Genova, Italy; 2) Orthopaedic Unit G. Gaslini Institute Genova, Italy.

About 30-50% of children with NF1 have orthopaedic complications. Among these, scoliosis is the most common, while pseudoarthrosis of the tibia is the principal lower leg deformity. Typical non orthopaedic complications (NOCs) of NF1 are: optic pathway gliomas, plexiform neurofibromas (PNF), epilepsy, hydrocephalus, Noonan phenotype, other CNS malformations (myelomeningocele, tumor brain, arachnoids cyst, Chiari malformation) and malignancy.

**PATIENTS:** We considered 184 children (73 M / 111 F; median age at diagnosis 7.9) with NF1. They were subdivided in three groups: A Group: 140 pts (63 M / 77F) without orthopaedic complications; B Group: 27 pts (10 M / 17 F) with severe dystrophic scoliosis; C Group: 17 pts (6 M / 11 F) with tibial pseudoarthrosis. NOCs were evaluated in all 184 pts. The three groups were therefore compared in order to evaluate any different frequency of NOCs. **RESULTS:** NOCs occurred in 73 group A pts (52.1%): PNF (19.3%); glioma (13.6%); epilepsy (9.3%); hydrocephalus (6.4%), other CNS malformations (5%), Noonan phenotype (5%), malignancy (0.7%). Frequency of NOCs in group B was 51.8%: PNF (33.3%); glioma (22.2%), other CNS malformations (22.2%); tumours extra-CNS (18.5%), epilepsy (7.4%), hydrocephalus (3.7%). Frequency of NOCs in group C was 17.6%; glioma (11.8%) and PNF (5.8%). The association of three or more NOCs in the same patient was observed in 3.6% pts of group A and in 38.5% of group B. No patient of group C had more than one complication. **DISCUSSION:** Incidence of NOCs in C group was significantly lower than in two other groups, while incidence of NOCs in group B was the same as group A. Moreover in C group there was no more than one NOC in the same patient, while in B group we observed more frequently the association of three or more NOCs in the same patient. Our data point to a lower incidence of NOCs in NF1 patients with pseudoarthrosis of the tibia.

**Assessment of the translocation frequency between 4q and 10q in the South African FSHD population: a pilot study.** *M. Alessandrini*<sup>1</sup>, *A. Van der Merwe*<sup>1</sup>, *C-M. Schutte*<sup>2</sup>, *A. Olckers*<sup>1,3</sup>. 1) Centre for Genome Research, Potchefstroom University, Pretoria, South Africa; 2) Dept of Neurology, University of Pretoria, South Africa; 3) DNAbiotec Pty (Ltd), Pretoria, South Africa.

Facioscapulohumeral muscular dystrophy (FSHD) is a progressive autosomal dominant myopathy, preferentially affecting facial, shoulder girdle and upper-arm muscles. It is one of the most common muscular dystrophies with a prevalence of 1 in 20,000. The rearrangement that results in FSHD entails a deletion of an integral number of 3.3 kb repeat arrays on chromosome 4q35. A candidate gene for this disorder has, however, yet to be identified. Data suggests a position effect variegation model resulting in FSHD. Southern blot analysis has led to the identification of an additional locus with more than 98% homology to 4q35, which was subsequently mapped to chromosome 10q26. This region may also display 3.3 kb repeat deletions, similar to chromosome 4q35. A deletion fragment located on chromosome 10q is, however, non pathogenic and does not result in FSHD, but rather compromises accurate molecular diagnoses. Previous data suggested a model for subtelomeric plasticity due to the occurrence of DNA translocations between the 4-type and 10-type arrays. The high degree of homology between these fragments may be the predisposing factor that has led to these translocations being observed in 20% of the Dutch population. The objectives of this study were to optimise the Bgl II-Bln I dosage test via a non-radioactive protocol and to verify the presence of translocation events between the 4q and 10q arrays of affected and unaffected individuals selected from South African FSHD families. Results obtained from this study suggest that 4q-10q plasticity is indeed observed in the South African FSHD population. However, the observed translocation frequency of 8.7% is considerably lower than that obtained from previously reported population studies. Since a relatively small cohort was investigated in this pilot study, additional analyses with a significantly larger sample size are foreseen.

**Synpolydactyly associated with an apparently balanced reciprocal 2;3 chromosome translocation.** *C. Moore<sup>1</sup>, M. Macera<sup>2</sup>, A. Babu<sup>2</sup>, A. Dagum<sup>3</sup>, L. Hurst<sup>3</sup>, L. Mehta<sup>1</sup>*. 1) Schneider Children's Hospital at North Shore, Manhasset, NY; 2) Wyckoff Heights Medical Center, Brooklyn, NY; 3) University Hospital, Stony Brook, NY.

A mother and daughter presented with surgically corrected, bilaterally symmetrical synpolydactyly of the hands and feet. Maternal family history was significant for variable synpolydactyly in a total of nine individuals over five generations. Digit anomalies in the child are best described as 4,5 syndactyly of the hands with a duplicated digit in the web, camptodactyly of digits 2,3, and incomplete metacarpal synostosis of digits 3,4; both feet had broad 1st digits, short 4th digits and mild 2,3,4 digit syndactyly. The mother was described as having 3,4 digit syndactyly of the hands, a duplicated digit in between and camptodactyly of digits 3 and 4. She had syndactyly of digits 4,5 with a 6th digit on both feet. Other family members are described to also have extra as well as fused digits with contractures. No other significant birth defects were detected in our patients. The 3 y.o. child had a history of hypotonia but was showing good developmental progress. Chromosome analysis revealed an apparently balanced reciprocal translocation  $t(2;3)(q32.2;q25.1)$  in the mother and the child. These findings indicate that the autosomal dominant synpolydactyly segregated with the chromosome translocation in these two individuals tested. It is of interest that the breakpoint on chromosome 2 is in the region of the HOXD gene cluster at 2q31-q32. Synpolydactyly (syndactyly type II) and other limb malformations are associated with mutations (such as amino acid substitutions and truncations), polyalanine expansions, and deletions of the HOXD13 gene located within this cluster. It is highly likely that the breakpoint on chromosome 2, in this inherited translocation, is located within the HOXD13 gene or adjacent to regulatory elements affecting expression of HOXD13. DNA analysis of the breakpoint and additional cytogenetic studies on affected family members will help determine if this is the first reported case of an inherited chromosome translocation causing synpolydactyly.

**A new Kabuki-like syndrome in siblings.** *B. Hall.* Pediatrics, Genetics, University of Kentucky, Lexington, KY.

Kabuki syndrome (Nikawa N, et al, Amer J Med Genet 31:565, 1988) is a distinct multiple congenital anomaly syndrome of unknown etiology. Most cases are sporadic occurrences in their families. The face is very distinctive with long appearing palpebral fissures, eversion of lower lateral eyelids, arched eyebrows, flat nasal bridge, and laterally protruding ears. I present male and female siblings with Kabuki-like face and multiple anomalies who represent an apparent phenocopy of the Kabuki syndrome.

Both pregnancies were uncomplicated except for Crohn's disease. During both pregnancies, mother took sulfasalazine the first trimester (Case 1) or Asacol (Case 1 and 2). Both children were IUGR, had poor postnatal growth, and were moderately psychomotor delayed. Each child's features included large laterally protruding ears, long appearing palpebral fissures, mild eversion of lower eyelids, long eyelashes, thick eyebrows, thin upper lip, inverted v-shape mouth, and small mandible. Case 1 (female) also had short incurved 5th fingers with small nails and microcephaly. Case 2 (male) had bilateral cryptorchidism and borderline macrocephaly. Both children lacked digital fat pads. Both had normal chromosome studies and CNS imaging studies.

While clinical differentiation appears adequate to separate out the above siblings from reported cases of Kabuki syndrome, identification of the etiology of Kabuki syndrome will greatly aid in excluding phenocopies or outliers.

**Is Autism Caused by Numerous Genetic and Cytogenetic Syndromes?** *S. Lucchese, N. Takahashi, J. Miles.* Dept Child Health, Med Gen Div, University of Missouri Hospital, Columbia, MO.

To learn whether chromosome abnormalities and genetic syndromes cause autism or merely lower the threshold in the genetically susceptible host, we examined etiologically distinctive groups of autism probands. The 3 study groups had either a cytogenetic abnormality (9), an autism related syndrome (6), or complex autism (defined on the basis of multiple dysmorphic features) (21). Each of the three study groups was compared with a group of 65 autism probands with essential autism (normal morphology, brain structure, HC>2%). Cytogenetic syndromes included: del(2)(q37.1), + ring 8, del(8)(p22.2), del(11)(q24), + der(15)t(4;15)(p16;q13), + isodic(15)(q13), + der(15)(q14), + (21), add(2)(q35), XXY. Syndromes were Tuberous Sclerosis, Fragile X, Sotos, Fetal Valproate and a private macrocephaly syndrome. All met DSM-IV diagnostic criteria. Results: Family histories of autism related disorders - alcoholism, affective disorders, OCD, seizures, cognitive and other psychiatric disorders were obtained. In all 4 groups, the family histories revealed comparably high levels of these neurologic and psychiatric disorders. The 3 study groups differed from the essential autism group in the sib recurrence risks and sex ratios, indicating genetic differences between them. The latter sib recurrence risk was higher when the proband had essential autism (9.2% (6/65)) compared to no risk (0/36) when the proband had a cytogenetic, genetic or complex autism ( $P=0.086$ ). Sex ratios were lower in the cytogenetic and complex groups, compared with essential autism (1.2:1 vs 7.8:1,  $p=0.013$ , 2.5:1 vs 7.8:1,  $p=0.08$ ). Family histories of psychiatric and cognitive disorders are assumed to indicate genetic loading that predisposes to the development of autism. For autism caused by a cytogenetic or genetic syndrome, one might assume that family loading would not be higher than in the general population. The similarity of family histories across the groups implies that for most cytogenetic and genetic syndromes, which occur in autism, their causal effect is only partial and may just lower the threshold for the development of autism.

**Intra-familial correlations of symptoms and clinical characteristics in multiplex Korean families with schizophrenia.** *K.S. Hong<sup>1</sup>, K-S. Choi<sup>1</sup>, S.W. Kim<sup>1</sup>, Y-S. Lee<sup>2</sup>, H.Y. Yoe<sup>3</sup>, E.Y. Cho<sup>1</sup>, Y.L. Jang<sup>4</sup>, W-S. Jang<sup>1</sup>, D.Y. Park<sup>1</sup>.* 1) Department of Psychiatry, Sugkyunkwan University School of Medicine, Samsung Seoul Hospital, Seoul, Korea; 2) Yong-In Mental Hospital, Yong-In, Kyunggi-Do, Korea; 3) Eumsung Mental Hospital, Eumsung, Korea; 4) National Chuncheon Hospital, Chuncheon, Korea.

This study aims at examining familial associations of symptoms and clinical characteristics in affected sibling or relative pairs of schizophrenia as an effort to identify genetically homogenous phenotypes in this complex genetic disorder. Seventy-five subjects with DSM-IV diagnosis of schizophrenia from 35 Korean families multiply affected with schizophrenia were ascertained from clinics of general hospitals and mental hospitals. Direct interviews were done using Korean version of Diagnostic Interview for Genetic Studies. Krawieka Rating Scale and The Schedule for the Deficit Syndrome were also applied for further evaluation of psychopathologies. Intra-familial concordances and correlations of clinical variables were tested using  $\chi^2$ -test and Spearman's correlation, respectively. Significantly high concordance rate within relative pairs was found for the diagnosis of paranoid vs. non-paranoid subtypes. Deficit vs. non-deficit syndromes showed only trend of concordance. Single item score of hallucination and factor score of negative symptoms showed significant intra-familial correlations. Ages at onset of prodromal symptoms, onset of recognized psychotic symptoms and first hospitalization did not show any correlation within the relative pairs. Familial factors, possibly the genetic factor contribute to the phenotypic characteristics of paranoid vs non-paranoid subtype, hallucination, and negative or deficit syndrome. It is suggested that these variables are candidates of phenotype marker for genetic linkage studies.

**Chromosomal Markers and their genotype/phenotype correlation- Preliminary data.** *L. McCarthy*<sup>1</sup>, *A. Maleki*<sup>2</sup>, *L. McGavran*<sup>1, 2</sup>, *C. Tsai*<sup>1</sup>. 1) Division of Genetics/Pediatric, The Children's Hospital, Denver, CO; 2) Colorado Cytogenetic Lab, Department of Pathology, The Children's Hospital, Denver, University of Colorado.

Supernumerary chromosomal markers are frequent findings during amniocentesis or routine chromosome testing. The incidence of supernumerary markers is approximately 1 in 2500. The genotype has been recognized for many years; however, insufficient information was available genetic counseling. These results from difficult characterization of the small markers by traditional cytogenetic technology and lacking long term follow up literature on the result of the pregnancy. We herein report the preliminary data on the study we conduct to correlate supernumerary marker genotypes to their specific phenotype. With the advance of molecular cytogenetic techniques, including florescence in-situ hybridization (FISH), these markers can be more clearly described. Sixty-five patients, including adults, children and markers identified during prenatal testing, CVS or amniocentesis, with supernumerary markers ascertained through the Colorado Cytogenetics Laboratory over the last ten years were invited to this study. We also ascertain the on-going new patients identified through the lab and the genetic clinic. Each patient who was enrolled in the study was asked to provide a complete history with medical records and undergo a physical exam. The endpoint of the study is to correlate a specific genotype with its phenotype. We summaries the preliminary data on seven patients participated to date for this conference. Complete data will follow. Hopefully this research will help us better understand the clinical affects of specific supernumerary markers and provide specific information for genetic counseling.

**Subtle unbalanced t(2;14)(p25;q32) uncovered by subtelomeric FISH in a patient with congenital anomalies.** *H.A. Overcash, S.J. Hassed, P.L. Wilson, J. Lee, S. Li, J.J. Mulvihill.* Department of Pediatrics, OUHSC, Oklahoma City, OK.

A six-month-old baby girl was referred for chromosomal evaluation because of multiple congenital anomalies. The dysmorphic features included: developmental delay, Dandy-Walker malformation, mild epicanthal fold of the right eye, wide nasal bridge, deep and short philtrum, slight widely spaced nipples, dimples on both elbows and knees and others. Routine chromosome analysis was performed and revealed that each of the cells had a derivative chromosome 2 with a small fragment of chromosomal material of unknown origin attached, plus a questionable inversion of chromosome 21q. None of parents were available for chromosome studies. To determine the origin of unknown chromosomal material, FISH was performed utilizing commercial probes corresponding to the subtelomeric regions of all 22 autosomes and the sex chromosomes, X and Y, except for the short arms of the acrocentric chromosomes 13, 14, 15, 21 and 22. All the cells analyzed had a der(2)(2;14)(p25;q32). Clearly, the minimal deletion of 2p25 and duplication of 14q32 contribute our patients clinical features, which will be compared to the previously reported limited number of cases with 2p- or 14q+.

**Revised diagnostic criteria for neurofibromatosis 2 (NF2).** *R.T. Ramsden*<sup>1</sup>, *D.G.R. Evans*<sup>2</sup>, *A.J. Wallace*<sup>2</sup>, *H. Joe*<sup>3</sup>, *M.E. Baser*<sup>4</sup>. 1) Department of Otolaryngology, Manchester Royal Infirmary, Manchester, UK; 2) Department of Medical Genetics, St. Mary's Hospital, Manchester, UK; 3) Department of Statistics, University of British Columbia, Vancouver, BC, Canada; 4) Los Angeles, CA, USA.

We recently reported that each of the four sets of clinical diagnostic criteria for NF2 had low sensitivity at the time of the initial clinical assessment, although the Manchester criteria were the most sensitive (Neurology 2002;59:1759-65). In this study, we propose and evaluate modifications to the Manchester criteria. The study had 163 NF2 patients in the United Kingdom registry who did not have a family history of NF2 and who presented without bilateral vestibular schwannomas; this group presents the greatest diagnostic difficulties. The proposed modifications are A) in people without a family history of NF2, permitting the diagnosis when there are multiple meningiomas and only one, instead of two, other tumors or cataract (as in the NNFF criteria), B) adding childhood mononeuropathy (ages  $\leq 10$  years) as a diagnostic criterion, and C) in addition to clinical criteria, permitting the diagnosis when constitutional *NF2* mutations are identified. We used Kaplan-Meier analysis to determine the time course, from initial assessment to the most recent clinical evaluation, of the increasing proportion of people who would be diagnosed with NF2 using the current Manchester criteria and the modifications. The jackknife method was used to compute pointwise standard errors for differences in proportions of pairwise Kaplan-Meier curves between different sets of criteria. Modification A significantly increased sensitivity above the Manchester criteria from 4-17 years after initial assessment. Modification B did not increase sensitivity above modification A, because all patients who were identified earlier by adding childhood mononeuropathy as a criterion had already been identified earlier using modification A. Modification C significantly increased sensitivity above modification A from initial assessment to 5 years after initial assessment. We conclude that simple modifications to the Manchester criteria significantly increase sensitivity from initial assessment to 17 years after initial assessment.

**Triploidy with a karyotype 69,XXX.** *G. P. Akpınar<sup>1</sup>, E. Ergül<sup>1</sup>, O. Karlı<sup>2</sup>, G. Turker<sup>2</sup>, M. Unlu<sup>3</sup>, K. Cetin<sup>1</sup>, A. Sazci<sup>1</sup>.*  
1) Department of Medical Biology and Genetics,; 2) Pediatrics,; 3) Radiology, Faculty of Medicine, University of Kocaeli, Derince, 41900, Turkey.

Triploidy is a chromosomal abnormality where three complete sets of the haploid genome are present, and occurs in about 2 percent of conceptuses. Most are lost as miscarriages, are responsible for about 20 percent of chromosomally abnormal spontaneous abortions. The live birth rate for triploidy is 1/50.000 live births. There seem to be three different mechanisms producing triploidy: firstly, diandry, secondly, likewise, digyny, thirdly and finally, dispermy. A triploid infant (karyotype 69,XXX), 1440 grams, 32 weeks gestation, 44 cm head circumference, was born with caesarean section. The mother was 22 years old and father 19 years old who used hashish with antisocial behavioural manifestations. Both had a gipsy origin. She had one abortion, a 2 years old healthy daughter, and a triploid daughter. The triploid baby had a problem with breathing and positioning the body, muscular hypotonia, aberrant skull shape, omphalocele, syndactyly of third and fourth fingers, short neck, dysplastic calvaria with large posterior fontanel, simian crease of the hands, pulmonary hypoplasia, low set ears. Left ear had an accessory in front of tragus. Eyes were spaced farther apart than usual. In MRI; agenesis of corpus callosum was observed. There were irregularities in posterior interhemispheric fissure and minimal interdigitation in cerebral sulcus. In abdominal USG; there were heart problems including VSD, and bilateral renal hypoplasia. In transfrontal USG; corpus callosum posterior was not formed. The baby did not have ability to suck. In addition, we also studied APOE, AT1, MTHFR polymorphisms in the four members of the family. They all had APOE3/3 genotype. Triploid baby and father had MTHFR A1298A genotype and mother and sister had MTHFR A1298C genotype. The family all had MTHFR C677C genotype. Father and triploid baby had AT1 AC genotype, mother and sister had AT1 AA genotype.

**Monosomy 1p36.** *C. Tsai.* Dept Pediatrics/Div Genetics, Childrens Hosp, Denver, CO.

Monosomy 1p36 is the most common terminal deletion syndrome. Most commonly associated features and medical problems in patients with this deletion syndrome include large anterior fontanelle, motor delay/hypotonia, moderate to severe mental retardation, growth delay, prominent forehead, microcephaly, deep set eyes, vision problems, seizures, flat nasal bridge, midface hypoplasia, clinodactyly and/or short fifth finger, low-set/ asymmetrical ear, hearing deficits behavioral problems and thyroid diseases. This contiguous gene deletion syndrome is presumably caused by haploinsufficiency of the involved genes. I am reporting 7 patients with chromosome 1p36 deletions ascertained through a tertiary childrens hospital pediatric genetic service. Their cytogenetic anomalies ranged from pure terminal deletions, interstitial deletions secondary to complex rearrangements, to subtelomere deletion. All are de novo cases. Other than one with 1p36.23 deletion and on has subtelomeric deletion distal to the commercial 1p36.3 FISH probe, the rest of the patients have 1p36.3 deletion. I summarized the findings according to the following perspective: hearing, palatal and ophthalmological, echocardiograms, ultrasound findings, neurological assessments (some with image studies), thyroid function tests, and developmental findings. The result demonstrated that subtelomeric deletion has relatively milder phenotype and not very characteristic in the facial features. One patient also demonstrated the importance of performing MTHFR mutation analysis because of the born haploinsufficiency and relatively common gene frequency of thermal labile mutation.

**A quantitative assessment of limb anomalies in CHARGE syndrome: Correlation with diagnosis and characteristic CHARGE anomalies.** *K.E. Brock<sup>1</sup>, M.A. Mathiason<sup>1</sup>, B.L. Rooney<sup>1</sup>, M.S. Williams<sup>2</sup>*. 1) Medical Foundation, Gundersen Lutheran Med Center, La Crosse, WI; 2) Dept. of Pediatrics Gundersen Lutheran Med Center, La Crosse, WI.

CHARGE syndrome was initially not thought to involve the limb. Several subsequent reports have shown that limb anomalies are not uncommon. To date, there have been no quantitative studies of limb anomalies in CHARGE syndrome. This study was designed to answer several questions: Do CHARGE patients with limb anomalies represent a subgroup within CHARGE syndrome? Are there correlations between certain CHARGE syndrome anomalies and limb anomalies? Are certain types of limb anomalies seen with increased frequency in CHARGE syndrome? **METHODS:** All described patients were categorized utilizing the expert diagnostic model proposed by Mitchell (1985). Patients with chromosomal anomalies or familial CHARGE were excluded, as were patients with inadequate clinical descriptions, and patients in large series where individual characteristics could not be ascertained. Multivariate analysis was performed. **RESULTS:** 172 patients with definite or probable CHARGE syndrome were analyzed. 37% of these patients have at least one limb anomaly. Limb anomalies were significantly associated with coloboma, urinary tract anomalies and genital anomalies when definite and probable CHARGE patients are analyzed together ( $p < 0.005$ ,  $p < 0.019$  and  $P < 0.026$  respectively). These associations were not significant when the definite or probable CHARGE patients were analyzed separately, with the exception of genital anomalies in definite CHARGE ( $p < 0.035$ ). Association with choanal atresia is significant only for probable CHARGE patients ( $p < 0.016$ ). **CONCLUSIONS:** Limb anomalies are present in more than one-third of CHARGE syndrome patients. Limb anomalies are seen more frequently in association with certain CHARGE anomalies, which could provide insight into common embryologic pathways. There is not a common limb anomaly seen in CHARGE syndrome, with the possible exception of dermatoglyphic abnormalities.

**NSD1 - deleted Sotos syndrome patients with delayed bone age. -Is the advanced bone age essential for Sotos syndrome?-. T. Doi<sup>1</sup>, T. Kondoh<sup>1</sup>, E. Kinoshita<sup>1</sup>, T. Matsumoto<sup>2</sup>, M. Hara<sup>1</sup>, S. Oka<sup>1</sup>, N. Kurotaki<sup>3</sup>, N. Harada<sup>3</sup>, N. Matsumoto<sup>3</sup>, N. Niikawa<sup>3</sup>, H. Moriuchi<sup>1</sup>.** 1) Dept Pediatrics, Nagasaki Univ Sch Medicine, Nagasaki, Japan; 2) Dept Nursing, Nagasaki Univ Sch Medicine, Nagasaki, Japan; 3) Dept Human Genetics, Nagasaki Univ Sch Medicine, Nagasaki, Japan.

Sotos syndrome is a malformation syndrome characterized by overgrowth from the prenatal stage through childhood, advanced bone age, macrocephaly, a distinctive facial appearance, and developmental delay. Recently, NSD1 was identified as a causative gene for Sotos syndrome and haploinsufficiency of the NSD1 is one of the main etiologies of Sotos syndrome. We here present two cases of NSD1 - deleted Sotos syndrome with delayed bone age. Patient 1 is now a five-year-old boy. At the age of 14 months, he was diagnosed as Sotos syndrome from such clinical features as tall stature of 79.4 cm (+1.9SD), heavy weight of 12.6 kg (+3.1SD), large head circumference of 51 cm (+3.4SD), frontal bossing, pointed chin, hypertelorism, down-slanting palpebral fissures, high-arched palate and developmental delay. NSD1 gene analysis revealed 2.2-Mb deletion in heterozygous state. At the age of 61 months, his height was 105.2 cm (+0.3SD), weight was 20 kg (+1.0SD), and bone age (52 months old) was 9 months behind. Brain MRI revealed cephalomegaly, ventriculomegaly, thinning of the corpus callosum and thinning of the pituitary fossa. Hormonal examinations showed normal secretion of growth hormones and thyroid function. Patient 2 is now a one-year-old girl. At 12 months of age her head circumference was 49 cm (+2.7SD), and height was 74 cm (mean). FISH using NSD1 as a probe showed only one signal in her peripheral lymphocytes, indicating heterozygous deletion of NSD1. CT scan of the brain revealed no abnormality. The carpal bones X-ray showed no appearance of capitate and hamate bone, indicating delayed bone age. The advanced bone age with overgrowth is one of major criteria of Sotos syndrome. However, our NSD1 - deleted Sotos syndrome patients showed delayed bone age that was not associated with hormonal abnormality, suggesting that the advanced bone age may be dispensable for Sotos syndrome and result from unknown factor(s) other than NSD1.

**MeCP2 mutations and gastrointestinal phenotype in Rett Syndrome.** *G. Bibat*<sup>1</sup>, *C. Cuffari*<sup>2</sup>, *S. Naidu*<sup>1</sup>. 1) Neurogenetics Unit Kennedy Krieger Inst, Baltimore, MD; 2) Division of Pediatric Gastroenterology, Johns Hopkins Hospital, Baltimore, MD.

Rett syndrome (RS), a neurodevelopmental disorder predominantly affecting females, results from mutations in the methyl-CpG-binding protein 2 (MeCP2) gene located on chromosome Xq28. Mutations in MeCP2 are associated with developmental regression and significant gastrointestinal (GI) dysfunction. The GI manifestations include: 1) constipation; 2) reflux; 3) dysphagia; 4) failure to thrive (z-score < -2SD), which vary in severity. To determine if the GI features may be genotype dependent, we evaluated 36 females with the phenotype of RS (ages 3-15 years with mean age of 7.4 years) of whom 26 tested positive for the MeCP2 mutation and 10 were negative, all of whom were correlated with their GI dysfunction. Mutation positive patients had a wide distribution of mutations throughout exons 3 and 4 of the MeCP2 gene. Among these mutation positive patients, all manifested varying degrees of GI dysfunction requiring medical intervention except one subject. Interestingly, this one patient without GI symptoms had a mutation (1161del 6) in the most distal portion of the gene. Patients with more proximal mutations (R168X and R270X) had the greatest number of GI manifestations. The more severe oropharyngeal dysphagia associated well ( $p < 0.05$ ) with mutations (R106Q, T158M and R168X) affecting the proximal portion of the protein suggesting that such mutations may predispose to considerable neuroenteric dysfunction. A similar association between the proximal MeCP2 mutations and severity of neurologic and autonomic dysfunction in RS was noted by Hoffbuhr et al (Neurology, 2001). Conclusion: Severe GI manifestations of RS, such as dysphagia, occur when the proximal portions of the gene are involved reflecting significant brain stem neuronal involvement in addition to the generalized autonomic dysfunction that contributes to reflux and constipation.

**Exploration of the neurobehavioral aspects of Marfan syndrome.** *S. Grimes*<sup>1,2</sup>, *A. Matthews*<sup>1,2</sup>, *J. Bubb*<sup>1,2</sup>, *M. Drumm*<sup>2,3</sup>, *C. Ievers-Landis*<sup>2,3</sup>, *G. Wiesner*<sup>1,2</sup>. 1) Center for Human Genetics, University Hospitals of Cleveland, Cleveland, OH; 2) Case Western Reserve University, Cleveland, OH; 3) Rainbow Babies & Children's Hospital, Cleveland, OH.

Preliminary studies suggest that children with Marfan syndrome (MFS) may be at increased risk for learning problems, attention difficulties, and hyperactivity. Clinical observations also suggest that some may have decreased energy and poor coordination. To explore these possible associations, this study examined parent perceptions of development and neurobehavioral problems in children followed in a multidisciplinary MFS clinic. Fifty parents of children (aged 7-21) with features of MFS and 212 parents of unaffected control children were asked to participate. Parents of 20 affected children and parents of 34 control children completed mailed questionnaires regarding their child's motor and speech development, activity level, attention, and learning problems. Respondents also completed the Child Behavior Checklist, a well-validated measure of competencies and behavioral problems in school-aged children. Affected children were perceived by parents to have significantly more speech ( $p=0.023$ ) and motor deficits ( $p=0.018$ ) and decreased activity levels ( $p<0.001$ ) compared to unaffected peers. The prevalence of learning problems was higher in affected children than in controls, with 30% of affected children reportedly diagnosed with a learning disability. Parents of affected children were more likely to report that their child had attention problems, but they were not more likely to report a diagnosis of Attention-Deficit/Hyperactivity Disorder. These results support previous findings of an association between attention and learning problems in children with features of MFS. Affected children may also be at increased risk for speech and motor delays. These data may help genetic professionals provide appropriate medical and developmental services to affected individuals. Further research is necessary to delineate whether learning and attention problems as well as speech and motor delays represent a behavioral phenotype for MFS.

**Anophthalmia-Microphthalmia in an extended family with consanguinity: further confirmation of Anophthalmia-Plus Syndrome.** *E. Elsobky*<sup>1</sup>, *S.M. Elsayed*<sup>1</sup>, *A. Parsian*<sup>2</sup>. 1) Medical Genetics Center, Heliopolis, Cairo, Egypt; 2) University of Louisville Birth Defects Center, Louisville, KY.

We report an extended pedigree with several members affected with Anophthalmia/Microphthalmia. The proband was a 4 years old female with bilateral extreme microphthalmia with foreshortening of eyelids in all directions, left oblique facial cleft which ended in lower lid coloboma, high arched palate with cleft palate, brachycephaly, and low set ears. Chromosome analysis from blood using high resolution banding was normal 46, XX female karyotype. The younger sister was 3 months old and had bilateral microphthalmia, low set ears and no cleft palate. The parents are first cousins and father's 3 cousins have bilateral microphthalmia without cleft palate or facial clefts. Our pedigree probably is the second one reported so far with microphthalmia-anophthalmia and autosomal recessive mode of inheritance that further confirms anophthalmia-plus syndrome [Fryns et al., 1995].

**Expansion of Wiedemann Beckwith syndrome spectrum, description of a non-viable form discovered at 13 weeks of gestation.** *M. Gerard*<sup>1</sup>, *M. Sinico*<sup>2</sup>, *C. Touboul*<sup>3</sup>, *B. Haddad*<sup>3</sup>, *F. Encha-Razavi*<sup>2</sup>, *J.B. Paniel*<sup>3</sup>, *C. Gicquel*<sup>4</sup>. 1) Medical Genetics, CHIC, Creteil, France; 2) Foetopathology, CHIC, Creteil, France; 3) Obstetrics, CHIC, Creteil, France; 4) Molecular Biology, Pediatric endocrinology, hopital Trousseau, Paris, France.

Wiedemann Beckwith syndrome (WBS) associates macrosomia, macroglossia, omphalocele, visceromegaly, and embryonic tumors. Others frequent features are neonatal hypoglycaemia, facial dysmorphism, frontal nevus flammeus, ear fissures and body hemihypertrophy. Prenatal discovery of WBS is based on the combination of polyhydramnios, fetal macrosomia with macroglossia and parietal defect. A 29-years-old, gravida 2, para 0 was referred. Ultrasound at 13 weeks showed large megacystis and abnormal abdominal wall. The parents were not consanguineous. Karyotype was normal, 46 XY. Termination of pregnancy was elected by the couple. Fetal measurements were between 75P and 90P. A large omphalocele was present, containing small bowel loops, liver left lobe and megacystis. The abdominal wall was very thin, with no evidence of muscle, in a Prune-Belly sequence. Organomegaly were present on liver, brain, kidneys and adrenals. Adrenal cytomegaly was present. Molecular analysis of the 11p15 imprinted region showed an isolated demethylation of KvDMR1 of the KCNQ1OT. The methylation pattern of KvDMR1 was strictly normal in fetus of the same term. Karyotype and methylation analysis of the 11p15 region was normal from both parents. This presentation is particularly severe, non-viable large omphalocele with Prune-Belly sequence. Association of WBS and Prune-Belly sequence has been described in 3 cases. In one familial case, WBS and Prune-Belly sequence were associated in one proband, the other sibling showing BWS and obstructive uropathy (Watanabe and Yamanaka, 1990). Other publications report isolated cases of WBS with complete Prune-Belly sequence (Knight et al., 1980; Silengo et al., 2002). No molecular analysis were reported in these clinical reports. Search for WBS should be conducted for lethal malformative pattern, associating large omphalocele, prune belly sequence signs and adrenal cytomegaly.

**Total asymmetry in a case of severe Silver Russell syndrome.** *L. Bobadilla-Morales<sup>1, 4</sup>, A. Corona-Rivera<sup>1,2,4</sup>, J.R. Corona-Rivera<sup>1,3,4</sup>, Cuerpo Académico Genética Clínica y Médica, CUCS, U. de G..* 1) Laboratorio de Genética Humana, Universidad de Guadalajara, CUCS, Guadalajara, Jalisco, México; 2) Unidad de Citogenética, OPD Hospital Civil de Belén, Guadalajara, Jal., México; 3) OPD, Hospital Civil Juan I Menchaca, Guadalajara, Jal., México; 4) Doctorado en Genética Humana, CUCS, U. de G.

Silver-Russell syndrome (SRS) is characterized by low birth weight, prenatal onset short stature, triangular face, café au lait spots and fifth finger clinodactyly. Besides, unilateral upper or lower limb asymmetries are reported in about 60-85% of the cases with usual variations of around 2.5 cm. Most cases are sporadic, but several modes of inheritance have been proposed. We report a 4.6 yr old boy with severe SRS and total body asymmetry. He was born at term to healthy, non-consanguineous 28-years-old parents. Birth weight was 1600 g and birth length was 42 cm. Intrauterine growth retardation and asymmetry were noticed at birth. He also showed severe psychomotor retardation. Physical examination at 4.6 years of age showed total left asymmetry, left body side length was 92.5 cm and right body side length was 81.5 (11 cm of difference), Right hand and foot were 7.9 cm and 8.4 cm, respectively. Left hand and foot were 8.9 cm and 9.6 cm, respectively. OFC was 47 cm (-3 SD). Triangular left-sided asymmetric face, right iris coloboma, fifth fingers clinodactyly and café au lait spots on limbs were present. On the right side, renal hypoplasia, cryptorchidism and small testicle were observed. The karyotype was 46,XY. Total and severe asymmetry (including the structures of the head, trunk and limbs) has not been previously reported in SRS. Although etiology asymmetry in SRS is unknown, disturbances in the control of symmetry have been proposed. Severe asymmetry in our patient may represent a hemihypertrophy. Chitayat et al. (1988) reported a child with SRS and a hepatocellular carcinoma, a neoplasia more frequent in hemihypertrophy and suggest that common pathologic factors may underlie the development of SRS and hemihypertrophy. Current report supports a probable pathogenic relation between SRS and hemihypertrophy.

**The FG syndrome: report of a large italian series.** A. Battaglia<sup>1</sup>, C. Chines<sup>1</sup>, A. Novelli<sup>2</sup>, J.C. Carey<sup>3</sup>. 1) Inst Child Neurology & Psych, Stella Maris Inst/Univ Pisa, Pisa, Italy; 2) IRCCS-CSS San Giovanni Rotondo Mendel, Univers. La Sapienza, Roma, Italy; 3) Division of Medical Genetics, Dept. of Pediatrics, Univ. of Utah, Salt Lake City, UT, USA.

FG syndrome was first described by Opitz and Kaveggia in 1974, as a rare MCA/MR syndrome occurring only in boys, due to a recessive mutation on the X chromosome. Based on over 50 reported cases, FG syndrome is associated with developmental delay (especially speech), hypotonia, postnatal onset relative macrocephaly, prominent forehead, frontal hair upsweep or whorls, ocular hypertelorism, thin vermilion border of the upper lip, relatively short fingers with broad thumbs and halluces, persistent fetal fingertip pads, anal anomalies, and/or constipation. Major malformations are rare, including pyloric stenosis, anal agenesis, cryptorchidism, hypospadias, inguinal hernias, congenital heart defects. Abnormal EEGs and seizures have been reported in 70% of patients. Brain MRI shows corpus callosum abnormalities, dilatation of lateral ventricles, periventricular nodular heterotopias, mild cerebellar defects, reduced periventricular white matter, and Chiari 1 malformation. Behavior is characterized by ADHD, less developed language and fine motor and executive function skills, whereas visual-spatial abilities seem to be a relative strength. At present, due to an improved awareness, FG syndrome emerges as a rather common MCA/MR syndrome, occurring in boys and girls, presumed to be due to incompletely recessive mutations of genes on chromosome X. Three candidate loci are already at hand, making it possible the cloning of causal gene/s in the next future. We describe 20 patients, referred for evaluation of DD/MR, and diagnosed as FG syndrome. This is the first reported italian series of FG syndrome cases, with particular emphasis on physical, neurological and developmental findings, and natural history. Follow-up ranged between 6 months and 7 years. Subtelomeric analysis, performed in all of them, gave normal results. Experience with our series of patients suggests that FG syndrome may be more common than previously thought and should be routinely considered in the evaluation of children with DD/MR.

**Deletion of paternal 7q21.2-q21.3 is found in some patients with a Seckel-like Syndrome.** *P. Benke<sup>1</sup>, M. Quintero<sup>1</sup>, T. Zuluaga<sup>2</sup>.* 1) Univ Miami Sch Medicine, Miami, FL; 2) Universidad del Valle, Cali, Colombia.

An 11 yr old male with intrauterine growth retardation, short stature, microcephaly, moderate mental retardation, deafness, and facial features resembling the Seckel Syndrome (SS) was found to have an interstitial deletion of chromosome 7q21.2-q21.3. Growth hormone deficiency and a partially empty sella were also found. Experiments with microsatellite markers showed that the 7 q deleted area was 8.5 cM, and extended from D7S1813 to D7S491. The deleted region was paternal, not maternal in origin. An insulin receptor substrate-like gene (IRS3L) in the deleted region may be responsible for much of the short stature seen in this child. A review of previous cases with 7q21.2-q21.3 deletions suggests that some but not all have SS-like features. We suggest that paternal chromosome 7q21.2-q21.3 deletion is a unique form of Seckel Syndrome.

**Familial congenital bilateral perisylvian syndrome: Clinical spectrum and neuroimaging findings.** *I.L. Brandao-Almeida<sup>1</sup>, M.M. Guerreiro<sup>2</sup>, N.F. Santos<sup>1</sup>, C.A. Guimares<sup>2</sup>, S.R. Hage<sup>2</sup>, F. Cendes<sup>2</sup>, L.L. Min<sup>2</sup>, A.M.S.G. Piovesana<sup>2</sup>, M.A. Montenegro<sup>2</sup>, I. Lopes-Cendes<sup>1</sup>.* 1) Department of Medical Genetics, UNICAMP, Campinas - SP, Brazil; 2) Department of Neurology, UNICAMP, Campinas - SP, Brazil.

**Purpose:** The congenital bilateral perisylvian syndrome (CBPS) is frequently caused by polymicrogyria. Clinical features consist of epilepsy in most patients and varying degrees of cognitive deficits. CBPS may have familial recurrence and genetic heterogeneity is likely present. The objective of this work is to correlate clinical and neuroimaging findings in patients with familial CBPS. **Methods:** Family histories were obtained and pedigrees were constructed. Patients were also assessed by neuropsychological tests, language evaluation and high resolution MRI scans. **Results:** We have identified 6 unrelated families with 19 patients with CBPS, 13 males and 6 females. Ages ranged from 3 to 42 years old. Ten patients (53%) had a polymicrogyric appearance of the perisylvian cortex. More detailed imaging analysis revealed that 6 patients had diffuse bilateral perisylvian polymicrogyria, 3 with bilateral posterior parietal polymicrogyria and 1 patient with bilateral fronto-parietal polymicrogyria. Prenatal events were reported in only 3 patients. All patients had similar neurologic dysfunction, mainly primarily pseudobulbar paresis, feeding difficulties in the perinatal period, as well as swallowing and sucking problems. Hemiparesis was present in only 1 patient. None of our patients had epilepsy. Specific language impairment was found in all 19 patients and psychological assessment showed that global cognitive deficit was not present in most patients, although they usually have lower verbal IQ as compared to performance IQ. **Conclusion:** CBPS should be considered as a possible diagnosis in all infants or children with oromotor dysfunction/pseudobulbar signs and developmental language delay. Epilepsy is not a common feature and the most frequent imaging findings in familial CBPS are variable degrees of bilateral perisylvian polymicrogyria. Despite limited verbal IQ, our results support the observation that perisylvian polymicrogyria does not necessarily lead to intellectual disability. Supported by FAPESP.

Program Nr: 606 from 2003 ASHG Annual Meeting

**Wolf-Hirschhorn Syndrome: Clinical and Molecular Cytogenetic Studies in Taiwan.** *J. Hou.* Medical Genetics, Chang Gung Children's Hospital, Taoyuan, Taiwan.

**Background:** Wolf-Hirschhorn syndrome (WHS) is a rare chromosomal disorder characterized by the deletions in the short arm of chromosome 4. There is still very little data on its natural history and wide spectrum of somatic abnormalities, related to the underlying genetic changes. **Methods:** Ten patients (7 females, 3 males) in Taiwan with the 4p- syndrome were followed up for five to fifteen years. The genetic changes were detected by standard cytogenetics (regular G-banding and high-resolution banding) and fluorescence in situ hybridization via painting probe for chromosome 4 and the unique sequences for WHS critical region. **Results:** All of them had severe psychomotor and growth retardation, and a characteristic facies but not changing with time. A total of 9/10 had congenital cardiac defects (most are atrial septal defect); 4/10 had oral facial clefts; 4/10 had a seizure disorder, that tended to disappear with age; 3/10 had agenesis or hypoplasia of corpus callosum; and 3/10 had renal problems. One had sensorineural deafness and one had a bilateral split hands defect. The causes of death in two patients were aspiration pneumonia and end-stage renal failure, respectively. The deleted segments on 4p were from the breakpoints to 4pter: p16.2 (n=2), p16.1 (n=2), p15.33 (n=4), 15.31(n=1), and 15.1(n=1). Karyotype-phenotype correlation study was also performed. **Conclusions:** This experience will help delineate more thoroughly the natural history of WHS, and to obtain better information to answer parents questions in a clinical setting.

**Hypothyroidism in Peters plus syndrome.** *K. Kosaki<sup>1</sup>, R. Kosaki<sup>2</sup>, A. Kamiishi<sup>3</sup>, M. Kawai<sup>4</sup>, T. Takahashi<sup>1</sup>*. 1) Dept Peds, Keio Univ, Tokyo, Japan; 2) Div Med Genet, Saitama Child Med Ctr, Iwatsuki, Japan; 3) Dept Peds, Saitama Chuo Hosp, Saitama, Japan; 4) Dept Ophthalmol, Keio Univ, Tokyo, Japan.

Hypothyroidism has not been previously described in patients with either Peters anomaly or Peters Plus syndrome, with the exception of one report by Jung et al. We report a male patient who exhibited Peters plus syndrome phenotype and hypothyroidism, adding further evidence that hypothyroidism may represent a previously underappreciated feature of the syndrome. The patient was delivered at 38 weeks gestation to a 34 year-old G3P2 woman and a 34 year-old father who were first cousins. The birth weight of 1842 g, length of 41.5 cm, and head circumference of 30.0 cm were all less than the third percentile. He was rhizomelic. At 4 months, he had short palpebral fissures, corneal clouding, mild micrognathia, absence of the antihelix on the right ear, and short neck. Both hands were remarkable for single transverse crease, no flexion crease on the thumb, and clinodactyly of the fifth finger. Ophthalmologic evaluation revealed microcornea and corneal opacity bilaterally. Iridocorneal adhesions were noted in the left eye. Brainstem auditory evoked response revealed bilateral hearing loss. Neonatal screening revealed elevated TSH level. TSH was 33 IU/ml, free T4 was 4.1 pg/ml, and free T3 was 0.19 ng/dl. He was diagnosed as having congenital hypothyroidism and was started on thyroxin and her free T4 and T3 levels were normalized in a week. Ultrasound examination did not reveal thyroid tissue. Consanguinity of the parents in the present case points to a homozygous defect of a single gene responsible for the normal morphogenesis of both the anterior chamber and the thyroid gland, leading to the Peters anomaly and congenital hypothyroidism. We suggest that thyroid function tests are warranted because lack of treatment would potentially aggravate developmental and growth delay that are relatively prevalent among patients with Peters plus syndrome.

**Monozygotic twins with concordant cervical segmentation defects: evidence for genetic basis of Klippel-Feil anomaly.** *R. Kosaki, H. Ohashi.* Div Medical Genetics, Saitama Children's Medical Ctr, Saitama, Japan.

Klippel-Feil anomaly (KFA) is defined as the congenital fusion of two or more vertebrae within the rostral spine. Although it is well accepted that KFA represents a faulty segmentation along the embryo's developing axis during weeks 3-8 of gestation, the origin of this malsegmentation has been a subject of debate. Vascular disruption as well as geneticalteration have both been entertained as possible causes. Relatively popular hypothesis proposes that fetal vascular disruptions in the subclavian artery blood supply during the embryonic period leads to specific patterns of defects in the rostral end of the embryo, collectively referred to as the subclavian artery supply disruption sequence. Familial cases, even if rare, provide support to the concept that the genetic background may contribute to the pathogenesis of KFA. The present report describes diamniotic-monochorionic twins with concordant cervical segmentation defects. Case 1 had a low posterior hair line and a limited range-of-motion for the abduction of the left shoulder joint. A skeletal survey revealed segmentation defects of the spines at the cervical to upper thoracic level. The left scapula was elevated and medially displaced, this condition was diagnosed as a Sprengel deformity. Case 2, twin brother of Case 1 had a short neck with a low posterior hair line but no Sprengel deformity; the range-of-motion his neck and shoulder joints were normal. A skeletal survey revealed a hypoplastic atlas, dense odontoid process, block vertebrae at the C5-C7 level, and a broad clavicle with hypoplasia of the distal ends. To our knowledge, this is the first report of monozygotic twins with concordant cervical segmentation defects. This report supports the existence of a genetic component to the origin of KFA in some cases. Although both twins in the present case exhibited the cervical segmentation defects, the severity of the defect was unequal. Stochastic events during the twinning process could have contributed to the discordance in severity considering that the timing of diamniotic-monochorionic twinning follows that of cleavage when embryonic axes are specified.

**APERT SYNDROME WITH PREAXIAL POLIDACTYLY: A NEW SYNDROME?** *J.M. Mantilla, L.E. Figuera, L. Arnaud, M. Diaz, P. Barros.* Division de genetica.CIBO-IMMS. Guadalajara,Mexico.

Acrocephalosyndactyly type I or Apert syndrome is characterized by craniosinostosis, particular facial dysmorphic features and abnormalities of hands and feet. Although most cases are sporadic, representing new mutations, autosomal dominant transmission with complete penetrance is accepted. The FGFR2 gene is involved and two mutations (Ser252Trp and Pro253Arg) account for most of the patients. We report a case of apparent Apert syndrome with preaxial polydactyly of hands and feet. Rarely, the association of these abnormalities has been reported and, in all the cases, acrocephalopolysyndactyly as the Carpenter syndrome and other diagnostic alternatives have been considered. In 1987, Maroteaux et al. proposed that this association should be considered a new syndrome. Case report: The proposita, a five-month-old female, was born after 38 weeks of an uneventful pregnancy from healthy and unrelated young parents. Her two older brothers are healthy. At birth, she measured 48 cm, weight 3450 gr and the head circumference was 36 cm. She presented the characteristic facial appearance of Apert syndrome: turribrachycephaly, large fontanelles, high forehead, midface hypoplasia, telecanthos, inner epicanthos, prominent eyes, depressed nasal bridge with small parrot-beaked nose, hypoplastic ears and short neck. She had mitten hands with complete syndactyly of 2nd to 5th digits. The feet showed cutaneous fusion of all toes, with very broad first toes. No other abnormalities were observed and the psychomotor development is considered normal to date. X-rays revealed preaxial polydactyly for hands and feet. Cariotype and metabolic screening were normal. Physical findings in the proposita suggest the rare form of Apert syndrome with polydactyly. A review of the reported cases, in order to validate the proposition that this association constitute a new syndrome is made.

**Five new cases of 48,XXXY & 49,XXXXY syndromes & a literature review.** *K. Keppler-Noreuil, A. Muilenburg, S. Patil.* Division of Medical Genetics, Dept Pediatrics, Univ Iowa Hosps & Clinics, Iowa City, IA.

There have been over 50 cases of 48,XXXY and over 100 cases of 49,XXXXY reported with few reported in the recent literature. Although these syndromes are considered to be variants of Klinefelter syndrome, 47,XXY, the clinical findings and natural history are quite different. The purpose of this report is to describe 5 cases with sex chromosome tetrasomy and pentasomy ranging in age from infancy to late adulthood, including a review of their clinical findings, prenatal and natural history with comparison to those cases in the literature.

**CASE 1**, age 30 yrs, was <5th% born at term to a 24 yr old G2P2 mother with IUGR and small placenta. Karyotype 49,XXXXY/50, XXXXXY with 80% having 49,XXXXY. He had IQ 53, and aggressive behaviors. He has multiple skeletal anomalies, microcephaly, hypertelorism, & absent pectoralis muscles. **CASE 2**, 47.5 yrs, was <5th%, born at term in breech SVD to a 30 yr old G3P3 woman. He required NG feeds due to poor feeding. His IQ was <50 with no speech, and impulsive disorder. He has wt and ht ~95%, HC 50%, prominent supraorbital ridging, microphthalmia, hypertelorism, broad nose, prognathism, camptodactyly, radioulnar synostosis, and scoliosis with karyotype 49,XXXXY. **CASE 3**, now 12 yrs, has 48,XXXY/49,XXXXY. He was <5th% born at term to a 25 yr old G2P2 woman. He had microcephaly, suprorbital ridging, prognathism, wide nasal tip, and brachydactyly. He has had SIB, and aggressive behaviors. **CASE 4**, 3 yrs, with 48,XXXY had IQ 73, and normal growth and exam. He was 50th% born at term to 35 yr old G3P3 woman. **CASE 5**, 1 yr, had developmental delay, wt, ht, and HC <5th%, and undescended testis with 49,XXXXY.

These cases highlight the characteristic findings in these two conditions. All but one case in the neonatal period had growth retardation, hypotonia, and poor feeding with absent prenatal complications. Physical features, more prominent with increasing age, involved primarily craniofacial, skeletal and gonadal systems. Lack of dysmorphic findings was noted in 2 of the cases in early infancy. None of these cases had other anomalies, such as cardiac, renal or brain malformations.

**The discordance between clinical findings and molecular genetics in a male patient with some clinical features for Prader-Willi syndrome.** *S. Ninomiya, H. Maruyama, T. Une, M. Kawakami, Y. Yokoyama.* Dept Pediatrics, Okayama Univ. Medical School, Okayama, Japan.

Prader-Willi syndrome (PWS) results from the loss of expression of paternally expressed genes on human chromosome 15q11-q13. Here we report a male patient who had some clinical features for PWS but did not show the paternal deletion or maternal uniparental disomy. Surprisingly, the analysis of microsatellite markers showed only maternal D15S986 locus was deleted and others were biallelic.

**Clinical summaries:** The patient who is now 18-year-old boy was born after 40 weeks of gestation as the offspring of healthy parents with no consanguinity. He showed microcephaly, short neck, webbed neck, low set of ears, down slanting palpebral fissurae, and cryptorchism. He has moderate mental retardation. His hyperphagia has been remarkable since about 12-year-old. His clinical features did not completely satisfy the PWS diagnostic criteria.

**Cytogenetics:** Neither the chromosomal analysis using GTG banding method nor the FISH using a probe of SNRPN showed deletion of 15q11-q13.

**Molecular analysis:** Microsatellite markers within 15q11-q13 and other 15q regions were analyzed by PCR. Primer loci were D15S11, D15S128, D15S122, D15S210, D15S986, D15S1234, GABRB3, D15S165, D15S126, D15S153, D15S211 and D15S127. Each sample was loaded onto denaturing gels and electrophoresis condition was 1,400 V constant volt. The gel was stained by the silver stain kit. It demonstrated biparental inheritance at four loci within 15q11-q13 (D15S11, D15S210, D15S1234 and D15S165) and at four loci distal to 15q13 (D15S126, D15S153, D15S211 and D15S127). Remarkable interestingly only one locus, D15S986, within 15q11.2-q12 showed maternal deletion. The DNA methylation pattern of the patient using by SNRPN probe was normal.

**Conclusions:** The result of maternal deletion at the very small region in this patient does not coincidence with general rule, and suggests that a gene (genes) which is not imprinted but needs biallelic expression exists nearby the deleted region.

**ASSOCIATION OF OPITZ SYNDROME AND PENILE AGENESIS AFTER IVF-ET (ICSI).** *T. Sonoda, H. Nuno.* Dept Pediatrics, Miyazaki Medical Col, Miyazaki, Japan.

Penile agenesis is a rare congenital anomalies that occurs once in every 10 to 30 million births. Though anomalies of the genitourinary tract are the cardinal features of Opitz syndrome, there has been no report presenting the co-occurrence of Opitz syndrome and penile agenesis so far. The male infant proband was born after a 41-week gestation. He was the result of the second pregnancy of healthy and unrelated parents. The father was 58 and the mother was 34 years of age at the time of birth. The facial appearance and intelligence of the parents were normal. None of the family members showed recognizable anomalies. A healthy girl was born by the mothers first pregnancy which was accomplished by *in vitro* fertilization-embryo transplantation (IVF-ET). The proband was also conceived by IVF-ET after intra cytoplasmic sperm injection (ICSI) due to the paternal factor. The proband had a birth weight of 2,356 g, a length of 49.0 cm and a head circumference of 33.0 cm. Because of a peculiar facial appearance and penile agenesis, he was referred to the Department of Pediatrics, Miyazaki Medical College on the 8th day after birth. Physical findings included the following: micrognathia, widows peak, hypertelorism, wide and flat nasal bridge, bulbous nose, shallow philtrum, high arched palate, low-set, post-rotated and cupped ears, left club foot, and hypoplastic nails. The scrotum was normal in appearance and size, and bilateral testes were palpable. The raphe was preset. Position of the urinary meatus was in front of the anus. Movements of bilateral lower extremities were good. Urination and bowel movement were seen periodically. His karyotype was 46,XY. In Opitz syndrome, heterogeneity has been demonstrated. We believe that our case is the autosomal dominant type. Our case probably represents a new mutation, and advanced paternal age may have played a role. Sperms with a certain pathogenic gene may have a low capability of fertilization *in vivo*, but be able to fertilize *in vitro*. Our case adds to the list of midline anomalies previously described in Opitz syndrome. If penile agenesis is a severe form of micropenis or hypospadias, our case also supports the characterization of Opitz syndrome as a developmental defect in the midline field.

**Referral Dx: R/O Turners; Goldenhar; Smith Lemli Opitz; Frontonasal Dysplasia; Post Clinic Dx: 22q11.2 deletion.** *E.H. Zackai, K.L. Russell, J.E. Ming, M.K. Meisenbacher, D.M. McDonald-McGinn.* Div Human Gen/Molec Biol, The Children's Hosp Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA.

It is not surprising that over time, the phenotype of a new syndrome will be expanded to include findings that have been cardinal features of well-established syndromes: primary amenorrhea and the webbed neck of Turners syndrome; pre-auricular skin tags of Goldenhar; post axial polydactyly of Smith-Lemli-Opitz syndrome (SLO) and the median nasal groove of Frontonasal Dysplasia. In fact, these findings often prompt a referral to Clinical Genetics to rule out the classical syndrome. Here we present a series of such patients, all of who were subsequently diagnosed with the 22q11.2 deletion. This emphasizes the importance of a comprehensive approach to the patient and expands the phenotype of the 22q11.2 deletion. To illustrate, patients 1 and 2 were referred to rule out Turner syndrome despite normal 46,XX karyotypes. Patient 1 was a 19-year-old female with short stature, primary amenorrhea and a bicuspid aortic valve. Past medical history revealed a renal ultrasound in childhood, which demonstrated an absent right kidney and no mullerian structures, compatible with Mayer-Rokitansky-Kuster(MRK). We noted short stature, normal breast development, hooded eyelids, a bulbous nasal tip, and learning differences. This prompted 22q11.2 studies, which were positive. The association of MRK and the 22q11.2 deletion has been reported twice before (Huff et al. XXII DW Smith Workshop 2001; Devriendt et al. J Med Genet 34:423, 1997). Patient 2, a 7-year-old was referred because of a webbed neck. Past medical history revealed mild reflux and nasal regurgitation. On physical exam we noted: hooded eyelids, low set ears with thick helices and a prominent nasal root prompting 22q11.2 deletion studies which were positive. Patients with features found in Goldenhar, SLO and Frontonasal Dysplasia will also be discussed. Recognition of the 22q11.2 deletion in these patents is critically important for medical management and recurrence risk counseling.

**Sibs With Hyperekplexia and Status Epilepticus. A New Autosomal Recessive Syndrome.** *C. Vinkler<sup>1</sup>, N. Watemberg<sup>2</sup>, D. Lev<sup>1</sup>, T. Lerman-Sagie<sup>2</sup>.* 1) Inst Medical Genetics, Wolfson Medical Ctr, Holon, Israel; 2) The Metabolic-Neuro-Genetic Clinic. Wolfson Medical Center, Holon, Israel.

Hyperekplexia is a predominantly an autosomal dominant rare disorder often related to a mutation in the alpha 1 subunit of the glycine receptor GRLA1. It is characterized by exaggerated startle response to handling and to noise. Usually increased muscle tone is observed in the neonatal period which improves later in life. Atypical sporadic and autosomal recessive cases were reported with additional variable manifestations. We describe a severe form of hyperekplexia and refractory status epilepticus in two sibs. They were both born to healthy unrelated parents of Ashkenazi-Jewish origin. Their first offspring was a female who was diagnosed with hyperekplexia after her birth. She also had hypotonia and slow motor development. Metabolic evaluation was normal, her muscle biopsy was normal and she had a normal EEG. 80% of the GRLA1 gene was screened for mutation and no mutation was found. When she was 15 months she developed status epilepticus refractory to treatment. She was admitted to the ICU, where she stayed for 17 days before she died. Her brother, was born 4 years later. When he was 3 days old, he was diagnosed as suffering of hyperekplexia. He had normal development. He had status epilepticus for the first time at the age of 11 months. His EEG at that time, was normal. Two weeks later, he had again status epilepticus. He was put on pentobarbital coma and died at the age of one year. The unusual presentation of hyperekplexia together with hypotonia in the girl, and status epilepticus in both children, suggest that this is a new autosomal recessive syndrome, possibly a channelopathy that affects both, spinal cord and brain.

**Chromosome 22q11.2 microdeletion syndrome: Clinical features in 65 Chilean patients.** *G.M. Repetto<sup>1</sup>, M. Aracena<sup>2</sup>, C. Mellado<sup>3</sup>, M. Arriaza<sup>4</sup>, C.P. Astete<sup>2</sup>, T. Aravena<sup>3</sup>.* 1) Genetics, U Desarrollo-Clnica Alemana, Santiago; 2) Hospital Luis Calvo Mackenna, Santiago; 3) Hospital Dr. Stero del Ro, Santiago; 4) Hospital Gustavo Fricke, Via del Mar, Chile.

Chromosome 22q11.2 microdeletion syndrome (del22q11) has variable clinical presentations. Objective: To illustrate the clinical features of Chilean patients with del22q11. Methods: Retrospective review of medical records of patients with FISH-demonstrated deletions from 3 tertiary centers from Santiago and one from Via del Mar, Chile. Results: Sixty-five patients with del22q11 were diagnosed from 1998 to 2002, 53% male. Mean age SD at diagnosis was 37.9 65.2 months, ranging from newborn to 30 years. Ten patients (15.4%) died due to congenital heart defects (CHD), all before 18 months. Height/age was below the 50th centile in 83%, and below the 5th centile in 47%. Forty six individuals (70.8%) had CHD, and 5 others had structural anomalies not requiring surgery. The most common CHD were tetralogy of Fallot (43% of patients with CHD), interrupted aortic arch (IAA)(26%), and VSD (20%). Eight children with IAA had a type B defect and four were type C. Mean ages SD at diagnosis for patients with and without CHD were 21.6 36 and 81.0 101.2 months, respectively ( $p < 0.05$ ). Calcium levels were recorded in 48 patients; 23 had neonatal hypocalcemia, 2 of them required long term therapy. Otolaryngeal problems were present in 30/56 patients, and included submucous cleft palate, velopharyngeal insufficiency, overt cleft palate, and laryngeal membrane, the latter present in 3 newborns. One of the three adults in this series has been diagnosed with schizophrenia. Conclusions: though probably biased by the retrospective nature of the study, the results provide additional useful data for patient counselling and care. Frequency and types of clinical features are similar to published US and European series, but diagnosis tends to occur later, and mortality is higher.

**Arnold-Chiari malformation in Kabuki Syndrome.** *K.L. Russell, E.H. Zackai, J.E. Ming.* Division of Human Genetics & Molecular Biology, Children's Hospital of Philadelphia, Philadelphia, PA.

Structural brain anomalies have only occasionally been described in association with Kabuki syndrome and include hydrocephalus, polymicrogyria, cerebellar and brainstem atrophy, periventricular nodular heterotopia and subarachnoid cyst. Arnold-Chiari malformation, characterized by caudal herniation of the cerebellar tonsils through the foramen magnum, has been described infrequently in association with defined syndromes, and has been reported only once in Kabuki syndrome (McGaughran et al., 2001). We report two children with Kabuki syndrome who also have Arnold-Chiari type I malformation. Patient #1 has a history of cleft palate, developmental delay, a clavicular anomaly, hypodontia and idiopathic thrombocytopenia purpura. On exam, she has epicanthal folds, clinodactyly and prominent fingertip pads. She was diagnosed with Kabuki syndrome at the age of 7 years. At the age of 6 years 10 months, she complained of intermittent headaches and subsequently developed swallowing problems and neck pain. An MRI showed Chiari I malformation with left cerebellar herniation. She underwent surgical decompression. Patient #2 has a history of strabismus, hearing loss, short stature & developmental delay. On exam she has long palpebral fissures, prominent eyelashes, arched eyebrows, mildly protuberant ears with a preauricular pit and fingertip pads. She was diagnosed with Kabuki syndrome at the age of 3 years. She presented at the age of 9 years with a several month history of headache as well as neck pain. She was noted on MRI to have a Chiari I malformation. The incidence of Chiari anomaly may be higher in Kabuki syndrome than published reports suggest. The two patients we report were diagnosed in mid-childhood with Chiari I malformation, and most reported cases of Kabuki syndrome are of younger children. Further, symptoms of Chiari I can be relatively non-specific. Thus, we suggest that this malformation should be considered in children with Kabuki syndrome who present with persistent headache or neck pain. In addition, the diagnosis of Kabuki syndrome could be considered in children with Chiari I malformation if other characteristic findings are present.

**Genetic Studies: A significant component of the Canadian Paediatric Surveillance Program.** *A.M. Summers<sup>1</sup>, A. Medaglia<sup>2</sup>, D. Grenier<sup>2</sup>.* 1) Genetics Program, North York General Hosp, Toronto, ON, Canada; 2) Canadian Paediatric Surveillance Program, Ottawa, ON, Canada.

The Canadian Paediatric Surveillance Programme (CPSP) started in January 1996 under the sponsorship of the Canadian Paediatric Society and the Centre for Infectious Disease Prevention and Control, Health Canada. The purpose of the CPSP is to study relatively rare conditions (<1000 cases/year in Canada) with clear paediatric or public health issues for which there is limited information. Researchers submit protocols which are assessed by a Steering Committee. Approximately ten studies run concurrently, each for 1-3 years. Each month, the CPSP sends out a list of study disorders with a postage paid return envelope to all paediatricians and geneticists in Canada asking them to indicate if they have seen any cases. If a physician has seen a case, he/she is sent a follow-up questionnaire. Compliance is approximately 82%. The initial projects were primarily paediatric, e.g. hemorrhagic disease of the newborn although some, such as progressive intellectual and neurological deterioration, had a genetic component. In January 2001, a project to look at the incidence and prevalence of Smith-Lemli-Opitz syndrome was initiated and that project has now been completed. Currently, there are two genetic projects underway. The first of these is to identify cases of CHARGE association and the second, new cases of Prader-Willi syndrome. A third study on osteogenesis imperfecta has been approved and will start in September, 2003. Of the 21 studies either completed or underway, 7 are genetic or have a genetic component. All of the studies are designed to look at the incidence and/or prevalence of these disorders in Canada but in addition, each study is able to ask specific questions regarding the disorder and has the potential for building up a research base involving interested physicians and families. An added benefit of these projects is that they educate Canadian clinicians about the disorder in question. The CPSP provides an infrastructure which is becoming increasingly utilized by Canadian investigators for research into rare paediatric genetic disorders.

**Unusual digital anomalies in a patient with Brachio-Oculo-Facial Syndrome (BOFS).** *E.J. Ramírez-Lizardo<sup>1,2</sup>, S.E. Totsuka-Sutto<sup>1</sup>, J.R. Corona-Rivera<sup>1,3</sup>, Cuerpo Académico Genética Clínica y Médica CUCS U de G.* 1) Laboratorio de Genética Humana, Departamento de Fisiología, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara. Guadalajara, Jalisco México; 2) Instituto Jalisciense de Cirugía Reconstructiva. SSJ. Guadalajara, Jalisco México; 3) OPD, Hospital Civil Juan I Menchaca. Guadalajara, Jalisco México.

The brachio-oculo-facial syndrome (BOFS) is an entity characterized by craniofacial alterations consisting in branchial anomalies, as auricular pit/sinuses and aplastic or hemangiomatous cervical skin lesions, ear and ocular anomalies and pseudocleft of the upper lip. Other manifestations on the outside of craniofacial area are rare. We report a patient with BOFS and previously unreported digital anomalies. The 3-years-old propositus showed mild disproportionate short stature, dolichocephaly, blond hair, telecanthus, epicanthal folds, lacrimal duct obstruction, short nose, bilateral cleft lip and complete cleft palate, tongue hamartoma, delayed dentition, low-set displasic ears and narrow external auditory canals with apparent aplasia cutis congenita of lateral neck. Limbs were shortened with small hands, A3 brachydactyly and clubbing of fingers. Hallux valgus, mild skin syndactyly, and short second finger toe were also observed. Limb anomalies reported in about 50 BOFS reported cases are rare and includes hand polydactyly, clinodactyly and hipoplastic thumb. To our knowledge, this is the first instance of peculiar digital anomalies in BOFS. Therefore we suggest that these anomalies may be part of this entity.

**Noonan syndrome (NS): PTPN11 gene mutation and phenotype / genotype correlations: the French experience.**

*Y. Sznajder*<sup>1,2</sup>, *B. Keren*<sup>2</sup>, *C. Baumann*<sup>2</sup>, *S. Perreira*<sup>3</sup>, *J. Elion*<sup>3</sup>, *H. Cavé*<sup>3</sup>, *A. Verloes*<sup>2,4</sup>. 1) Clinical Genetics Unit, Pediatric dept, HUDERF, Brussels, Belgium; 2) Clinical Genetic Unit; 3) Genetic Biochemistry Dept; 4) INSERM E9935, Hôpital Robert Debré, Paris, France.

Noonan syndrome (NS) is characterized by facial dysmorphism, short stature, mental retardation and heart defect. Almost 50% of patients (sporadic and familial) carry mutation in PTPN11. PTPN11 gene on 12q24 codes for SHP2, an ubiquitous cytoplasmic protein phosphatase involved in the signalling pathway of several growth factors and cytokines. 95% of the mutation published so far have been identified in exons 3, 7, 8 and 13. About 250 unrelated patients with NS, LEOPARD, Costello, Baraitser-Winter or CFC syndrome diagnosed by a network of clinical geneticists were referred to our institution for PTPN11 analysis. The following data were collected: antenatal ultrasound, feeding difficulties, growth chart, dysmorphism, cardiac status, skeletal-, dermatologic-, ophthalmologic-, auditory- and hematologic anomalies, learning difficulties and pictures over time. Direct sequencing of the key exons of PTPN11 is still going on. At time of submission, 66 out of 158 patients with NS screened for mutations in exons 3, 7, 8, 13 carry a PTPN11 mutation (42.6%). 5 patients with LEOPARD syndrome had mutations in exons 7 (2) and in exon 12 (2), no mutation was identified for CFC (5), Costello (4), Noonan-NF1 (2) and Baraitser Winter (2) syndrome. Among patients carrying a mutation, 11 novel mutations were found. Dysmorphic features were: low set ears (90%), hypertelorism (81%), micrognathia and ptosis (56%). Heart defect were: 59% pulmonic stenosis, 35% ASD, hypertrophic cardiomyopathy 10%. Cryptorchidism was noted for 45% of the males. No phenotype/genotype correlation could be clearly delineated by comparing NS patients with or without mutation except for the cardiac defect (pulmonary valvular stenosis more common and cardiac hypertrophy less common in mutation carriers) as noted in previous studies. We expect to present complete genotype analysis of the cohort for the meeting.

**Mental retardation, facial dysmorphism, skeletal anomalies in first cousins; KBG or a new syndrome? C.**

*Prasad<sup>1</sup>, S. Nikkel<sup>2</sup>, M. Reed<sup>1,3</sup>, S. Sanders<sup>1</sup>, S. Marles<sup>1</sup>.* 1) Department of Pediatrics and Child Health & Biochemistry and Medical Genetics, Children's Hospital, University of Manitoba, Winnipeg; 2) Eastern Ontario Regional Genetics Program, Children's Hospital of Eastern Ontario; 3) Section of Pediatric Radiology.

We present two patients (first cousins) of Caucasian background with short stature, developmental delay, facial dysmorphism, skeletal and dental anomalies reminiscent of KBG syndrome (OMIM #148050). The proposita was delivered prematurely at 32 weeks gestation (birth weight of 1.721 kg). Both parents had developmental delay of unknown etiology. At 5 years, she was below the 10th centile for both height and weight, and her head circumference was 48cm (<3rd centile). The facial features revealed brachycephaly, telecanthus, bilateral epicanthal folds, synophrys, and retrognathia. She had poorly formed nasal bridge and normally placed ears. The dental assessment at 8 years revealed large central incisors, the vertical overbite was 80%, and horizontal overjet was 2.5mm. Numerous primary teeth were present. She had significant bilateral clinodactyly and brachydactyly of her hands, and syndactyly of her 2nd and 3rd toes. The maternal first cousin (male) at the age 5 mos. shared similar facial features to the proposita with bilateral clinodactyly of the hands, without syndactyly of the toes. The proposita had a normal karyotype and subtelomeric deletion studies. Initial skeletal survey showed significantly delayed bone age, questionable fusion anomalies of the spine at the craniocervical junction and the upper thoracic region. The subsequent skeletal survey showed bilateral drumstick 4th digits terminal phalanges. Cone shaped epiphysis were absent. There was diminished carpal height; middle phalanx was mildly hypoplastic in the 5th digits bilaterally and short femoral necks. The skeletal survey on the cousin showed minimal involvement. Though our patients share a few features of the KBG phenotype, we believe that these patients may represent a new entity.

**Missense mutation in the PANK2 gene in a patient with atypical Pantothenate kinase associated**

**neurodegeneration.** *J. Pappas*<sup>1</sup>, *J. Borsuk*<sup>1</sup>, *S. Das*<sup>2</sup>, *H. Bennett*<sup>3</sup>. 1) Clinical Genetic Services, New York Univ, Sch of Med, New York, NY; 2) Department of Human Genetics, The University of Chicago, Chicago, IL; 3) The Stanley S. Lamm Institute for Child Neurology and Developmental Medicine, Brooklyn, NY.

Pantothenate kinase associated neurodegeneration (PKAN), also known as Hallervorden-Spatz syndrome, is an autosomal recessive disorder that usually presents in childhood with dystonia, dysarthria and rigidity. There is a classical form with usual onset of symptoms prior to six years of age and rapid neurodegeneration, and an atypical form with later onset and variable presentation and progression. (SJ Hayflick et al, 2003). We describe a 19-year-old boy (proband) and his 16-year-old sister with the atypical form of PKAN. The proband presented at 8 years of age with dysarthria and excessive drooling. Progressively, he had difficulty closing his mouth with worsening of the dysarthria and drooling, inability to eat solids and regression in his fine and motor abilities. His brain MRI revealed abnormal signal medially at the level of right and left globus pallidus extending to the posterior limbs of the internal capsules. These findings are described as the eye of the tiger usually seen in PKAN. At age 19 his mental abilities were not affected, his mouth remained constantly open with his tongue protruding out and his gait was parkinsonian. His sister presented with learning disabilities, dysarthria and drooling at age sixteen. The parents are first cousins twice removed from the Dominican Republic. The proband was found to have a missense mutation, Y117C, in the homozygous state in the PANK2 gene. This is a non-conservative amino acid change that occurs in a highly conserved region of the PANK2 protein, which has not been described before. This result provides another example of an atypical PKAN patient with a missense mutation in the PANK2 gene. This case represents the first patient with PKAN and a PANK2 mutation from the Dominican Republic. The proband demonstrates that dysarthria progressing to constantly open mouth and protruding tongue can be the main and most dramatic presenting symptoms of atypical PKAN.

**Roberts Syndrome: definition and diagnosis by numerical syndromology.** *H. Vega, M. Gordillo.* Instituto de Genética, Universidad Nacional de Colombia, Bogotá, Cundinamarca, Colombia.

Roberts Syndrome (RS) is a rare autosomal recessive disorder characterized by pre and postnatal growth retardation, phocomelia, craniofacial anomalies and premature centromere separation (PCS). We propose that the RS clinical picture follows a precise pattern defined by five criteria: -The RS facies: microbrachycephaly, malar hypoplasia, hypertelorism, hypoplastic alae nasal, micrognathia and bilateral lip and cleft palate (in severe cases). -Symmetrical mesomelic limb reduction or tetraphocomelia affecting proximal-distal and antero-posterior limb axes. -Characteristic hand pattern with brachydactily that always affects the first finger by agenesis or hypoplasia. The second affected finger is the fifth by clinodactily, and hypoplasia or agenesis. -The clinical picture follows always a cephalocaudal pattern in which the upper limbs are more affected than the lower limbs. -There is a high degree of concordance between the severity of the craniofacial and limb abnormalities. Patients with severe phocomelia and only three digits present prominent eyes, bilateral cleft lip and palate and premaxilla protrusion. Less affected patients present the characteristic Roberts facies without cleft lip and palate, and moderate upper limb reduction and normal lower limbs. Using these criteria we evaluated by numerical syndromology 105 patients reported in the literature in addition to 10 new Colombian patients. We found that all of the 52 patients with PCS were located in the same group in addition to 38 patients that also fulfil all the clinical criteria but were not analyzed for PCS. All of the PCS negative patients were grouped with other cases that also did not fulfil the five criteria. These cases excluded from the RS group can be assigned to other entities such as Zimmer phocomelia, tetraamelia and pulmonary hypoplasia, Splenogonadal fusion limb defect syndrome and TAR. Additionally, we propose two new entities, the Virchow and Freeman Syndromes. We propose RS is not a heterogeneous entity and patients without PCS must be assigned a different diagnosis. Our clinical criteria are a valuable tool for the differential diagnosis of the phocomelias.

**Chromosomal rearrangements in Cornelia de Lange Syndrome: A new case and review of all reported cases. C.**

*DeScipio<sup>1</sup>, M. Kaur<sup>1</sup>, L.G. Jackson<sup>2</sup>, N.B. Spinner<sup>1</sup>, I.D. Krantz<sup>1</sup>*. 1) Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Dept. of Obstetrics and Gynecology, Drexel University College of Medicine, Philadelphia, PA.

Cornelia de Lange syndrome (CdLS), a dominantly inherited disorder, is characterized by facial dysmorphism, limb abnormalities, somatic and cognitive retardation and growth abnormalities. A diagnosis of CdLS relies entirely on clinical findings; the molecular etiology remains unknown. There have been more than thirty reports describing chromosomal abnormalities associated with the CdLS phenotype. Rearrangements have been described in chromosomes 1-5, 7-14, 17, 21, 22, X. With the exception of 3p26, (overlap of the dup3q syndrome phenotype with that of CdLS) there has not been a consistent chromosomal rearrangement involved with CdLS. We report two half sibs with features of CdLS with an unbalanced rearrangement (der(3) t(3;12)(p25.3;p13.3)) inherited from a balanced translocation t(3;12)(p25.3;p13.3) in an unaffected mother. While these children have many features consistent with CdLS (microcephaly, growth retardation, mental retardation, hirsutism, synophrys, anteverted nares, single palmar creases, 2-3 syndactyly of the toes), they also have features seen in other children with rearrangements of 3p and/or 12p. These chromosomal regions may be candidate loci for a CdLS disease gene, however these children may also represent a phenocopy of CdLS. A review of all chromosomal rearrangements associated with CdLS will be presented.

Program Nr: 624 from 2003 ASHG Annual Meeting

**Premature Ovarian Failure and Chromosome Xq28 deletion. A clinical cytogenetic report.** *A.M. Alshafie, M. Abuhenedi, S. Alawadi, L. Bastaki, M. Marafie, M. Krishna, R. Alnaggar.* Obstetric&Gynecology, Kuwait Medical Genetics Center, Kuwait, Kuwait.

The relationship between both primary/secondary ovarian failure(POF) and structural chromosomal rearrangement is well documented. Secondary amenorrhea is mostly recognized as premature menopause in which Xq25-26 deletion has been previously reported. Herein we describe two sisters with premature menopause and deletion Xq28. The two daughters were product of DFC Consanguinous parents. They had normal height, well developed 2ry sexual characters and absence of any stigma of Turner's syndrome. They were infertile and the menopausal symptoms started at 22years for the elder lady and 27years for the younger one. Hypergonadotropic hypogonadism and absence of ovarian follicles have been found. The two sisters had POF, one of them had Xq28 chromosome deletion and the 2nd not yet confirmed. Nevertheless the two daughters possibly have mutation of the assigned gene in the deleted region of chromosome X and we are in favour of recessive mode of inheritance as the parents had DFC consanguinity.

**PROXIMAL 5p TRISOMY IN NEWBORN.** *C. Arioni<sup>1</sup>, A.E. Covone<sup>2</sup>, C. Bellini<sup>1</sup>, C. Cuoco<sup>2</sup>, R. Sacchi<sup>1</sup>, A. Rossi<sup>3</sup>, S. Ciotti<sup>1</sup>, M. Baldi<sup>1</sup>, E. Bonioli<sup>1</sup>, G. Serra<sup>1</sup>.* 1) Dept Pediatrics, Gaslini Inst, Genoa, Italy; 2) Lab Citogenetica, Genetica Molecolare, Gaslini Inst, Genoa, Italy; 3) Dipart Neuroradiologia, Gaslini Inst, Genoa, Italy.

A female infant was born at term of uncomplicated pregnancy to healthy non-consanguineous parents. APGAR scores were 3/7. The patient was referred to our Service on 17th day of life. At birth weight 2,875 g (50th percentile), length 52 cm (90th percentile), head circumference 35.5 cm (75th-90th percentile), anterior fontanelle 0,5 x 0,5 cm, macrocephaly, prominent parietal (fore head), right microphthalmia with skew pupil and iridis coloboma, apparent absence of left globe, low-set ears, bilateral preauricular pits, broad nasal bridge, arachnodactyly, central hypotonia, stridulous cry, poor spontaneous movements. Ocular US scan and Ocular MRI demonstrated right microphthalmos with cystic coloboma of the head of optic nerve which was adherent to the retina, and left microphthalmos with large inferior cyst. Echocardiography showed the presence of large ASD (secundum) with left-to-right shunt, and partial anomalous pulmonary venous return. Kidney tomography showed right pyelectasis. Electromyography showed spontaneous discharge of anterior tibial muscle, possibly related to denervation. Karyotype was 46,XX, der(4)t(4;5)(4qter->4p16::5p12->5pter) (standard Q-banding technique; FISH analysis: probes WCP4, WHS, TEL p/q 1-22 + X and Y, Cri-du-Chat region, and EGR1 x 3). Both parents karyotypes were normal. We could identify the additional chromosomal material as belonging to the short arm of chromosome 5 and therefore the abnormal chromosome 4 present in our patient was deriving from a translocation rearrangement occurred between the two chromosomes. We could establish that this translocation rearrangement occurred de novo in our patient because the karyotype of both parents resulted normal. The patient clinical findings, including facial dysmorphisms, limb abnormalities, cardiac defects, renal and intestinal malformations, mental retardation, fulfilled trisomy 5p clinical picture; our patient presented monolateral coloboma iridis not previously reported.

**Two new cases with a small interstitial deletion within the distal region of chromosome 7q.** B. Faas<sup>1</sup>, P. Poddighe<sup>2</sup>, G. Merks<sup>1</sup>, H. Brunner<sup>1</sup>, D. Smeets<sup>1</sup>, B. de Vries<sup>1</sup>, C. van Ravenswaaij<sup>1</sup>. 1) Department of Human Genetics, UMC St Radboud Nijmegen, Nijmegen, The Netherlands; 2) Department of Clinical Genetics, Rotterdam, the Netherlands.

Interstitial deletions within the distal region of 7q have only rarely been reported. We present two patients with such an interstitial deletion.

Patient 1 is an 11 years old mildly retarded girl who presented with short stature (-3,5 SD), microcephaly (<- 2 SD), arched eyebrows, hypertelorism, upward slanting palpebral fissures, prominent eyes, high nasal bridge, broad mouth, long columella, clinodactyly and short fifth fingers. She had more than 6 cafe-au-lait spots and freckling in the axillary and inguinal region, and was therefore suspected of neurofibromatosis type 1 (NF-1). Patient 2 is an 11 years old moderately retarded girl with short stature, congenital heart anomaly, hypertelorism, a wide nasal bridge, broad mouth and club feet.

Routine karyotyping as well as additional FISH analysis was performed in both patients. Blood from patient 1 was also sent in for DNA diagnostics on NF-1.

Karyotyping showed an apparently identical deletion of 7q32q34 in both patients. FISH analysis, however, proved that the deletions were not identical. The definite karyotypes were: 46,XX,del(7)(q32.2q33) (patient 1) and 46,XX,del(7)(q31.3q32.3) (patient 2). The deletion was excluded in the parents of patient 2; the parents of patient 1 were not available. In patient 1, no known mutations in the NF-1 gene could be detected so far.

We present two patients with a small common deleted region, 7q31.3-q32.2. They strongly resemble a patient recently reported by McGhee *et al.* (Am J Med Genet 2000;93:241-3) who had a t(7;22)(q32;q11.2) and was suspected of Coffin-Siris syndrome. The most prominent features in all three cases are: mild mental retardation, short stature, coarse facial features, hypertelorism, broad base of the nose and a wide mouth with full lower lip and short stubby hands. This indicates that patients with 7q31.3-q32.2 deletions might share a common phenotype.

**A complex and unique chromosomal abnormality.** *E. Elias*<sup>1</sup>, *A. Maleki*<sup>2</sup>, *L. McGavran*<sup>2</sup>. 1) Genetics and Pediatrics, Children's Hospital, Denver, CO; 2) Colorado Genetics Laboratory Denver, CO.

A patient is presented with dysmorphic facies, FTT, and developmental delay. High resolution cytogenetic studies revealed two apparently independent chromosomal abnormalities, with the karyotype: 46,XX,del(1)(p36.3),add(4)(p16.3).

Delivery was at term to a 25 yr old primagravida with BW 2 kg. Subsequent medical course was notable for feeding issues. A genetic evaluation for growth failure and developmental delay occurred at age 18 mo, when she could not crawl, or walk. Language and social skills were at a 10 mo level. Parents were healthy. There was no family history of infertility or fetal loss.

She was a tiny, dysmorphic girl. Weight, height, OFC, and wt/ht were all below the 2nd percentile. Dysmorphic features included hypertelorism, small eyes, prominent pinnae, short philtrum, small mouth, bifid uvula, and brachydactyly. Neurologic exam revealed hypotonia. Echocardiogram was normal. Abdominal ultrasound revealed a solitary kidney.

A small terminal deletion of the distal 1p sub telomere was observed in all cells. Molecular studies showed that the 1p36.3 locus was not deleted. Additional material was present on distal 4p, which was heterochromatic and contained an acrocentric satellite stalk, indicating that add 4 was actually a 4ps. In addition, molecular testing confirmed a deletion of 4p sub telomere sequences, distal to the Wolf-Hirschhorn Syndrome critical region. The maternal karyotype was normal. The father had the identical abnormality of chromosome 4, but normal chromosome 1p.

A patient is presented with a novel chromosomal rearrangement, including deletion of distal 1p, and 4ps. The 4ps abnormality is inherited. As reports indicate that 4ps results in a normal phenotype, her abnormalities are presumed to derive from the de novo 1p deletion. This case helps expand the phenotype of distal 1p deletions, and illustrates the utility of parental and molecular studies in further delineation of complex chromosomal abnormalities.

**Atypical phenotype associated with del 18q21.31: Case study and review of the literature.** *D. Barbouth, M. Zohouri, K.H. Ramesh, L.A. Cannizzaro, V.R. Pulijaal, R.W. Marion.* Departments of Pediatrics and Pathology, Albert Einstein College of Medicine and the Children's Hospital at Montefiore, Bronx, New York.

First described by de Grouchy et al. in 1964, the 18q- syndrome is a well-described disorder that combines small stature, mental disability, hypotonia, craniofacial malformations (including midface hypoplasia, flat philtrum, carp-shaped mouth, broad nasal bridge), hearing loss, ophthalmic anomalies and minor abnormalities of the hands. We describe a 21 year old patient with a deletion of chromosome 18q21.31 qter region and the clinical features of this patient are atypical of 18 q- syndrome. The 5 pound 11 ounce product of a 38 week gestation, was born by vaginal delivery to an 18 year old woman, G4P1021 (SAB x 2) and a 21 year old man after an essentially uncomplicated pregnancy. At birth, he was found to have hypospadias, a bicuspid aortic valve, and talipes equinovarus. Work-up in the newborn period included CT scan of the head, EEG, metabolic screen, and metaphase karyotype, all of which were normal. On the basis of the clinical features, a diagnosis of Smith-Lemli-Opitz syndrome was made. At 21, the patient presents with repaired hypospadias and mild mental retardation. He also has hypothyroidism, which was diagnosed at age 20, and a seizure disorder, which was first noted at age 18, both of which are being treated. On physical exam, his height is at the 25th percentile and weight is at the 50 percentile; he has mild dysmorphic facial features including facial asymmetry, high arched palate and submucous cleft, hypertelorism, up-slanting palpebral fissures, raised nasal bridge, high placed ears and scoliosis. High resolution chromosome studies reveal a de novo terminal deletion of the long arm of chromosome 18 at band 21.31. Further characterization of this deletion by FISH using whole chromosome painting and subtelomeric probes for chromosome 18 confirm that the deletion is terminal and there is no rearrangement of 18q subtelomeric region i.e, 46,XY,del (18) (q21.31) ish del(18) (q21.31) (WCP18x2, TEL18q11). Molecular studies are in progress seeking genotype-phenotype correlation of this patients 18q deletion and atypical 18q- phenotype.

**ATR-16 syndrome: Further delineation of the phenotype.** *R.J. Lin, A.M. Cherry, L. Hudgins.* Division of Medical Genetics, Departments of Pediatrics and Pathology, Stanford University School of Medicine, Stanford, CA.

Alpha-thalassemia retardation-16 (ATR-16) syndrome is associated with microdeletions involving the terminal 2 Mb of 16p13.3. It is characterized by  $\alpha$ -thalassemia and mild to moderate mental retardation. The other features that have been described include hypertelorism with down-slanting palpebral fissures, epicanthic folds, strabismus, a broad flat nasal bridge, talipes equinovarus, and an asymmetric chest. Although many of the individuals with ATR-16 syndrome have unbalanced translocations, there have been a few reported cases with pure monosomy of 16p. However, the small number of cases has only allowed for limited clinical characterization. We report the case of a 17 year-old Hispanic female with the above findings, along with cleft lip and palate, high frequency hearing loss, ventriculoseptal defect, short stature, congenital onychodystrophy, microcephaly, and craniosynostosis of the right lambdoid suture. High resolution chromosome analysis was normal; however, subtelomeric FISH probe study demonstrated a terminal deletion of 16p13.3 and no evidence of a translocation. The abnormality was not present in the mother; the father was unavailable for study. This is the sixth reported case of pure monosomy of 16p13.3, and expands the clinical phenotype. The previously reported cases are of a milder phenotype than our patient, with deletions in the range of 750-2000 kb. ATR-16 syndrome is most likely a contiguous gene syndrome. Several genes have been identified in this region including the  $\alpha$ -globin genes. Further analysis of the extent of the deletion in our patient will be helpful in determining whether a larger region of monosomy leads to a more severe phenotype. However, other factors may also contribute to a more severe phenotype including chromosomal position effects, parental imprinting, and genetic background.

**Molecular characterisation of ring chromosome 22.** *A.R. Jeffries<sup>1</sup>, S. Curran<sup>2</sup>, P. Sham<sup>2</sup>, H. Fiegler<sup>3</sup>, K. Woodfine<sup>3</sup>, N.P. Carter<sup>3</sup>, J. Powell<sup>1</sup>.* 1) Neuroscience, Institute of Psychiatry, London, United Kingdom; 2) SGDP Research Ctr, Institute of Psychiatry, London, United Kingdom; 3) Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Ring chromosome 22 (r22) is a rare human cytogenetic abnormality. Individuals with ring chromosome 22 exhibit a phenotype of global developmental delay with severe delay or absence of speech associated with more variable features including hypotonia, minor facial anomalies and 2-3 toe syndactyly. In common with other ring chromosomes, r22 is assumed to arise from breakage and subsequent fusion of both chromosome arms to generate a ring chromosome with concomitant loss of short and long arm sequences. Loss of short arm sequences is unlikely to be of clinical importance but hemizyosity for critical genes on the long arm of chromosome 22 has phenotypic implications. We have characterised the long arm breakpoints in 34 families, the largest reported collection of r22 patients. Microsatellite analysis was carried out to determine the 22q breakpoints and the parental origin of the r22. From 27 individuals, 11 were of maternal and 16 of paternal origin. Four individuals were also found to be mosaics. 22q DNA loss varied from less than 69 kb up to 10.1 Mb (0.15% to 21% of the total chromosome length). Visual inspection of the breakpoint positions suggested that these were clustered. We conducted a simulation study to formally test this hypothesis. Genotypes for each chromosome were simulated, using marker positions obtained from Ensembl and heterozygosity values from Genethon. An algorithm was used that scored the number of pairs of simulated chromosomes that overlapped in the interval that contained the breakpoint i.e. between the first homozygous deleted and heterozygous markers. This simulation was repeated ten thousand times and the score distribution plotted. The score of the real data was within the highest 0.3% of this empirical distribution providing significant evidence for clustering of breakpoints. We are now fine mapping the breakpoint positions using a chromosome 22 tiling path genomic microarray.

**A novel genomic rearrangement of 7q11.23 in multiple unrelated families with Williams-Beuren syndrome.** *L. Osborne<sup>1</sup>, M. Haddad<sup>2</sup>, M. Schachow<sup>2</sup>, M. Li<sup>2</sup>, J. Skaug<sup>2</sup>, R. Lokkesmoe<sup>3</sup>, K.W. Gripp<sup>4</sup>, E. Thompson<sup>5</sup>, L. Perez-Jurado<sup>6</sup>, S.W. Scherer<sup>2</sup>.* 1) Medicine, University of Toronto, Toronto, ON; 2) Genetics & Genomic Biology, The Hospital for Sick Children, Toronto, ON; 3) Genetic and Molecular Medicine, Kingston General Hospital, Kingston, ON; 4) Clinical Genetics Service, Women's & Children's Hospital, North Adelaide, SA; 5) Medical Genetics, DuPont Hospital for Children, Wilmington, DE; 6) Ciencias Experimentals i de la Salut, Universidad Pompeu Fabra, Barcelona, Spain.

Williams-Beuren syndrome (WBS) is commonly caused by the heterozygous deletion of a 1.6 Mb region of chromosome 7q11.23, but a small proportion of individuals with symptoms do not carry this deletion. We had previously identified an inversion of the WBS region, INV-I, which was associated with WBS phenotypes in a few cases, and was present in approximately 30% of transmitting WBS parents where it was proposed to predispose the chromosome to subsequent deletion. To determine whether inversions of the WBS region are common in families with a typical (deleted) or atypical (no apparent deletion) WBS proband, we have studied the 7q11.23 region using three-colour interphase FISH in more than 50 families. In one family with two WBS children with deletions, we found that in both affected siblings the deletion had occurred on an inverted chromosome 7 inherited from their father. This is the first example of a multiplex WBS family carrying a parental inversion. In six individuals with features of WBS we have now identified a second inversion, INV-II, with completely different breakpoints from INV-I. Whilst INV-I had endpoints located within the duplicated segments flanking the WBS common deletion, INV-II has endpoints within apparently single copy regions: one within the deletion region between WBSR1 and CYLN2, and the other distal to the deletion region, between SCYA26 and TMPIT. The clinical features of the individuals with this rearrangement vary but include developmental delay and sometimes other features of WBS such as hypersensitivity to sound, anxiety, characteristic facies, hoarse voice and musculoskeletal abnormalities. Interestingly, in some individuals INV-II is present on 50% of chromosomes examined, whilst in others it is present on only 30-40% of chromosomes examined. This raises the possibility of mitotic instability of the WBS region and the presence of a threshold effect for normal chromosomes, below which clinical features start to manifest. Further analysis of these rearrangements and identification of the exact breakpoints will help to explain the molecular mechanism for the inversion and the associated phenotypes.

**A Novel Case with 49 chromosomes: Implications of trisomies other than 13,18,21 and X chromosomes in live borns.** *S. MOVVA<sup>1</sup>, M. KUMAR<sup>1</sup>, S. NAJEEB<sup>1</sup>, P.S. MURTHY<sup>1</sup>, Q. HASAN<sup>1,2</sup>*. 1) Bhagvan Mahavir Hospital And Research centre Hyderabad-500 004, AP, INDIA; 2) Kamineni Hospitals, L.B. Nagar, Hyderabad-500 068, AP, India.

A ten-month-old boy, with delayed developmental milestones was referred to our department for cytogenetic evaluation. The child was 3rd in birth order delivered vaginally to a consanguineous couple at full term. At birth the only phenotypic abnormalities noticed were low set ears and wide spaced eyes. A suspicion of some abnormality arose at 5 months when the child failed to attain head holding. There is H/o recurrent respiratory tract infections with failure to thrive. On detailed evaluation, the child appeared conscious, irritable, moderate pallor, no cyanosis/icterus, no general lymphadenopathy or Pedal oedema. He weighed 5.5kgs(<50th percentile), length 67cm, arm span 58cms, US/LS 48/37 (1:1.3), Normal hair line, anterior fontanel 3/4cms, PF closed, hypertelorism with interpupillary distance of 4cm (95th percentile), depressed nasal bridge, high arched palate, normal philtrum, low set ears, short stubby fingers with normal dermatoglyphics. Bilateral undescended testis with phallic length of 12mm. Respiratory system showing bilateral crepts with wheeze, CVS-S1, S2 no audible murmurs, hepatosplenomegaly, and D/Q assessment developmental age of 5 months. CNS- no focal deficit. Family and antenatal history were unremarkable apart from an earlier male sibling who had multiple skeletal deformities and died at the age of 5months (medical reports not available). Lymphocyte culture revealed a karyotype of 49, XXXY + Trisomy10. There is no evidence of mosaicism. Buccal epithelium showed 16% cells with a double X chromatin body. Parental age and karyotype doesnt provide any evidence for the cytogenetic compliment of the proband. Extensive search in publications and internet didnt provide any information on live borns with a high chromosome compliment apart from cases of myelodysplastic syndrome and hematological malignancies. The mild phenotypic dysmorphisms seen in this child is surprising and he represents a novel case of a survivor with double trisomy, other than trisomies involving 13,18, 21 and X.

**Sotos syndrome with submicroscopic deletion of 5q35.** *K. Kurosawa<sup>1</sup>, Y. Igarashi<sup>1</sup>, T. Yamamoto<sup>1</sup>, M. Masuno<sup>1</sup>, K. Imaizumi<sup>1</sup>, N. Matsumoto<sup>2</sup>, Y. Kuroki<sup>1</sup>.* 1) Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Department of Human Genetics, Nagasaki University School of Medicine, Nagasaki, Japan.

Sotos syndrome is characterized by pre- and postnatal growth acceleration, advanced bone age, developmental delay and characteristic facial appearance. Recently haploinsufficiency of NSD1 gene at 5q35 is suggested to be the major cause of Sotos syndrome, especially for two-thirds of Japanese patients. We have evaluated 11 individuals (7 boys and 4 girls) with Sotos syndrome who are between age 4 months and 16 years, in order to better define the Sotos syndrome of deletion type. We review the clinical features and the spectrum of congenital anomalies. Conventional chromosome analysis did not detect visible rearrangements of 5q35. The diagnosis was based on the clinical features and FISH analysis with RP1-118M12 PAC clone, involving the NSD1 gene. Of the 11 patients, all have moderate to severe mental retardation. Mean birth weight was 3315.427g, length 49.525cm, OFC 35.519cm. Prenatal overgrowth (>3,500g) was noted in 4 out of 11. Paternal ages are 29.852, maternal ages 28.145, which is not significantly different from those of general population in Japan. As the CNS involvements, hypoplasia of corpus callosum is found in 2, in addition to the ventricular dilatation. 7 out of 11 have developed epilepsy. The age of the onset of seizures is early childhood. The seizures include grand mal and focal seizures. Congenital heart defects, involving hypoplastic left ventricle, A-P window, tetralogy of Fallot, and PDA were repaired in early infancy. Vesicoureteral reflux was noted 6 in 11. Postnatal overgrowth was noted only in 2 cases, which is the most significant difference compared with those of Sotos syndrome without submicroscopic deletion of 5q35. The information of the natural history of Sotos syndrome with submicroscopic deletion of 5q35 is suggested to be important for health practitioner and patient families for caring the disorder.

**Mosaicism for trisomy 17q in a female with normal intelligence.** *T. Mononen, R.L. Meltoranta.* Dept Clinical Genetics, Kuopio Univ Hosp, Kuopio, Finland.

We report a 13-year-old female with mosaic trisomy 17q. She presented with short stature (height about -2 SD) and a 3-cm leg length discrepancy. She had uneven, patchy skin pigmentation on the trunk, arms, and thighs that was not strikingly apparent due to her light complexion. She had dysmorphic features e.g. telecanthus, a low nasal bridge, a short anteverted nose, thick lips, posteriorly rotated ears, fleshy ear lobes, a low nuchal hairline, and fetal finger pads. There was no major malformations. Echocardiogram and renal ultrasound examination were normal. She had reached her developmental milestones but she was hypotonic and nonathletic. Her school performance was good.

Chromosome analysis of peripheral blood lymphocytes showed a normal female karyotype. Skin biopsies were taken from several separate sites. The G-banding and FISH analysis revealed the karyotype to be: mos 47,XX,+del(17)(p11.2)/46,XX in all the skin specimens studied. The percentage of the abnormal cells averaged 50% (60/120 cells). Parental karyotypes were normal.

This case illustrates the importance of obtaining skin fibroblast chromosome analyses even in patients with normal peripheral blood chromosomes who have multiple minor malformations and slight alterations in growth, body asymmetry, or skin pigmentation.

**Decreased Cholesterol synthesis as a possible aetiological factor in malformations of Trisomy 18.** *W. Lam<sup>1</sup>, J. Kirk<sup>2</sup>, N. Manning<sup>3</sup>, W. Readon<sup>4</sup>, R.I. Kelley<sup>5</sup>, D. FitzPatrick<sup>1,6</sup>.* 1) Dept Clinical Genetics, Univ Edinburgh, Edinburgh, United Kingdom; 2) Department of Clinical Biochemistry, Royal Hospital for Sick Children, Edinburgh; 3) Department of Paediatric Pathology, Sheffield Childrens Hospital, Sheffield; 4) National Centre for Medical Genetics, Our Ladys Hospital, Dublin; 5) Kennedy Krieger Institute, Johns Hopkins Medical Institutions, Baltimore, MD USA; 6) Medical Research Council, Western General Hospital, Edinburgh.

Cholesterol is a 27-carbon mono-unsaturated sterol and the major sterol in mammals. It serves as an important structural lipid of cell membranes. Cholesterol is also the precursor of all known steroid hormones. In human cells, most cholesterol is from de novo synthesis. Over the past decade, several human malformation syndromes have been identified as disorders of cholesterol biosynthesis. Trisomy 18 is a well-known malformation syndrome characterized by intrauterine growth retardation and multisystemic involvement including skeleton, cardiac, central nervous system and urogenital abnormalities. At present how the extra chromosome cause malformations is unknown. We report a series of 3 neonates and 6 fetuses with trisomy 18 in whom the cholesterol level in serum at birth or in amniotic fluid at 16-18 weeks gestation were abnormally low. The proband was born with IUGR and multiple congenital abnormalities suggestive of trisomy 18, which was confirmed by cytogenetics. However a subsequent report of the cholesterol level was 0.2 mmol/L (control 1.7 +/- 0.2 mmol/L) associated with a 7 dehydrocholesterol level of 0.1 mol/L (control 1-2 mol/L),  $p < 0.001$ . Two other trisomy 18 neonates with abnormally low levels of cholesterol were subsequently identified. In addition we found the mean level of cholesterol in 6 mid-trimester amniotic fluids from fetuses with trisomy 18 to be significantly low compared to the level of cholesterol in control amniotic fluids from normal fetuses 16.9 mmol/L (control 33.9 +/- 11.7 mmol/L),  $p < 0.05$ . We propose that hypocholesterolemia is a common characteristic of trisomy 18 and may have a role in causing the malformations. The recurrent finding of an abnormally low serum cholesterol level suggests a disruption of cholesterol biosynthesis.

**CHROMOSOME 1 IN THE GENETIC CLINIC.** *B. Kousseff, G. Jervis.* Pediatrics & Genetics, USF Regional Genetics Prog, Tampa, FL.

Chromosome 1 contains 10% of the human genome and it is not known for predilection to chromosome anomalies. Numerous reports have addressed a variety of chromosome 1 abnormalities but laboratory/clinic correlations are lacking. Between 1/2/82 and 12/31/02 through busy (2002 patient volume 2,797) prenatal and pediatric clinics at University of South Florida Genetics clinic 42,795 probands/families were evaluated. Forty-three had anomalous chromosome 1. Twenty-four had translocations, three had complex chromosome rearrangements (CCR) with 3 or more break points, seven had *inv(1)* and 2 had *del 1p*. One each had *ins(1p)*, *der(1)* secondary to questionable translocation, mosaic trisomy 1 (Clinical Genetics 1988: 33; 73-77), *del 1q*, *dup 1q*, *dup 1p* and *1qh+* initially thought to represent *inv(1)* leading to prematurity of 32 weeks and fatal outcome due to congenital diaphragmatic hernia, respectively. (The *1qh+* heteromorphism was not considered an anomaly and was not kept track of). One of the *inv(1)* pat was with interstitial deletion *15q* and was evaluated through the prenatal clinic as were 18 other probands. Two were evaluated for family history of anomalous chromosome 1 and the remaining 22 through the pediatric clinic. Among the 24 translocations 5 were paternal, 9 maternal and 10 *de novo*. Translocation *1;4* was encountered four times, *t(1;11)* and *t(1;6)* three times each and *t(1;5)* two times. However the break points were different, without predilection to a particular break point. The anomalies in the 5 unbalanced translocations varied as did the break points. The 3 CCR had 3, 4, and 5 breakpoints respectively and anomalous chromosome 1 was the only chromosome shared. The seven *inv(1)* were 5 pericentric and 2 paracentric. Only one was *de novo*; it was paracentric. The rest were 3 paternal and 3 maternal. Altogether the probands were 35 Caucasians, 7 Hispanics and 1 African-American. There was no explanation for the under representation of African-Americans. The study illustrated the wealth of cytogenetic, clinical, and outcome findings of patients with anomalous chromosome 1 in busy tertiary genetic centers.

**Molecular analysis of a translocation t(17;20)(q25;q13) associated with Silver-Russell syndrome.** *F. Matthes, M. Ayala-Madrigal, I. Hansmann, D. Schlote.* Martin-Luther-University Halle, Institute of Human Genetics, Halle, Germany.

A severe Silver-Russell syndrome (SRS), a heterogenous disorder mainly characterized by lateral asymmetry, pre- and postnatal growth retardation and other morphological abnormalities, ascertained in a girl with a translocation t(17;20)(q25;q13) inherited from her phenotypically not affected father, was reported by Ramirez-Dueñas et al. (1992). Here we report the molecular analysis of the breakpoint region on both chromosome 17q25 as well as 20q13 based on specific BAC / PAC clone contigs established for these regions. FISH analysis using proband metaphase chromosomes in order to map the molecular breakpoint in 17q25 determined several BAC and PAC clones giving signals on both chromosomes 17 and derivative 17 thus establishing a refined clone contig for the region of interest. According to the mutation analysis of a 3,5 cM interval on chromosome 17q25 for hereditary neuralgic amyotrophy (HNA; Meuleman et al., 2001) we started mapping several candidate genes onto this contig. One of the genes (SEC14L1) could be localized nearby the region of interest by PCR approach. Further refining the existing clone contig by STS content mapping and sequencing the BAC / PAC insert ends resulted in defining the breakpoint within 81,5 kb in the 5'-region of SEC14L1. Corresponding analysis of the breakpoint region on chromosome 20 led to the identification of a PAC clone spanning the breakpoint including one exon of the gene PTPRT, encoding a receptor protein tyrosine phosphatase, now being considered another candidate gene for Silver-Russell syndrome. Subcloning PAC and BAC subfragments and using these clones for Fluorescence-in situ-hybridization experiments facilitates refining the molecular breakpoint on chromosome 20. RFLP analysis in order to identify aberrant fragments specific for the translocation is furthermore being used to localize the molecular breakpoints hence giving novel information on the genetic background of the development of Silver-Russell syndrome.

**Balanced translocation 6q/21q predisposing to multiple miscarriages and trisomy 21 in a three generation**

**pedigree.** *S.H. Morelli*<sup>1,2</sup>, *A.M. Meloni-Ehrig*<sup>1</sup>, *B. Issa*<sup>1</sup>, *T.J. Pysher*<sup>3</sup>, *Z. Chen*<sup>1</sup>. 1) Dept Pediatrics, University of Utah, Salt Lake City, Utah; 2) Dept of Neonatology, Utah Valley Regional Medical Center, Provo, Utah; 3) Dept of Pathology, University of Utah, Salt Lake City, Utah.

We present a case of trisomy 21 with a balanced 6q/21q translocation who died at 10 days of age from complications of prematurity. This 1201 gm female infant was born to a 24 year old G3 P1121 mother. Pregnancy was complicated by rupture of membranes at 20 wks without re-accumulation of fluid. She remained on bedrest and went into labor and progressed to spontaneous vaginal birth at 27 weeks gestation. At birth the infant had positional deformities of her extremities and face consistent with oligohydramnios, but she also had facial features of Down syndrome. Her chromosome analysis revealed a 47, XX, t(6;21)(q25.3;q22.3), +21 karyotype. She lived for 10 days with severe complications including probable hypoplastic lungs, bilateral pneumothoraces, small membranous VSD, intraventricular hemorrhage, and PDA. Autopsy confirmed the findings: physical features of Down syndrome, bronchopulmonary dysplasia, tracheitis, bilateral germinal matrix hemorrhage with extension into right ventricle. Family history revealed extensive fetal loss in three generations: 5 women had a total of 24 miscarriages, many in the second trimester. One male had a prolonged, 15-year period of infertility. At least one miscarriage was shown to have trisomy 21. There is a first cousin once removed to the proband with Down syndrome. Preliminary studies confirm that the mother of the proband carries the balanced 6q/21q translocation. Additional studies of the family are pending. There are few reports of balanced translocations in individuals who also have trisomy 21. Balanced 6q translocation has been previously described as a predisposing factor for miscarriages. The mechanism may be that unbalanced gametes are formed by unfavorable adjacent 1 or 2 segregation leading to the high risk for miscarriage in this family. The 3 individuals with trisomy 21 in the extended family and the young maternal age in the case presented support that the balanced 6q/21q translocation may also predispose to non-dysjunction and trisomy 21.

**Molecular and cytogenetic characterization of an interstitial deletion of 14q [del(14)(q12)] in a child presenting with microcephaly and frontal lobe cortical dysplasia.** *G. Macintyre*<sup>1</sup>, *B. Lo*<sup>2</sup>, *D. Kamnasaran*<sup>1</sup>, *S. Meyn*<sup>2</sup>, *D.W. Cox*<sup>1</sup>. 1) Department of Medical Genetics, University of Alberta, Edmonton, Canada; 2) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Canada.

Interstitial deletions or translocations of 14q11-12, rarely reported, are associated with diseases including benign hereditary chorea (NKX2.1), tetramelic mirror image polydactyly (MIPOL1), oligodontia (PAX9), holoprosencephaly (Kamnasaran *et al*, 2001, *Am J Med Genet* 102:173) and schizophrenia (NPAS3; Kamnasaran *et al*, 2003, *J Med Genet*. 40:325). We have characterized a de novo deletion in a boy who presented in infancy with microcephaly (<3rd %), hypotonia and developmental delay. Soft dysmorphisms at eight months included prominent metopic suture, bitemporal narrowing, upslanting palpebral fissures, thin upper lip and posteriorly rotated ear. MRI imaging (1 year) showed a solitary cyst in the left lateral ventricle and subtle cortical pachygyria involving the frontal lobes. A hearing test and ERG exam were normal. Focal seizures developed at 1.5 years. Chromosomal analysis by G-banding revealed a karyotype of 46XY,del(14)(q12q13.1). Parental karyotypes were normal and family history was non-contributory. FISH analysis with BAC genomic clones and STS marker analysis on flow sorted chromosomes were then used to ascertain the extent of the deletion, which spans at least 2Mb and encompasses D14S80 and D14S262. The deletion is outside a locus we have recently defined for holoprosencephaly. A similar, but not identical, deletion has been reported. The two cases share some features including generalized hypotonia and microcephaly. A third reported case, with a potential small overlapping deleted region, has pachygyria, suggesting the location of a gene influencing brain structure. Two previously described genes reside within or adjacent to the deleted region, as well as several predicted genes supported by ESTs. FOXG1 is a transcription factor that may play a role in brain and telencephalon development and NOVA1 is a neuron-specific RNA-binding protein.

**Hypoplasia of portal vein and intrahepatic tumor in a patient with Wolf-Hirschhorn syndrome.** *T. Kosho<sup>1,5</sup>, H. Hisazumi<sup>2</sup>, K. Yakubo<sup>3</sup>, K. Matsushima<sup>4</sup>, T. Tsuchiya<sup>1</sup>, T. Ichikawa<sup>1</sup>, K. Mori<sup>1</sup>, K. Maeyama<sup>1</sup>, Y. Fukushima<sup>5</sup>, A. Tsuji<sup>1</sup>, H. Ohashi<sup>6</sup>, S. Sato<sup>1</sup>.* 1) Dept of Pediatrics, Saitama Municipal Hospital, Saitama, Japan; 2) Dept of Radiology, Saitama Municipal Hospital; 3) Dept of Obstetrics and Gynecology, Saitama Municipal Hospital; 4) Dept of Clinical Laboratory, Saitama Childrens Medical Center, Saitama, Japan; 5) Div. Clinical and Molecular Genetics, Shinshu University Hospital, Nagano, Japan; 6) Div. of Medical Genetics, Saitama Childrens Medical Center.

Wolf-Hirschhorn syndrome is a chromosomal disorder caused by microdeletion of the short arm of chromosome 4. It shows variable clinical manifestations such as severe growth and developmental retardation, characteristic facies, cleft lip and palate, skeletal abnormalities, cardiac defect, urogenital defect, and convulsion, but liver complications have not been reported. We present a female neonate with Wolf-Hirschhorn syndrome exhibiting hypoplasia of portal vein and intrahepatic tumor. At 30 weeks of gestation, amniocentesis was performed for intrauterine growth retardation and the chromosomes were 46,XX,del(4)(p16.1). At 37 weeks of gestation, she was born with growth retardation (birth weight 1572g (-3.0SD), height 39.6cm (-3.5SD), and OFC 29.6cm (-1.5SD)), characteristic face, cleft lip and palate, preaxial polydactyly, and hip joint contracture. Ultrasonography showed no flow in portal vein and reversed flow in dilated splenic vein. Enhanced 3D-CT demonstrated severe hypoplasia of portal vein and dilatation of splenic vein draining into inferior vena cava (IVC) via left renal vein. Mild hyperammonemia and galactosemia were noted. Thus, extrahepatic shunt from portal vein to IVC via splenic vein and left renal vein was confirmed. Enhanced 3D-CT also showed low density tumor (1.3cmx1.6cm) in the right lobe of the liver with significant hypervascularity. Hemangioendothelioma or nodular hyperplasia was suspected, while hepatoblastoma was excluded due to no elevation of serum AFP. This is the first report of liver complications of Wolf-Hirschhorn syndrome and careful evaluation of liver might be recommended in patients with this syndrome.

**Cluster of Down's syndrome cases in Belarus - possible consequence of Chernobyl accident.** *G. Lazjuk, I. Zatsepin, R. Khmel.* Dept Monitoring Cong Malform, Inst Hereditary Disease, Minsk, Belarus.

In Belarus Institute for Hereditary diseases a National register of congenital malformations is running since 1979. The data base contains information about 3104 cases of Down's syndrome (DS), more than half of them are verified cytogenetically. The study performed on liveborns and stillborns as well as cases aborted for genetic reasons with DS revealed a significant increase of monthly prevalence at birth in January 1987 (2.5 as compared to 1.2 for 1987 and 1.1 for the whole period under study). The largest increase was marked in the most affected by the Chernobyl accident Gomel oblast where the population obtained the largest doses. The association with external dose due to the increase of the exposure dose rates by one and even two orders of magnitude in majority of regions of Belarus during first days of the accident as a result of Chernobyl plum passage is supposed. According to the created model the pick of conception followed by the birth of DS children coincide the time of the highest exposure dose rates, thus the time around the conception is supposed to be the critical one. The obtained results are in accordance with the experimental data. The studies performed on laboratory mice (Tease, C., 1982; Evans, H.J., 1986) showed the most radiosensitive stage of oogenesis for induction of nondisjunction of chromosomes during this very short period (meta-anaphase of meiotic divisions). The temporal deviations of maternal age isn't responsible for the revealed pike. The average age of the women who gave birth to DS children was approximately the same as for other periods and in Gomel oblast it was even somewhat lower (23.1 years as compared to 29.3 years). The prenatal diagnostics couldn't be the cause as well, because it was introduced only in early 90-s. The results need additional experimental investigations.

**A case of balanced reciprocal translocation t(15q13;17q23) and repeated miscarriage due to Meckel syndrome. S. Tayel.** Clinical Cytogenetics Unit, Department of Anatomy, Alexandria Faculty of Medicine, Alexandria, Egypt.

Peripheral blood karyotyping was performed to a 42-year old lady with recurrent fetal loss. A balanced translocation between 15q and 17q was diagnosed with the karyotype of 46,XX,t(15q;17q)(17pter -->17q23 :: 15q13 --> 15qter,15pter--> 15q13 :: 17q23-->17qter). FISH analysis using WCP for chromosomes 15 and 17 confirmed the translocation. The lady had 3 mid-trimester abortions with fetal ultrasonography illustrating Meckel syndrome features in the form of occipital encephalocele, polycystic kidneys, cardiac defect, growth retardation with decreased fetal movement, single umbilical artery, ascites, oligohydramnios and breech presentation. Cases with balanced translocation usually have normal phenotype. The abnormal phenotype in such patients could be explained by the presence of microdeletion at the break points or the gene position effect. This case adds more proof to the known MKS gene locus (17q21-q24) and it may extend the genetic heterogeneity of Meckel syndrome beyond the 11q13 (MKS2), and 8q24 (MKS3) to 15q13. Translocation carriers with such history (high age, and recurrent abortion) could be advised to get benefit from ICSI and PGD using specific FISH probes to select a normal embryo.

**Molecular cytogenetic characterization of multiple intrachromosomal rearrangements of chromosome 2q in a patient with Waardenburg syndrome and other defects.** *S. Shim*<sup>1</sup>, *H.E. Wyandt*<sup>1</sup>, *E.H. Zackai*<sup>2</sup>, *D.M. McDonald-McGinn*<sup>2</sup>, *A. Milunsky*<sup>1</sup>. 1) Ctr Human Genetics, Boston Univ, Boston, MA; 2) Children's Hospital of Philadelphia, Philadelphia, PA.

Waardenburg syndrome type I (WS-1) was diagnosed clinically in a 6 year old boy with bilateral sensorineural deafness, lateral displacement of the inner canthi, a bulbous nasal tip, synophrys and cryptorchidism. Neither parent showed signs of this disorder and the family history was negative. In addition, he had a lumbar spina bifida with hydrocephalus shunted on day 2 of life, and severe mental retardation with a head circumference at the 5%tile. Initial karyotyping was reported as normal. Because of the WS-1 features, attention was focused on the PAX 3 location in 2q, at which time a de novo paracentric inversion of 2q23-q37.1 was noted (Zackai et al, *Am J Hum Genet* 57:A106, 1995). Subsequent high-resolution chromosome analysis indicated a complex rearrangement involving regions 2q31-q35 and 2q13-q21. Whole chromosome painting and high-resolution CGH yielded negative results for any translocation, duplication or deletion of any chromosome segment. Sequencing of the PAX 3 gene yielded no detectable mutation. FISH studies with human BAC clones revealed 5 breakpoints in chromosome 2q resulting in 2 paracentric inversions and 1 insertion, the karyotype being interpreted as 46,XY,der(2)inv(2)(q13q21)inv(2)(q21q23)ins(2)(q23q33q35). In this extremely rare chromosomal rearrangement, the FISH result showed a breakpoint at 2q35 being proximal to and without involvement of the PAX 3 gene. While further studies continue, possible interpretations include involvement of a regulatory gene(s) for PAX 3 and other genes at the other breakpoints related causally to the spina bifida and mental retardation.

**Familial pure partial trisomy of chromosome segment 7q32-q34: further delineation of phenotype.** *J.A. Phalen<sup>1</sup>, G.H. Scharer<sup>2</sup>, A. Maleki<sup>3</sup>, E. Sujansky<sup>2</sup>.* 1) Child Development Unit, The Children's Hospital, Denver, CO; 2) Genetics and Metabolism Services, The Children's Hospital, Denver, CO; 3) University of Colorado Health Sciences Center, Denver, CO.

We report a mother and son with pure trisomy 7q32-q34. To our knowledge only 3 prior cases are reported. All were secondary to insertion of maternally-derived chromosomal material. The propositus was a 13-month-old mildly dysmorphic male with global developmental delay born to a 23-year-old mother with moderate mental retardation. Prenatal ultrasound showed unilateral hydronephrosis, which resolved by six months of age. He was born vaginally to unrelated parents at 38 weeks gestation weighing 3.04 kg. At age 13 months his height was 69 cm and weight 8.36 kg (both < 2nd percentile), wt-to-ht ratio 53rd percentile; OFC 46.5 cm (50th percentile). Dysmorphic features included positional occipital plagiocephaly, prominent mid-face with micrognathia, slightly low-set ears, hypoplastic nose, long philtrum, high-arched palate, and single palmar crease. He had truncal hypotonia with peripheral hypertonia. MRI of the brain and an EEG were normal. Mother had a long thin face, high frontal hairline, slightly low-set ears, long philtrum, and high-arched palate. High-resolution chromosome analysis from blood lymphocyte cultures of the child and mother, analyzed by standard GTG-banding at the 450-650 band range, revealed a 46,XY and 46,XX karyotype, respectively, both with extra chromosomal material on chromosome 7, at position 7q32.3q34. FISH on metaphase cells using a whole chromosome paint probe for chromosome 7, a 7q subtelomeric probe, and a probe specific for the 7q31 region confirmed duplication of segment 7q32-34. Common to all 5 reported patients are normal gestational and birth data, mental retardation or developmental delay, minor skull abnormalities, a prominent mid-face, high frontal hairline, low-set ears, long philtrum, and abnormal palate. Unique to our family are absence of eye, hand, and foot anomalies. Unlike 2 adult brothers previously reported, this mother had no seizures. Thus, it appears that patients with pure trisomy 7q32-34 may be less severely affected than those previously reported.

**Delayed diagnosis of chromosome abnormalities in non-dysmorphic individuals with epilepsy.** *J.L. Tolmie<sup>1</sup>, S. Macleod<sup>2</sup>, A. Mallik<sup>3</sup>, J.B.P. Stephenson<sup>2</sup>, M.E. O'Regan<sup>2</sup>, S.E. Zuberi<sup>2</sup>.* 1) Duncan Guthrie Institute of Medical Genetics, Yorkhill Hospitals NHS Trust, Glasgow, U.K; 2) Fraser of Allander Neurosciences Unit, Royal Hospital for Sick Children, Glasgow; 3) Regional Clinical Neurophysiology Department, Southern General Hospital, Glasgow.

It is well known that there is increased risk of epilepsy associated with chromosomal abnormality syndromes such as Miller-Dieker syndrome, 1p36 deletion and Angelman syndrome, conditions that present with profound developmental delays, dysmorphism and congenital malformation. However, it is not so well known that an epilepsy phenotype may be the presenting feature that leads to diagnosis of a chromosome abnormality. We identified 11 patients who each had a clinical presentation with an epilepsy phenotype. Five patients had sex chromosome abnormalities, four patients had ring chromosome 20, one had ring chromosome 14 and one had a balanced reciprocal translocation. Most likely, in these patients the absence of dysmorphism explained delayed diagnosis of the chromosome abnormality and accounted for inappropriate investigations and treatments, especially in patients with ring chromosome 20, three of whom underwent epilepsy surgery evaluation before the chromosome diagnosis was made. We conclude that chromosome studies should not be delayed in children who have learning difficulties dating from or after the onset of epilepsy, nor should they be delayed in individuals with atypical non-lesional epilepsy, even in the absence of learning difficulties.

**Trisomy 8 Mosaicism Syndrome.** *A.L. Torres-Rodriguez<sup>1</sup>, M. Diaz-Garcia<sup>1</sup>, G. Garcia-Sanchez<sup>1</sup>, C.F. Martinez-Cruz<sup>2</sup>, S.G. Juarez-Garcia<sup>1</sup>, F. Castillo-Lorca<sup>1</sup>.* 1) Departamento de Genetica.Instituto de la Comunicacion Humana/Centro Nacional de Rehabilitacion, Mexico, D.F; 2) Servicio de Comunicacin Humana, Departamento. de Seguimiento Pediatrico.Instituto Nacional de Perinatologia, Mexico, D.F.

Complete trisomy 8 occurs in 0.8% of spontaneous pregnancy loss. Mosaic trisomy 8 is a well-described syndrome, characterized by rather specific combination of congenital malformation. And a pattern of minor physical abnormalities. Over 75 cases have been reported. This is more frequent in males. The face is characterized by large, pear shape nose, evert lower lip, small mandible, high palate, unusual ear morphology, and long neck. The features are extremely variable but may include; mental retardation, skeletal anomalies, congenital heart defects and kidney malformations. A significant number of cases have ocular manifestations. The most commonly reported in the literature have been corneal abnormalities and strabismus. We present a 4-year-old male child with phenotype of mosaic trisomy 8. The patient present low anterior hairline, narrow and flat forehead, arched eyes brown, broad nose, protuberant lips, micrognathia, flat cleft, small fingers and toe joints resulting camptodactyly in hands and feet. The patient shows the characteristic deep plantar creases in feet. The thorax is long and narrow, present scoliosis, supernumerary nipple vestige in both axillas and had interventricular septal defect. The audiometric study was normal. Chromosome analysis was done in lymphocyte and fibroblast culture, the result of the karyotypes was 46;XY in lymphocyte and 46,XY/47,XY+8 (12% / 88% respectively) in fibroblast. The literature to make mention which the percentage in the expression cellular are more variable. The distribution of the additional chromosome in different tissues is highly variable too. In this case the trisomy 8 only was observed in fibroblast cells.

**A Syndrome of partial trisomy of 16q and partial monosomy of 18p.** *R. Siddiqui*<sup>1,3</sup>, *E. Pergament*<sup>2</sup>, *J.B. Ravnan*<sup>4</sup>, *L. Guohui*<sup>4</sup>, *J.G. Davis*<sup>3</sup>. 1) Medical Genetics, Memorial Sloan Kettering, New York, NY; 2) Northwestern University Medical School Chicago, IL; 3) New York Weill Cornell Medical Center, NY; 4) Genzyme Genetics.

Partial trisomy of chromosome 16q and monosomy of chromosome 18p are uncommon chromosomal disorders. Individuals who present with both partial trisomy of chromosome 16q and partial monosomy of chromosome 18p are rare. We report a second case of a female child who presents with this combination.

NJ was born at 39 weeks of gestation to unrelated parents ages 32 each. The couple had difficulties with conception. Conception was achieved using clomiphene and intrauterine insemination. A second trimester ultrasound revealed mild hydrocephalus. Cytogenetic studies using GTG banding performed on amniocytes, obtained at 27th weeks of gestation, showed 46,XX,add(18)(p11.2). FISH analysis of cord blood cells after birth demonstrated that the additional genetic material was derived from a translocation between chromosomes 16 and 18; ish der(18)t(16;18)(wcp16+,wcp18+). Chromosome analyses of both parents revealed normal karyotypes.

At birth, NJ weighed 9 lbs. 2 oz (97th percentile) and was 21 inches long (97th percentile). Physical examination at birth revealed an infant with asymmetric skull; dysmorphic facial features, including down slanting palpebral fissures, small nose with anteverted nares, low set ears, grooved philtrum, recessed chin; overlapping fingers: 2 over 3 and 5 over 4, and bilateral dislocated hips. The patient was hypotonic and had clonus at both ankles. Echocardiogram showed an atrial septal defect and brachial artery stenosis. There were no other congenital anomalies. NJ developed gastroesophageal reflux requiring Nissen fundoplication. Subsequently, NJ has enjoyed good general health. Her hypotonia persists. She now exhibits developmental delay.

This is the second case report of an individual who presents with multiple congenital anomalies and developmental delay who has both partial trisomy for long arm of chromosome 16 and monosomy for short arm of chromosome 18 with multiple congenital anomalies.

**6q subtelomeric deletion: Case report and review of the literature.** *D.A. Stevenson, K.M. Dent, J.C. Carey, Z. Chen, N. Longo.* Pediatrics, University of Utah, Salt Lake City, UT.

We report on a girl with an abnormal hybridization pattern for the subtelomeric fluorescence in-situ hybridization (FISH) probe panel showing deletion of the long arm telomeric region of chromosome 6. All other subtelomere DNA probes showed normal hybridization patterns. Metaphase cells analyzed from cultures of peripheral blood revealed a normal female chromosome complement at the 650-band level. Whole chromosome painting probes for chromosome 6 showed both homologs 6 to be entirely painted in 10 metaphase cells analyzed. In both parents, FISH using locus-specific probes for the subtelomeric region of 6q showed no evidence for a deletion as seen in the patient. Clinical findings include: developmental delay, seizures, hypoplasia of the corpus callosum, dextrocardia, unusual dimpling of knees and elbows, and minor facial anomalies. We are aware of only two other reports of a 6q subtelomeric deletion. Retinal abnormalities have been associated with distal deletions of 6q but the cases with subtelomeric deletions of 6q did not have retinal abnormalities. Genes responsible for such retinal abnormalities seen in other terminal 6q deletions may be proximal to 6q27. These three cases support the use of subtelomeric FISH probes in patients with developmental delays and minor anomalies with apparently normal karyotypes or balanced chromosome rearrangements. As more cases are reported we may be able to establish a discrete phenotype and natural history to aid in counseling.

**Non-syndromic mental retardation: Identification of candidate X-chromosome loci.** *E. Sherr*<sup>1</sup>, *P. Cotter*<sup>2</sup>. 1) Dept Neurology, Univ California, San Francisco, San Francisco, CA; 2) Cytogenetics and Molecular Genetics, U.S. Labs, Irvine, CA.

Profound cognitive impairment is a significant health issue, affecting approximately 1-3% of children worldwide. Recent progress has been made in identifying a few genetic mutations underlying this disorder, yet for the majority of these patients, no diagnosis or specific treatment options are available. We have evaluated a young girl with significant cognitive impairment and difficulties with adaptive functioning who has an X chromosome inversion. Her developmental progress was delayed, more in language than in gross or fine motor milestones. Her exam is significant for no dysmorphic features, mild lower extremity hypertonicity and awkward gait. Comprehensive metabolic testing did not reveal any significant abnormalities and a high resolution MRI did not detect a structural CNS cause for her difficulties. A WISC-III demonstrated a full scale I.Q. of 54. Cytogenetic analysis (>550 bands) detected a pericentric inversion, (46,X, inv (X) (q13.1; q26.3). To evaluate this further, we have undertaken FISH analysis to more precisely determine the breakpoints of this inversion with the aim of identifying candidate genes as the cause of her mental retardation. Genomic BACs spanning both Xq13 and Xq26 were labeled by nick translation with fluorescent dUTP and hybridized to metaphase spreads of a control and the patient. BAC 177A4 hybridized within the inversion, thus defining the proximal breakpoint centromeric to Xq13.1. BAC 112H23 also hybridized within the inversion, defining the distal breakpoint telomeric to Xq26.3. Replication studies in lymphocytes demonstrated that the inverted chromosome was the early replicating. Ongoing FISH analysis will enable precise localization of these two breakpoints and identification of candidate mental retardation genes.

**Paternal origin of LMNA mutations in Hutchinson-Gilford progeria.** *M.R. D'Apice<sup>1</sup>, R. Tenconi<sup>2</sup>, M. Biervliet<sup>3</sup>, I. Mammi<sup>2</sup>, J. van den Ende<sup>3</sup>, G. Novelli<sup>1</sup>.* 1) Biopathology, University of Tor Vergata, Rome, RM, Italy; 2) Dept. of Pediatrics, University of Padua, Italy; 3) Department of Medical Genetics, University of Antwerp, Belgium.

Hutchinson-Gilford progeria syndrome (HGPS; OMIM #176670), is a rare and progressive disorder characterized by multiple anomalies, including slowed growth, facial disproportion with prominent eyes, receding mandible and protruding ears, hair loss, osteoporosis and thin, parchment-like skin with depleted subcutaneous fat deposits. HGPS is caused by sporadic mutations in the lamin A gene. At least 5 different mutations within the LMNA gene have been found in patients with HGPS. The mutation responsible for the majority of cases of HGPS is a de novo single-base substitution C-to-T resulting in a silent gly-to-gly change at codon 608 within exon 11 (G608G). The G608G mutation causes the activation of a cryptic splice site within exon 11 of the LMNA gene, resulting in the production of a protein product that deletes 50 amino acids near the C terminus. We analyzed the parental origin of LMNA G608G mutation detected in our sporadic cases of HGPS. Paternal and maternal haplotypes were established by segregation analysis of SNP markers at the previously reported in LMNA gene in position 861T/C (ex5), position 1338T/C (ex7); position 1698C/T (ex10). The genomic region encompassing the exon 10, intron 10 and exon 11 was PCR amplified for each patient and the resulting 1200-bp PCR product was cloned and sequenced as described above. By using the polymorphism data, we established the phase of the mutation, and therefore also its origin. We found that the germline mutation occurred in all four analyzed cases, on the paternal haplotype and concluded that de novo mutations in HGPS occur exclusively on the paternally derived 1 chromosome. This is in accord with the observation of certain human genetic conditions where incidence of new mutations increases with the age of the father. We confirm this hypothesis in progeria, since an age significantly higher (p<0.001) than expected paternal age was also observed in our families and provided molecular evidence that HGPS new mutations originate during spermatogenesis.

**FGFR2 and severe anomalies: phenotype-genotype correlation.** *R.E. Dugan<sup>1</sup>, E. Bawle<sup>2</sup>, K. Kalche<sup>3</sup>, A. Rozelle<sup>2</sup>, A.D. Gilbert<sup>1</sup>, R. Romero<sup>3</sup>, A. Johnson<sup>1</sup>.* 1) Obstetrics and Gynecology, Wayne State University, Detroit, MI; 2) Children's Hospital of Michigan, Detroit, MI; 3) Perinatal Research Branch, National Institute fo Health, Bethesda MD.

Background: The FGFR-related craniosynostosis syndromes are associated with coronal synostosis, midfacial hypoplasia with proptosis, and variable hand and foot anomalies. Traditionally, these disorders have been defined by clinical observation and variable severity; however, molecular observation has shown that these disorders are in fact allelic conditions that can share identical mutations. Case Report: MT is a 26 Y.O. G7P5025 of Hispanic and Caucasian ancestry. Targeted 2-D and 3-D ultrasounds at 36 wks revealed cloverleaf skull, exophthalmia, bowing of long bones, large great toe, shortened, flexed thumbs, and disorganized cervical-thoracic spine. A male neonate was born at 39 wks with cloverleaf skull, remarkable proptosis, and severe midface hypoplasia. Skeletal survey revealed 2-3 finger syndactly, adducted thumbs, synostosis of the elbow with fusion of the proximal radius, ulna and distal humerus, knees fixed at 80-90 , and anterior curvature of the tibia. The vertebrae appeared abnormal on CT. Additional findings included imperforated anus, hypospadias, VSD, and PDA. Postnatal DNA analysis revealed a TYR340Cys mutation in exon 9 of FGFR2. The child is alive at 1y.o. Conclusion: This is a case of severe craniosynostosis with additional skeletal anomalies associated with a suspected de novo FGFR2 mut. In a study of Antley-Bixler syndrome (ABS), 4/7 cases with an indentifiable FGFR2 mutation involved the creation of a new Cys residue. One of the first reported cases of ABS associated with a FGFR2 mut involved the creation of a Cys residue and severe spinal dysraphism, a finding not of ABS but similar to those reported here. These mutations have been reported with severe Pfeiffer syndrome. An unpaired Cys is thought to result in ligand-independent activation yielding a severe phenotype. Given the allelic nature of these mutations, the spectrum of disease and new therapeutic interventions, determining prognosis based on FGFR2 analysis remains difficult, especially in a prenatal setting.

**9q34.3 Terminal Deletion in Three Unrelated Patients: A new MCA/MR Syndrome.** *N. Matsumoto*<sup>1, 2</sup>, *M. Iwakoshi*<sup>3</sup>, *N. Okamoto*<sup>4</sup>, *N. Harada*<sup>1, 2, 5</sup>, *T. Nakamura*<sup>6</sup>, *S. Yamamori*<sup>6</sup>, *H. Fujita*<sup>6</sup>, *N. Niikawa*<sup>1, 2</sup>. 1) Department of Human Genetics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 2) CREST, Japan Science and Technology Corporation, Kawaguchi, Japan; 3) Nishinomiya Municipal Wakaba-en, Nishinomiya, Japan; 4) Department of Planning and Research, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 5) Kyushu Medical Science Nagasaki Laboratory, Nagasaki, Japan; 6) Research Department, Mitsubishi Kagaku Bio-Clinical Laboratories, Tokyo, Japan.

A de novo 9q34.3 terminal deletion was found in three unrelated patients by all-subtelomere FISH analysis and/or subtelomere-specific microarray CGH. The 9q34.3 deletion in two patients was simply terminal, while that of the other was due to an unbalanced translocation, der(9)t(9;6)(q34.3;p25)de novo. All patients presented with common characteristic craniofacial abnormalities including flat round face, light thin soft hair, arched eyebrows, hypertelorism, short nose, anteverted nostrils, open carp mouth, thick lower lip, protruding tongue, and pointed chin. Severe mental retardation was recognized in all of them. Cardiac anomaly and hydronephrosis were observed in two cases, and obesity was found in one case. We propose that the 9q34.3 deletion is a distinct MCA/MR syndrome.

**Deletion of GPR35 Gene On 2q37.3 May Account For Albright Hereditary Osteodystrophy Like Phenotype : Defining Further Genetic Variants Within and Around GPR35 Gene.** *J. Hoo<sup>1</sup>, A.E. Shrimpton<sup>1,2</sup>, B.R. Braddock<sup>1</sup>, L.L. Thomson<sup>1</sup>, C.K. Stein<sup>1,2</sup>.* 1) Dept Pediat, SUNY Upstate Med Univ, Syracuse, NY; 2) Dept Pathology, SUNY Upstate Med Univ, Syracuse, NY.

Patients with a cytogenetic diagnosis of terminal band 2q37 deletion can be divided into two groups on the basis of their clinical features. The first group comprises the majority of cases and is associated with significant growth and mental retardation but rather nonspecific physical features. The second group, a minority of less than 10 reported cases, clinically resembles Albright hereditary osteodystrophy (AHO) / pseudohypoparathyroidism (PHPT) and has only mild to moderate mental retardation. We report three patients of group 2. Cytogenetic FISH studies followed by molecular analyses showed that the gene for G protein-coupled receptor 35 (GPR35) on 2q37.3 is deleted in all three patients. We postulate that absence of this particular G protein receptor gene may account for the phenotypic resemblance to the Albright hereditary osteodystrophy. We also believe that the deletion of GPR35 is responsible for the entity Brachydactyly - Mental Retardation syndrome (OMIM #600430). We have further defined several polymorphic variants within the coding region and flanking regions of GPR35 gene, which could potentially be useful for rapid detection of GPR35 gene deletion. We recommend that every patient with AHO/PHPT phenotype should undergo 2q subtelomeric FISH screen and further molecular study on the GPR35 gene as necessary.

**Subtelomeric deletions detected in 6.7% of mr/mca patients by multiplex ligation-dependent probe amplification (MPLA).** *Y. van Bever, L. Rooms, E. Reyniers, R. van Luyck, J. Wauters, J.J. van den Ende, R.F. Kooy.* Department of Medical genetics, University of Antwerp, Antwerp, Belgium.

Subtelomeric rearrangements are estimated to be responsible for 5-10% of cases of unexplained mental retardation. Despite the high frequency, routine methods to screen for these rearrangements are scarce.

We screened 75 patients with unexplained mental retardation and either a familial history of mental retardation or facial dysmorphism/multiple congenital anomalies (MCA) or both, for a subtelomeric deletion using multiplex ligation-dependent probe amplification (MPLA). A subtelomeric deletion was identified in 5 patients. Two patients had a 1pter deletion, (the most frequently described deletion), whereas a 1qter deletion, a 21qter and a 3pter were found once in three different patients. The patient with the 3pter deletion also had a duplication of the subtelomeric region of chromosome 11q as detected by FISH analysis. The two patients with 1pter deletion both had MR, hearing impairment and dysmorphic facies, compatible with reports of patients described with a similar deletion. The 1qter deletion patient had MR, epilepsy, growth retardation, a single kidney, and hypospadias. The patient with a 21qter deletion had severe PMR, truncal obesity, a lax and somewhat translucent skin, strabismus, fleshy nose and thick lips. The patient with the 3pter deletion had a phenotype compatible with the 3p- syndrome: severe MR, growth retardation, microcephaly and dysmorphism.

Our conclusions are that subtelomeric screening is an important tool in diagnosing patients with unexplained MR and that MLPA is a sensitive method to perform this screening.

**Quantitative PCR (QPCR) screening detects atypical 22q11.2 microdeletions in adults with features of 22q11.2 deletion syndrome negative by diagnostic FISH testing.** *R. Weksberg*<sup>1,2,3</sup>, *J.A. Squire*<sup>4</sup>, *E. Chow*<sup>5</sup>, *A.S. Bassett*<sup>5</sup>. 1) Div Clinical & Metabolic Genetics, Dept Paediatrics, Hosp Sick Children, Toronto; 2) Dept Molecular & Medical Genetics, Univ Toronto, Toronto; 3) Research Inst, Hosp Sick Children, Toronto; 4) Ontario Cancer Institute and Depts of Lab Medicine, Pathology and Medical Biophysics, Univ Toronto, Toronto; 5) Centre for Addiction and Mental Health, and Dept of Psychiatry, Univ Toronto, Toronto.

Chromosome 22q11.2 deletion syndrome (22q11.2 DS) encompasses a heterogeneous group of disorders. Clinical features include palatal anomalies, cardiac malformations, learning and psychiatric disorders. The majority of 22q11.2 deletions are 3Mb or 1.5Mb long and can be detected by a standard diagnostic FISH assay using the TUPLE1 (Vysis) probe. However, a significant number of patients with features of 22q11.2 DS are atypical in that they do not exhibit hemizyosity with this diagnostic FISH assay. A number of reports of such patients describe atypical microdeletions that are unique within this 3Mb region. To map and screen for atypical hemizygous microdeletions in adult syndromal patients negative for 22q11.2 deletion by diagnostic FISH with TUPLE1 we have used real time QPCR with fluorescent dye SYBR Green 1 chemistry and the ABI Prism 7700 sequence detection system. This screen of the 22q11.2 region uses 9 primer pairs that are evenly spaced within the commonly deleted 3Mb region and 5 primer pairs in the flanking regions. We have tested 3 normal controls, 15 adults with deletions and 2 adults without deletions by standard diagnostic FISH testing. Our QPCR data demonstrate for these 2 latter patients a microdeletion in 22q11.2 which does not include TUPLE1. Hemizyosity in these 2 cases was confirmed with FISH probes from the region of hemizyosity detected by QPCR. Currently we are analyzing 17 adults with features of 22q11.2 DS who are negative by standard FISH testing. Preliminary data shows that at least one with tetralogy of Fallot has a small atypical microdeletion detectable by QPCR. This approach will ameliorate diagnosis of individuals with 22q11.2 DS and will generate high resolution deletion maps elucidating the genetic basis of 22q11.2 DS.

**Uniparental disomy of the X chromosome in a female with recessive X-linked ichthyosis.** *C. Thauvin-Robinet Jr<sup>1</sup>, P. Caillier<sup>2</sup>, G. Vaillant<sup>3</sup>, A. Donzel<sup>4</sup>, V. Cusin<sup>1</sup>, B. Favre<sup>2</sup>, F. Huet<sup>5</sup>, J.R. Teyssier<sup>4</sup>, F. Mugneret<sup>2</sup>, L. Faivre<sup>1</sup>.* 1) Centre de Genetique, Hopital d'Enfants, Dijon, France; 2) Laboratoire de Cytogenetique, Hopital Le Bocage, Dijon, France; 3) Service d'Endocrinologie, Hopital Le Bocage, Dijon, France; 4) Laboratoire de Genetique Moleculaire, Faculte de Medecine, Dijon, France; 5) Service de Pediatrie 1, Hopital d'Enfants, Dijon, France.

Recessive X-linked ichthyosis is a genetic disorder of keratinization characterized by generalized desquamation of large, adherent, dark brown scales. Extracutaneous manifestations include corneal opacity and cryptorchidism. Abnormal cutaneous scaling results from steroid sulphatase gene (STS) deficiency. The STS gene is mapped to the Xp22.3-pter region, which escapes X chromosome inactivation. Complete deletions of the STS gene have been found in up to 90% patients, using FISH studies. Here, we report the case of a karyotypically normal female affected with a maternally inherited recessive X-linked ichthyosis as a result of a homozygous deletion of the STS gene, detected by FISH studies. The patient presented with mild ichthyosis (located on face and arms) and labia minora hypertrophy. PCR analysis of microsatellite polymorphic markers spanning the STS gene region consistently demonstrated a single allele in favor of maternal X chromosome isodisomy. PCR analysis of other microsatellite polymorphic markers spanning the entire X chromosome in order to delimitate the extension of the isodisomy showed partial maternal short arm of X chromosome isodisomy. The manifestation of mild to severe symptoms of recessive X-linked disorders in female carriers results usually from Turner syndrome or skewed X inactivation with preferential inactivation of the X chromosome carrying the normal allele. In the literature, only one female case with uniparental disomy of the entire X chromosome is reported, in association with Duchenne muscular dystrophy.

**Prenatally diagnosed isodicentric Yp.** *H. Bruyere*<sup>1</sup>, *M.D. Speevak*<sup>2</sup>, *B. de Freminville*<sup>3</sup>, *B. McGillivray*<sup>4</sup>, *D. McFadden*<sup>1</sup>, *V. Adouard*<sup>3</sup>, *D. Terespolsky*<sup>2</sup>, *F. Prieur*<sup>3</sup>, *T. Pantzar*<sup>1</sup>, *M. Hrynychak*<sup>5</sup>. 1) Department of Pathology, UBC, Vancouver, BC, Canada; 2) Department of Laboratory Medicine Credit Valley Hospital Mississauga, ON, Canada; 3) Cytogenetics Laboratory, Jean Monnet University, Saint-Etienne, France; 4) Department of Medical Genetics, UBC, Vancouver, BC, Canada; 5) Cytogenetics Laboratory, Royal Columbian Hospital, New Westminster, BC, Canada.

Prenatally detected chromosome abnormalities are known to have a different prognosis from those detected postnatally because of ascertainment bias of the latter. Postnatally, isodicentric Yp (iso Yp) presents with wide phenotypic variation, from Turner syndrome females to phenotypically normal, infertile males. Few data are available on the outcome of prenatally diagnosed isochromosome Yp. Five cases of prenatally diagnosed iso Yp are presented. Four of the 5 cases had amniocentesis on the basis of advanced maternal age (cases 1-4) and one was diagnosed after nuchal translucency was detected in one twin (case 5). One case showed no other cell lines (case 3) while one had a 45,X cell line and a cell line with two copies of the iso Yp (case 2) and case 4 had a 45,X cell line only. A 45,X cell line alone was present in one case (case 5) and a 45,X cell line and a 46,XY cell line were present in another (case 1). Cases 1-3 resulted in the delivery of normal male infants, with essentially normal follow-up at 3-8 months. Case 4 was terminated and showed a normal male fetus. Case 5, diagnosed after prenatal diagnosis of nuchal translucency, resulted in the birth of a male infant with ambiguous genitalia. These cases of prenatally diagnosed isodicentric Yp demonstrate the cytogenetic variability encountered prenatally and that prenatally diagnosed iso Yp appears to have a good prognosis that results in a phenotypically normal male infant in most cases.

**Terminal 6p deletion detected by subtelomeric screening using fluorescence in situ hybridization.** *C. Le Caignec*<sup>1,2</sup>, *J.M. Rival*<sup>2</sup>, *C. Delnatte*<sup>2</sup>, *M. Boceno*<sup>2</sup>, *A. David*<sup>2</sup>. 1) Fac Medecine, LEPA, Nantes, France; 2) Service de genetique medicale, Nantes, France.

Terminal 6p deletions are relatively rare. However, a distinct clinical phenotype has emerged, including developmental delay, congenital heart malformations, ocular abnormalities, hearing loss, and a characteristic facial appearance. To our knowledge, four patients have been previously reported with detailed FISH analyses. For three of them, the size of the deleted region was estimated to 6 Mb. The fourth case had a smaller deletion, estimated to 2.1 Mb. In contrast to previously reported cases, this patient had no mental retardation, but severe language impairment and difficulties in social interaction. We report a patient with a terminal 6p deletion, detected by subtelomeric screening using fluorescence in situ hybridization (FISH). The girl presented with facial dysmorphic features, hearing impairment, malformation of the anterior eye segment, and mental retardation. Detailed FISH analysis with 17 BAC probes covering the distal 6p25 region estimated the size of the terminal deletion to 6.1 Mb. The breakpoint was located between RP11-232P20 and RP11-525O21 clones. The forkhead transcription factor gene *FKHL7*, involved in a spectrum of anterior eye chamber disorders, is deleted in this patient. These data suggest that patients with complete terminal 6p deletion phenotype, including mental retardation, have a possible major breakpoint at 6 Mb. More patients with detailed FISH analyses are needed to confirm these findings.

**A de novo deletion (5)(q15q22). Further phenotypic description including APC gene analysis. Prognostic and therapeutic implications.** A. Iglesias, B. Davidoff-Feldman. Division of Genetics, Department of Pediatrics, Nassau University Medical Center, East Meadow, NY.

A 5 year-old boy was referred for speech and motor delay. Pregnancy and perinatal period were normal. Birth weight was 3264 gr. At 3 years he was active, partially interactive and barely verbal. Weight, height, and head circumference were normal. He had a narrow forehead with a prominent medial ridge and mild synophris. Eyes were normal. He had a flat nasal bridge and anteverted nares. Philtrum was prominent with full lips. Ears were soft, cupped and rotated. Neck was normal. Chest was flat. Respiratory, cardiovascular and abdominal exams were normal. External male genitalia were normal. Cubitus valgus and joint hyperextensibility were noted. Thenar and hypothenar eminences were flat bilaterally. Neuromuscular exam was essentially normal except for mild strabismus. Skin was normal. Developmental delay was noted. A hearing evaluation, CT scan of the head and cervical spine were normal. Bone age was mildly delay. High-resolution chromosomes showed 46, XY, del (5)(q15q22). Parental chromosomes were normal confirming the de novo nature of the defect. Similar deletions have been linked with multiple congenital anomalies and mental retardation. Moreover a de novo deletion of chromosome 5q21-q22 causing dysmorphic features, mild mental retardation, and Familial Adenomatous Polyposis (FAP) has been reported. Since the deleted region in our patient theoretically encompassed the APC area, cytogenetic analysis was done. Results were normal. Molecular analysis is in progress to rule-out small deletions and/or point mutations in the APC gene before proceeding or not with more invasive procedures (i.e. colonoscopy). Search for APC deletions and mutations in patients with FAP are standard. However, the same is not customary for patients with 5q deletions involving the APC region. Since management and prognosis would dramatically change if the APC gene were not present, detailed analysis of the APC region would benefit these patients. Moreover, comprehensive studies of the area might increase our understanding of the genotype-phenotype correlations in this type of patients.

**Deletion of 9p associated with sex reversal in a patient with multiple congenital anomalies.** *D. Mayen, M. Aguinaga, G. Razo, J.L. Saucedo, R. Garcia-C.* Dept Genetics, Inst Nacional de Perinatologia, Mexico City, Mexico.

**Introduction:** Multiple congenital anomalies have been associated with unbalanced structural chromosomal anomalies. Deletion of 9P has been associated with turricephaly, facial dysmorphism and sex reversal in 70% of the patients. **Case report:** We present a newborn patient who was the first pregnancy of a young couple, the mother had epilepsy of unknown origin treated with valproic acid during pregnancy. The patient had ocular hypertelorism, broad nasal bridge, bilateral cleft lip and palate, small and low-positioned ears, short and broad neck, bivalvular and cardiac insufficiency, bilateral renal cysts, female external genitalia, bilateral camptodactyly in hands, right hand with postaxial polydactyly and anomalous position of fingers of both feet. The karyotype was 46,XY,der(9)t(6;9)(q15;p22), so we performed chromosomal analysis in both parents finding a balanced translocation in the mother: 46,XX,t(6;9)(q15;p22), the father had a normal karyotype. We performed FISH analysis with painting probes for chromosomes 6 and 9 and a probe for the unique sequence SRY. **Conclusion:** We report a patient with multiple congenital anomalies and sexual reversion caused by an unbalanced chromosomal anomaly which deletes autosomal genes involved in sex determination.

**Detection of a cryptic subtelomeric insertion in a child with global development delay.** *F-Y. Han<sup>1,4</sup>, L. Russell<sup>1,2</sup>, C. Morel<sup>1,2</sup>, A. Duncan<sup>1,2,3</sup>*. 1) Department of Human Genetics, McGill University, Montreal, Que. Canada; 2) Department of Pediatrics, Montreal Children's Hospital, Montreal, Que. Canada; 3) Department of Pathology, Montreal Children's Hospital, Montreal, Que. Canada; 4) Laboratory Medicines, Memorial University of Newfoundland, St. John's, NL. Canada.

Cryptic chromosomal rearrangements involving the subtelomeres are emerging as an important cause of human dysmorphism and mental retardation. Clinical investigation of subtelomere rearrangement is now available by FISH analysis using a set of probes specific to the ends of each chromosome. Using FISH with these chromosome-specific subtelomeric probes, we identified a de novo insertion of 9p subtelomeric sequences into the long arm of the X chromosome in a 3 year-old boy with global development delay, hypotonia and esotropia associated with isolated congenital motor nystagmus. Standard cytogenetic assessment of G-banded metaphases at the 500-band level of resolution revealed no structural chromosome anomalies in this patient and his parents. FISH subtelomere analysis with commercial chromoprobe multiprobe-T system revealed an extra subtelomeric signal of 9p on one of the C group chromosomes in all metaphases of the patient. FISH with multiple probes from chromosome 9 (9ptel30) and X (STS and DXZ1) confirmed that the rearranged C group chromosome was the X chromosome. The patient's karyotype was determined to be: 46, XY .ish der (X) ins (X; 9) (q?22; p24p24) (9ptel30+, STS+, DXZ1+). FISH analysis of both parents was negative for subtelomeric rearrangements. Therefore, the subtelomeric insertion detected in the proband is a de novo event. Baker et al (2002) reported a case with a similar rearrangement. However, the X; 9 insertion in that case was paternally inherited and the proband also had a subtelomeric 1pter deletion. Mental retardation and down-slanting palpebral fissures were the only features shared by our patient and the child described by Baker et al. Although cross-hybridization between 9p subtelomeric sequences and Xq has not been reported, we cannot completely eliminate the possibility of a rare interstitial cross-hybridization in our case.

**A new tool for study of multifactorial inheritance: electrocardiographic investigation in Down syndrome families.**

A. Sinkus, L. Jurkeniene, I. Andriuskeviciute. Dept Biol, Lab Cytogenetics, Kaunas Univ Medicine, Kaunas, Lithuania.

There is no one clinical sign which could be typical to chromosome diseases in general or to a single disease. According to our present hypothesis, the chromosome diseases are polymorphic, because the chromosome imbalance decreases the threshold of appearance in familial pathology. In order to detect multifactorial traits with prevalent inherited factors, one must choose i) a sufficiently frequent chromosome disease, and ii) a sufficiently frequent multifactorial sign which could be additionally divided into smaller units. The most frequent of autosomal diseases is Down syndrome (DS). Electrocardiogram (ECG) was used as a typical multifactorial trait. Standard 12-lead ECG was recorded for all of 1004 DS patients and their relatives. The ECGs were studied in a group of 297 DS patients (average age 14.1 years) with cytogenetically proven additional chromosome 21. ECG was taken also for 269 siblings (average age 18.7 years). Should any of the ECG parameters occur with the same frequency in siblings and parents and be present more frequently in DS patients, we might affirm that it reflects hereditary damage of this ontogenetic channel. Therefore ECG was also studied in 438 parents (average age 49.0 years). The formal ECG diagnosis was divided into 21 trait. ECG changes have been found in 77.8% of DS patients, 63.3% of siblings and 69.2% of parents. If trisomy-21 provokes manifestation of multifactorial pathology, one can expect that inheritance of some ECG parameters in chromosome patients would be close to Mendelian. For 10 ECG diagnoses parental trait was inherited by offsprings. Only the difference between the frequencies of inherited bundle branch block in DS patients and their siblings was statistically significant ( $P=0.004$ ). Parents with bundle branch block (right or left, complete or incomplete) had 41 offspring suffering from DS, and for 12 (29.3%) of these bundle branch block was established. In 42 healthy siblings this block was found in three cases (7.1%). The analysis of familial patterns enabled to conclude that the bundle branch block was inherited by DS patients in autosome dominant type with penetrance of 60%.

**ATR-16 due to a chromosomal rearrangement involving partial 4p trisomy.** *L. Titomanlio<sup>1</sup>, D. De Brasi<sup>1</sup>, F. Fabbrini<sup>2</sup>, R. Genesio<sup>2</sup>, A. Conti<sup>2</sup>, L. Pecoraro<sup>1</sup>, M. Tardi<sup>1</sup>, C. Di Stefano<sup>1</sup>, D. Melis<sup>1</sup>, E. Del Giudice<sup>1</sup>, G. Sebastio<sup>1</sup>.* 1) Department of Pediatrics, Federico II University, Naples, Italy; 2) Department of Cellular and Molecular Biology and Pathology, Federico II University, Naples, Italy.

Alpha thalassemia/mental retardation 16 (ATR-16) is a recognizable condition whose constant clinical features are mental retardation (MR) and anemia. Unbalanced chromosomal translocations involving chromosome 16 and resulting in 16p terminal deletions are the most frequent causes of the syndrome. A mild alpha-thalassemic phenotype results from deletion of alpha-globin genes, localized in 16p13.3. We report on a 10-year old girl affected by severe mental retardation, dysmorphic face, and mild microcytic anemia. At birth, intestinal malrotation was diagnosed. Clinical phenotype included: upswept frontal hairline, marked eyebrows with synophris, bilateral epicanthic folds, telechantus, down-slanting palpebral fessures, open held mouth, bilateral simian creases, right talipes, severe mental retardation, mild generalized hypotonia. FISH analysis with telomeric probes disclosed a distal 16p deletion spanning at least 3 Mb, associated with partial trisomy of 4p. Complete karyotype was: 46,XX,der(16)t(4;16)(16q->16p13.2::4p16.2->4pter), paternally derived (father's karyotype: 46,XY,t(4;16)(p16.2;p13.2). The phenotype of the patient overlaps ATR-16 syndrome. The deletion includes alpha-globin genes and, possibly, SOX8 gene, mapping to 16p13.3, whose haploinsufficiency might be related to mental retardation in ATR-16. Trisomy 4p has never been described in association with del 16p. In our patient, it involves approximately 8 Mb of distal 4p. Only some features of the classical trisomy 4p were present. Intestinal malrotation has never been described in ATR-16 and it might represent an accessorial finding of the syndrome. The case here reported outlines the crucial role of the detection of cryptic subtelomeric rearrangements in mentally retarded patients.

**Costello syndrome: report of a child with severe feeding problems.** *S. Ala-Mello*<sup>1,2</sup>. 1) Biomedicum Helsinki, Department of Medical Genetics, Helsinki, Finland; 2) The Family Federation of Finland, Department of Medical Genetics, Helsinki, Finland.

In 1971, Costello described a new syndrome characterised by postnatal growth deficiency with severe failure to thrive and feeding problems, coarse facial features, loose soft skin with deep palmar and plantar creases, benign nasal papillomata, hypertrophic cardiomyopathy and developmental delay. During the last ten years this multiple congenital anomaly syndrome has been increasingly recognized. The pathogenesis and molecular basis of the syndrome are unknown and the diagnosis is based on the characteristic pattern of anomalies. This is a report of a child with Costello syndrome having extremely severe feeding problems. This girl is the first child of healthy unrelated parents. Birth weight in the 36th gestational week was 3950 g and length 48 cm. Since the birth she has suffered from vomiting and feeding problems. She was treated with naso-gastric tube. The feeding problems continued and one year ago at the age of one year and nine months gastrostoma was operated. This has not improved the growth. Since the birth she has been sweating a lot, but the reason for that has been unknown. The skin of the palms and feet is loose. The characteristic facial features are described and shown by the photographs. At the age of nine months she was operated because of hydrocephalus. Hypertrophic cardiomyopathy was also found, and has been later followed up by cardiac ultrasound. Now, at the age of three years she still has gastrostoma.

**Egyptian patient with OFD I&II Phenotypes overlap:brief clinical report.** *M.M. Abuhenedi, R.L. Alnaggar, S. Alawadi, L. Bastaki.* Obstetric & Gynecology, Kuwait Medical Genetics Center, Kuwait, Kuwait.

We describe a female patient aged 6 months-old. She was a product of preterm/ND after uneventful pregnancy. Her parents were blood relatives and there were no similar conditions in the family. She had feeding difficulties and failing to thrive. The DQ assessment was below 3rd percentile. Somatic features included facial dysmorphism, overhanging forehead, hypertelorism, proptotic eyes, broad nasal root, low set/posteriorly rotated ears, micrognathia, high/narrow arched palate and hyperplastic lingual tissue. Limb anomalies included clinodactyly, unilateral polysyndactyly of the big toe have been found, as well as congenital hip dislocation, VSD and conductive deafness. Skeletal survey confirmed limb anomalies and chromosomal analysis showed normal female karyotype. The girl had an overlapping OFDI/OFDII phenotype. The mode of inheritance could be autosomal recessive.

**Congenital anterior cervical hypertrichosis and mental retardation: a new association?** *J.R. Corona-Rivera<sup>1,2</sup>, A. Corona-Rivera<sup>1,3</sup>, L. Bobadilla-Morales<sup>1</sup>, S. González-Abarca<sup>2</sup>, J. Hernández-Rocha<sup>2</sup>, D. García-Cruz<sup>4</sup>*. 1) Laboratorio de Genética Humana, C.U.C.S., Universidad de Guadalajara, Guadalajara, Jalisco, México; 2) División de Pediatría, Hospital Civil de Guadalajara Dr. Juan I. Menchaca, Guadalajara, México; 3) Unidad de Citogenética, Hospital Civil Fray Antonio Alcalde, Guadalajara, México; 4) División de Genética, Centro de Investigaciones Biomédicas de Occidente, IMSS, Guadalajara, México.

Congenital anterior cervical hypertrichosis (CACH) refers to the presence of a patch of hypertrichosis just above the laryngeal prominence. To the best of our knowledge, CACH have been reported in 9 previous cases. We report a boy with CACH associated with mental retardation. We review the phenotypic variation of sporadic and familial reports of CACH and propose a new association. The proband was a product of normal gestation and delivery except for hemorrhage during the third trimester. BW was 2800 g. He showed developmental delay and null scholastic achievements. Physical examination at 11-years-old showed weight 27.5 kg (-1.74 SD), height 128 cm (-2.08 SD), OFC 48 cm (-3.5 SD), synophris, fine short vellus blonde hairs on the face, CACH, and excessive hair growth on back. Inverted nipples, clinodactyly of the fifth right finger, hallux valgus and left overriding third to second finger toes were also observed. Fundoscopic examination of the eye was normal. Psychometric evaluation achieved an IQ score of 39 on the WISC-R test (verbal IQ was 46, and performance IQ score was 41), corresponding to moderate mental retardation. Intracranial structures were normal at cranial CT scan. EEG was abnormal. Nerve conduction studies, electromyography, T3, T4, TSH, and metabolic screening test were normal. Karyotype was 46,XY. CACH as isolated trait is a rare form of localized hypertrichosis with suggested dominant inheritance, either X-linked or autosomal (OMIM 600457). CACH has been associated with hereditary motor and sensory neuropathy (HMSN), severe chorioretinal pathology and optic atrophy with probably autosomal recessive inheritance (OMIM 239840). This report supports the existence of a new association of CACH-mental retardation without HMSN.

**Mandibuloacral dysplasia due to homozygosity for the R527H mutation in lamin A/C.** *J.J. Shen<sup>1</sup>, C.A. Brown<sup>3</sup>, J.R. Lupski<sup>1, 2</sup>, L. Potocki<sup>1</sup>.* 1) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Pediatrics, Texas Childrens Hospital, Houston, TX; 3) Molecular Diagnostics Laboratory, Fairview-University Medical Center, Univ of Minnesota, Minneapolis, MN.

Mandibuloacral dysplasia (MAD) is a rare autosomal recessive disorder characterized by mandibular hypoplasia, acro-osteolysis, joint contractures, poikiloderma, and lipodystrophy. Recently, a specific point mutation (R527H) in *LMNA*, which encodes lamins A and C, was reported to cause MAD.

We present the clinical features of a 12-year-old Latin American male with MAD. This patient was phenotypically normal until approximately 1 1/2 years of age and progressively developed camptodactyly, limb contractures, lipodystrophy, regional skin atrophy and poikiloderma, unusual facies, micrognathia, and dental crowding. He has normal cognitive function and has no history of chronic illnesses. Skeletal survey revealed generalized osteopenia and acro-osteolysis. Sequence analysis of *LMNA* revealed the R527H mutation, yet the haplotype in our patient is distinct from that of the previously reported families.

Lamins are important structural components of the nuclear lamina with hypothesized roles in many different cellular processes. In addition to MAD, other diverse diseases caused by mutations in *LMNA* and other lamins (collectively referred to as the laminopathies) include Charcot-Marie-Tooth type 2B, dilated cardiomyopathy, Emery-Dreifuss muscular dystrophy, familial lipodystrophy, limb-girdle muscular dystrophy, and Hutchinson-Gilford progeria. For most of these laminopathies, allelic heterogeneity has been reported. In contrast, the vast majority of Hutchinson-Gilford progeria cases result from a single mutation. In families with MAD in which a mutation has been described, a similar pattern is emerging as all are homozygous for the identical R527H substitution in *LMNA*. Interestingly, haplotype analysis of affected individuals reveals that in each case, the mutation arose independently. Thus, a highly specific genotype-phenotype correlation appears to exist for the *LMNA* R527H mutation and MAD.

**3D dense surface modeling defines a characteristic facial phenotype in Bardet-Biedl syndrome.** *P. Hammond<sup>1</sup>, N. Hindocha<sup>2</sup>, T. Hutton<sup>1</sup>, P.L. Beales<sup>2</sup>.* 1) Biomedical Informatics, Eastman Dental Institute, London, UK; 2) Molecular Medicine Unit, Institute of Child Health, London, UK.

For the Bardet-Biedl syndrome (BBS), a genetically heterogeneous disorder characterised by retinal dystrophy, obesity, polydactyly, renal and cognitive impairment, indistinct facial features have been reported. We sought to determine a reproducible BBS facial phenotype objectively through novel 3D dense surface modelling of the face. We acquired 3D face images of 29 UK BBS patients. 21 were matched for age (8 - 50 yrs) and race to 83 Caucasian controls. A dense surface model, principal component analysis (PCA) of the densely corresponded face surfaces, was computed. Using in-house software we sought key differences for the two groups in 1) 3D morphs of mean faces 2) mode distributions 3) virtual anthropometric measurements. Portrait and profile views of morphs between the mean BBS and control faces strongly suggest a relatively shorter, narrower nose; a broader zygomatic arch; and a longer lower-face. The ears are also set lower than the controls. These are confirmed by virtual measurements. There is significant bias for the BBS group in the distribution of two higher modes, one emphasising the mid-face findings above and the other retrognathic posture. As BBS is genetically heterogeneous we also focussed on those patients who were homozygous for the same BBS1 mutation, M390R, the result of a single base substitution (n=9). Even more marked differences in the morphs and modes were noted suggesting this is a consistent and reproducible phenotypic trait with a common underlying molecular pathology. The overall impression is that of midface retraction giving the appearance of a dishd face with the net effect that the nose is turned up. This novel method of defining subtle dysmorphic features has confirmed structural anomalies of the midface consistent with the same underlying gene mutation. This is not surprising as high-arched palate, dental anomalies and phonation defects have been reported in a majority of BBS patients. These findings should aid clinicians in the diagnosis of BBS and provide clues to the developmental role of the underlying genes.

**The prevalence of major congenital malformations in AL-Jahra regional liaison community of Kuwait.** *R.L. Alnaggar<sup>1</sup>, S.A. Madi<sup>2</sup>, S.A. AL-Awadi<sup>1</sup>, M.M. Abu-Henedi<sup>1</sup>, M.J. Marafie<sup>1</sup>, R. Mary<sup>1</sup>, M. Krishna<sup>1</sup>, L. Bastaki<sup>1</sup>.* 1) Dept Genetics/OB, Kuwait Medical Genetic Ctr, Nasser, Kuwait; 2) Pediatric Department AL-Jahra Hospital.

Eighty percent of AL-Jahra region population is of Bedouin origin and they have high rate of consanguinity. The major congenital malformations(MCM) have high incidences among the nations of Arabian Gulf. We aim to establish a profile of these malformations in this area of Kuwait. 7739 newborn babies were ascertained by family history,clinical examinations and the relevant investigations were done. 97 babies were found to have MCM with incidence 12.5/1000 births.49 babies(50.6%)had multiple system anomalies and 48 babies(49.4%) had single system anomaly.21 babies (42.8%) had recognized syndrome,most of which were AR disorders.17 babies had chromosomal anomalies.Isolated system anomalies included CNS(12 cases),CVS(9 cases),Skeletal system(7 cases)and GIT(6 cases).68% of couples were consanguinous compared to 56% in controls( $P<0.01$ ).The study showed the high prevalence of MCA among Bedouins despite of many cases escaped diagnosis and registration.The genetics services should provided as an effective means of preventions.

**Genetic epidemiology of the exstrophy-epispadias complex.** *S.A. Boyadjiev Boyd<sup>1</sup>, J.L. Dodson<sup>2</sup>, C.L. Radford<sup>1</sup>, T.H. Beaty<sup>3</sup>, R.I. Mathews<sup>2</sup>, J.P. Gearhart<sup>2</sup>.* 1) McKusick-Nathans Inst Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Divison of Ped Urology, The James Buchanan Brady Urological Institute, Johns Hopkins Univ Sch Med; 3) Dept of Epidemiology, Johns Hopkins University.

Exstrophy-epispadias complex (EEC) is a spectrum of midline urologic defects ranging in severity from epispadias (EP) and classic bladder exstrophy (BE), to cloacal exstrophy (CE). **Hypothesis:** EEC is a complex trait caused by both genetic and non-genetic factors. **Methods and results:** Through our pediatric urology clinic and an advertisement on the Internet, we have identified 204 EEC families, 5 of which (2.5%) were multiplex. Proband in these families were 95% Caucasians. Male predominance was significant in the EP group (3.2:1; n=25), less evident in the BE group (1.6:1; n=151) and absent in the CE group (1:1; n=20). No significant differences were observed in the analyses of paternal age, birth weight, reproductive history of the families, and exposures during the first trimester. The median maternal age at birth was 29 (n=103), slightly higher than national averages corresponding to birth year. More than half (54%) of the probands were first born. Two patients with BE had omphalocele and one had spina bifida, suggesting intermediate phenotypes between BE and CE. Five probands had renal defects and 7 had anomalies outside the EEC spectrum. Twenty-two probands (23.6%) had relatives with congenital anomalies. Of interest, cleft lip and palate (CLP) was observed in 7 families and midline defects (omphalocele, imperforated anus, spinal defects, hypospadias) were present in 11 families. 112 families donated biologic specimens for molecular studies. Karyotype analysis on 39 cases detected two chromosomal abnormalities- 46, XY, t(8;9)(p11.2;q13) and 47, XYY. **Conclusions:** The observed differences in the sex ratio suggest a stronger genetic component for CE than for EP or BE. Further studies are needed to evaluate race, advanced maternal age, and birth order as possible risk factors for EEC. Unexpected aggregation of birth defects in EEC families, specifically CLP and midline defects, warrant detailed clinical genetic evaluation of all families and may help identify putative candidate genes.

**Variable expression of abdominal wall defects and external genital anomalies in a three generation family.** S. Fokstuen, A. Wonkam. Division of Medical Genetics, Geneva, Switzerland.

**Background:** A few familial cases of isolated abdominal wall defects with variable expressivity have previously been reported. We report a three generation family with either variable abdominal wall defects or external genital anomalies as isolated defects suggesting a possible common genetic background of the two groups of congenital malformations.

**Case :** A 27 year old man was referred for genetic counselling following the birth of a female child with isolated gastroschisis. Family history revealed that he had with another woman a daughter with hypoplasia of the external genitalia and synechia of the labia minora. His father was born with an umbilical hernia and the consultant himself, who has no brothers and sisters suffered from umbilical hernia with associated hernia of the linea alba.

**Conclusion :** This pedigree supports a vertical mode of transmission of abdominal wall defects carried through the father as well as the hypothesis that in some families gastroschisis and umbilical hernia are different expression of the same primary defect. In addition our family suggests that embryologically external genital anomalies may represent an additional malformation within the spectrum of abdominal wall defects. This observation may be considered in genetic counselling of families with recurrence of abdominal wall defects.

**Autosomal dominant nonsyndromic cleft lip and palate linked to chromosome 4.** *M. Edwards*<sup>1, 2</sup>, *L. Roddick*<sup>2, 3</sup>, *R. Scott*<sup>2, 4</sup>. 1) Hunter Genetics, Hunter Area Health Service, Waratah, New South Wales, Australia; 2) Faculty of Health, University of Newcastle, NSW Australia; 3) Department of Paediatrics, John Hunter Hospital, Newcastle, NSW; 4) Department of Genetics, Hunter Area Pathology Service, Newcastle, NSW.

There were seven affected relatives in six generations of a family with autosomal dominant non-syndromic cleft lip and palate, with no consanguinity. Fourteen unaffected family members, three affected relatives and three obligate carriers who were non-penetrant were assessed by a clinical geneticist. None had oligodontia, nail abnormalities or any other syndrome associated with orofacial clefts. Nineteen relatives from four generations contributed blood samples for linkage study. Cleft lip with or without cleft palate has been mapped to chromosomes 2, 4, 6, 14, 17 and 19 in European populations and chromosomes 1, 2, 3, 4, 6, 18 and 21 in Chinese families (Carinci et al 2000 *Cleft Palate Craniofac J* 37:33-40; Prescott NJ et al *Hum Genet* 106:345-50; Marazita et al 2002 *Am J Hum Genet* 71:349-364). Mutations in *MSX1* have recently been identified in families with Witkop tooth-nail syndrome, in families with cleft lip or palate and oligodontia, and most recently in families with non-syndromic cleft lip or palate (Jesewski PA et al 2003, *J Med Genet* 40:399-407). Markers from these regions were analyzed in the family. The results revealed that there was positive linkage to two chromosomal loci, one on 4p in the vicinity of the *MSX1* gene (D4S3023) with a score of 0.40 and a second locus on 4q, which revealed a much stronger association with a maximum score of 1.66 (D4S402). The linkage results, although not highly significant point to the possibility that another locus exists at position 4q26. Further analysis will be undertaken to identify the genetic basis of this disease in this family.

**Bartsocas-Papas syndrome further Mediterranean cases.** *F.S. Al-Harbi<sup>1</sup>, E.A. Al-Awad<sup>2</sup>, W.E. Eyaid<sup>3</sup>.* 1) pediatrics, NorthWest armed Forces Hospita, Tabook, Northen region, Saudi Arabia; 2) Pediatrics, NorthWest Armed Forces Hospital. Tabook 2424, Northen Region. Saudi Arabia Essa H. Al-Awad pediatrics, NorthWest armed Forces Hospita, Tabook, Northen region, Saudi Arabia; 3) Wafaa Eyaid, Pediatrics, King Fahad Hospital, Riyadh, Central region. 11246.p.o box 22490.

Bartsocas-Papas syndrome, BPS (omim 263650) is an autosomal recessive disorder characterized by oral cleft, filiform bands between the jaws, ankyloblepharon, popliteal pterygium, syndactyly of fingers and toes, phalangeal anomalies with synostosis, club feet, nail hypoplasia, and genital anomalies. Additional traits included cutis aplasia, widely spaced nipples, low-set umbilicus, and unilateral renal hypoplasia. We report on 5 infants who had BPS. The index case was a 4-days old baby who was born at 35 weeks by breech with birth weight of 2.3 kg. He was microcephalic, bald, with wide anterior fontanel, absent nose bridge, anophthalmia, severe bilateral cleft, lip and palate, forehead scars, absent hands, ambiguous genitalia, no palpable gonads. There was a tail-like band at the pubic area, and another band at the anus extending posteriorly. Parents are far relatives. One brother died at the age of 11-months with similar congenital anomalies. Also, there were 3 maternal first cousins who died in early infancy period with the same congenital anomalies. The parents were first cousin. This is the 8th family from the Mediterranean area reported with this very rare condition. Banking of DNA on these cases is important for further study of these cases.

**Lateral Meningocele Syndrome: Vertical Transmission and Expansion of the Phenotype.** *K. Chen<sup>1</sup>, L.M. Bird<sup>2</sup>, P. Barnes<sup>1</sup>, R. Barth<sup>1</sup>, L. Hudgins<sup>1</sup>.* 1) Stanford University, Stanford, CA; 2) Children's Hospital and Health Center and University of California, San Diego, CA.

Lateral meningoceles were first described by Lehman et al. in 1977 in a patient with other skeletal findings and distinctive craniofacial features. Subsequently, six more patients with the so-called lateral meningocele syndrome (LMS) have been reported. We describe the findings in three new patients with this condition, which expand the phenotype and support the hypothesis that this is an autosomal dominant disorder affecting primarily the connective tissue.

In addition to multiple arachnoid cysts of the spinal canal, Case 1 was noted to have hypertelorism, down-slanting palpebral fissures, ptosis, low-set ears, and micrognathia. Case 2, the mother of case 1, exhibited similar craniofacial features as well as palpable bilateral flank masses, mild scoliosis, hearing loss and a congenital umbilical hernia. Both individuals exhibit normal intelligence, short stature and significant joint hypermobility. History of hypotonia is denied in these two cases. Case 3 exhibited cleft palate, VSD, inguinal hernias, and hypotonia. If one combines the findings in our cases with those found in the six previously reported cases, it is clear that there is a consistent craniofacial phenotype comprised of ocular hypertelorism (5/7), downslanting palpebral fissures (9/9), ptosis (7/7), low-set posteriorly rotated ears (8/8), high arched palate (9/9) and micrognathia (9/9). We were also impressed with the frequency of findings suggestive of an underlying connective tissue disorder including joint hypermobility (5/7), scoliosis/kyphosis (7/9), umbilical/inguinal hernias (4/5), and Wormian bones (4/6). Procollagen studies in one previously reported case were normal.

The findings present in the mother and child support an autosomal dominant pattern of inheritance for LMS. The connective tissue findings in our three patients and the previously reported patients suggest that an underlying defect of the connective tissue is responsible for this condition.

**A case of acrocallosal syndrome complicated with congenital nephrotic syndrome.** *K. Nakashima<sup>1</sup>, T. Sato<sup>1</sup>, T. Hasuwa<sup>1</sup>, T. Kondoh<sup>1</sup>, T. Taguchi<sup>2</sup>, M. Noguchi<sup>3</sup>, M. Aoki<sup>4</sup>, H. Moriuchi<sup>1</sup>.* 1) Department of Pediatrics, Nagasaki University School of Medicine, Nagasaki, Japan; 2) Department of The Second Pathology, Nagasaki University School of Medicine, Nagasaki, Japan; 3) Department of Urology Nagasaki University School of Medicine, Nagasaki, Japan; 4) Department of Pediatrics, National Nagasaki Medical Center, Nagasaki, Japan.

Acrocallosal syndrome (ACS) is a congenital malformation disorder characterized by hypoplasia/aplasia of corpus callosum, polydactyly, craniofacial anomalies, and severe psychomotor retardation. We here report an ACS patient complicated with congenital nephrotic syndrome (CNS). Patient, an 8-month-old Japanese boy, is the first child of non-consanguineous healthy parents. Family history was unremarkable. He was born at 40 gestational weeks as AFD. Clinical manifestations included wide fontanelles, prominent forehead, telecanthus, micrognathia, low-set ears, stenosis of both external ear canals, bilateral broad thumbs, ectopic unilateral testis, and postaxial polydactylies of the hands and feet. Systemic bone surveys showed the 13th ribs. UCG showed mild myocardial hypertrophy. Proteinuria was noted soon after birth. His developmental milestones were delayed. Neuroimaging studies showed thin corpus callosum and fluid retention of bilateral internal ears. ABR revealed bilateral mixed-type hearing loss. Ophthalmological examination showed bilateral macular degenerations. His karyotype was normal, 46,XY. Because of CNS, he underwent kidney biopsy at 8 months of age, which was compatible to CNS. Four-weeks treatment with prednisolone was ineffective. CNS is a novel complication of ACS. The etiology of ACS is unknown. Pfeiffer et al. (1992) suggested that the mutation for ACS located on 12p from his patient with a de novo inverted tandem duplication of 12p13.3-p11.2. High-resolution chromosomal examination for his chromosome 12 failed to identify any mutation, however. As regards CNS, two genes, nephrin located on chromosome 19q13.1 and podocin on 1q25-q31, are identified as causative genes. Thus, our case may suggest that the gene locus of ACS locates near 19q13.1 or 1q25-q31, or one gene for the CNS locates near the gene locus for ACS.

**Nonsyndromic Supernumerary Teeth in Families.** *E. Severin*<sup>1</sup>, *D. Stanciu*<sup>2</sup>. 1) Department of Human Genetics, "Carol Davila" University of Medicine and Pharmacy, Bucharest, ROMANIA; 2) Department of Orthodontics, "Carol Davila" University of Medicine and Pharmacy, Bucharest, ROMANIA.

Supernumerary teeth in the permanent dentition is relatively common in man. Heredity is often involved, but specific genes are not identified. In dental practice occurs a vast spectrum of clinical manifestations in patients with extra teeth. Objective: the aim of our study was to clarify the relationship between variation in clinical phenotypes and genetic heterogeneity. Subjects and methods: the study population comprised 13 patients with supernumerary teeth, aged 10-27 years, and their family members. The diagnosis of supernumerary teeth was based on both clinical and radiographic examinations. Pedigrees were constructed according to data from family history. Segregation analysis was used to determine the mode of inheritance. Statistical analysis was carried out too. Results: phenotypic variation included the number, location and morphologically type of the supernumerary teeth. 92.3% of the probands had one isolated extra tooth and 7.7% had multiple supernumerary teeth. The most common region of the jaws affected was premaxilla. The most frequent permanent supernumerary tooth was mesiodens, conically shaped, followed by the supplemental upper lateral incisor and paramolar. Extra teeth were erupted or impacted. Associated tooth number abnormalities were recorded. Familial inheritance occurred and involved two or three generations. Pedigrees of nine probands indicated an autosomal dominant mode of transmission with complete penetrance and variable expressivity. Sex-linked inheritance pattern was observed in one family. In three families the dental anomaly did not follow a simple mendelian pattern, but showed a familial predisposition to increase the number of teeth. Familial multiple supernumerary teeth showed a complex inheritance. Conclusions: supernumerary teeth are genetically heterogeneous. Various clinical phenotypes of an isolated extra tooth are determined by mutations in different genes (locus heterogeneity). Familial multiple supernumerary teeth, which are not part of a syndrome, involves an interaction between polygenic and environmental factors within initiation stage of tooth morphogenesis.

**Anophthalmos with limb anomalies: Three cases in a Japanese family.** *T. Tohma<sup>1</sup>, K. Ameku<sup>1</sup>, M. Miyagi<sup>1</sup>, S. Shimabukuro<sup>1</sup>, H. Ageda<sup>1</sup>, Y. Chinen<sup>2</sup>, Y. Izumikawa<sup>3</sup>, K. Naritomi<sup>4</sup>.* 1) Dept Pediatrics, Okinawa Prefectural Naha Hosp, Okinawa, Japan; 2) Dept Pediatrics, Univ Ryukyus Sch Medicine, Okinawa, Japan; 3) Nago Ryoikuen , Okinawa, Japan; 4) Dept Medical Genetics, Univ Ryukyus Sch Medicine , Okinawa, Japan.

Anophthalmos with limb anomalies is a rare autosomal recessive disorder characterized by eye malformations and acromelic malformations. There are many reported cases from Turkey , and most of them are from consanguineous parents. We report on two brothers and a sister from a nonconsanguineous Japanese family, who have bilateral microphthalmia and oligodactyly of toes. The elder brother was stillbirth. He also had holoprosencephaly as an additional finding. The younger brother had an operation for right cryptorchidism. This is the first report from Japan.

**Tetrasomy 9p with no apparent phenotypic characteristics.** *S.N.J. Sait<sup>1</sup>, M. Wetzler<sup>2</sup>*. 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst, Buffalo, NY; 2) Department of Medicine, Roswell Park Cancer Inst, Buffalo, NY.

Tetrasomy 9p is a rare syndrome described in about 30 cases in the literature. Cases with tetrasomy 9p appear to have characteristic phenotypic features which include facial dysmorphism, developmental delay, central nervous system and limb defects, heart and renal anomalies and the presence of abnormal genitalia. Survival in patients with this defect varies from a few hours to several years, however, the effects of the anomaly are fairly severe. We present a new case of tetrasomy of 9p in a 41-year old male with no apparent phenotypic malformations who presented with complaints of skin lesions. Blood work revealed hypereosinophilia which was confirmed by a bone marrow aspiration and biopsy. Karyotypic analysis of the bone marrow revealed tetrasomy 9p in all cells analyzed. This was confirmed by fluorescence in situ hybridization (FISH) using the LSI p16(9p21)/ CEP 9 probe (Vysis; Inc). Subsequent analysis using PHA stimulated lymphocytes revealed the presence of the tetrasomy in 43% of cells analyzed. A comparison of the results using the FISH probe showed the anomaly to be present in 86% of bone marrow cells while in the PHA stimulated lymphocytes it only occurred in 43% of cells. Review of the literature shows that the degree of mosaicism appears to correlate with the extent of the phenotype and particularly with the severity of prognosis. Over 60% of nonmosaic patients die in the first couple of months after birth. The patient presented, however, showed no evidence of any phenotypic anomalies apart from hypereosinophilia.

**Conductive deafness, choanal atresia and Treacher Collins-like facial dysmorphia : Burn syndrome or autosomal recessive TCS.** *L. Van Maldergem<sup>1</sup>, A. Splendore<sup>2</sup>, M.R. Passos-Bueno<sup>2</sup>, J. Desir<sup>1</sup>, Y. Gillerot<sup>1</sup>*. 1) Centre de Genetique Humaine, Institut de Pathologie et de Genetique, Loverval, Belgium; 2) Department of Biology, Instituto de Biociencias, Universidade de Sao Paulo, Sao Paulo, Brazil.

A 10 y-old girl born to Turkish first cousins was referred for a dysmorphologic advice during her evaluation for a syndromic conductive deafness. A malformation of uncus with fusion of the ossicles, for which she underwent a curative surgery (she recovered hearing) six months earlier, was associated with malar hypoplasia and microretrognathism. A diagnosis of probable recessive Treacher Collins syndrome was made. A search for a mutation in the TCOF1 gene encoding treacle protein was negative. After the birth of a normal sister, a severely affected male was delivered. Marked downward slant of palpebral fissures, malar hypoplasia and the same conductive deafness due to ossicles malformation was present. A first cousin (also born to consanguineous parents) presented at birth with choanal atresia and microretrognathism but no conductive deafness. Although the clinical picture is similar in many respects to the so-called autosomal recessive Treacher Collins syndrome, of which at least ten pedigrees have been reported in medical literature, it is also compatible with a new entity described by Burn in 1992. The clinical picture consists of a TCS-like facial dysmorphia, choanal atresia, conductive deafness, congenital heart disease and autosomal recessive inheritance. In the present family, a homozygosity mapping study is likely to be successful due to its large size and to multiple inbreeding.

**Hypohydrotic ectodermal dysplasia with immune deficiency in a family with a mutation in the NEMO gene.** *J.J. van den Ende, N. Peeters, K. Storm.* Medical Genetics, University of Antwerp, Antwerp, Belgium.

Hypohydrotic ectodermal dysplasia (HED) is a congenital disorder of teeth, hair and eccrine sweat glands, that is mostly inherited in an X-linked way. The combination of X-linked HED with immunodeficiency (HED-ID) causes severe infections in males, with high morbidity and mortality, whereas in females a very variable picture is seen, with hypodontia or conical teeth, and skin abnormalities with spotty hyperpigmentation as in Incontinentia Pigmenti (IP), but no vesicular or verrucous stage as in the classical IP. Classical IP is caused by mutations in the IKK-gamma (NEMO) gene, which activates transcription factor NF- $\kappa$ B, necessary for activation of multiple target genes involved in normal T and B cell development. In 80% of the classical IP cases a recurrent genomic deletion of exons 4-10 of the NEMO gene is found, leading to a complete loss of IKK-gamma function. In HED-ID `hypomorphic` (less severe) mutations are found in the C-terminal region of the NEMO gene, that diminish, but do not eliminate stimulation of NF- $\kappa$ B, with preservation of partial IKK-gamma function. This does not lead to lethality in utero in males, showing normal numbers of B and T cells, but gives dysgammaglobulinemia and defective ability to produce some antibodies. Because of the ectodermal abnormalities the IKK protein might also be involved in development of teeth and eccrine sweat glands. We describe two sisters who showed abnormal pigmentation over the entire body, following the Blaschko lines, from birth on. They never showed vesicles or a verrucous stage. Their mother showed the same pigmentation disorder, as well as a third sister, who died at the age of 1 year in an accident. A younger brother didn't show the abnormal pigmentation, but died at the age of 2 months of meningitis. Both sisters showed some hypoplastic teeth. Because of the unusual pattern and absence of the vesicular and verrucous stage classical IP was less likely. Since the brother died of an infection HED-ID was a possibility and mutation detection of the C-terminal region of the NEMO gene was performed. Indeed a mutation (1167ins C in exon 10) was found, confirming the diagnosis.

**Evidence of unique dermatoglyphic phenotypes in Nail Patella Syndrome (NPS).** *C.A. Brandon<sup>1</sup>, N.M. Scott<sup>1</sup>, K. Neiswanger<sup>1</sup>, S.M. Weinberg<sup>1</sup>, A.L. Towers<sup>2</sup>, M.L. Marazita<sup>1</sup>.* 1) Center for Craniofacial and Dental Genetics, Sch of Dental Med, Univ of Pittsburgh; 2) Div Geriatric Med, Univ of Pittsburgh.

NPS is a rare genetic disease (22/1,000,000) due to mutations in the LMX1B gene, which has been shown to play a major role in dorsoventral patterning and limb development. NPS often affects the distal limb; clinical features include nail dysplasia, triangular lunulae, and loss of skin creases over the distal interphalangeal joints. Abnormal dermatoglyphics have been reported in a number of genetic syndromes affecting the distal limb, however the dermatoglyphics of NPS have never been characterized. Therefore, we investigated dermatoglyphic data from 29 NPS cases, ascertained at the Fifth International Symposium on Nail Patella Syndrome (sponsored by Nail Patella Syndrome Worldwide). Pattern types analyzed by three independent raters and were categorized into ulnar loop, radial loop, whorl, or arch. Approximately 3% of the fingerprint patterns observed in the NPS cases were unique and therefore categorized as other. Control pattern data was obtained from the literature (n= 720). The frequency of arches was significantly increased in affected individuals compared to controls (16.1% vs 4.7 %,  $p < 0.0001$ ) while ulnar loops and radial loops were significantly decreased ( $p=0.01$  and  $p=0.01$ , respectively). Affected males had more whorls ( $p=0.006$ ) and arches ( $p < 0.001$ ), and fewer ulnar loops ( $p < 0.0001$ ) than controls. Affected females also had more arches ( $p < 0.0001$ ), and fewer ulnar loops ( $p < 0.0001$ ) than controls, but fewer whorls ( $p=0.01$ ). Interestingly, as is seen in the general population, females with NPS have more ulnar loops than males ( $p < 0.0001$ ), and males have more whorls than females ( $p < 0.0001$ ). This is the first study of dermatoglyphic patterns in NPS. Our results clearly demonstrate the impact of the LMX1B gene on the dermatoglyphic phenotype of individuals with NPS, specifically resulting in an increase in arches, ulnar loops and unique patterns. Supported by NIH grant DE-13076.

**A case of Restrictive Dermopathy with survival beyond the neonatal period and novel experience with thalidomide therapy.** *P. Pan*<sup>1</sup>, *K. Omlin*<sup>2</sup>, *J. Rosenthal*<sup>2</sup>, *O. Padilla*<sup>3</sup>, *M. Stadecker*<sup>3</sup>, *L. Demmer*<sup>1</sup>. 1) Dept Pediatrics, Division of Genetics, NEMC Box 394, Tufts-New England Medical Ctr, Boston, MA; 2) Dept Dermatology; 3) Dept Pathology.

We report a case of a now 9 m/o male with Restrictive Dermopathy (RD) who was born 2.4kg at 37wk gest. to unrelated parents. Fetal movements were reportedly normal. SROM occurred 10 days PTD. Micrognathia and contractures of knees/ankles and thickened abdominal skin were noted at birth. Karyotype was 46XY. He presented at 7 wks w/FTT and constant vomiting. The skin over his chest, abdomen, back, buttocks and extremities was now thick, tight and bound-down; the skin of the head was relatively spared but scalp veins were very prominent. Joint contractures had worsened. Skin biopsy was characteristic for RD showing thickened epidermis with absent rete ridges, collagen fibers arranged parallel to the epidermis, decreased elastic fibers, increased connective tissue mucin at the dermo-pannicular junction and poorly developed skin appendages. Skin restriction, poor weight gain despite continous NG feeds, and respiratory difficulty progressed over the next six weeks. Thalidomide was begun at 3.5 mo. of age. Repeat biopsy after 4 months of treatment showed no significant change however clinically the skin has softened and the tachypnea and contractures have improved.

RD, usually lethal in the neonatal period, is an AR genodermatosis characterized by prematurity, thickened skin which restricts chest wall and abdominal movement, contractures, and typical facies and skin biopsy findings. Differential diagnosis includes progeria and Parana Hard Skin Syndrome. The etiology of RD is unknown; hypotheses include a defect in collagen synthesis or orientation, inflammatory-mediated disease and modified epidermal-dermal differentiation. This case is unusual in that, due to the later onset of skin restriction, pulmonary hypoplasia was absent at birth. The apparent arrest in progression of symptoms may indicate a response to the immunomodulatory effects of thalidomide, or may represent the natural course of this milder presentation of RD, allowing for survival beyond the neonatal period.

**A novel elastin gene mutation results in autosomal dominant form of cutis laxa.** *L. Rodriguez-Revenga*<sup>1,3</sup>, *P. Iranzo*<sup>2</sup>, *C. Badenas*<sup>1,3</sup>, *S. Puig*<sup>2,3</sup>, *A. Carrio*<sup>1,3</sup>, *M. Mila*<sup>1,3</sup>. 1) Genetics Service, Hospital Clinic, Barcelona, Barcelona, Spain; 2) Dermatology Service. Hospital Clinic. Barcelona. Spain; 3) IDIBAPS (Institut d'Investigacions Biomediques Agusti Pi i Sunyer). Hospital Clinic. Barcelona. Spain.

Cutis laxa is an extremely rare disorder characterized by marked skin laxity. Less than a few hundred cases worldwide have been described. Clinical presentation and mode of inheritance show considerable heterogeneity. Autosomal dominant, autosomal recessive, and X-linked recessive patterns have been noted in inherited forms. Only three mutations in the elastin gene have been reported as the genetic cause of the autosomal dominant form of cutis laxa. A 45 year-old woman and her 19 year-old son were clinically diagnosed of cutis laxa as their skin was inelastic, loose-hanging and wrinkled, with premature ageing appearance. Mutational analysis of the elastin gene evidenced a novel mutation (2292delC) that predicts a frameshift in the coding region and causes translation to proceed into the 3-untranslated region. This would replace the C-terminal amino acid of the normal elastin protein with a novel sequence. This is one of the few cases described in the literature presenting autosomal dominant cutis laxa in which a mutation in the elastin gene has been detected. Acknowledgements: Marato-TV3 98TV1110.

**Dermatoglyphics in Filipinos with nonsyndromic cleft lip with or without cleft palate (NS CL/P), and their relatives.** *N.M. Scott<sup>1</sup>, S.M. Weinberg<sup>1</sup>, S. Daack-Hirsch<sup>2</sup>, K. Neiswanger<sup>1</sup>, S. O'Brien<sup>2</sup>, B. Nepomunceno<sup>3</sup>, J.C. Murray<sup>2</sup>, M.L. Marazita<sup>1</sup>.* 1) Center for Craniofacial and Dental Genetics, Sch of Dental Med, Univ of Pittsburgh; 2) Dept of Pediatrics, Univ of Iowa; 3) HOPE foundation, Bacolod, Philippines.

Orofacial clefts are common birth defects (1/500- 1/1000) with a complex etiology. Evidence of a relationship between orofacial clefting and dermatoglyphic patterns has been reported in several populations, but has never been investigated in a Filipino population. Dermatoglyphic patterns serve as a marker of the developmental disturbances (environmental and genetic) and increased fluctuating asymmetry (FA) often reported in orofacial cleft study populations. Therefore, we investigated dermatoglyphic patterns in 100 Filipinos with NS CL/P and 89 of their relatives, ascertained from 1998-1999. Patterns were categorized as arch, ulnar loop, radial loop, whorl, or other, by two independent raters, who resolved any discrepancies by re-evaluation. No significant differences were found in the frequency of types of patterns between males and females; this is notable because typically males have more whorl patterns and fewer arches than females. Overall, the frequency of arches was significantly increased and whorls decreased in the affected group ( $p= 0.006$  and  $p= 0.02$ , respectively.) Affected females had significantly more ulnar loops and arches ( $p= 0.037$  and  $p= 0.033$ , respectively), and fewer whorls ( $p < 0.0001$ ) compared with unaffected females. There were no significant differences between affected and unaffected males. As a measure of FA, dissimilarity between pattern types on homologous fingers was quantified, and t-tests were performed. However, no significant differences in dissimilarity scores were found between males and females or between affected and unaffected groups. These results indicate that in this Filipino population, differences in frequency of dermatoglyphic pattern types exist between individuals with orofacial clefts and their unaffected relatives, with the major effect seen in females. This research was supported by NIH grants DE-08559 and DE-13076.

**Sisters with Prenatal Exposure to Alcohol Exhibiting Noonan Phenotype.** *R. Blackston*<sup>1</sup>, *C. Coles*<sup>2</sup>. 1) Div Med Gen, Dept Human Gen, Emory Univ Sch Medicine, Atlanta, GA; 2) Dept Psychology, Marcus Center, Atlanta, GA.

Previous reports have cited isolated cases of Noonan Syndrome phenotype in children with prenatal exposure to alcohol. We report sisters born to a mother who reportedly drank 12 beers daily during the pregnancies and review previous cases in the literature. The proband is a pre-adolescent with short stature, webbed neck, thick hair with low posterior hairline, ptosis, hypoplastic philtrum, thin upper lip, small chin, pectus deformity, mild to borderline developmental delays by educational reports. The adolescent sister has a similar phenotype but reportedly has a normal IQ with visual perceptual motor problems requiring learning disability resources. Chromosome studies of the proband are normal. We have been unable to accomplish desired DNA studies of the PTPN11 gene at 12q (12q21.2q22).

Previous publications have related differentiation between Fetal Alcohol Syndrome (FAS) and other syndromes such as Noonan by facial photographs and facial measurements to be effective. We continue to advocate the full body, Peds Score, we utilize as being more comprehensive lest we miss important findings such as webbed neck, low hair line, pectus deformity. We further stress the necessity of the new DNA studies in Noonan/FAS overlap for objectivity in exact diagnosis in order to provide accurate genetic counseling, and to learn more about this missense mutation.

**Genotype/Phenotype Correlations in Split Hand Foot Malformation (SHFM).** *A.M. Elliott<sup>1</sup>, M.H. Reed<sup>1,2,3</sup>, J.A. Evans<sup>1,3</sup>.* 1) Dept Biochem & Medical Gen, Univ Manitoba, Winnipeg, MB, Canada; 2) Dept Radiology, Children's Hospital, Winnipeg, MB, Canada; 3) Dept Pediatrics and Child Health, Children's Hospital, Winnipeg, MB, Canada.

*Background:* Split Hand Foot Malformation (SHFM) is genetically heterogeneous with 5 loci mapped to date. SHFM is highly variable in its presentation and can occur as an isolated finding or in association with other anomalies.

*Objective:* To perform a clinical epidemiological study of SHFM patients mapped to chromosomes 7, X and 2.

*Methods:* We reviewed the literature of mapped SHFM1 (chromosome 7), SHFM2 (X chromosome) and SHFM5 (chromosome 2) patients. Cases were included if they had: central ray deficiency, a large gap between first and second digits or longitudinal clefting. Cases analyzed included 43 SHFM1, 22 SHFM5 and 36 from the single reported SHFM2 kindred.

*Results:* All SHFM5 patients had chromosomal deletions compared to 30% of SHFM1. None of the SHFM2 cases had deletions, signs of ectodermal dysplasia, craniofacial dysmorphism or other malformations. Almost all SHFM2 cases were males compared to 67% of SHFM1 and 41% of SHFM5. Involvement of both lower extremities was more common with both autosomal loci (SHFM1: both hands affected 35%, both feet 77%; SHFM5: 41% both hands, 95% both feet). Craniofacial findings included: dysplastic ears (35% SHFM1, 41% SHFM5); oral clefts (33% SHFM1, 50% SHFM5); micro/retrognathia (23% SHFM1, 55% SHFM5). Ptosis, microstomia and beaked nose were also common in SHFM5. Deafness, present in 28% of SHFM1, was not seen in SHFM5. Syndactyly, camptodactyly; cardiac defects; seizures and failure to thrive were more common in SHFM5.

*Conclusions:* SHFM1 and SHFM5 patients are at risk for certain craniofacial anomalies and other defects. A proposed animal model for SHFM1 (*Dlx5* and *Dlx6* homozygous mutant mice) shows hindlimb clefting and disturbances of craniofacial development (ears, eyes and branchial arch derivatives) manifesting striking similarities to SHFM1 patients.

**A Kuwaiti boy with multiple joint contracture/Facial dysmorphism "Freeman-Sheldon syndrome":brief clinical report.** *L. Bastaki<sup>1</sup>, R.L. AL-Naggar<sup>1</sup>, S.A. AL-Awadi<sup>1</sup>, R. Usha<sup>2</sup>, M.J. Marafie<sup>1</sup>.* 1) Maternity Hosp, Kuwait Medical Genetic Ctr, Khaldiya, Kuwait; 2) Pediatric Department AL-Jahra Hospital.

We describe a male patient aged one year and seven months-old. He was a product of FT/CS delivery after uneventful pregnancy. The parents were consanguineous/healthy and their previous child was normal. There were two similar conditions, male and female cousins in the family. The boy was failing to gain weight and he had dysmorphic features including long face, full forehead, sunken/small eyes, blepharophimosis, small nose with hypoplastic alae nasi, long philtrum, small mouth, puckered upper lip, ulnar deviation and contracture involving small and large joints. Skeletal survey showed abnormal skull anterior cranial fossa and scoliosis of the spine. Chromosomal analysis showed normal male karyotype (46,xy). The consanguinity of parents and the similar conditions (male/female) raise the possible autosomal recessive mode of inheritance.

**A phenotype reminiscent of FG syndrome in a boy with a submicroscopic deletion of 22q11.2.** *D.J. Aughton, C.E. Harper.* Wm Beaumont Hosp, Royal Oak, MI.

FG syndrome is an X-linked recessive condition characterized in part by cognitive impairment, relative macrocephaly, hypotonia, and severe constipation. Broad forehead and persistent fetal fingerpads are often seen.

Submicroscopic deletion of 22q11.2 (ish del[22][q11.2q11.2]) is a cause of an astonishingly broad array of phenotypes, including DiGeorge sequence, velocardiofacial syndrome, and Opitz G/BBB syndrome. Microcephaly, growth retardation, and cleft palate/bifid uvula are common but not universal findings. Although features suggestive of FG syndrome have been described in association with a submicroscopic *terminal* deletion of 22q (*Clin Genet* 2000;58:483-487), we know of no reports of the joint occurrence of a similar phenotype with ish del(22)(q11.2q11.2). We report such a case.

A 4-year-old boy presented to our clinic in 2002 for further evaluation of developmental delay. He was adopted but was known to have been normally grown at birth. His mother had developmental delay in childhood. The boy's postnatal history was remarkable for hypotonia, severe constipation, and developmental delay. Routine chromosome analysis in 1998 was normal (46,XY). The boy's examination was remarkable for height = ~p25, weight = p25-p50, and OFC = p50-p75 (~p75 for height-age); high, broad, and prominent forehead, without frontal upsweep; prominent supraorbital ridge; downslanting palpebral fissures; intact palate, without clefting of the uvula; overfolded helices; and mild persistent fetal fingerpads.

We considered the boy's findings suggestive of FG syndrome. However, since DNA diagnostics relevant to FG syndrome were not yet clinically available, since the differential diagnosis of FG syndrome includes Opitz G/BBB syndrome (McK \*300000), and since some cases of Opitz G/BBB syndrome owe to ish del(22)(q11.2q11.2), we included FISH studies of 22q11.2 in the boy's further genetic evaluation. The results of these were ish del(22)(q11.2q11.2)(TUPLE1-).

Hence, we propose that a phenotype reminiscent of the FG syndrome is among the many that may be caused by ish del(22)(q11.2q11.2).

**A patient with a genomic deletion encompassing *FOXL2* and *ATR*.** J.J.P. Gille, M.H. de Ru, A.W.M. Nieuwint, J.M. van Hagen. Clinical Genetics, VU University Medical Center, Amsterdam, The Netherlands.

Blepharophimosis-Ptoxis-Epicanthus inversus Syndrome (BPES) is caused by mutations in *FOXL2*. We investigated a boy with BPES who had some additional clinical features: microcephaly, mild mental retardation and growth delay. Chromosome analysis demonstrated a 46,XY karyotype with an interstitial deletion of 3q23-q25. Molecular analysis using VNTR markers showed that the deletion was of maternal origin and encompasses the region between markers D3S1535 and D3S1593. This region contains not only the *FOXL2* gene but also the gene encoding ataxia-telangiectasia and Rad3-related protein (*ATR*). *ATR* has been identified as a candidate gene for Seckel syndrome, an autosomal recessive syndrome characterized by growth retardation, microcephaly and mental retardation. Recently, it was reported that in two Pakistani families a homozygous founder mutation 2101AG segregated with Seckel syndrome (O'Driscoll *et al.*, Nature Genet. 33:497-501, 2003). This mutation results in aberrant splicing of exon 9 although normally spliced mRNA was also detected. It was suggested that only rather mild mutations may cause Seckel syndrome whereas severe mutations are lethal. We hypothesize that also hemizygoty of *ATR* may cause some clinical features of Seckel syndrome and that our patient has a contiguous gene syndrome. The BPES phenotype is caused by deletion of *FOXL2* whereas the other clinical features (microcephaly, mild mental retardation and growth delay) are the result of deletion of *ATR*. Further research is necessary to excluded that other genes in this region contribute to the phenotype of our patient.

**Minor Physical Anomalies in Autism.** *T. Foran<sup>1</sup>, M. Bocian<sup>1</sup>, P. Flodman<sup>1</sup>, J.H. Miles<sup>2</sup>, M.A. Spence<sup>1</sup>.* 1) Division of Human Genetics, Department of Pediatrics, University of California, Irvine, Irvine, CA; 2) The Children's Hospital, University of Missouri-Columbia, Columbia, Missouri.

Minor physical anomalies (MPA) arise from errors in morphogenesis during early embryonic development. Several studies have found an increased frequency of MPA among autistic individuals in comparison to the general population. Increased frequencies of specific MPA in association with autism have also been reported, but no recurring constellation of anomalies has been identified. Using a clinical morphology exam, Miles & Hillman (2000) found that 20% of their autistic sample was dysmorphic (6 MPA). The sex ratios differed significantly between normal and abnormal morphology groups, suggesting different underlying genetic causes between groups.

In this study, clinical morphology exams were used to determine the average number of MPA and frequency of individual MPA in a sample population ( $n = 117$ ) consisting of autistic disorder (79), autistic spectrum (21), and control groups (17). The average number of MPA in the autistic disorder sample is 3.65. The following anomalies occur with increased frequency among those with autistic disorder but not significantly so ( $p < 0.05$ ): increased head circumference, large ears, ptosis, and anomalies of the cranium, forehead, teeth, nose, nipples, columella, philtrum, and mandible. Based on the number of MPA, the sample is classified as morphologically normal (66%), abnormal (20%), or equivocal (14%). The sex ratios in these groups are 5.5:1, 3:1 and 10:1, respectively. When chromosomally abnormal subjects are excluded, the sex ratios are 5.25:1, 5.5:1, and 10:1, respectively. The overall sex ratio in the autistic disorder group is 5.1:1. Assuming that differences in sex ratios result from genetic differences, these findings suggest that autism in abnormal and normal morphology subgroups is causally different. The dysmorphic subgroup may be representative of an autistic population with unidentified chromosomal abnormalities.

**An apparent cluster of gastroschisis: A single center experience.** *S. Chabra, B.D. Hall.* Pediatrics, University of Kentucky, Lexington, KY.

A cluster of 10 neonates diagnosed with gastroschisis at the University of KY in 1996 prompted us to do an analysis to determine possible environmental or genetic causes. A chart review of all neonates admitted to the Neonatal Intensive Care Unit (NICU) with gastroschisis from January 1992- December 1997 was performed. A compilation of maternal and patient demographics were reviewed. A chi-square analysis to determine uniformity of distribution of cases over the 5-year period and an Ederer-Meyers-Mantel test to detect clustering of cases in any one year were performed. Results: 36 neonates with gastroschisis were admitted to the NICU during this period. The mean maternal age was 21.5 years (14-35 years) with the following findings: teenagers (42%), cesarean section (44%), primiparous (66%), smokers (42%), drug users (11%), history of STD (11%), increased amniotic fluid AFP (33%), oligohydramnios (11%) and IUGR (14%). Mean birth weight was 2438g (990-3700g) with mean gestational age of 36 weeks (29-40 wks). Forty-eight percent were males, 54% preterm, 25% had other GI anomalies, and 5% died. The chromosome studies (25%) were normal and there were no familial instances. There was no recurring environmental or drug exposure in the study group. The mothers were from 24 different counties. The 36 cases were not uniformly distributed over the 5 year period (chi square statistic=46.8, degrees of freedom=4,  $p<0.0001$ ). There is no evidence that the cases clustered in any 1 year ( $p=0.99$  for Ederer-Myers-Mantel test). This is one of the few studies of a cluster of babies born with gastroschisis. Many of the mothers were teenagers, primiparous with preterm babies and had an increased frequency of smoking. There is no evidence of temporal clustering and the sparse distribution over 24 different counties showed no spatial clustering. In the majority of cluster studies, there is often initial anxiety as to the etiology of the apparent cluster, however, after epidemiological investigations, frequently such clusters turn out to a random effect. We conclude that the cluster of gastroschisis cases in our study occurred by chance. Epidemiological evaluation of neonates with gastroschisis in different geographic areas of the world would be beneficial.

**Pure trisomy 12p in a mexican patient.** *B. De La Fuente, R. De la Rosa, C. Espinosa.* Genetics Dept., Faculty of Medicine, Universidad Autonoma de Nuevo Leon, Monterrey, NL, Mexico.

**INTRODUCTION:** Trisomy 12p is an unusual chromosome anomaly. There have been only 24 cases of trisomy 12p in the medical literature, 14 with a complete trisomy and 11 were partial, most of them caused by an abnormal segregation of a parental balanced translocation or due to de novo duplications. The clinical characteristics include: retarded psychomotor development, hypoplasia of the middle 1/3 of the face, epicantal folds, flat nose, wide nasal bridge, up-slanting palpebral fissures, long philtrum, full cheeks, thick lower lip, macroglossia, small ears, wide, short hands, 5th finger clinodactyly. **DESCRIPTION:** The patient is a 14 months of age female, product of the first pregnancy among young, non-related parents, and no family medical history of relevance. She had dolicocephaly, peculiar face, up-slanting palpebral fissures, strabismus, high nasal bridge, anteverted nostrils, retrognathia, short neck, hypoplastic right ear, left polythelia, 1st and 2nd toes. A cytogenetic analysis was carried out with GTG banding showing: 46,XX,22,+der(22),t(12;22)(p11;p11)pat. The mother karyotype analysis was 46,XX normal and the father showed: 46,XY,t(12;22)(p11;p11). As a newborn the patient phenotype resembled Down syndrome, between 4 and 6 months of age it resembled that of the Pallister Killian syndrome, both syndromes were discarded by the karyotype analysis. The patient has been in psychomotor stimulation that has improved the muscular tension although the psychomotor delay is present. **CONCLUSIONS:** The medical genetics counseling helps to integrate a diagnosis in order to evaluate and give a better management of associated complications, besides offering prenatal diagnosis to the parents.

**Autism and Dysmorphology: A Valid Observational Measure.** *J. Miles<sup>1</sup>, M. Bocian<sup>3</sup>, J. Farmer<sup>2</sup>, N. Takahashi<sup>1</sup>, M. Spence<sup>3</sup>, S. Braddock<sup>1</sup>, R. Martin<sup>4</sup>, J. Hong<sup>1</sup>.* 1) Dept Child Hlth, Med Gen Div, Univ MO Hosp, Columbia, MO; 2) Dept Health Psych, Univ of MO, Columbia, MO; 3) Div Hum Gen & Birth Defects, Univ of CA, Orange, CA; 4) Wash U School of Med, St. Louis, MO.

Physical dysmorphology is a clear indicator of altered morphogenesis. We previously reported that ~ 15% of individuals with autism had pervasive dysmorphology. To see whether dysmorphology assessments by different dysmorphologists are consistent, four fellowship trained medical geneticists rated the same 30 autistic children with only 73% reliability. We have now formulated a reliable instrument to 1) enumerate the dysmorphic features that denote altered embryogenesis and 2) to score the features so that individuals can be classified as either dysmorphic or non-dysmorphic. The 221 consecutive individuals who met DSM-IV criteria for autism between 1994 & 2001 were studied: 77% (171/221) were nondysmorphic, 12% (26/221) were dysmorphic, 11% (24/221) were equivocal. Individuals with syndromes were excluded. The dysmorphology instrument is organized into a portfolio of 36 physical structure categories. In each category are a list of physical features that reflect altered morphogenesis, can be measured by non-invasive exam, are easy to define or measure and are relatively stable. The features are taken directly from the London Dysmorphology Database feature list (Winter and Baraitser, 1996). Scoring is by category, rather than separate features to measure the breadth of dysmorphology over multiple organ systems. Analysis of the 221 subjects showed that 10 categories distinguished the dysmorphic from nondysmorphic subjects with P values < 3x 10<sup>-6</sup>; 15 additional categories were significant to the 0.05 level. Recoding the 30 exams by this method (without training) increased reliability to 83%. Further validity and reliability studies are in progress. Three features (macrocephaly, ligamentous laxity and deep set eyes) are equally prevalent in all groups and appear to be autism specific. We conclude that a standardized dysmorphology instrument can be user friendly and can classify autistic individuals into distinct subgroups based on their morphogenesis and provide more homogenous groups for genetic study.

**Smith Magenis syndrome - a study of 7 cases in Northern Ireland.** *A. Magee, F. Stewart.* Regional Genetics Service, Belfast City Hosp Trust, Belfast, United Kingdom.

Smith Magenis syndrome (SMS), a contiguous gene syndrome due to interstitial deletions of chromosome 17p11.2, was first described in 1982. The classical features include behavioural problems, major sleep disturbance, developmental delay and self-injury, with a high pain threshold due to varying degrees of peripheral neuropathy. There are characteristic dysmorphic features, although the facial phenotype can show marked variation. Seven sporadic cases of SMS have been identified in the Northern Ireland population (1.8 million) over the last 8 years. There are 2 females and 5 males, ages range from 3 to 36 years. The youngest age of diagnosis was 1 year, and the oldest 34 years. Four of the diagnoses were suspected clinically. All were confirmed by FISH analysis, and 6 had deletions visible on G-banding. All exhibit midface hypoplasia, brachycephaly and a degree of brachydactyly. Five have the characteristic fair hair and blue eyes. All had neonatal feeding problems and hypotonia, and all have speech delay varying from mild in one individual to absent communication skills in one adult. All exhibit behaviour problems including hand and wrist biting, disturbed sleep pattern, and are reported to have high pain thresholds. One boy, now 12 years old, has managed to stay in mainstream education. Four individuals have scoliosis, including one girl with very severe kyphoscoliosis. Three are known to have mild hearing loss. None appear to have renal or cardiac anomalies. Unusual observations include one child with postaxial polydactyly left hand, and 2 have dark hair and sallow skin. The diagnosis of SMS can be difficult on clinical grounds and requires the clinician to be alert to the possibility of SMS, often on the behavioural phenotype alone. These observations, particularly in the adults, give further information on the evolving SMS phenotype.

**Prader-Willi syndrome caused by complex chromosomal rearrangements and uniparental disomy.** *M. Li<sup>1,2</sup>, K.C. Kim<sup>1</sup>, K. Jackson<sup>1,2</sup>, C. Dvorak<sup>1</sup>, H. Andersson<sup>1,2</sup>.* 1) Hayward Genetics Ctr; 2) Department of Pediatrics, Tulane Univ School Med, New Orleans, LA.

We report a novel etiology for Prader-Willi Syndrome (PWS), a de novo Robertsonian translocation of chromosomes 13 and 15 resulting. The 4-year-old boy was referred for genetic evaluation. His medical history was notable for neonatal hypotonia, cryptorchidism and failure to thrive followed by hyperphagia and accelerated weight gain. Physical examination unveiled characteristic facial features of PWS, including bitemporal narrowing, almond-shaped eyes and metopic ridging. His weight was above the 95<sup>th</sup> percentile, and height between the 75<sup>th</sup> and 90<sup>th</sup>. His mental development was delayed. Cytogenetic studies revealed that the patient carried two apparently balanced translocations, t(1;2)(q21;p23) and der(13;15)(q10;q10). FISH with probe SNRPN displayed two copies of the gene. Methylation study uncovered the absence of paternal allele of the SNRPN gene. Maternal chromosomal study performed elsewhere was reported normal. The inheritance pattern of the t(1;2) was not clear since the father was not available for study. These results confirmed the clinical diagnosis of PWS, which had resulted from maternal uniparental disomy (UPD). Maternal UPD accounts for about 25% of PWS patients. Recent publications show that in the majority of PWS patients with UPD, the additional chromosome 15 is due to meiotic nondisjunction. Much less frequently, de novo or inherited isochromosome 15 is the cause. Several cases of familial Robertsonian translocation involving chromosome 15 are also known. The case presented here is the first case of PWS reported to be associated with a de novo Robertsonian translocation involving chromosomes 13 and 15. The mechanisms of the formation of UPD in this patient could be: 1) maternal meiotic nondisjunction (MI or MII) followed by trisomy rescue; 2) a disomic egg fertilized by a nullisomic sperm (in this case, both maternal and paternal nondisjunction are required); or 3) mitotic duplication and paternal nondisjunction. Molecular studies with chromosome 15 microsatellite markers are needed to further define the UPD and better understand the mechanism of its formation.

**Tetra-amelia: Clinical findings in a consanguineous family with four affected siblings.** *S. Niemann<sup>1</sup>, F. Pascu<sup>2</sup>, U. Stahl<sup>2</sup>, U. Aulepp<sup>1</sup>, U. Mueller<sup>1</sup>.* 1) Department of Human Genetics, Justus-Liebig-University, Giessen, Germany; 2) Department of Pathology, Justus-Liebig-University, Giessen, Germany.

Tetra-amelia, the complete absence of all four limbs, is a rare human genetic disorder. In the four families described to date tetra-amelia was most likely inherited as an autosomal recessive trait and the absence of limbs was associated with craniofacial, nervous system, pulmonary, skeletal, and urogenital anomalies. Here we report on a consanguineous Turkish family of Aramaic descent with four affected fetuses displaying autosomal recessive tetra-amelia and urogenital defects associated with craniofacial and skeletal anomalies. In eight pregnancies, tetra-amelia was diagnosed four times prenatally and pregnancies were terminated between the 13th and 20th week of gestation. Autopsy was possible in three of the four affected fetuses: In the first affected fetus, a female, findings were cleft lip with cleft palate, gastroschisis, diaphragmatic defect with malposition of the right lung which was bilobular, agenesis of the left kidney, left supraadrenal gland and spleen, a malformed uterus with only a right, rudimentary ovary and salpinx, and only one umbilical artery. In the second affected fetus, a female, findings were a protrusion and cataract of the left eye, microphthalmia of the right eye, cleft lip with cleft palate, malformed nose with a single naris and choanal atresia, hypoplasia of the pelvis, and atresia of the urethra, vagina and anus. In the third affected fetus, a male, findings were agenesis of left kidney and left supraadrenal gland, hypoplasia of the pelvis, persistence of cloaca, and no external genitalia. The clinical findings of limb agenesis and urogenital defects in all affecteds indicate a link between the early development of the limbs and the urogenital system in humans.

**Rieger syndrome and a de novo (4;17)(q25;q23.3) translocation.** *J. Saraiva<sup>1</sup>, E. Engenheiro<sup>2</sup>, N. Tommerup<sup>2</sup>, E. Matoso<sup>3</sup>, I. Marques<sup>3</sup>.* 1) Servico Genetica Medica, Hospital Pediatrico, Coimbra, Portugal; 2) Department of Medical Genetics, Wilhelm Johannsen Center for Functional Genome Research, University of Copenhagen, Denmark; 3) Laboratorio de Citogenetica, Instituto de Biologia Medica, Faculdade de Medicina de Coimbra, Portugal.

Rieger syndrome has an autosomal dominant inheritance due to mutations in the PITX2 gene in 4q25q26. There is a second locus ascribed to 13q14. Several case reports describe Rieger syndrome in patients with chromosomal abnormalities. We report a further case of Rieger syndrome with chromosomal breakpoint in 4q25 in a de novo reciprocal translocation t(4;17)(q25;q23.3). A deletion of approximately 2 Mb has been found at the 4q25 breakpoint. We discuss the possible clinical classification of Rieger syndrome in types 1 and 2 related to the 4q25 and the 13q14 loci, the reasons why reporting of chromosomal abnormalities with breakpoints in 4q25 is common and the molecular differences in PITX2 mutations that are the cause of Rieger syndrome or isolated iridogoniodysgenesis.

**Cryptic interstitial deletion of chromosome 16q12 : a novel recognizable deafness/mental retardation syndrome ?**

*M. Rio*<sup>1</sup>, *S. Lyonnet*<sup>2</sup>, *M. Prieur*<sup>2</sup>, *S. Briault*<sup>3</sup>, *M. Vekemans*<sup>2</sup>, *A. Munnich*<sup>1</sup>, *L. Colleaux*<sup>1</sup>. 1) INSERM U393, Hosp Necker-Enfants Malades, Paris, France; 2) Departement de genetique, Hosp Necker-Enfants Malades, Paris, France; 3) INSERM U316, Hosp Bretonneau, Tours, France.

Syndromic hearing loss represents an extremely heterogeneous group of conditions (more than 300 entries) which includes mendelian diseases such as Fountain syndrome or Juberg-Marsidi syndrome, and chromosomal anomalies including deletions of chromosomes 1p36 or Xq21. Here we report a novel form of syndromic hearing loss ascribed to an interstitial deletion on chromosome 16q11.2-q12.1 in three sibs with severe mental retardation, deafness, post-natal growth retardation, hand and foot anomalies, dysplastic ears and distinctive facial features. FISH and molecular analyses showed that the three children carried the same interstitial deletion of chromosome 16 encompassing SALL1, the gene which accounts for a syndromic form of hearing loss, Townes-Brocks syndrome (TBS). TBS is an autosomal dominant inherited syndromic hearing loss associated with anus malformation, hand and foot anomalies. Interestingly, the clinical presentation of our patients is relatively different from TBS phenotype. We propose therefore that the del16q12 is a novel clinical recognizable deafness/mental retardation syndrome.

**Identification of eleven possible regions for NSCLP loci.** *S.H. Blanton*<sup>1</sup>, *T. Bertin*<sup>2</sup>, *S. Patel*<sup>2</sup>, *S. Stal*<sup>3</sup>, *J. Mulliken*<sup>4</sup>, *M.E. Serna*<sup>2</sup>, *J.T. Hecht*<sup>2</sup>. 1) University of Virginia Hlth Sci Ctr, Charlottesville, VA; 2) University of Texas Medical School, Houston, TX; 3) Texas Children's Hospital, Houston, TX; 4) Children's Hospital, Boston, MA.

Nonsyndromic cleft lip with or without cleft palate (NSCLP), a common birth defect affecting 1/700 live births and 4,000 newborns/year in the United States, is associated with short and long-term morbidity. As such, it has significant impact on the health care system. NSCLP is a complex disorder that results from the interaction of genetic and environmental factors that are slowly being defined. Recently, two genomic scans have suggested a number of regions that may contain NSCLP loci. However, there remain a number of additional viable candidate genes and regions that have not been sufficiently investigated. These include chromosomal translocations in patients with NSCLP, growth factor genes, metalloproteinase (MMP) and transcription factor (patterning) genes, including those in the WNT family. In this study, we have evaluated regions identified by a previously published genomic scan of affected sib pairs in addition to screening the 10p13 chromosomal translocation region associated with NSCLP, MMP genes clustered on chromosomes 1p36, 11q22.3, 16p13.3 and 16q12-13, and the region containing the WNT5A gene on chromosome 3p21. Using linkage disequilibrium methods as implemented in Genehunter2 and PDT in our sixty-five multiplex families, we have found evidence of association for eight chromosomal regions from the genome scan. Four of these regions, 2q37, 11p12-14, 12q13 and 16p13, have also been identified in second genomic scan of multiplex families from China. In addition, markers from three of the candidate regions, 10p13, 16p13.3 (MMP25) and 3p21.2, yielded findings that are sufficiently significant to warrant closer investigation. These results suggest chromosomal regions that should be targeted in order to identify NSCLP loci. We are currently examining additional markers in these regions and evaluating candidate genes.

**Phenotypic and Molecular characterization of distal 19q trisomy detected by FISH.** *J. Ganesh<sup>1</sup>, M.K.*

*Maisenbacher<sup>1</sup>, L. Medne<sup>1</sup>, E.C. Moore<sup>1</sup>, M. Nimmakayalu<sup>1</sup>, T. Moshang<sup>2</sup>, E.H. Zackai<sup>1</sup>, N.B. Spinner<sup>1</sup>.* 1) Division of Human Genetics and Molecular Biology The Children's Hospital of Philadelphia and University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Division of Endocrinology, The Children's Hospital of Philadelphia.

The use of sub-telomeric FISH probes to augment cytogenetic studies has resulted in the identification of previously unrecognized chromosomal anomalies not detected by conventional banding techniques. Sub-telomeric FISH studies led us to identify 5 patients in three families with trisomy of the subtelomeric region of 19q. In two families, the 19q was translocated to the short arm of an acrocentric chromosome. Family 1 was segregating a cryptic t(13;19)(p12;q13.3) in 3 generations. Six individuals were balanced carriers and 3 individuals (2 siblings and their maternal uncle) inherited the der(13), which resulted in trisomy for distal 19q. Affected individuals were non-dysmorphic, had mild to moderate developmental delay, attention deficit disorder (ADD) and short stature. Growth hormone (GH) deficiency was identified in the two siblings. The proband in Family 2 had an unbalanced translocation with der15 t(15;19)(p13;q13.3) (mat), with mild developmental delay, hypotonia, ADD, growth failure and short stature with normal GH levels. She also had joint hypermobility, ptosis, epicanthic folds and down slanted palpebral fissures, which were also seen in her mother. The proband in Family 3 had a der14t(14;19)(Tel 14q-, Tel 19q+). His height and weight were normal but he had moderately severe cognitive and behavior problems. The phenotype in this cohort was considerably milder than that which has been associated with cytogenetically visible trisomy 19q. FISH mapping with chromosome 19 specific BAC clones was done to map the breakpoints of these translocations. The patient without short stature had the most distal breakpoint, between 19q13.43 to qter, while individuals with short stature had breakpoints between 19q13.33 and 19q13.41 implying this to be a critical region for growth. Further molecular studies are needed to characterize this region, specifically regarding GH deficiency.

**Mutation Analysis of the VSX1 Gene in Patients with Posterior Polymorphous Corneal Dystrophy.** *A.J. Aldave<sup>1</sup>, V. Yellore<sup>1</sup>, N. Udar<sup>2</sup>, K. Small<sup>2</sup>.* 1) Cornea Service, The Jules Stein Eye Institute, Los Angeles, CA; 2) Retina Service, The Jules Stein Eye Institute, Los Angeles, CA.

**Purpose:** To screen for mutations in the VSX1 gene, in which mutations have been previously identified in patients with posterior polymorphous corneal dystrophy (PPMD). **Methods:** DNA extraction, PCR amplification and direct sequencing of the VSX1 gene was performed in 10 affected patients (9 families) as well as in unaffected family members and healthy control subjects. **Results:** No coding region mutations were identified in affected patients. However, a synonymous substitution (Ala182Ala) was identified in 4 patients (4 families), present in the homozygous state in 1 patient. Four affected patients (4 families) and 1 unaffected patient demonstrated a duplication in the 5'UTR (11\_20dup). **Conclusion:** No VSX1 gene coding region mutations were identified in PPMD patients, suggesting other genetic factors are involved in this autosomal dominant disorder.

**Molecular characterization of chromosomal breakpoint in a patient with CHARGE Syndrome.** *S.R. Lalani<sup>1</sup>, A. Safiullah<sup>1</sup>, S.D. Fernbach<sup>1</sup>, D.M. Martin<sup>3</sup>, J.W. Belmont<sup>1,2</sup>.* 1) Dept of Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Dept of Pediatrics and Human Genetics, University of Michigan, MI.

CHARGE syndrome is characterized by congenital heart disease, coloboma of the eyes, choanal atresia, retardation of mental and somatic development, genital abnormalities, ear abnormalities and/or deafness. While significant progress has been made in the clinical delineation of this syndrome, the molecular basis for the disorder remains unknown. Rare familial cases, increased paternal age, concordance between monozygotic twins, and reports of patients with unbalanced chromosomal anomalies suggest a genetic basis for CHARGE syndrome. We have been studying a child with CHARGE syndrome who has an apparently balanced de novo t(2;7)(p14;q21.11) chromosomal translocation. The child has bilateral choanal atresia, absence of semicircular canals, cranial nerve dysfunction, growth retardation, and genital hypoplasia, features consistent with CHARGE syndrome. We hypothesized that this apparently balanced translocation interrupts a gene with extreme pleiotropy, or contributes to the phenotype secondary to a positional effect. We have used fluorescence in situ hybridization (FISH) to identify the breakpoints in this patient and used BAC and PAC clones from the genome assembly database. By FISH analysis, we have identified the clones that span the breakpoints on both 2p14 and 7q21.11 loci. Using a long range PCR product of 9 kb as a FISH probe, we have further characterized the breakpoint within this region and identified a gene disrupted in this patient. Efforts are currently underway to sequence this gene in sixty patients with CHARGE syndrome. This study has facilitated characterization of a gene that may be involved in a subset of patients with CHARGE syndrome.

**Deletion 2q22-q23 syndrome: a contiguous gene syndrome including clinical features manifested in SIP1 deficiency.** *N. Ishihara*<sup>1,2</sup>, *K. Yamada*<sup>2</sup>, *Y. Yamada*<sup>2</sup>, *K. Miura*<sup>3</sup>, *J. Kato*<sup>4</sup>, *N. Kuwabara*<sup>5</sup>, *Y. Kobayashi*<sup>6</sup>, *T. Kumagai*<sup>3</sup>, *M. Nagaya*<sup>4</sup>, *N. Wakamatsu*<sup>2</sup>. 1) Dept Pediatrics, Nagoya Univ Sch Medicine, Nagoya, Aichi, Japan; 2) Dept Genetics, Inst Dev Res, Aichi Human Service Ctr, Aichi, Japan; 3) Dept Pediatr Neurol, Centl Hosp, Aichi Human Service Ctr, Aichi, Japan; 4) Dept Pediatr Surg, Centl Hosp, Aichi Human Service Ctr, Aichi, Japan; 5) Dept Pediatr Cardiol, Gifu Pref Hosp, Gifu, Japan; 6) Dept Pediatrics, Takuto Rehabil Ctr for Children, Miyagi, Japan.

SIP1 deficiency is caused by heterozygous mutations in *ZFHX1B* or deletions at 2q22 containing *ZFHX1B* resulting in profound mental retardation, delayed motor development, microcephaly, facial dysmorphism with a variety of combinations of epilepsy, congenital heart disease, Hirschsprung disease and failure of development of midline structures. However, there are several points to be elucidated. 1) What is the size of the deletions located at 2q22, if the patients present with the same clinical features of SIP1 deficiency. 2) What kind of clinical features might be newly manifested if deletions span 2q23-q24 as a contiguous syndrome. To address these questions, we analyzed clinical features and determined precise breakpoints of eight patients underlying deletions at 2q22-q24. We identified 0.2- to 5.1-Mb deletions including *ZFHX1B* at 2q22 from six patients presenting similar clinical features of SIP1 deficiency. In contrast, 8.8-Mb and 10.5-Mb deletions at 2q22-q23 and 2q22-q24 were identified in two cases presenting with more severe clinical features including cleft palate and complicated heart diseases. It is noteworthy that four of the patients with a common deletion at 2q23 had both clinical features (Lurie et al, Genet Couns. 1994; 5:11-14). Thus, loss of heterozygosity of genes located at 2q22-q23 causes a contiguous gene syndrome including features of SIP1 deficiency, cleft palate and heart disease.

**Assessment of association between TBX1 variants and haplotypes with manifestation of congenital heart defects in 22q11.2 deletion patients.** *A. Rauch<sup>1</sup>, K. Devriendt<sup>4</sup>, A. Koch<sup>2</sup>, R. Rauch<sup>6</sup>, M. Gewillig<sup>5</sup>, C. Kraus<sup>1</sup>, M. Weyand<sup>3</sup>, H. Singer<sup>2</sup>, M. Hofbeck<sup>6</sup>, A. Reis<sup>1</sup>.* 1) Institute of Human Genetics, Friedrich-Alexander Univ, Erlangen, Germany; 2) Departments of Pediatric Cardiology of the Friedrich-Alexander University Erlangen-Nuremberg,; 3) Department of Heart Surgery of the Friedrich-Alexander University Erlangen-Nuremberg,; 4) Centre for Human Genetics, Leuven, Belgium; 5) Centre for Pediatric cardiology, Leuven, Belgium; 6) Department of Pediatric Cardiology of the University of Tuebingen, Germany.

Deletion 22q11.2 is a major cause of congenital heart disease. However, presence of the deletion does not allow to predict the phenotype as patients with a 22q11.2 deletion usually show a broad clinical variability. TBX1 was shown by knockout mice experiments to play a role in congenital heart defects and therefore constitutes a candidate gene for a modifier in deletion 22q11.2 patients, in terms of uncovering of recessive mutations by hemizyosity. Thus we sequenced the entire coding region of TBX1 in a total of 174 patients with 22q11.2 deletion and detected 16 different variants, 7 of which represent common SNPs. Up to 96 dizygous control persons were additionally typed for these 16 variants. A combined approach with pair wise LD calculation on 174 due to hemizyosity naturally given haplotypes and analysis of background haplotypes of rare variants in a total of 366 chromosomes allowed us to define a reliable haplotype structure consisting of 3 LD blocks within the coding region and a further LD block including the 5'UTR exon 1. 14 of the 16 variants as well as the common haplotypes were detected at equal frequencies in deletion patients with and without CHD as well as in healthy controls. Thus we excluded common TBX1 variants or haplotypes as modifiers of expression of congenital heart defects in 22q11.2 deletion patients. Nevertheless, one 9 bp deletion was not detected in normal controls and segregated CHD in one family and might therefore constitute a causative factor for CHD in this family, as might apply for one further variant in one patient with PA-VSD, which was not detected in normal controls and which was the only variant to affect a conserved nucleotide.

**Analysing the molecular basis of Proteus Syndrome by genomic sequencing of candidate genes *PTEN*, *GPC3* and *p57*.** I. Thiffault<sup>1,2,3</sup>, C.E. Schwartz<sup>4</sup>, V. Der Kaloustian<sup>1</sup>, W.D. Foulkes<sup>1,2,3</sup>. 1) Department of Human Genetics, McGill University, Montreal, PQ, Canada; 2) Research Institute of the McGill University Health Centre, McGill University, Montreal, PQ, Canada; 3) Cancer Prevention Centre, Sir M B Davis-Jewish General Hospital, McGill University, Montreal, PQ, Canada; 4) Greenwood Genetics Center, Greenwood, SC, USA.

Proteus syndrome (PS) is a rare and complex disorder comprising an association of asymmetrical gigantism, epidermal naevi, vascular malformations, hamartomas, lipomas and hyperstosis. Since the first description of the syndrome by Cohen and Hayden, many hypotheses have been proposed to explain its occurrence. The most plausible is Happle's somatic mosaic hypothesis, but no somatic mutation in candidate genes have been reported to be clearly involved in PS. Mutation studies provided contradictory results on the association of germline mutations in children with Proteus and Proteus-like disorders: in a total of 48 patients with PS (n=42) or PS-like (n=6) syndrome, 7 have been reported to harbour a germline *PTEN* mutation (4 of 7 are PS-like). The classification of PS as a *PTEN*-hamartomatous syndrome remains controversial and given these data, the molecular basis of PS remains elusive. In this study, affected and unaffected tissues from 8 patients diagnosed with PS were screened by direct sequencing to determine the role of *PTEN*, *GPC3* and *p57* in PS development. Mutation analysis did not reveal any mutation in the coding sequence of *PTEN*, *GPC3* and *p57* in these PS patients. These mutational findings indicate that genomic alterations in *PTEN*, *GPC3* and *p57* are unlikely to play a major role in the pathogenesis of PS. Giving these results, a genome-wide, 10cM 388 marker microsatellite screen is currently underway to uncover putative somatic genomic microdeletions or other rearrangements by comparing the allelotype of the affected and unaffected tissues from PS patients. The aim of this molecular study is to shed light new understanding of this rare disorder.

**Identification of a novel locus for nanophthalmos, a form of severe hyperopia.** *O.H. Sundin<sup>1</sup>, J.M. Yang<sup>1</sup>, G.S. Leppert<sup>1</sup>, S. Dharmaraj<sup>1,2</sup>, I.H. Maumenee<sup>2</sup>, E. Weinberg<sup>1</sup>, E.D. Silva<sup>1</sup>.* 1) Developmental Genetics, Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD; 2) Center for Hereditary Eye Diseases, Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD.

Nanophthalmos, also known as uncomplicated microphthalmia, is a rare genetic disorder of the human eye characterized by extreme bilateral hyperopia (farsightedness), with a refractive error greater than +8 diopters. Although the cornea and lens are typically of normal proportions, the optic axis of the eye is unusually short, in the range of 14-20mm, relative to the 23-24mm axis characteristic of a normal adult eye. With this condition, angle-closure glaucoma and detachment of the retina are common complications in adults. We have identified a large kindred with 9 affected individuals distributed in a recessive pattern of inheritance over 4 sibships. The affected show classic features of the disorder, with refractions ranging from +10 to +25 diopters, thickened sclera, and narrow angles between the iris and cornea. The 4 most severely affected have either extensive or incipient retinal detachments. A whole genome screen using tandem repeat polymorphisms was carried out with 5 affected and 9 unaffected siblings. We obtained linkage to a novel 3 cM interval on chromosome 11q with a maximum LOD score of 6.8. This interval is distinct from the previously described dominant NNO1 nanophthalmos locus on chromosome 11. Identification of mutations underlying this disorder promise insight into how embryonic and postnatal development of the eye normally achieve an organ with remarkably standard shape and optical parameters.

**An Unusual Presentation of Angelman Syndrome due to an Imprinting Error on Chromosome 15.** *L. Steele<sup>1</sup>, T. Wright<sup>1</sup>, L. Oman-Ganes<sup>2</sup>, R. Munn<sup>2</sup>, D. Mills-Tettley<sup>2</sup>, I. Teshima<sup>1</sup>, T.L. Stockley<sup>1</sup>, P.N. Ray<sup>1</sup>.* 1) Dept Paed Lab Med, Hosp Sick Children; 2) Toronto, ON, Canada.

Prader Willi (PWS) and Angelman (AS) syndromes are clinically distinct but both are due to aberrant expression of genes at 15q11-13. PWS is caused by lack of paternally imprinted genes at 15q11-13, whereas AS is due to the lack of maternally imprinted genes. Each disorder has a frequency of about 1 in 20,000 live births. Children with PWS often present in the newborn period with hypotonia, obesity and developmental delay. In contrast, AS is difficult to diagnose in the newborn period since the characteristic behavioral features are usually recognized after the first few years of life. Approximately 70% of PWS and AS cases are due to parent-specific deletions in the 15q11-q13 region. Uniparental disomy (UPD) accounts for ~25% of PWS cases (matUPD) and 3-5% of AS cases (patUPD). Specific defects in genetic imprinting are less common, having been described in ~5% of PWS and AS cases. These defects are detected by molecular testing for SNRPN methylation status, followed by STR marker analysis to determine the etiology of the disorder. Here we report a 14 month old female presenting with severe hypotonia and developmental delay without other characteristic features of PWS. The child was delivered to a 42-year-old primigravida following artificial insemination for a 3-year history of infertility. Blood chromosome analysis revealed a 46,XX karyotype. Molecular testing for PWS was requested due to unexplained hypotonia. SNRPN methylation analysis revealed the presence of a paternally imprinted chromosome 15 but no maternally imprinted chromosome 15. This indicates that the patient has AS and not PWS. STR analysis revealed biparental inheritance of chromosome 15, indicating that the maternally derived chromosome 15 that the child inherited from the mother has a paternal imprint producing a rare, atypical clinical presentation of severe hypotonia and developmental delay. This finding suggests young children with hypotonia should be evaluated with molecular SNRPN testing in order to detect this unusual clinical presentation.

Program Nr: 708 from 2003 ASHG Annual Meeting

**Germline mosaicism of a novel mutation of *UBE3A* in Angelman syndrome.** S. Saitoh, K. Hosoki, K. Takano, A. Sudo. Dept Pediatrics, Hokkaido Univ Sch Medicine, Sapporo, Japan.

Approximately 10% of Angelman syndrome (AS) cases are caused by a mutation of *UBE3A*. The *UBE3A* gene shows tissue-specific imprinting and only the maternally derived allele is expressed in certain areas of the brain, including the hippocampus and cerebellum. More than 50 mutations of *UBE3A* have been described, and these mutations have been either maternally inherited or have arisen *de novo*. We have investigated two siblings with a typical AS phenotype. Lymphoblastoid cell lines were established from the affected sibs, a non-affected sib, and the parents. PCR amplification of genomic DNA and direct sequencing of all coding exons and flanking sequences identified a novel splicing mutation of *UBE3A* (IVS14-2AG). RT-PCR using RNA from lymphoblastoid cells revealed the skipping of exon 15 that created a translational frameshift and premature termination. This mutation was not present in the mother or father, although we could only examine lymphoblastoid cells. Further genetic studies revealed that the affected sibs inherited identical haplotypes from the mother as well as from the father, while the non-affected sib inherited different haplotypes from the mother and father. Thus, the parental origin of the chromosome 15 that carried the mutation could not be determined. Nonetheless, the combined data indicate that the mutation most likely is present as maternal germline mosaicism. This is the first report of germline mosaicism for a mutation of *UBE3A*, and has important implications for genetic counseling in Angelman syndrome.

**Yellow Nail Syndrome: Evidence of autosomal recessive trait.** *L.V. Furtado<sup>1</sup>, C.D. Martinhago<sup>1</sup>, J.C. Bruno<sup>3</sup>, J.M. Pina Neto<sup>1,2</sup>*. 1) Medical Genetics, HCFMRP, University of Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil; 2) Dept. Genetics, School of Medicine of Ribeirao Preto- University of Sao Paulo, Brazil; 3) Dept. of Pneumology, HCFMRP- University of Sao Paulo, Brazil.

The yellow nail syndrome (153300 OMIM) is a rare disorder delineated by Sammon and White (1964), characterized by slow growing yellow dystrophic nails and adult onset peripheral lymphoedema. Associated abnormalities include: bronchiectasis, chronic recurrent pleural effusion, chylous ascites, immune deficiency, chyluria, nephrotic syndrome, chronic sinusitis and other respiratory infections. Inheritance is autosomal dominant, although there are sporadic cases reported. However, Kamatani et al (1978) reported two adult brothers, the offspring of first cousins, with apparent yellow nail syndrome and mental retardation. The condition differed from classical yellow nail syndrome in that mental retardation was present and the parents were normal, suggesting recessive inheritance in this particular family. We reported a family in which a 36 year- old man, the second sib of a consanguineous marriage, was found to have neonatal onset slow growing, excessively curved, yellowish nails. At 29 years old was detected oedema of lower limbs, feet and hands; intermittent oedema of face; chronic sinusitis; chronic recurrent pleural effusions; bronchiectasis and immune deficiency, without intellectual handicap. Neither hepatic nor renal failures were found. Review of his family pedigree reveals that he was the most affected sib. Immediate family history is notable for normal parents, but not his two sisters which had neonatal onset typical nails changes; adult onset peripheral oedema and associated pulmonary features. One of these women had two offspring that were spared, suggesting a novel form of yellow nail syndrome with presumed autosomal recessive inheritance and normal intelligence. Supported by FAEPA-HCFMRP, University of Sao Paulo.

**Pseudodominance in pseudoxanthoma elasticum - a common phenomenon: Implications for genetic counseling.**

*F. Ringpfeil, K. McGuigan, H. Kozic, J. Utto.* Dept of Dermatology and Cutaneous Biology, Jefferson Medical College, Philadelphia, PA.

Pseudoxanthoma elasticum (PXE), a heritable disorder affecting skin, eyes and cardiovascular system with protean manifestations, has an estimated incidence of 1 in 70,000. Through mutation analysis in the ABCC6 gene, we and others have previously established the inheritance pattern as autosomal recessive with complete penetrance. However, several clinical investigators have reported dominant inheritance in families with affected individuals in two generations. Also, obligatory heterozygous carriers may have a very limited phenotype, often reflected only by positive histopathology from predilection sites of skin or by asymptomatic eye findings. Within our cohort of over 65 PXE families, we have ascertained several families that meet both criteria. We have haplotyped these families using microsatellite markers and SNPs spanning 3 cM around the ABCC6 locus and we have sequenced the entire coding region of ABCC6 in affected individuals and presumed carriers with a limited phenotype. All affected individuals and those with a limited phenotype harbor two mutated alleles, most mutations being private and novel. In one of these families, consanguinity in previous generations was detected through haplotype analysis. In the other families, affected individuals in two generations carried two sets of affected alleles, with a total of three different mutations. Haplotype analysis confirmed that the affected alleles were inherited independently. These data emphasize that PXE is an autosomal recessive disease that requires mutations in both alleles even for minimal signs of disease. Phenotypic variation between generations may be attributed to the consequences of mutations at the level of the encoded protein, MRP6. Furthermore, our findings imply a much higher prevalence of PXE than previously estimated, thus impacting on genetic counseling and disease prevention. It may therefore not be unreasonable to subject clinically unaffected individuals at risk for PXE to a skin biopsy to screen for subclinical disease.

**Split hand/split foot malformation with sensorineural deafness: a case report.** *F. McAuliffe*<sup>1</sup>, *S. Blaser*<sup>2</sup>, *B. Papsin*<sup>2</sup>, *D. Chitayat*<sup>1</sup>. 1) Obstetrics & Gynecology, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) Hospital for Sick Children, Toronto, Canada.

Ectrodactyly and sensorineural deafness is a rare association. We report an isolated case with this combination. The patient is a 1-year-old boy affected with four limb ectrodactyly and severe sensorineural deafness. He is the only member in his extended family with such a defect. The limb abnormality was detected antenatally. He was born after a full-term pregnancy and the delivery was spontaneous and vaginal with birth weight of 4250 gr. His karyotype is normal and male and neither dysmorphic features nor ectrodermal defects are evident. His general development is age appropriate apart from language. On the right hand 2nd and 3rd fingers are absent and on the left hand the 3rd finger is missing, with syndactyly of 4th and 5th fingers. On the right foot the 2nd and 3rd toes are absent and on the left foot the 2nd toe is missing with syndactyly of 3rd and 4th toes. He is completely deaf in the left ear and some hearing is present in the right ear. MRI reveals fused bones of the inner ear and a short cochlea. He received a cochlear implant in his right ear at a year of age. Four loci for split hand-split foot malformation have been mapped: SHFM1 on chromosome 7q21, SHFM2 on chromosome Xq26, SHFM3 on chromosome 10q24, SHFM4 recently found caused by mutations in the p63 gene, a homologue of the archetypal tumor suppressor TP53, on chromosome 3q27. This boy does not have the ectodermal defects or facial clefting, thus making the diagnosis of ectrodactyly-ectodermal dysplasia-clefting syndrome unlikely. An autosomal dominant ectrodactyly with sensorineural deafness was reported recently (1,2) and this case may represent a new dominant mutation. References 1. Mishra P, Muranjan M, Bharucha BA. Autosomal dominant ectrodactyly with sensorineural deafness. *Clin Dysmorphol* 2000 Apr;9(2):119-21. 2. D Tackels-Horne, A Toburen, E Sangiorgi, F Gurrieri, X de Mollerat, R Fischetto, F Causio, K Clarkson, Re Stevenson and Ce Schwartz. Split hand/split foot malformation with hearing loss: first report of families linked to the SHFM1 locus in 7q21. *Clinical Genetics*; 59 (1): 28.

**Genome Scan of Cleft lip with or without Cleft Palate (CL/P): Part I. Broadening the Phenotype to Include Lip Muscle Defects.** *S.M. Weinberg<sup>1</sup>, K. Neiswanger<sup>1</sup>, M.P. Mooney<sup>1</sup>, M.E. Cooper<sup>1</sup>, T.H. Goldstein<sup>1</sup>, A. Bowen<sup>2</sup>, R.A. Martin<sup>3</sup>, M.L. Marazita<sup>1</sup>.* 1) Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh; 2) Radiology Division, Childrens Hospital of Pittsburgh; 3) Division of Medical Genetics, St. Louis Childrens Hospital.

To date, genetic studies of CL/P have defined affection status narrowly, resulting in a potential loss of power for gene mapping studies if there are subclinical phenotypes present in non-cleft carriers of CL/P susceptibility genes. Studies using ultrasound have found a higher frequency of subclinical defects in the lip muscles of non-CL/P individuals within CL/P families compared to controls. A genome wide scan using 392 markers, with average spacing of 8.9 cM, was performed on 24 CL/P multiplex families from Western PA (122 family members genotyped by CIDR). Analyses were performed for both narrow and broad affection status definitions, with the broad definition including both overt CL/P plus subclinical lip muscle defects. There were 36 affected family members under the narrow definition, and 44 under the broad. Two-point and multipoint parametric linkage analyses were performed by the method of LOD scores. Results of the genome scan under the narrow affection status definition found suggestive LOD scores (between 1 and 2) on chromosomes 2, 6, 7, 8, 10 and 18. The highest two-point LOD was 1.97 on Chr 2. The highest multipoint LOD was 1.36 on Chr 6. Results of the genome scan with the broad affection status differed substantially. LODs greater than 1 were seen on chromosomes 1, 2, 5, 6, 8, 10, and 17. The highest two-point LOD was again found on Chr 2, but the LOD increased to 2.32. The highest multipoint LOD was 1.83 on Chr 17. Compared to the results of the narrow definition scan, seven LODs increased to over 1, seven decreased below 1 and three initially over one increased further. These results suggest that several of the genes responsible for CL/P also lead to lip muscle defects, and highlight the potential importance of including subclinical markers in gene mapping studies of CL/P. Supported by NIH grants DE13076 & RR00084; genotyping provided by a grant from the Center for Inherited Disease Research.

**POF in a mentally retarded girl with epilepsy and duplication of p arm of chromosome 22.** *M.E. Ahmad, R. Dada, K. Kucheria.* Division of Genetics, Department of Anatomy, All India Institute of Medical Sciences (AIIMS), New Dehli-110029, India.

There is an increased risk of reproductive disorders in women with epilepsy. Generalized tonic clonic seizures are associated with hypothalamic hypogonadism and polycystic ovarian disease. Premature Ovarian Failure (POF) affects 1% of women and is known to be caused by chromosomal abnormalities. Chromosomal rearrangements are also the most frequent cause of mental retardation. We report a case of a 20 year old mentally retarded girl with POF and history of epilepsy. On cytogenetic analysis of 30 G-banded metaphases we found duplication of 22p (46,XX dup22p). The proband had poorly developed secondary sexual characters. The FSH and LH levels were in the normal range and USG showed complete absence of ovarian follicles and the uterus was small in size. The proband was a product of non consanguineous marriage and there was no family history of delayed menarche or epilepsy. Though it is well known that chromosomal abnormalities lead to POF and mental retardation, it is important to understand their correlation and analyse more such cases to understand if genes controlling mental development and ovarian development are linked. Thus understanding the genetic basis of these disorders is important in order to counsel these cases and manage them most appropriately.

**Phenotypic characterisation of ring chromosome 22.** *S. Curran*<sup>1</sup>, *A. Jeffries*<sup>2</sup>, *J. Powell*<sup>2</sup>. 1) SGDP Research Ctr, Inst Psychiatry, London, United Kingdom; 2) Neuroscience, Inst Psychiatry, London, United Kingdom.

Ring chromosome 22 (r22) is a rare human cytogenetic abnormality. Individuals with ring chromosome 22 exhibit a phenotype of global developmental delay with severe delay or absence of speech, hypotonia and more variable minor dysmorphic features. Autistic disorders as well as seizures have also been reported. Formation of the ring chromosome is assumed to arise from breakage and subsequent fusion of both chromosome arms to generate a ring chromosome with concomitant loss of short and long arm sequences. Hemizygoty of genes on the long arm of chromosome 22 is assumed to determine the phenotype. We have determined the breakpoints of 30 phenotypically characterised individuals, the largest reported collection of r22 patients to date. Families were mailed questionnaires, a disposable camera and buccal swab kits for DNA sampling of affected individuals and their natural parents where available. A clinical history questionnaire, gathered information on basic demographic information as well as a detailed history of the pregnancy, birth, developmental, medical and educational history of the child. The majority of the children in this study were globally developmentally delayed, with severe impairment in functioning. In order to try to quantify the developmental level achieved we used the PIP developmental charts which focus on 'milestones' of development in the five main areas: physical development, social development, eye-hand development, development of play, and language development. The 40-item Social Communication Questionnaire (SCQ), was used to screen for autistic symptoms. Microsatellite analysis of ring 22 individuals and their parents using twenty two published and two unpublished markers was used to determine the 22q breakpoints of the r(22) chromosomes. Even though, 22q DNA loss varied from less than 69 kb up to 10.1 Mb or <0.15% to 21% of the total chromosome length we found no significant association of breakpoint positions with dysmorphological features, developmental attainment, medical problems or behavioural features of the r22 individuals. We discuss the reasons for this and note a high prevalence of autistic behaviours in this group.

**Infantile Systemic Hyalinosis in a patient with chromosome 22 inversion.** *N. Macias-Gomez*<sup>1,2</sup>, *L. Arnaud*<sup>1,3</sup>, *J.A. Nastasi*<sup>1,2</sup>, *J. Durán*<sup>1,2</sup>, *H. Gomez-Sanchez*<sup>2</sup>, *R.M. Davalos-Pulido*<sup>2</sup>, *A.I. Vásquez*<sup>2</sup>, *J.E. Garcia-Ortiz*<sup>4</sup>, *M.P. Gallegos-Arreola*<sup>3</sup>, *L.E. Figuera*<sup>2</sup>. 1) División de Genética, CIBO, IMSS, Guadalajara, Jalisco, México; 2) Doctorado en Genética Humana, UDG, Guadalajara, Jalisco; 3) División de Medicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, México; 4) Facultad de Medicina, Universidad de Coahuila, Coahuila, México.

Hyalinosis is a rare autosomal recessive inherited entity (OMIM 236490). There are 3 types that includes infantile (IH), juvenile hyalinosis (JH) forms and Urbach-Wiethe disease (hyalinosis cutis et mucosae). Infantile Systemic Hyalinosis (ISH) has been proposed as a disorder of collagen type VI characterized by thickening and nodularity of the skin, joint contractures, osteoporosis, and gingival enlargement. Failure to thrive that starts from the neonatal period, with death usually occurring before the third year of life, mainly before the second year. There is associated severe persistent diarrhea, wasting and recurrent severe respiratory infections. We report the case of a Mexican one-year-old boy. The propositus, the fourth child of healthy unrelated parents, was born after a gestation of 40 weeks. Birth weight was 3.6 Kg and length was 40 cm. Since first months of life he presented stiff skin and painful joint contractures, as well as all the typical features above mentioned. Increased excretion of urinary glycosaminoglycans was found in our patient (dermatan sulfate, heparan sulfate and chondroitin-4-sulfate) He had anemia microcytic hypochromic. The karyotype in the patient was 46,XY,inv (22) (p13;q13). The karyotype in the father was 46,XY,inv(22)(p12;q12). Increased excretion of urinary glycosaminoglycans has been reported in some cases, a data inconsistent in other reported cases. It is important point out the data of the karyotype witch could suggest a possible localization of a ISH gene.

**Genetic Investigation of association between presence of LHON primary point mutations and occurrence of MS phenotype in Iranian patients.** *F. Sharifpanah<sup>1</sup>, M. Houshmand<sup>1</sup>, M.H. Sanati<sup>1</sup>, Sh. Lavasani<sup>1</sup>, I. Rashedi<sup>2</sup>, J. Lotfi<sup>2</sup>.*  
1) Medical Genetics Unit, National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran; 2) Shariati Hospital, Tehran, Iran.

The hypothesis that mitochondrial genes may be implicated in susceptibility to multiple sclerosis (MS) is supported by an increasing number of case reports on Leber Hereditary Optic Neuropathy (LHON) associated mitochondrial DNA (mtDNA) point mutations in patients with MS. A number of mtDNA mutations with primary pathogenic significance for LHON, a maternally inherited disease causing severe bilateral visual loss predominantly in young men, have been detected in patients with a MS-like phenotype. To evaluate the link between MS and LHON primary point mutations, we investigated 31 unrelated Iranian clinically definite MS patients (23 females and 8 males) with optic nerve involvement, 3 of them with severe bilateral visual loss, as well as 25 patients (16 females and 9 males) without involvement of optic nerve as controls, for the presence of LHON mitochondrial mutations at nucleotide positions (np) 11778, 3460 and 14484 by mutation specific polymerase chain reaction (PCR), restriction fragment length polymorphism (RFLP) and single strand conformation polymorphism (SSCP). Our results suggest that there is no association between Iranian patients with MS and mtDNA point mutations at np 11778, 3460 and 14484.

**Human Growth Hormone Treatment of Amyoplasia.** *C. Techakittiroj, E. Felner, D. Africk, H. Neitzschman, J. Thoene.* Hayward Genetics Center, Tulane University School of Medicine, Departments of Pediatrics, Neurology, and Radiology, New Orleans, LA.

Amyoplasia is a severe birth defect of unknown pathogenesis. A 38 week 3 kg female fit the diagnostic criteria: no spontaneous movement at birth; Apgar scores of 1, 4 and 6 at 1,5 and 10 minutes; elbows limited to extension; syndactyly of right 3rd and 4th digits; normal height; midline facial hemangioma; scaphycephaly; dimples over bony prominences; fractured right femur; hip flexion; fingers and toes locked in extension; equinovarus; hyperlordosis and hirsutism. An initial CNS MRI was normal. A total body MRI disclosed absence of limb muscle and "thready" psoas, paraspinous and gluteal muscles. An upper arm biopsy showed no muscle grossly or on Gomori-trichrome stain. EMG and NCV were non-conclusive. She began monthly HGH injections (depot Nutropin 1.5 mg/kg) at 21 months of age. After 4 months of therapy she has some voluntary finger grasp, and moderate head control. She has an ongoing vocabulary of 20 words and is intellectually normal for age at this time. Her urinary creatinine has varied from 1.9 g/kg body weight/8 prior to GH therapy to 2.3 after 4 months of treatment. A repeat MRI demonstrated increase in the volume and signal of the paraspinous, psoas and pelvic muscles with increase in gluteal muscle development as well. There are also minimal strands of muscle signal within the fat of the proximal extremities. The natural history of most (85%) patients with this condition is to show significant gains in strength and to ambulate unaided by age 5 years (Sells JM, Jaffe KM, and Hall JG, *Pediatr*, 97, 225-231, 1996). A positive effect of growth hormone therefore cannot be inferred in this patient. Follow up MRI studies of limb and axial musculature in this patient will permit better delineation of acquisition of muscle tissue in this condition.

**Clinical and genetic heterogeneity in familial dominant muscular dystrophy with pathological fractures. S.**

*Mehta<sup>1</sup>, G.D.J. Watts<sup>1</sup>, J. Wymer<sup>1</sup>, S.J. Hamilton<sup>1</sup>, B. McGillivray<sup>2</sup>, V.E. Kimonis<sup>1</sup>.* 1) Division of Genetics and Metabolism, Childrens Hospital, Harvard Medical School, 300 Longwood Avenue, Fegan 5, Boston, MA 02115; 2) Provincial Medical Genetics Programme, Children's and Women's Health Centre of British Columbia C234, 4500 Oak Street, Vancouver, British Columbia, Canada.

We have previously reported the unusual combination of autosomal dominant Paget disease of the bone (PDB) with a limb-girdle/inclusion body myopathy associated with dementia (IBMPFD). This disorder has been mapped to chromosome 9p22.3-q12 (Kovach et al, 2001). This present study describes an unrelated family previously reported by Henry et al. (1958) with an autosomal dominant progressive limb girdle muscular dystrophy, early onset of fracturing with poor healing, osteomyelitis and limb amputations. Some members also have herniae, premature greying, and a Von Willebrand type haematological picture.

Informed consent was obtained. Clinical, biochemical and radiological features have been documented in 9 males and 4 females. The average age of onset of the limb girdle myopathy was 29 y. occurring in 77% of affected individuals. The average age of onset of fractures was 20 y. occurring in 69% of affected individuals. Biochemical analysis showed a low normal alkaline phosphatase of 60 U/L (Normal 30-120) and high creatinine phosphokinase of 236.5 U/L (Normal 0-150). Radiographs show coarse trabeculation, sclerosis, cortical thickening, and narrowing of the medullary cavity. They were not suggestive of Pagets however there were features of fibrous dysplasia. Muscle biopsies and electromyograms showed myopathic changes. Nerve conduction studies were normal. Collagen studies were normal. Linkage analysis was undertaken for markers for the chromosome 9p22.3-q12 locus. This family does not map to this locus suggestive of a unique locus.

Screening of candidate genes and genome wide genotyping is in progress to identify the gene involved in the pathogenesis of this unique disorder. We report a unique autosomal dominant disorder with the combination of muscular dystrophy and bone fragility.

**Investigation of mtDNA common deletion in a patient affected with HIBM.** *S. Joughehdoust<sup>1</sup>, Y. Shafeghati<sup>1</sup>, M. Ataii<sup>1</sup>, D. Darvish<sup>2</sup>, M. Houshmand<sup>1</sup>.* 1) NRCGEB, Tehran, Iran; 2) American Board of Internal Medicine, USA.

Hereditary Inclusion Body Myositis is a chronic progressive muscle disorder that is prevalent in Jewish descendants from Iran and other middle east countries. There are several types of this disorder but HIBM(IBM2) have autosomal recessive pattern. It is started with insidious onset in second or third decades of life and associated with distal muscle weakness in the upper extremities and proximal muscle weakness in the lower extremities. Our patient was 24 years old girl that suffered from muscle weakness. Positive findings in her physical exam were mild weakness in limbs muscles. The quadriceps was normal. EMG showed myopathic feature and muscle biopsy was compatible with muscular atrophy, neurogenic. All of the clinical and laboratory findings were typical for HIBM. The patient is from an unconsanguineous marriage and her grand parents were from Iranian Jewish ancestors. In our lab we have analyzed a mutation in the 3'UTR region of CNTFR mRNA gene, this gene is a 305 bp long. The method was PCR/RFLP(Res/ENZ:MspI). She was Homozygous for this mutation. MtDNA myopathies and HIBM share some similarities in their clinical findings and the base of both disorder is lack of ATP synthesis and IBM is another type of myositis that its relation with mtDNA deletions has been evaluated in recent reports. We checked the patient for mtDNA common deletion but no mutation was detected. Further investigation will confirm the relation between mtDNA mutations and HIBM.

**Partial deletion of the NSD1 gene in a patient with Sotos syndrome.** *V. Drouin-Garraud<sup>1</sup>, P. Saugier-veber<sup>1</sup>, C. Lecointre<sup>2</sup>, C. Hervé<sup>3</sup>, S. Fehrenbach<sup>1</sup>, T. Frebourg<sup>1</sup>.* 1) Department of Genetics, Rouen University Hospital, France; 2) Department of Paediatrics, Rouen University Hospital, France; 3) Department of Neonatology, Rouen University Hospital, France.

Sotos syndrome is an overgrowth syndrome characterized by pre- and postnatal overgrowth, macrocephaly, advanced bone age, and typical facial features. Recently, large 5q35 microdeletions detected by FISH, encompassing the NSD1 gene, and intragenic NSD1 mutations were reported in Sotos patients. Nevertheless, despite careful clinical screening, mutations or deletions have been detected in only 76 % of Sotos patients. Here we report on the case of a young girl affected with Sotos syndrome associated with athyreosis and harboring a partial deletion of the NSD1 gene. The patient is the second child of unrelated parents. Neonatal screening revealed hypothyroidism secondary to athyreosis which was treated with L-thyroxin. She developed West syndrome at 5 months of age. At 8 years, overgrowth and macrocephaly were obvious, with height and head circumference above the 98th centile. She had characteristic dysmorphic facial features of Sotos syndrome and mild mental retardation. Hands radiographs showed advanced bone age. R-banding lymphocyte karyotype was normal. We analyzed the NSD1 gene, using QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments), a simple method for the detection of heterozygous rearrangements which is based on the simultaneous amplification of short fluorescent fragments. In this patient, we identified a partial deletion of the NSD1 gene removing exon 23 but respecting exon 2. The FLJ21458 gene located 3.4 Mb telomeric from NSD1 was not deleted. This case report demonstrates that partial deletions of the NSD1 gene can arise and may account for some of the 24 % of cases in which no NSD1 mutation / deletion has been detected.

**The paternal age effect in Apert syndrome is due in part to the increased frequency of mutation in sperm in the general population and group-specific characteristics of Apert syndrome fathers.** *R.L. Glaser<sup>1</sup>, K.W. Broman<sup>1</sup>, R.L. Schulman<sup>1</sup>, B. Eskenazi<sup>2</sup>, A.J. Wyrobek<sup>3</sup>, E.W. Jabs<sup>1</sup>.* 1) Johns Hopkins Univ, Balto, MD; 2) Univ Calif. Berkeley, CA; 3) Lawrence Livermore National Lab, Livermore, CA.

An increased incidence of affected children with paternal age and the paternal origin of mutations have been observed for sporadic cases of several autosomal dominant disorders. Mutations in these disorders are all single nucleotide changes thought to result from DNA copy errors during spermatogonial stem cell replication. One such disorder is Apert syndrome (AS) which is characterized by craniosynostosis and syndactyly of the hands and feet and occurs in 1/65,000 to 160,000 live births. As the incidence of sporadic AS births increases exponentially with paternal age, we hypothesized that the frequency of AS mutations in sperm would also increase. To determine the frequency of two recurrent FGFR2 mutations, 755C>G and 758C>G, accounting for 99% of all cases of AS, we developed allele-specific peptide nucleic acid-PCR assays sensitive enough to detect 1/50,000 mutant sperm. Using this method to analyze sperm DNA from 148 men ages 21-80 years we showed that the number of sperm with either FGFR2 mutation increased in the oldest age groups among men who did not have an AS child ( $p=0.008$ ). These older men were also more likely to have both mutations in their sperm. However, this age-related increase in mutation frequency was not sufficient to explain the AS birth frequency. In contrast, a significantly increased mutation frequency was observed in men who had AS children ( $p=0.002$ ), most of whom were younger than 45 years old. These younger fathers had sperm mutation frequencies that resembled those of men older than 60 years who had not fathered AS children. Therefore, the paternal age effect may be due to a higher number of mutant sperm and an earlier occurrence of mutations in the subset of men ascertained because they had a child with AS. No age-related increase in the frequency of these mutations was observed in leukocytes. Selection and/or quality control mechanisms, including DNA repair and apoptosis, may contribute to the cell type differences in mutation frequency.

**Mosaicism for two large, different MECP2 gene deletions in a classic RTT female, apparently caused by the increased size of an original mutation.** *L. Giunti<sup>1</sup>, S. Guarducci<sup>1</sup>, U. Ricci<sup>1</sup>, C. Bravaccio<sup>2</sup>, M.L. Giovannucci Uzielli<sup>1</sup>.* 1) Paediatrics - Genetics Unit, University of Florence, Florence, Florence, Italy; 2) Children Neuropsychiatry Unit, II University of Naples, Italy.

Rett syndrome (RTT) is one of the most frequent neurodevelopmental disorders occurring almost exclusively in females. In 1999, RTT was reported to be caused by mutations in the gene encoding methyl-CpG-binding protein 2 (MECP2), located at chromosome Xq28. RTT had been thought to be an X-linked dominant condition leading to prenatal death in hemizygous males. Since the discovery of mutations of the MECP2 gene as the cause of Rett syndrome, MECP2 mutations have, however, also been reported in males. It is now clear that in males with classical Rett syndrome the mutation of MECP2 arises as somatic mosaicism or in presence of an extra X chromosome. Detection rate of MECP2 gene in classical cases of RTT females is 75-85%. Approximately 70% of sporadic RTT patients have missense or truncated mutations. Over 95% of mutations are de novo. About 95% of the missense, nonsense, and one or two base pair insertion or deletion mutations occur in the 3 half part of exon 3 and the 5 half of exon 4 of MECP2 gene. The gross deletions were in the 3 half of exon 4. Few cases of multiple deletions of MECP2 gene were reported. Two descriptions of somatic mosaicisms are published. In a group of 160 RTT patients positive for MECP2 mutation, by direct sequencing analysis, we found more than 15 large deletions with all breakpoints within a 3 185-bp region of MECP2 exon 4. In all cases, the gross deletion was single and apparently homogeneous. In a classic RTT female we demonstrated the absence of the entire exons 3 and 4 by using the MLPA technique (Multiplex Ligation-dependent Probe Amplification). We report here a new case of classic RTT female with a very large deletion of MECP2 genes exon 4, with three alleles. The wild allele, and two mutated alleles with different sized deletion: one with a 412 bp deletion and a L408X stop codon, a second one with an intermediate deletion starting at the same nucleotide 22611. Further studies are in progress to better characterize the origin of the mutations.

Program Nr: 723 from 2003 ASHG Annual Meeting

**Deletion of exons 3 and 4 of MECP2 gene, revealed by MLPA technique, in a RTT Italian girl with a classic phenotype.** *M.L. Giovannucci Uzielli, L. Giunti, S. Guarducci, U. Ricci, I. Sani, E. Lapi, E. Andreucci, C. Bacci, B. Toschi, M. Ottaviani.* Paediatrics, Genetics Unit, Univ Florence, Florence, Italy.

A novel mutation detection approach, called Multiplex Ligation-Dependent Probe Amplification (MLPA), was able to reveal a large genomic deletion not identified by direct sequencing. Federica is an Italian girl with classical Rett syndrome. The direct sequencing analysis of the entire coding region did not reveal any mutation of MECP2 gene. We identified a heterozygous C>A transversion at 375 (1125) in the mother, while the father showed a wild normal allele. The daughter showed only the maternal allele with the C>A substitution, and we placed the hypothesis of a lack of entire exons as cause of RTT phenotype. We used the MLPA (Multiplex Ligation-Dependent Probe Amplification Technique), a quantitative multiplex PCR approach, to determine the relative copy number of each MECP2 gene exons. We were able to confirm the deletion of entire exons 3 and 4. This method reveals alterations of genomic DNA that might escape detection using conventional diagnostic techniques. It is especially useful in RTT mutational studies, because the direct sequencing of MECP2 gene does not reveal any apparent MECP2 mutation in 15-25% of Classic and non-classic RTT patients.

**Uncommon FBN1 mutation in Marfan syndrome family with severe ectopia lentis.** *M. Manning<sup>1</sup>, J. Hyland<sup>2</sup>, A. Kwan<sup>1</sup>, D. Liang<sup>1</sup>, L. Hudgins<sup>1</sup>.* 1) Stanford University, Stanford, CA; 2) Tulane University Health Sciences Center, New Orleans, LA.

Marfan syndrome (MFS) is a multisystem disorder involving the skeletal, cardiovascular and ocular systems. Mutations in the gene fibrillin-1 (FBN1) have been identified as causing MFS as well as other related disorders, such as ectopia lentis (EL) and familial aortic aneurysm. There have been 337 mutations in FBN1 located throughout the gene. Due to clinical variability within the condition, work is ongoing to determine genotype/phenotype correlation in order to provide appropriate management.

We present a family in which the 8 yo male proband was originally referred to rule out a suspected diagnosis of MFS. Bilateral EL was noted in 3 family members, with no other Ghent diagnostic criteria present for the diagnosis of MFS. Familial EL was the presumed diagnosis. FBN1 mutation analysis revealed a 364 C>T in exon 4 resulting in a cysteine for arginine substitution at aa 122, a change that results in an extra cysteine in the EGF#2 domain. The mutation has been reported on 4 other occasions and is considered disease causing. Published clinical descriptions are brief, however all affected individuals had major ocular manifestations (EL) with only minor skeletal system involvement. One family demonstrated late onset minor cardiovascular findings. Our 3 subjects were also noted to have a second, previously unreported mutation at aa 124 in which valine was substituted for methionine. This sequence variation results in 2 aa substitutions in *cis* separated by only one other aa. The effect on protein structure of this domain has not been determined. Subsequent echocardiograms in 2 of our subjects revealed aortic root dilation for their body mass index.

The findings in our family suggest that FBN1 mutation analysis is indicated in families with primarily EL, as results may provide additional criteria to make a diagnosis of MFS. In particular, individuals with the 364 C>T mutation may be at high risk for cardiovascular involvement, as well as EL, and should be followed expectantly.

**Noonan syndrome with café-au-lait spots and LEOPARD syndrome: evidence for genetic heterogeneity.** *A.M. Nyström, G. Annerén, M.L. Bondeson.* Dept of Genetics & Pathology, Uppsala University, Rudbeck Laboratory, Sweden.

Noonan syndrome (NS) is an autosomal dominant disorder characterised by facial dysmorphism, congenital heart defects and short stature. Among associated findings are skin manifestations such as café-au-lait spots and lentigines. Several clinical features of NS overlap with other syndromes, e.g. LEOPARD syndrome and Neurofibromatosis type I. Missense mutations in the *PTPN11* gene at 12q24.1 are associated with NS in about 50% of the patients. Recently, mutations in the *PTPN11* have also been reported to be associated with LEOPARD syndrome. Mutations in the *NF1* gene at 17q11.2 are associated with Neurofibromatosis type I and *NF1* mutations have also been identified in some patients with Neurofibromatosis-Noonan syndrome (NFNS). Here, we report the findings of mutation screening and linkage analysis of the *PTPN11* and *NF1* genes in two families affected by NS and/or café-au-lait spots and one family with the LEOPARD syndrome. Linkage to the *PTPN11* gene was found in a two-generation family affected by the LEOPARD syndrome. The coding region of the *PTPN11* gene was screened by dHPLC followed by direct sequencing in the probands. The result revealed a missense mutation 836A>G; Y279C segregating with the disorder in the family. The Y279C mutation has previously been described in LEOPARD patients, suggesting that it may represent a recurrent mutation in the *PTPN11* gene for the LEOPARD syndrome. A mutation in the *PTPN11* gene (F285L; 853T>C) was also identified in a proband with NS and café-au-lait spots. In this family, the sister of the proband and the father presented with short statures and café-au-lait spots but with no other clinical manifestations of NS. However, mutation analysis revealed that they were not carriers of the F285L mutation, suggesting that the café-au-lait spots and NS in this family are caused by distinct genetic entities. Linkage analysis in a three-generation family diagnosed with NS and café-au-lait spots revealed that the disorder in this family is neither linked to the *NF1*- nor to the *PTPN11* locus. Our result thus suggest that NS with café-au-lait spots is genetically heterogeneous and may even present as different genetic entities.

**Identification of two novel mutations of IRF6 in Korean families affected with Van der Woude syndrome. J.-Y.**

*Park*<sup>1</sup>, *H.-W. Yoo*<sup>1,2</sup>, *Y. Kim*<sup>1</sup>. 1) Genome Research Center for Birth Defects and Genetic Disorders, Ulsan University of College of Medicine, Asan Medical Center, 388-1, Pungnap-Dong, Songpa-Gu, Seoul 138-736, Korea; 2) Department of Pediatrics, Ulsan University of College of Medicine, Asan Medical Center, 388-1, Pungnap-Dong, Songpa-Gu, Seoul 138-736, Korea.

Van der Woude syndrome (VWS; OMIM 119300) is an autosomal dominant disorder with a high degree of penetrance. Clinical characteristics of VWS include cleft lip with or without cleft palate (CL/P), bilateral lip pits, isolated cleft palate, and hypodontia. Recently, the interferon regulatory factor 6 gene (*IRF6*) has been identified as the gene mutated in VWS. *IRF6* belongs to a family of nine interferon regulatory factors, all of which share a highly-conserved DNA-binding domain in the N-terminus. Through the DNA-binding domain, IRFs elicit their effects of transcription activation on the target genes. *IRF6* also contains a putative Smad-binding domain in the C-terminus. The Smads proteins are a family of transcription factors known to transduce signals of the TGF- superfamily. Using PCR-direct sequencing of the exonic regions of *IRF6*, we found two novel mutations of *IRF6*, 399delC and G74C, from two unrelated Korean families with VWS. The 399delC mutation was identified from a family showing complete cleft lip and palate with a lower lip pit in an affected daughter. Her father, carrying the same mutation, showed bifid uvula with a pit on his lower lip. This mutation caused a frame-shift at pro133 and resulted in a premature termination at codon 165, abolishing the C-terminal region of *IRF6*. The second mutation, G74C, was detected from an affected son and his mother, both suffered from bilateral cleft lip and palate with pits on the lower lip. The G74C mutation substituted an alanine for a glycine at codon 25 in the DNA-binding domain. Both mutations are presumably expected to disturb the transcription regulatory function of *IRF6*. Our findings further confirm that haploinsufficiency of *IRF6* is responsible for the phenotypic features of VWS. The newly identified mutations will be useful for further understanding of the essential roles of *IRF6* in morphogenesis of the palate and lip.

**Candidate syndromic genes in nonsyndromic cleft lip and palate.** *N. Prescott, C. Garcia-Rodriguez, M. Lees, RM. Winter.* Clinical & Molecular Genetics, Inst Child Health, London, United Kingdom.

Nonsyndromic Cleft lip with or without cleft palate (CL/P) is an epithelial fusion defect that occurs during the first few weeks of pregnancy. This congenital anomaly is influenced by genetic factors as demonstrated by an elevated sibling relative risk of 30-40. Despite, the underlying genetic etiology of CL/P is likely to be complex/ multifactorial and influenced by environmental factors. Recently a mutation in the poliovirus receptor-like 1 (PVRL1) gene has been found in a rare syndromic form of cleft lip with ectodermal dysplasia (CLPED1) the same mutation has a high frequency of carriers in sporadic cases of NSCL/P from a geographically adjacent region in Venezuela (Sozen et al., 2001). It seems very likely that there will be examples where allelic changes in other genes underlying syndromic forms of CL/P will cause nonsyndromic CL/P. We can use this hypothesis to predict potential candidate genes for nonsyndromic CL/P. We have used 96 sporadic cases with CL/P and two dominant families with CL/P and associated anomalies to screen the candidate genes PVRL1, SKI oncogene, IRF6 and EDN1 by fluorescent heteroduplex analysis to identify variations that may influence risk for nonsyndromic CL/P. We have identified a number of individuals giving heteroduplexes (HD) that may represent novel variants in SKI, IRF6 and EDN1. DNA sequencing of HDs in EDN1 has revealed a novel variation in exon 5 in one affected male and his unaffected father. Further sequencing result on the remaining genes will be presented.

**CONFIRMATION OF GENETIC HETEROGENEITY IN SUBCORTICAL BAND HETEROTOPIA.** *F.R. Torres<sup>1</sup>, M.A. Montenegro<sup>2</sup>, M.M. Guerreiro<sup>2</sup>, F. Cendes<sup>2</sup>, I. Lopes-Cendes<sup>1</sup>*. 1) Department of Medical Genetics, UNICAMP, Campinas, Brazil; 2) Department of Neurology, UNICAMP, Campinas, Brazil.

**Purpose:** Subcortical band heterotopia (SBH) is a neuronal migration disorder causing developmental delay and epilepsy. Female patients with SBH, who have a malformation gradient with anterior predominance, usually have mutations in the *DCX* gene. In addition, there are few male patients with SBH and mutation in the *LIS1* gene. The objective of this study is to describe neuroimaging and molecular findings of a cohort of patients with SBH. **Methods:** All patients included in this study had high resolution MRI scans. We searched for mutations in the *DCX* and *LIS1* genes. In addition, a total of 50 unrelated normal control subjects were also genotyped. PCR reactions were performed with primers designed to amplify the coding region and intron/exon boundaries of *DCX* and *LIS1*. PCR samples were analyzed by the single-strand conformation polymorphism method. The nucleotide sequence of all fragments showing an altered band shift were subsequently determined using the Big Dye Terminator Sequencing kit for megaBACE1000. **Results:** We have studied a total of 6 patients with SBH and divided them into 2 groups, according to neuroimaging criteria, in: typical and atypical SBH. We found 4 patients (1 male and 3 female) with the typical SBH, which is usually linked to *DCX* mutations; as well as, 2 female patients with atypical findings, such as SBH with posterior predominance and the association SBH-pachygyria. None of the patients, including those with typical phenotypes, showed mutation in *DCX* and *LIS1*. We only found a normal variant (1805CT) in the 3 untranslated region of the *LIS1* gene in 4 patients, which was also present in 9 control subjects. **Conclusion:** Our results confirm the presence of genetic heterogeneity in SBH and points to the possibility of mutations in at least a third, still undetermined, gene. In addition, we corroborate previous findings indicating that patients with atypical SBH do not have mutations in *DCX*, and that the occurrence of *DCX* and *LIS1* mutations in males with SBH is a very rare event. Supported by CAPES and FAPESP.

Program Nr: 729 from 2003 ASHG Annual Meeting

**Congenital temporomandibular joint ankylosis (CTMJA): clinical characterization of 3 unrelated affected.**  
*V.L.G.S.L. Lopes, D.V.L. Luquetti.* Medical Genetics Dept, State Univ Campinas, Campinas, Sao Paulo, Brazil.

Congenital temporomandibular joint ankylosis (CTMJA) is a rare feature characterized by facial disfigurement, significant reduction in mouth opening, difficulties in feeding and breathing. In some cases, secondary cor pulmonale can be detected. Etiology of this disorder seems to be heterogeneous; traumatic form, in which forceps delivery is considered an important factor, as well as infection diseases should be mentioned. It is often diagnosed around sixth month of life, in view of some joint mobility present at birth, before the ossification of the cranial sutures. At least, a genetic form has been suggested based upon a case report describing siblings of different sexes with no history of parental consanguinity or description of associated anomalies. However, there is few information about genetics aspects of this condition. We report 3 unrelated patients, 2 males and 1 female, presenting CTMJA. One of the male presented developmental delay and the girl had congenital general hypotonia. Clinical findings suggested different etiologies among them. Therefore, the dysmorphological characterization of these cases, including the clinical evolution, could be helpful in recognize and delineate this condition, favoring the clinical follow up of affected individuals.e-mail: cranface@fcm.unicamp.b.

**Long term outcome of feeding problems in Noonan syndrome.** *A.C. Shaw, M. Sharland, A.H. Crosby, K. Kalidas, G. Sivapalan, S. Jeffery, M.A. Patton.* Medical Genetics, St George's Hospital Medical School, London, UK.

Feeding problems are a common finding in infants with Noonan syndrome (NS). There is wide variation ranging from a weak suck and occasional vomiting to severe and protracted difficulties requiring feeding via nasogastric (NG) tube. The feeding histories of 144 infants with NS were published in 1992, and 117 (81%) of this cohort have now been followed up for in excess of 10 years.

Severity was graded on a scale of 0 to 3 where 0 indicates no feeding problems (24%), 1 for weak suck (14%), 2 for additional frequent and forceful vomiting (38%) and 3 for when NG tube feeding was required for over 2 weeks (24%). Analysis of this cohort reveals that for each grade of severity the proportion of patients with *PTPN11* mutations is 30%; 36%; 39% and 39% respectively. The mean age of onset of speaking in 2 word phrases for each grade is 27; 26; 36 and 40 months respectively ( $p=0.036$ ). The proportion of patients attending special school for each grade is 16%; 11%; 40% and 60% ( $p=0.005$ ). Educational attainment was better in those without feeding problems with 40% going on to higher education whereas the highest achievement reached in the severe group were GCSE exams (national exam for 16 year olds). The median childhood weight centile for each grade was 10<sup>th</sup>, 10<sup>th</sup>, 3<sup>rd</sup> and 2<sup>nd</sup> ( $p=0.08$ ) while the median childhood height centile was 2<sup>nd</sup>, 2<sup>nd</sup>, 3<sup>rd</sup> and 0.4<sup>th</sup> ( $p=0.5$ ).

In conclusion, severe feeding difficulties in infancy are a predictor of marked speech delay, special educational need and poor educational attainment in later life. Such feeding difficulties may be an early manifestation of neurological impairment and it is of note that there is little correlation with growth restriction, suggesting that the poor nutritional intake in infancy is not the major cause of developmental delay.

**Evaluation of genotype-phenotype correlations for vestibular schwannoma growth rates in neurofibromatosis 2**

**(NF2).** *D.M. Parry*<sup>1</sup>, *A. Jackson*<sup>2</sup>, *A.J. Wallace*<sup>3</sup>, *L. Kluwe*<sup>4</sup>, *V.-F. Mautner*<sup>5</sup>, *R.T. Ramsden*<sup>6</sup>, *D.G.R. Evans*<sup>3</sup>, *M.E.*

*Basler*<sup>7</sup>. 1) Genetic Epidemiology Branch, National Cancer Institute, Bethesda, MD, USA; 2) Division of Imaging Science and Biomedical Engineering, University of Manchester, Manchester, UK; 3) Department of Medical Genetics, St. Mary's Hospital, Manchester, UK; 4) Department of Neurosurgery, University Hospital Eppendorf, Hamburg, Germany; 5) Department of Neurology, Klinikum Nord Ochsensoll, Hamburg, Germany; 6) Department of Otolaryngology, Manchester Royal Infirmary, Manchester, UK; 7) Los Angeles, CA, USA.

We reported that age at onset of symptoms or age at diagnosis was an important determinant of vestibular schwannoma (VS) growth rates in NF2, although growth rates were highly variable, even among multiple patients of similar ages in the same family (J Neurosurg 2002;96:217-22 and 223-28). In this study, we evaluated genotype-phenotype correlations for VS growth rates in NF2. We retrospectively measured serial VS volumes from gadolinium-enhanced MRI scans in 80 patients from 62 NF2 families; the median length of observation was four years. SSCP was used to screen for constitutional *NF2* mutations. Linear regression was used to compare VS growth rates of patients with splice-site mutations, missense mutations, in-frame deletions, or unidentified mutations to growth rates in patients with nonsense or frameshift mutations. VS growth rates tended to decrease exponentially with increasing age at initial VS volume measurement ( $r^2 = 0.26$ ,  $P < .001$ ), and there was high intra-familial variability in VS growth rates. In three families with missense mutations, the intrafamilial variability in VS growth rates among patients of similar ages was 1.3-fold, 1.8-fold, and 31.2-fold. After accounting for age at initial VS volume measurement, VS growth rates were not significantly lower in people with any type of non-truncating mutation, or in people with unidentified mutations, than in people with nonsense or frameshift mutations. These results suggest that, in addition to age, as-yet-unknown factors are important determinants of VS growth rates in NF2 (e.g., growth factors, modifying genes, or complex interactions).

**Genome wide screen for cryptic deletion in case-parent trios with CHARGE Syndrome and development of an Expected Deletion Detection (EDD) metric.** *J. Belmont<sup>1,2</sup>, L.M. Lalani<sup>1</sup>.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept of Pediatrics; Baylor College of Medicine.

CHARGE syndrome is characterized by congenital heart disease, coloboma of the eye, choanal atresia, retardation of mental and somatic development, genital abnormalities, ear abnormalities and/or deafness. Because of the complex phenotype, overlap with velocardiofacial syndrome, and the relatively high frequency, one hypothetical etiological mechanism is a cryptic deletion. We undertook a high-resolution genome wide screen using 9 CHARGE case-parent trios testing for Mendelian inconsistency with 3258 single nucleotide polymorphism (SNP) markers. The average marker spacing was approximately 880kb. Across all markers, Mendelian inconsistencies could be used to estimate the observed and actual genotype error rate. We developed a novel analytical method to estimate the proportion, Expected Deletion Detection (EDD), of deletions of a specified size that might be detected in the experimental sample. The method takes into account the intermarker distances over floating windows of 3 markers each. It allows estimation of possible consequences of the suspected deletion covering 1, 2, or 3 markers depending on its size and position in the window. The model also takes into account the incomplete information provided by diallelic SNPs and the effect of allele frequencies on the proportion of undetected deletions. The model assumes a uniform deletion i.e. EDD increases with number of trios, but in order to accommodate the underlying genotype error rate a threshold of 2 inconsistencies per marker was employed. In this way single chromosome maps were generated giving an overview of the regions unlikely to bear a deletion of at least 2 Mb. A single marker gave genotypes violating Mendelian inheritance in 4 pedigrees. Followup FISH and genotypes of adjacent markers failed to confirm the presence of a deletion, however.

**A novel polymorphic site at the mutation hot-spot(TM VI)of the luteinizing hormone receptor in a patient with familial male-limited precocious puberty.** *M.YK. Leung<sup>1</sup>, V. Baxendale<sup>1</sup>, E. Leschek<sup>2</sup>, S.M. Wu<sup>1</sup>, K. Fichman<sup>3</sup>, W.Y. Chan<sup>1,4</sup>, O.M. Rennert<sup>1</sup>.* 1) LCG, NICHD, NIH, Bethesda, MD; 2) Developmental Endocrinology Branch, NICHD, NIH, Bethesda, MD; 3) Department of Pediatrics, Kaiser Permanente, San Rafael, CA; 4) Departments of Pediatrics and Cell Biology, Georgetown University, Washington, DC.

Activating mutation of the human luteinizing hormone receptor (hLHR) is the cause of familial male-limited precocious puberty (FMPP). The symptom is characterized by LH independent elevated testosterone level and the early onset of puberty in boys. There are at least 16 such hLHR mutations reported, which affect 13 a. a. residues. The mutations are located in transmembrane helices (TM) I, II, III, V, and VI and cytoplasmic loop 3. Eight of the mutations, are located in TMVI. TMVI is, thus, the hot-spot for activating mutations. A 4/12 year old patient with enlarged penis, pubic hair development, tall stature (39 inches), prepubertal LH levels but elevated testosterone was referred to our laboratory for molecular diagnosis of FMPP. Congenital adrenal hyperplasia in the patient had been excluded. Analysis of hLHR exon 11 by nucleotide sequencing revealed the presence of a heterozygous A1738G transversion mutation in TMVI. The mutation changed threonine-580 to alanine. The mutant hLHR cDNA was transiently expressed in HEK293 cells to study basal cAMP production and the response to hCG stimulation. The mutated receptor was unable to trigger a cAMP level higher than that of wild-type hLHR in the absence of hCG. The response of the mutated and wild-type hLHR to hCG stimulation was comparable. Thus, although the mutation is located in the hot-spot and caused considerable change in the characteristic of the affected a. a. residue, no increased activity of the mutant hLHR was observed. Therefore, it is unclear whether this patients precocious puberty can be ascribed to this mutation in hLHR. These observations suggest that caution should be taken in the interpretation of results of molecular analysis in the diagnosis of FMPP and emphasized the importance of in vitro expression studies to confirm the biological consequences of detected mutations.

**Description of the Pulmonary Function Tests in 13 Spondylothoracic Dysplasia Patients.** *A. Cornier<sup>1</sup>, A.A. Reis<sup>1</sup>, J.M. Massanet<sup>1</sup>, J.R. Acevedo<sup>3</sup>, S.E. Carlo<sup>1</sup>, V. Franceschini<sup>1</sup>, H. Rivera<sup>1</sup>, N. Ramirez<sup>2</sup>.* 1) Dept Biochemistry, Ponce Sch Medicine, Ponce, PR; 2) Departement of Orthopedics, Mayaguez Medical Center, PR; 3) Department of Nursing, Univ.PR-Arecibo, Arecibo, PR.

Spondylothoracic dysplasia (STD; MIM#277300) is an autosomal recessive disorder with high prevalence in the Puerto Rican population. Findings include segmentation and formation defects throughout cervical, thoracic and lumbar spine such as hemivertebrae, block vertebrae, and unsegmented bars with fusion of the ribs at the costo-vertebral junction (crab-like chest configuration). Pulmonary hypertension has also been described. It was generally regarded as a lethal condition in the neonatal period. However, we have prospectively followed a series of 13 patients, of which 6 were males and 7 were females, ranging from 7 to 49 years old, because the minimum age required for pulmonary function testing is 7 years, in our genetics clinic. Pulmonary function tests were performed by a respiratory care technician and supervised by a respiratory medicine specialist to all patients. The pulmonary function tests showed a severe restrictive pattern with an average FEV1/FVC ratio of 0.9. The average measurements were: FVC: 27.1 %, FEV1: 27.7 %, PEF: 43.0 %, of the predicted values for the group. Even though these values tend to be slightly higher in the female population (FVC: 30.1 %, FEV1: 28.5 %, PEF: 49.1 %) than in the male population (FVC: 23.8 %, FEV1: 25.4 %, PEF: 35.8 %), statistical analysis has not shown the differences to be significant (p values of 0.631 for FVC, 0.359 for FEV1, and 0.394 for PEF). This restrictive pattern may be due to the severely shortened thoracic vertebral column and the fusion of all the ribs at the costo-vertebral junction, which makes for a rigid chest wall that prevents the use of secondary muscles for breathing. Consequently, the diaphragm is pushed downwards and reaches the level of the iliac crests, resulting in a protuberant abdomen with increased pressure and propensity to hernias. Despite the harshly limited vital capacity, these patients do not show any impairment in their daily activities. They are able to work and exercise without major pulmonary problems.

**An obviously dysmorphic face maybe a predictor of cognitive impairment in Fetal Anticonvulsant Syndrome.** *U. Kini*<sup>1</sup>, *A. Fryer*<sup>2</sup>, *J. Clayton-Smith*<sup>1</sup>, *Liverpool Manchester Neurodevelopmental Study Group.* 1) Dept Clinical Genetics, St Mary's Hosp, Manchester, United Kingdom; 2) Dept Clinical Genetics, Alder Hey Children's Hospital, Liverpool, UK.

Prenatal exposure to antiepileptic drugs (AEDs) is known to cause dysmorphic facial features, major malformations and cognitive impairment in the child. Although the facial features and major malformations can be identified soon after birth, the cognitive impairment is not evident until later on in life. We determined the prevalence of dysmorphic features in children exposed prenatally to specific AEDs to investigate if the face of fetal anticonvulsant syndrome can be used as predictor of cognitive impairment in these children. **Methods:** In a retrospective study of 218 mothers recruited from regional epilepsy clinics in Manchester and Liverpool, we assessed 375 children exposed to different AEDs. Structured interviews, clinical examination and psychometric tests (WISC) were used to assess exposure, dysmorphic features and IQ (intelligence quotient). Blind assessment of photographs of children including those from early childhood were used to categorise children as mildly, moderately and severely affected based on dysmorphic features. **Results:** Dysmorphic features were more commonly seen in children exposed to valproate (VPA), with 44%; having moderate to severe dysmorphic features in contrast to those exposed to carbamazepine (9.2%) and the non-exposed, NE (2.2%). The mean full scale IQ in children exposed to VPA (87.2, CI 81.9 to 92.5) was lower than that in the NE group (89.5, CI 85.5 TO 93.4). The mean verbal IQ (VIQ) was significantly lower in the VPA group (83.61, CI 78.2 to 89.0) compared to NE (90.9, CI 87.2 to 94.6); of those with moderate to severe features had a very low IQ (less than 79). There was a significant correlation between VIQ and dysmorphic features in the VPA group (Spearman's rho = -0.436). **Conclusion:** The retrospective nature of our study precludes the ascertainment of absolute risks. Nonetheless, these results suggest that there may be a correlation between the degree of dysmorphism and the likelihood of significant cognitive impairment, particularly with VPA exposure.

**HOMOZYGOSITY FOR CAG MUTATION IN HUNTINGTON DISEASE IS ASSOCIATED WITH A MORE SEVERE CLINICAL COURSE.** *F. Squitieri*<sup>1</sup>, *C. Gellera*<sup>2</sup>, *M. Cannella*<sup>1</sup>, *C. Huntington disease (HD) patients with two mutant alleles are very rare. In this multicenter study, we sought differences in the disease features between eight homozygotes and 75 heterozygotes for HD mutation. We compared clinical features of subjects homozygotes (age at onset, symptom presentation, disease severity, and disease progression) with those of a group of heterozygotes, longitudinally assessed. The age at onset of symptoms in the homozygote cases was within the range expected for heterozygotes with the same CAG repeat lengths (homozygotes 51.32.7 vs heterozygotes 48.63.9 years), whereas homozygotes had a more severe clinical course ( $p=0.0002$ ). The observation of a more rapid decline in motor, cognitive and behavioural symptoms in homozygotes was consistent with the extent of neurodegeneration as available at imaging in three patients and at the post-mortem neuropathological report in one case. Our analysis suggests that though homozygosity for the HD mutation does not lower the age at onset of symptoms it affects the phenotype and the rate of disease progression pointing to the possibility that the mechanisms underlying age at onset and disease progression in HD may differ.

**A clinical, molecular genetic and neuro-otological features in 140 cases of Spinocerebellar ataxia type 6 subjects.**

*H. Takahashi*<sup>1</sup>, *K. Ishikawa*<sup>1</sup>, *T. Tsutsumi*<sup>2</sup>, *K. Kitamura*<sup>2</sup>, *H. Mizusawa*<sup>1</sup>. 1) Department of Neurology and Neurological Science, Tokyo Medical and Dental University Graduate School of Medicine, 1-5-45 Yushima, Bunkyo-ku, Tokyo 113-8519, Japan; 2) Department of Audio-Vestibular Neuroscience.

[Purpose] Spinocerebellar ataxia type 6 (SCA6) is one of autosomal dominant cerebellar ataxias (ADCAs) and is caused by a small CAG-repeat expansion in the alpha1A (P/Q type)-subunit of voltage-gated calcium channel gene. Although the main clinical feature of SCA6 is slowly progressive ataxia, other additional symptoms are highly variable in past reports. The purpose of this report is to clarify the clinical, molecular genetic and neuro-otological characteristics of SCA 6 in a large number of Japanese cases with SCA 6. [Methods] We retrospectively analyzed clinical features of SCA6 patients molecularly diagnosed in our department. In total 140 patients were available of detailed clinical information and their clinical and molecular genetic findings were analyzed. Neuro-otological examinations were performed in 22 patients in the Department of Audio-Vestibular Neuroscience. [Results] Cerebellar signs were seen in nearly 100 % of SCA6 patients and nystagmus was present in 66.6 %. Some SCA6 patients had additional neurological features such as hyperreflexia (6.0%), tremor (8.6%), hyporeflexia (15.2%) and impaired vibration sense (4.3%), but these additional signs were variable, infrequent and, of mild degree. Neuro-otological findings suggested the close relationship between downbeat positioning nystagmus (DPN) and positioning vertigo. In caloric test visual suppression was frequently observed without caloric weakness. [Conclusion] Although the main clinical feature of SCA6 was slowly progressive ataxia, other additional symptoms including episodic symptoms were infrequent. Neuro-otological findings demonstrated purely cerebellar eye movement disorders, and positioning vertigo with DPN indicating SCA6 seemed to be related to the disturbance of cancellation of the vestibulo-ocular reflex.

**Genetic disturbances in Silver-Russell syndrome and significance for molecular genetic testing.** *T. Eggermann<sup>1</sup>, E. Meyer<sup>1</sup>, C. Obermann<sup>1</sup>, H. Wollmann<sup>2</sup>.* 1) Human Genetics, University Hospital, Aachen, Germany; 2) University Childrens Hospital, Tuebingen, Germany.

Silver-Russell syndrome (SRS) describes a uniform malformation syndrome characterised by severe intrauterine and postnatal growth retardation (IUGR/PGR), a small triangular face, clinodactyly V, relative macrocephaly and other less constant features. The syndrome is heterogeneous and various genetic findings have been associated with SRS. However, only chromosomes 7 and 17 are consistently involved in SRS. A subset of 7-10% of SRS patients shows complete or segmental maternal uniparental disomy of chromosome 7 (UPD(7)mat); additionally, five SRS patients have been described carrying rearrangements in 7p. Thus a central role of chromosome 7 in the aetiology of SRS can be delineated, while the contribution of chromosome 17 is uncertain. Disease causing mutations in genes on chromosomes 7 and 17 have not yet been identified. Nevertheless, the following diagnostic procedure should be offered routinely to elucidate causative genetic factors in SRS: after exclusion of chromosomal aberrations patients with the typical clinical signs of SRS (severe IUGR/PGR <P3; triangular face, clinodactyly V, relative macrocephaly, asymmetry) should be tested for UPD(7)mat using microsatellite markers localised in the candidate regions 7p12-p14 and 7q31-qter. To exclude cryptic deletions or duplications in 7p12-p14 escaping the aforementioned techniques we now established a real-time PCR approach based on TaqMan technology. We thereby quantified the copy number of GRB10 in 50 SRS patients, a gene in 7p which has almost been affected by the chromosomal disturbances reported for this region. By testing DNA of a patient with a duplication in 7p we could demonstrate the reliability and robustness of this test.

**Familial blepharophimosis and female sterility report in three generations in an Iranian family, Mashhad, North East of Iran.** *R. Akbarzadeh<sup>1</sup>, K. Ghodsi<sup>1</sup>, D. Farrukh Tehrani<sup>2</sup>, N. Khadem<sup>3</sup>.* 1) Department of Medical Genetics, Ghaem Hospital, Faculty of Medicine, Mashhad University of Medical Sciences, Mashhad, Khorasan, Iran; 2) Department of Ophthalmology, Ghaem Hospital, Faculty of Medicine, Mashhad University of Medical Sciences, Mashhad, Khorasan, Iran; 3) Department of Gynecology, Imam Reza Hospital, Faculty of Medicine, Mashhad University of Medical Sciences, Mashhad, Khorasan, Iran.

**Introduction:** Blepharophimosis/ptosis/epicanthus inversus syndrome (BPES) is a rare genetic disorder, but a well documented genetic condition that occurs sporadically and is transmitted by autosomal dominant inheritance that is characterized by distinctive eyelid abnormalities. This syndrome has been mapped to 3q23 chromosome. **Materials and Method:** To describe the clinical features, mode of inheritance, and linkage analysis twelve affected members of a three-generation family with BPES. Diagnosis was definite based on the clinical findings. Peripheral blood samples were taken and cells were harvested. GTG banding chromosomes were analyzed. **Results:** We reported on twenty-two individuals a family referred for genetic evaluation because of (BPES). Twelve of these patients had the blepharophimosis syndrome. Pedigree analysis showed autosomal dominant inheritance in this family. Ocular examination revealed residual ptosis, blepharophimosis and epicanthus inversus in both eyes. There was no history of consanguinity. The mother had not received any medication and had not been exposed to radiation during pregnancy. None of the members of this family showed evidence of other systemic disorders and no other abnormality was detected. Chromosomal analysis of peripheral blood was performed after high resolution banding showed an apparently normal. **Conclusion:** All currently reported cases of BPES show interstitial deletions or balanced translocations involving 3q22-q23. Our patients demonstrated an autosomal dominant, characteristic with a very high penetrance and expressivity, preferentially affecting and being transmitted by males. Affected females were infertile. It is possible that our patient has a contiguous gene defect including at least one locus for a type of blepharophimosis.

Program Nr: 740 from 2003 ASHG Annual Meeting

**Anophthalmia, Esophageal atresia and Genital anomalies: Three new cases.** *A.S. Schneider, T.M. Bardakjian.* Dept Genetics, Albert Einstein Medical Ctr, Philadelphia, PA.

The A/M Registry at Albert Einstein Medical Center (AEMC) was established in 1994 and has been offering eye development gene screening to registry participants since 1999. Testing involves mutational screening of 17 eye development genes in 8 participating labs in the US and Europe. To date we have collected clinical information on 200 cases in the Registry and DNA on 280 affected individuals. A review of the Registry revealed three patients with bilateral anophthalmia, esophageal atresia and genital anomalies. We will introduce three new cases of Anophthalmia and Esophageal Atresia Association. Since 1988, when Rogers first described a boy with esophageal atresia and anophthalmia, 9 patients with the association have been reported in the literature. Our cases appear to be distinct from those already described in the literature, thus increasing the number of cases with this association to twelve. Patient 1 is a 4-year-old male with bilateral anophthalmia, TE fistula and hypospadias who had a VSD repair. Case 2 is a 9-year-old male with bilateral anophthalmia, esophageal atresia and cryptorchidism. His clinical findings include hydrocephalus and holoprosencephaly. Case 3 is an 11-year-old male with bilateral anophthalmia, TE fistula, cryptorchidism and developmental delay. Two of these 3 patients have participated in the gene screening and no mutations have been identified to date. Further screening of these individuals is underway and we are in the process of obtaining DNA on Case 3 for analysis. We will describe the clinical findings in these patients and the gene studies performed including the identification of unusual polymorphisms in some cases. Our goal is to ultimately use these phenotypic descriptions to help guide the labs to screen specific genes.

**Familial Horizontal Gaze Palsy: Report of a UAE Family Demonstrating Autosomal Recessive Inheritance.** *E.I. Traboulsi<sup>1</sup>, L.J. Wang<sup>1</sup>, Q. Wang<sup>1</sup>, A. Mousawi<sup>2</sup>, E. Engle<sup>3</sup>.* 1) Cole Eye Institute, Cleveland Clinic Foundation, Cleveland, OH; 2) Al-Jazeirah Hospital, Abu Dhabi, United Arab Emirates; 3) Departments of Genetics and Neurology, Boston Children's Hospital, Harvard Medical School.

**Purpose:**To report a UAE family with 5 siblings affected with horizontal gaze palsy. **Methods:** Clinical examination and surgery on four affected members of a family comprised of five affected siblings, five unaffected siblings and consanguineous parents. **Results:** Two brothers and two sisters (ages 4 - 17 years) had congenital bilateral esotropia and abnormal eye movements since birth. The clinical manifestations were identical in all four patients. There was no ptosis. Abduction was severely limited bilaterally. Vertical ocular movements were normal. There were convergence-like eye movements on attempted abduction in lateral gaze. Visual acuity was very good in all patients, reflecting probable alternating fixation. Forced duction testing under general anesthesia revealed very tight medial rectus muscles in all patients. None of the children had severe scoliosis. Bilateral medial rectus recession resulted in good ocular alignment in primary position of gaze without any alteration of the abnormal ocular movement pattern. **Conclusions:** This large family appears to have the rare disorder known as recessive horizontal gaze palsy with progressive scoliosis.

**Atypical X-Inactivation in an X;1 Translocation Patient with Oto-Palato-Digital Syndrome.** *C.E. Cottrell<sup>1,2</sup>, A. Sommer<sup>1,2</sup>, G.D. Wenger<sup>1,2</sup>, K. Krahn<sup>3</sup>, A. Modesto<sup>3</sup>, L. Van Westen<sup>3</sup>, S. Bullard<sup>3</sup>, W.R. Wilcox<sup>4</sup>, T. Ogata<sup>5</sup>, A.C. Lidral<sup>3</sup>, J.M. Gastier<sup>1,2</sup>.* 1) Columbus Children's Hospital, Columbus, OH; 2) The Ohio State University, Columbus, OH; 3) Univ. of Iowa, Iowa City, IA; 4) Cedars-Sinai/UCLA, Los Angeles, CA; 5) Natl Inst for Child Health and Dev., Tokyo, Japan.

X-inactivation is a critical mechanism which allows for dosage compensation in humans. Transcriptional silencing of one X-chromosome occurs in female somatic cells to prevent overexpression of X-linked genes. X-inactivation is random, but in cases of an X;autosome translocation, the normal X is inactivated to prevent monosomy of autosomal genes. Oto-palato-digital (OPD) syndrome is an X-linked (Xq28) craniofacial condition involving cleft palate, hearing loss, and multiple skeletal anomalies. Recently, Robertson et al. reported that mutations in the FLNA gene (Xq28) cause OPD [Nature Genet. 33, 487-491 (2003)]. The mutations are described as having gain-of-function effects on the protein product, filamin A. A patient with a translocation [46,X,t(X;1)(q28;q21)de novo] and clinical features of OPD was studied to characterize the molecular cause of OPD. **Purpose:** To characterize the etiology of OPD syndrome in the patient. **Methods:** The research plan included FISH to narrow the critical region, PCR analysis of somatic cell hybrids, RT-PCR using candidate genes, and X-inactivation studies of the patient. **Results:** The patient was found to have a breakpoint in the DKC1 gene (400kb downstream of FLNA). The patient has an extremely skewed pattern of X-inactivation, with preferential inactivation of the derivative X. RT-PCR results showed that both DKC and FLNA are being expressed. A PCR analysis of FLNA ruled out large deletions in the patient. **Conclusions:** Despite being clinically diagnosed with OPD syndrome, the etiology of the disease remains unclear in this patient. Functional disomy of genes in the Xq28 region, in addition to partial monosomy of chromosome 1q are possible consequences of the patients X-inactivation pattern. If the mutations in FLNA which cause OPD are truly gain-of-function (as reported in Robertson, et al.), it is possible that our patients phenotype is caused by overexpression of filamin A protein.

**Gonadal Mosaicism in Incontinentia Pigmenti: a case report.** *K.L. Chong<sup>1</sup>, B.R. Krafchik<sup>2</sup>, B.B. Roa<sup>3</sup>*. 1) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hosp, Toronto, ON, Canada; 2) Hospital for Sick Children Toronto, ON, Canada; 3) Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, Texas.

Incontinentia pigmenti (IP) is an X-linked dominant condition characterized by changes to the skin, hair, teeth and nails. Cognitive delays are occasionally seen. IP is lethal in most, but not all males. Gonadal mosaicism has been previously demonstrated in a father. We report a couple with two daughters with classical dermatological findings of IP. The older daughter is 5 years old and has skin findings, conical teeth, thin hair and pitted nails. Her development is normal to date. Molecular testing for the common deletion in the IKBKG gene is found in approximately 80% of female patients affected with IP. This deletion was absent in our patient as well as in her parents suggesting a de novo mutation in the IP gene. The couple's second daughter was born in 2002 and had skin findings at birth strongly suggestive of IP. This mother is not affected clinically with IP and both parents have negative molecular testing. Thus, the possibility of gonadal mosaicism in either parent is hypothesized.

**A new family with X-Linked Lissencephaly: description of Brazilian family.** *C.D. Martinhago<sup>1</sup>, A.C. Laus<sup>2</sup>, G.N. Simao<sup>3</sup>, L. Martelli<sup>1,2</sup>, J.M. Pina Neto<sup>1,2</sup>.* 1) Medical Genetics, HCFMRP - University of Sao Paulo, Brazil; 2) Dept. Genetics, School of Medicine of Ribeirao Preto - University of Sao Paulo, Brazil; 3) Dept. of Radiology, HCFMRP - University of Sao Paulo, Brazil.

X-linked lissencephaly and subcortical band heterotopia is familial neuronal migration disorder secondary with DCX mutations. The gene, doublecortin (DCX), is located in Xq22.3. Males have very limited development with neurological findings that begin soon after birth, develop seizures of variety types, hypotonia and spasticity. Female, however, often have mild to moderate mental retardation, but some have normal intelligence. Besides that, females usually have mild alterations with subcortical laminar heterotopia and severe form in males with agyria-pachygyria complex, like in this family, where a female has mild alterations in cerebral cortex than male. The LIS1 gene, located in 17p13.3, can be also associated with classical lissencephaly. In X-linked LIS, the malformation is more severe in the frontal lobes, whereas in chromosome 17, LIS severity is maximal in the occipital lobes. We reported a family, mother (patient 1), her two sons (patient 3 and 4) and their cousin (patient 6), that show the X-linked LIS abnormalities. The brain MRI study showed remarkable similarity structural alterations in the frontal lobes, characterized by abnormal thick cortex with broad but shallow gyri and a poorly defined boundary of the cortex and white matter, defined as pachygyria. These abnormalities were observed in patients 3, 4, 1 and 6 (two brothers, mother and a cousin). Patient 1 presents a mild form of pachygyria. All patients with this abnormal cortex present a subcortical band of gray matter, a laminar heterotopia. Patients 4, 1 and 6, the laminar heterotopia, was localized in frontal anterior lobes and in patient 3 in parietal lobes. The cortical sulci overlying the bands often appear abnormally shallow. There were areas with malformations between band heterotopia and pachygyria. Cytogenetic and FISH (Miller-Dieker 17p13.3 probe) studies were performed on peripheral lymphocytes of patient 1,3 and 4 which results were normal. Supported by: FAEPA-HCFMRP, University of Sao Paulo.

**FMRP, *FMRI*-mRNA, and psychopathology correlations in women with the fragile X premutation.** *S.W. Harris, F. Tassone, I. Barbato, R.J. Hagerman.* M.I.N.D. Institute, UC Davis Medical Center, Sacramento, CA.

Females with the premutation typically have a normal IQ, although approximately 25% may have limited physical features of fragile X, such as prominent ears, or psychological problems, such as depression or anxiety. We have only rarely seen the fragile X tremor/ataxia syndrome (FXTAS) in females. The presence of FXTAS in males is thought to be related to a gain of function toxic effect of elevated mRNA levels. Since it has been previously reported that females with the premutation also have elevated *FMRI*-mRNA levels, we wanted to explore whether the psychological features in premutation carrier females are related to molecular parameters, including *FMRI*-mRNA and FMRP levels.

We studied 10 females with the *FMR1* premutation, and carried out molecular analysis, including immunocytochemical FMRP levels and *FMR1*-mRNA levels. We also administered several cognitive and psychological measures, including the Symptom Checklist-90-Revised (SCL-90-R), which is a measure that quantifies several domains of psychopathological functioning. We found that FMRP was negatively correlated ( $p=.04$ ) with the depression domain on the SCL-90-R, such that lower levels of FMRP predicted higher scores, or more psychopathology, on the depression scale of the SCL-90-R. There was no significant relationship found between *FMR1*-mRNA level and any of the domains of the SCL-90-R. Thus far, these data suggest that depression is related to FMRP deficits and not to a toxic effect of elevated mRNA, and we plan to expand our analysis to over 30 subjects, so that we will gain a broader picture of the clinical-molecular phenotype in these women.

**A severe form of X-linked encephalopathy maps to chromosome Xp22.** *G. Viot*<sup>1</sup>, *I. Giurgea*<sup>2</sup>, *I. Desguerre*<sup>3</sup>, *A. Munnich*<sup>2</sup>, *P. de Lonlay*<sup>2</sup>. 1) Dept Genetics, Hopital Necker-Enfants Malades, Paris, France; 2) INSERM U393, Hopital Necker-Enfants Malades, Paris, France; 3) Dept Pediatrics, Hopital Necker-Enfants Malades, Paris, France.

We report a novel form of X-linked encephalopathy in a family of seven affected males over five generations. The affected males had cholestasis at birth, followed by hepatomegaly with steatosis and coarse facies. The neurological development was normal until one month, then the affected boys developed myoclonic seizures, dystonia, abnormal eye movement and dead in the first year of life. MRI investigation displayed white matter and brain stem abnormalities. Plasma (uricemia, very-long-chain fatty acid, phytanic and pipecolic acid) and urinary investigations (amino acids and organic acids, sulfites, oligosaccharides, mucopolysaccharides) were normal. Lactate, neurotransmitters, amino acid, glucose, creatine and guanidino-acetate in the CSF were normal as well. Visual evoked potentials, electroretinogram and respiratory chain enzyme activities in skeletal muscle and liver biopsies were unremarkable. Liver electronic microscopy revealed abnormal peroxysomes with vacuole density abnormalities. A chromosome X-wide linkage analysis allowed us to map the disease gene to chromosome Xp22 between DXS8051 and DXS8027 (Z=2, =0). This 15 Mb region encompasses the Serine/Threonine Kinase gene (STK9) which accounts for a mental retardation and West syndrome. The sequencing of this gene is in process. To date, not similar clinical presentation with severe encephalopathy and early death has been mapped to this region.

**Subtelomeric rearrangements in cases with mental retardation and dysmorphic features.** *C. Lozzio, T. Ryan, E. Bamberger, W. Carter, E. Ralston, C. Worthington, M. Huckaba.* Dept Medical Genetics, Univ Tennessee, Knoxville, TN.

Subtelomeric aberrations were studied using Vysis ToTelVysion probe panel. Abnormalities were detected in cases with normal karyotypes and the chromosomes involved in "de novo" rearrangements were identified. A 2 years old female with deletion 4p had a milder phenotype than the classical Wolf-Hirschhorn syndrome and showed developmental delay, failure to thrive, dysmorphic features and microcephaly. A deletion 4q was found in a 4 years old female with speech delay and dysmorphic features. A deletion 9q was observed in a 9 years old female with moderate mental retardation, autistic behavior, dysmorphic features and microbrachycephaly. A deletion Yq12 and trisomy Yp11.3 were observed in a 4 years old child with developmental delay and radioulnar synostosis. The father had a normal Y. A deletion 22q13.3 was found in a 4 years old female with developmental delay, ataxic gait, obesity and dysmorphic features. A der(13)t(5;13)(p15.3;q34)(tel5pX3,tel13qX1) was seen in a 4 years old female with developmental delay, microcephaly and Factor VII deficiency. Parental studies were normal. A der(1)t(1;8)(p36.3;q24.3)(1ptel-;8qtel+) was found in a 4 years old male with severe IUGR, microcephaly, developmental delay, ataxic gait and multiple dysmorphic features. A half cryptic "de novo" translocation with der(8)t(8;13)(p23;q22) was found in a 14 months old male with craniofacial asymmetry, developmental delay and hypotonia. Translocations of the telomeric regions 7q and 11p were observed in cases with apparently balanced karyotypes and abnormal phenotypes: two translocations of the 7q region included a complex rearrangement of chromosomes 2 and 7 in a 15 months old girl with infantile spasms, developmental delay, hypotonia and a t(7;8)(q36.3;q22.3) in a child with cleft lip and palate, hypodontia, microcephaly, and seizures. An inherited t(4;11)(q23;p15.30) was seen in the normal mother and in her child with Beckwith Wiederman syndrome (BWS). Maternal imprinting of the BWS region may explain these findings. These cases are examples of the types of patients in which studies with subtelomeric probes can detect or help to interpret chromosome aberrations of clinical significance.

**Cytogenetic Approaches to Finding Auditory Genes.** *R.E. Williamson<sup>1</sup>, W. Lu<sup>1,2</sup>, S. Michaud<sup>1,2</sup>, R.E. Peters<sup>2</sup>, B.J. Quade<sup>1,2</sup>, A.M. Michelson<sup>1,2,3</sup>, R.L. Maas<sup>1,2</sup>, C.C. Morton<sup>1,2</sup>.* 1) Harvard Medical School, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA; 3) Howard Hughes Medical Institute.

Hearing loss is a common sensory disorder with an estimated incidence of 1 in 1000 human births. Approximately half of cases are attributed to environmental factors, while at least 50% are due to genetic causes. Genes with a role in the auditory system have been identified through both genetic linkage studies of families with heritable deafness and positional candidate gene approaches. Another method for gene discovery is to ascertain deaf individuals that carry balanced translocations and identify disrupted or dysregulated genes at the site of chromosomal rearrangement. Here, FISH experiments were performed to map the breakpoint regions on each of four derivative chromosomes in two deaf individuals. One case, designated DGAP090, has a translocation between chromosomes 8 and 9 [t(8;9)(q13;p22)]. Breakpoints were assigned initially by GTG-banding and BAC probes for FISH experiments to map precisely the breakpoints were chosen based on proximity to the assigned region. Successive FISH experiments were then performed to identify a split BAC that hybridized to the normal chromosome as well as to both of the derivative chromosomes. Further refinement of the breakpoint was done using PCR products in FISH experiments and in Southern blot analysis. The chromosome 8 breakpoint disrupts a hypothetical annotated sequence and, on chromosome 9, a known gene, methylthioadenosine phosphorylase (*MTAP*), is located in the breakpoint region. It is hypothesized that a disruption of *MTAP* would lead to deafness due to its role in metabolizing an inhibitor of polyamine synthesis. The other case, DGAP056, has a translocation between chromosome 2 and chromosome 13 [t(2;13)(p24;q21)]. Initial analyses suggest that the chromosome 2 break is within the sequence for a hypothetical gene, *FLJ21820*. This gene is expressed in the cochlea and Northern blot analysis shows that it is more highly expressed in fetal tissues than in adult tissues. A knock out mouse is being created to establish the role of *FLJ21820* in the auditory system.

**Y chromosome microdeletions in male infertility.** *N.B. Abdelmoula<sup>1</sup>, L.A. Keskes<sup>1</sup>, T. Bienvenu<sup>2</sup>, T. Rebai<sup>1</sup>, A. Bahloul<sup>3</sup>, H. Ayadi<sup>4</sup>.* 1) laboratoire d'histologie, facult de mdecine de sfax, sfax, Tunisia; 2) Laboratoire de biochimie et de genetique moleculaire, Hpital Cochin AP-HP Paris, France; 3) Service d'urologie, CHU H. Bourghuiba Sfax, Tunisia; 4) Laboratoire de genetique moleculaire humaine facult de mdecine de sfax, sfax, Tunisia.

Microdeletions in Yq11 overlapping azoospermia factors (named AZFa, AZFb, AZFc and AZFd for azoospermia factors a, b, c and d) are recurrently detected in about 10-15% of idiopathic azoospermia and severe oligozoospermia. AZFc deletions, involving the DAZ gene, form the majority of these deletions. Screening for Y chromosome microdeletions is often performed by analyzing the presence of Y chromosome-specific markers using multiplex PCR. This strategy requires many precautions to minimize the number of false-negative or false-positive results. So, it becomes limiting in a clinical context. In this study we used a rapid molecular genetic strategy to identify DAZ gene deletion in a group of 36 infertile patients. The experiment consists of amplifying simultaneously DAZ and DAZ like-autosomal genes followed by a separation of the two PCR products with good resolution using denaturing gradient gel electrophoresis (DGGE). DAZ microdeletions were detected in one patient among 20 oligospermic men (5%) and in two patients among 16 azoospermic men (12,5%). Our finding suggest that Y microdeletions, especially at AZFc region, occur frequently in idiopathic male infertility and demonstrate that PCR-DGGE method for detection of DAZ gene deletion could be particularly useful for screening of the DAZ locus in the diagnosis workup of nonobstructive azoospermia and severe oligozoospermia in infertility clinics. Furthermore, they support the recommendation to perform genetic defect screening among infertile men before their enrolment an ICSI/IVF program.

**Sex-chromosome mosaicism in azoospermic men.** *A. Amouri<sup>1</sup>, N.B. Abdelmoula<sup>2</sup>, M.F. Portnoi<sup>3</sup>, A. Bahloul<sup>4</sup>, L. Keskes<sup>1</sup>, A. Saad<sup>5</sup>, T. Rebai<sup>1</sup>.* 1) LABORATOIRE DE CYTOGENETIQUE, INSTITUT PASTEUR DE TUNIS Tunisia; 2) LABORATOIRE D'HISTOLOGIE, FACULTE DE MEDECINE DE SFAX Tunisia; 3) LABORATOIRE DE CYTOGENETIQUE, HOPITAL SAINT-ANTOINE PARIS France; 4) SERVICE DUROLOGIE, HOPITAL HABIB BOURGUIBA SFAX Tunisia; 5) LABORATOIRE DE CYTOGENETIQUE HOPITAL FARHAT HACHED SOUSSE Tunisia.

Patients with azoospermia have an elevated impact of numerical abnormalities of X chromosome. mosaic have less severe features and may be fertile, as there may be a normal clone of the cells within the testes. They can be proposed for ICSI with testicular sperm extraction (TSE) after genetic counselling. Nonmosaic patients can also (but less better than mosaic patients) rely in ICSI with TSE and then become fathers. The aim of this study was to detect sex chromosome abnormalities among azoospermic men and to evaluate the sensitivity of fluorescence in situ hybridization (FISH) techniques to assess mosaicism mainly in Klinefelters patients in comparison with classical cytogenetic methods. Among 21 azoospermic patients who were karyotyped, 10 showed a numerical sex chromosome abnormalities. Three of them have mosaic karyotype with two cells populations: 46,XY and 47,XXY. The others were homogeneous: 46, XX (one patient) and 47,XXY (six patients). Using fluorescence in situ hybridization techniques for all klinefelters patients only one among 3 showed evidence of sex chromosomal abnormalities mosaicism. We suggest that FISH analysis should be applied when sex chromosome mosaicism is shown by G or R-banding technique. We suggest that FISH analysis which is a powerful tool for detecting more sensitively mosaicism in klinefelters syndrome is recommended as a complementary test before discussing prognosis and expected risk of chromosomal aberrations in the offspring after ICSI.

**Sequential cytogenetic and molecular cytogenetic characterization of an *SV40T* immortalized nasopharyngeal cell line transformed by Epstein-Barr virus latent membrane protein-1 gene.** C. Jin<sup>1</sup>, H. Zhang<sup>2, 5</sup>, S.W. Tsao<sup>4</sup>, B. Strömbeck<sup>1</sup>, P.W. Yuen<sup>2</sup>, Y. Kwong<sup>3</sup>, Y. Jin<sup>1, 2, 3</sup>. 1) Department of Clinical Genetics, University Hospital, Lund, Sweden; 2) Departments of Surgery, Queen Mary Hospital, University of Hong Kong, Medical Centre, Hong Kong, China; 3) Departments of Medicine, Queen Mary Hospital, University of Hong Kong, Medical Centre, Hong Kong, China; 4) Department of Anatomy, Faculty of Medicine, University of Hong Kong, Hong Kong, China; 5) Department of Otolaryngology, Ruijin Hospital, Shanghai Second Medical University, Shanghai, China.

Cytogenetic and molecular cytogenetic analyses were performed on four sublines derived from a newly established, *SV40T* immortalized nasopharyngeal (NP) cell line, NP69, with two of the sublines expressing *LMPI*, an EBV encoded gene. A total of 7 cytogenetically related subclones were identified, all having highly complex karyotypes with massive numerical as well as structural rearrangements. Centromeric rearrangements, in the form of isochromosomes and whole-arm translocations, were prevalent. Cytogenetic sign of gene amplification, i.e., homogeneously staining region (HSR), was detected at chromosomal loci 1q21 in all metaphase cells analyzed. Multicolor COBRA-FISH was used to confirm the karyotypic interpretations. Furthermore, multicolor COBRA-FISH showed also that part of the HSR contained chromosome 20 material. Extensive clonal evolution could be observed by the assessment of karyotypic variation among different subclones and individual metaphase cells. The evaluation of clonal evolution enabled the temporal order of chromosome aberrations during cell immortalization and malignant transformation to be identified. A striking karyotypic similarity was found between sublines expressing *LMPI* and an NPC cell line, with loss of genetic material from chromosome arm 3p being an important recurrent observation. More interestingly, the karyotypic features of NP69 were also similar to those of many epithelial malignancies. Our observations suggest that serial transformation of NP cell lines might provide a useful in vitro model for the study of the multistep neoplastic transformation of NP cells.

**A case of infantile ALL presenting with rearrangement of MLL at 11q23 and apparent insertion/translocation at 10p(12).** *C. Tirado<sup>1</sup>, J. Lager<sup>2</sup>, V. Golembiewski-Ruiz<sup>1</sup>, P. Rosoff<sup>2</sup>, J. Gong<sup>1</sup>, B. Goodman<sup>1</sup>.* 1) Pathology. Duke Univ Med Ctr, Durham, NC 27710; 2) Division of Hematology-Oncology-Department of Pediatrics. DUMC-Durham, NC 27710.

We report an 11 month old patient with infant ALL who presented circulating lymphoblasts, history of diarrhea, paleness and poor oral intake. Her white blood cell count was  $18 \times 10^3/l$  and hemoglobin 5.5g/dL. Bone marrow analysis showed that 80% of the nucleated cells were lymphoblasts. Four drug induction therapy was initiated (Berlin-Frankfurt Munster protocol). FISH studies using the MLL break apart probe from Vysis (Downers Grove, IL) showed rearrangement within the MLL locus (11q23) in 69% of the cells examined. A very subtle rearrangement involving the short arm of chromosome 10 and the long arm of chromosome 11, was seen by routine chromosome analysis and it could only be detected with certainty in 14% of the cells examined. To clarify the nature of the MLL rearrangement, the break apart probe was also applied to previously G-banded slides. In light of the FISH studies, this rearrangement was interpreted as a small inversion within 11q23 separating the 5'MLL from the 3'MLL region. The segment on 11q containing the rearranged MLL locus was then inserted/translocated to the short arm of chromosome 10 at approximately band 10p12. There have been previous reports of rearrangements of MLL with the MLLT10 gene locus at 10p12, including interstitial inverted insertion of 11q13q23, in one case or 11q14q23 in another case at 10p12. These both resulted in a derivative chromosome 10 and transcription of an MLL/MLLT10 fusion product. Because of the limited material available in our case, further FISH and molecular characterization were not possible. To our knowledge, the novel, very cryptic rearrangement detected in our patient has not been described previously. A follow up study of the bone marrow at the end of induction revealed no morphological evidence of residual leukemia and both FISH and chromosome analyses were normal. This case illustrates the importance of performing MLL FISH in addition to routine cytogenetic analysis when the differential diagnosis includes an MLL positive leukemia.

**DiGeorge syndrome in a patient with isochromosome 18p.** *R. Deberardinis, L. Medne, E.H. Zackai.* Div Human Gen & Molec Biol, The Children's Hospital of Philadelphia, Philadelphia, PA.

DiGeorge syndrome (DGS) is a well-known phenotype in which conotruncal heart defects, hypocalcemia, thymic hypoplasia, and characteristic dysmorphisms are major clinical features. The phenotype results from abnormal development of the third and fourth branchial arches. The 22q11.2 deletion syndrome is the best-characterized etiology of DGS, although other chromosomal abnormalities, including deletions affecting chromosome 10p13, have been reported in a few patients. We present a patient with interrupted aortic arch type B (IAA-B), neonatal hypocalcemia, thymic hypoplasia, and dysmorphic features including microcephaly, thick, overfolded helices, long fingers and toes, and anteriorly-placed anus. Cytogenetic studies revealed presence of a marker chromosome, identified by FISH as an isochromosome 18p. We did not detect a 22q11.2 deletion by FISH using a cosmid probe corresponding to locus D22S75. In retrospect, the patients dysmorphisms were consistent with the tetrasomy 18p syndrome, but this is the first case suggesting that tetrasomy 18p is a DGS phenocopy. The case is particularly interesting with respect to the patients heart defect. While 50% of patients with IAA-B have a 22q11.2 deletion, this rare conotruncal anomaly is not clearly associated with any other cytogenetic abnormality and has not been seen in any patients with tetrasomy 18p.

**Genomic alterations in the endometrium may be a proximate cause for endometriosis.** *S.W. Guo<sup>1</sup>, Y. Wu<sup>1</sup>, E. Strawn<sup>1</sup>, Z. Basir<sup>1</sup>, Y. Wang<sup>2</sup>, G. Halverson<sup>1</sup>, K. Montgomery<sup>1</sup>, A. Kajadacsy-Balla<sup>1</sup>.* 1) Medical College of Wisconsin, 8701 Watertown Plank Road, Milwaukee, WI; 2) University of California, Santa Barbara, CA.

One popular theory on the pathogenesis of endometriosis is Sampson's theory that retrograde menstruation causes endometriosis. Since retrograde menstruation is nearly universal, however, there is an apparent paradox as why only a fraction of women develop endometriosis. We hypothesize that certain genomic alterations in the endometrium may predispose women to endometriosis. This hypothesis can well explain the paradox, and may also explain why some women develop microscopic lesions while others have more serious endometriosis. To test this hypothesis, we carried out a genomic analysis of endometrial tissue samples from women with endometriosis. Endometrial tissue samples were taken from five women with endometriosis. For controls, we used endometrial tissue samples from four women who underwent elective abortions and one sample from placenta. Using array-based comparative genomic hybridization (CGH), we determined the normal range of variation in CGH signals using normal controls. CGH results were further confirmed by real-time quantitative PCR and loss of heterozygosity (LOH) analysis. We identified several regions of genomic alterations in all five patients. Some of these regions were the same regions identified previously in endometriotic lesions. For select markers, the genomic alterations were confirmed by real-time PCR and LOH analyses. Therefore, there is evidence that the endometrium in women with endometriosis has genomic alterations and that genomic alterations found in endometriotic lesions may originate from endometrium. This is consistent with numerous reports that the endometrium of women with endometriosis differ from those of women without. Our finding suggests that genomic alterations in the endometrium may be a proximate cause for endometriosis.

### **Characterization of the Chromosomal Duplication Associated with Hereditary Benign Intraepithelial**

**Dyskeratosis.** *W. Lambert<sup>1</sup>, M. Maready<sup>1</sup>, M. Bembe<sup>1</sup>, H. Xu<sup>1</sup>, R. Allingham<sup>2</sup>, J. Vance<sup>1</sup>, M. Hauser<sup>1,2</sup>.* 1) Center for Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Department of Ophthalmology, Duke Univ Medical Ctr, Durham, NC.

**Purpose:** Hereditary benign intraepithelial dyskeratosis (HBID) is an autosomal dominant cell proliferation disorder characterized by opaque epithelial plaques of the conjunctiva and oral mucosa. Found primarily among a Native American tribe in North Carolina and their relatives, HBID plaques appear at birth or in early childhood. Involvement typically includes the conjunctiva, cornea, and buccal mucosa. Loss of vision secondary to corneal involvement can occur. Recently, this disorder was linked to chromosome 4q35 and the presence of three microsatellite alleles in affected individuals revealed a near-telomeric DNA duplication in this region (Allingham RR, et al. *Am J Hum Genet* 2001).

The proximal duplication endpoint was found to lie between markers D4S2299 and D4S2390 (227 kb). The purpose of this study was to further localize the proximal duplication endpoint. **Methods:**

Tandyman([www.stdgen.lanl.gov/tandyman.index.html](http://www.stdgen.lanl.gov/tandyman.index.html)) was used to identify seven novel, potentially polymorphic microsatellite markers between D4S2299 and D4S2390. Analysis of a large HBID family (27 individuals, 16 affected, 7 non-affected, and 4 potentially affected) and a control population (48 individuals) was performed using these new markers.

**Results:** Two markers located 30 kb and 64 kb proximal to D4S2390 resulted in duplicated alleles in all HBID affected individuals and in two potentially affected individuals. No duplicated alleles were observed in the control population for any of the seven markers analyzed. **Conclusions:** Based on these results the proximal duplication endpoint is located within a 46 kb region on 4q. Southern blotting will be performed to further localize the duplication endpoint. A lambda phage-based genomic library is being constructed from patient DNA in order to clone and sequence the duplication endpoint.

**Mitotic Index and Dementia Status in Down Syndrome.** *E.C. Jenkins, L. Ye, S. Li, W.B. Zigman, N. Schupf, E.A. Sersen, N. Zhong, C.M. Miezieski, S. Sklower Brooks, W.P. Silverman.* NYS Inst Basic Res Dev Disab, Staten Island, NY.

Previously, we reported a decrease in mitotic index (MI) of skin fibroblast cultures from five people with Alzheimer's Disease (DS) (Jenkins et al., 1998). Now, we have found decreased MIs in short-term whole blood cultures from 12 of 15 people with trisomy 21 and dementia compared to 13 individuals with trisomy 21 who were not demented ( $p < .01$ ). The non-demented individuals were generally age- and sex-matched with demented individuals with DS. An MI  $\leq 25$  suggested dementia while an MI  $> 25$  suggested non-dementia. Only one of the 13 non-demented trisomy 21 individuals exhibited an MI of  $\leq 25$ . The individuals with and without dementia ranged in age from 50-66 years with a mean ages of 56.95, and 55.95 for dementia and non-dementia, respectively. All classifications of dementia were consistent with the recommended criteria of the American Association on Mental Retardation, the International Association for the Scientific Study of Intellectual Disability, and the World Health Organization. Additional preliminary studies with a second group of non-demented individuals with DS but who also exhibited "mild declines" also suggested that an MI  $\leq 25$  would indicate mild decline versus generally age- and sex-matched individuals with no dementia or decline and DS ( $p = .04$ , two-tailed). This group of individuals ranged in age from 50 to 73 years with a mean age for females with cognitive decline of 54.60 years while the age for females with no decline was 53.4. Our preliminary findings indicate that reduced MI may be associated with dementia and cognitive decline in adults with DS. We will now evaluate additional individuals with dementia or with preliminary signs that may lead to dementia, such as mild declines, in order to confirm our observations reported here and to determine whether MI may be used as a marker for the potential development of dementia. (This work was supported in part by the NYS Office of Mental Retardation and Developmental Disabilities, Alzheimer's Association Grant IIRG-09-1598, and by NIH grants PO1 HD35897, HD37425, and RO1 AG014673.).

**DNA studies of mono-and pseudodicentric isochromosomes 18q.** *M. Bugge*<sup>1, 2</sup>, *C.A. Brandt*<sup>3</sup>, *M.B. Petersen*<sup>2, 4</sup>. 1) Wilhelm Johannsen Centre for Functional Genome Research, Dept Medical Genetics, Univ Copenhagen, Copenhagen, Denmark; 2) Department of Medical Genetics, The John F Kennedy Institute, Glostrup, Denmark; 3) Department of Clinical Genetics Vejle County Hospital, Denmark; 4) Department of Genetics, Institute of Child Health, Athens, Greece.

The clinical syndrome associated with isochromosome 18 (both mono-and pseudodicentric) is very similar to Edwards syndrome (trisomy 18). The parental origin has only been investigated in a very few cases so far and very little is known about the mechanisms of formation. We have diagnosed four cases with de novo isochromosomes 18q by conventional cytogenetics techniques in combination with molecular cytogenetics investigations. One case was a fetus diagnosed at prenatal diagnosis due to advanced maternal age, and three cases were liveborn children. Two cases were monocentric and two pseudodicentric. We used 23 microsatellite DNA polymorphisms covering the entire length of chromosome 18 to determine the parental origin and mechanisms of formation. In one of the monocentric cases the isochromosome had two identical q arms of maternal origin. The other monocentric case had 48 chromosomes with supernumerary isochromosomes i(18p) and i(18q) of maternal origin, probably formed by postzygotic nondisjunction of chromosome 18 followed by centromeric misdivision. In the two dicentric cases the isochromosomes had genetically identical arms composed of a part of the short and the whole long arm of chromosome 18 and were of paternal origin. The formation of the dicentric isochromosomes can be explained by postzygotic exchange of sister chromatids on the short arm of chromosome 18 (breakage and U-shape reunion).

**A 13 Mb deletion on 2q21 in a patient with a t(1;2)(p31;q21), autism and multiple congenital anomalies.** *L. Edelmann*<sup>1</sup>, *A.L. Shanske*<sup>2</sup>, *P. Gosser*<sup>3</sup>, *N.B. Kardon*<sup>1</sup>, *B. Levy*<sup>1</sup>. 1) Dept Human Gen, Box 1497, Mt Sinai Sch Medicine, New York, NY; 2) Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY; 3) Dept de Genetique, et Unite INSERM U-393, Hopital Necker-Enfants Malades, Paris, France.

Comparative Genomic Hybridization (CGH) was previously used to detect the loss of chromosomal material from chromosome 2 in a child with a denovo translocation t(1;2)(p31;q22). The child presented with multiple congenital anomalies, chronic intestinal obstruction and mental retardation with severe language delay that was later diagnosed as autism. Reports of chromosome 2 deletions are rare in the literature; the most notable is a case of Mowat-Wilson syndrome (MWS) with a del(2)(q21q23). Mutations in the ZHFX1B gene, located on 2q22, were recently shown to cause MWS. To determine whether the deletion in this translocation patient included ZHFX1B, Fluorescence in Situ Hybridization (FISH) analysis was performed using a BAC clone containing this gene, RP11 9509. This BAC was not deleted in the patient and was present on the der(1) chromosome, indicating that the deletion was proximal to this region. To confirm the original CGH results and delineate the size and boundaries of the deletion, we performed FISH analysis using a total of nine BAC clone probes that span approximately 18 Mb from 2q14 to 2q22. The breakpoint on 2q14 was narrowed to the region flanked by BACs, RP11 270M20 (not deleted) and RP11 314L11 (deleted), which are 100 kb apart on genomic contig NT\_022135, at positions 124.4 Mb and 124.5 Mb, respectively. The breakpoint on 2q21 was narrowed to a region on BAC RP11 171B14 located at position 138.2 Mb, as hybridization to the der(2) chromosome was consistently weaker than to the normal 2. Therefore, the size of the deletion in this patient is approximately 13 Mb and spans almost the entire 2q21 band. This region of the genome contains hundreds of genes and the complex phenotype in this patient may result from a contiguous gene deletion, however, these results provide valuable information with respect to loss of 2q21 chromosomal material and may help to delineate a potential autism susceptibility region.

**De novo trisomy Xq28-qter detected by subtelomeric FISH screening.** *M.G. Bialer<sup>1</sup>, A. Anguiano<sup>3</sup>, I. Taff<sup>2</sup>, A. Shanmugham<sup>1</sup>, D. LaGrave<sup>3</sup>, B.J. White<sup>3</sup>.* 1) Div Med Genetics and; 2) Ped Neurology, North Shore Univ Hosp/NYU Med Ctr, Manhasset, NY; 3) Quest Diagnostics' Nichols Institute, San Juan Capistrano, CA.

An 18 mo old female was evaluated for microcephaly and developmental delay. Delivery was induced due to oligohydramnios. Birthweight was 1990 g at 36 wk gestation. The patient failed to thrive and developed hypotonia and microcephaly. At her 18 mo evaluation, length was 72.5 cm (5%), weight 9.24 kg (5-10%) and OFC 41.5 cm (5%). She had severe trigonocephaly, occipital flattening, epicanthal folds, wide nasal bridge, small downturned mouth, thickened maxillary alveolus and hypotonia. Developmentally, she babbled and razzed. She could roll and hold a sit. The child died at 24 mo of RSV pneumonia. High resolution blood chromosome analysis, metabolic workup, serum very long chain fatty acids, MECP2 gene sequencing and MRI scan of the brain were normal. Subtelomeric FISH screening revealed an unbalanced translocation of terminal Xq to 13p. FISH with subtelomeric probe (Tel Xq), whole X chromosome painting and centromeric probe identification were consistent with this result. Both parents had normal subtelomeric FISH studies. Usually an unbalanced translocation results in duplication of one chromosomal segment and deletion of another. It therefore can be difficult to determine which clinical features are caused by a specific chromosome anomaly. This child had trisomy of Xq28 without a clinically significant deletion, so her clinical features are entirely related to partial trisomy Xq28-qter. One of us (MGB) was co-author of a previous report of 4 boys with duplication of Xq27-qter onto distal Xp (Goodman BK et al, Am J Med Genet 1998;80:377-84). Like the subject of this report, their findings included prenatal onset growth retardation, microcephaly, developmental delay, hypotonia, epicanthal folds, relative hypertelorism and downturned mouth, but their growth problems were more severe. Two of them have died of pneumonia and a 3rd has frequent pneumonias. The present patient's result shows that their features are mainly related to trisomy Xq28 and adds a new finding, trigonocephaly, to the list of phenotypic features of this chromosome anomaly.

**Duplication 20q: Clinical, Cytogenetic and Array Comparative Genomic Hybridization Characterization of a New Case.** *P.D. Cotter*<sup>1,2</sup>, *A. Iglesias*<sup>3</sup>, *K.A. Rauen*<sup>2,4</sup>, *D.G. Albertson*<sup>4,5</sup>, *D. Pinkel*<sup>4,5</sup>. 1) Department of Pathology, Childrens Hospital Oakland, Oakland, CA; 2) Department of Pediatrics, University of California San Francisco, San Francisco, CA; 3) Nassau University Medical Center, East Meadow, NY; 4) Comprehensive Cancer Center, University of California San Francisco, San Francisco, CA; 5) Department of Laboratory Medicine, University of California San Francisco, San Francisco, CA.

Trisomy of the long arm of chromosome 20 is rare, with most cases the result of malsegregation of a parental translocation resulting in trisomy for variable regions of 20q. There is only one previous report of an interstitial duplication of the proximal long arm of chromosome 20. However no clinical information was provided. Consequently this syndrome is poorly characterized. We describe an 18 month-old male who was born at 36 weeks via C-section after an uneventful pregnancy. During the newborn period, upon examination, he was found to have a right-sided cleft lip and cleft palate, hypertelorism, strabismus, mildly over-folded ears with cupping and hypothyroidism. Cardiovascular examination was consistent with the diagnosis of severe aortic coarctation, which was confirmed by echocardiogram. Neurologic evaluation at 18 months revealed a hypotonic infant with delayed acquisition of motor milestones. Thus, the main clinical features of our patient are related to CNS development, facial/palate/lip development, thyroid development and aortic arch formation. Cytogenetic analysis showed a duplication of proximal 20q: 46,XY,dup(20)(q11.2q13.1). FISH analysis with a wcp20 probe confirmed the chromosome 20 origin of the extra material. Parental karyotypes were normal indicating a de novo origin for the duplication. Array CGH confirmed the duplication of proximal 20q and further allowed quantitation of the size of the duplication. The clinical, cytogenetic and molecular characterization of this patient presented here provides the first detailed description of this syndrome.

**Case report: molecular characterization of the terminal end deletion in an inversion duplication of the short arm of the chromosome 8.** *S. Bourthoumieu<sup>1</sup>, M.C. Vincent<sup>1</sup>, P. De Mas<sup>1</sup>, J.Y. Le Tallec<sup>2</sup>, P. Calvas<sup>1</sup>, E. Bieth<sup>1</sup>.* 1) Medical Genetics, hopital Purpan, Toulouse, France; 2) hopital des enfants, Toulouse, France.

Inversion duplications of the short arm of chromosome 8 (inv dup 8p) are considered as one of the more common cytogenetic abnormalities. This rearrangement usually results in a well defined clinical syndrome including hypotonia in children, mental retardation, agenesis of the corpus callosum, dysmorphic feature and occasionally congenital heart defect. Because terminal 8p deletions alone are usually associated with no or mild phenotypic effects, it has been thought that clinical features of the inv dup 8p syndrome are mainly due to the duplicated segment and poorly from the loss of 8p subtelomeric sequences. However, some reports suggest that differences in mental retardation severity or association with organ defects might be explained by partial monosomy for the telomeric segment. We report on a 21 month old girl who was referred for developmental delay . She had agenesis of the corpus callosum and morphological abnormalities including microcephaly, supernumerary nipples and deep plantar creases. Echocardiogram failed to detect any congenital heart defects. Cytogenetic analysis of her peripheral blood using R and G banding techniques revealed an inverted duplication 8p associated with a partial monosomy 8pter [(46,XX,inv dup(8)(p23p12)del(8)(pterp23)]. FISH using a centromere-specific probe showed hybridization at the terminal end of the short arm of the duplicated chromosome 8. These data are consistent with a proposed mechanism of inv dup 8p rearrangement which involves the formation of a dicentric intermediate (Floridia et al.). Molecular studies using microsatellite markers covering the entire chromosome 8 allowed us to obtain a fine characterization of the 8p23.18pter deletion in this patient. Our findings provide clarification on the phenotypic contribution of the concomitant terminal deletion in inverted duplication of chromosome 8p. We discuss more particularly the molecular involvement of this deletion in the generation of congenital heart defects.

**46,XX/46,XY mosaicism and not chimerism in a hermaphrodite infant confirmed by molecular analysis.** *I.K. Gadi<sup>1</sup>, P.R. Papenhausen<sup>1</sup>, P.D. Singh-Kahlon<sup>1</sup>, L. Wisniewski<sup>1</sup>, P.N. Mowrey<sup>1</sup>, P. Jayakar<sup>2</sup>, B. Williford<sup>1</sup>, C. Schott<sup>1</sup>, J.H. Tepperberg<sup>1</sup>.* 1) Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC; 2) Division of Genetics, Miami Childrens Hospital, Miami,FL.

To our knowledge, this is the second reported case of a true hermaphrodite confirmed by molecular methods. An infant born to a 27 year old mother by normal vaginal delivery was referred for peripheral blood cytogenetic analysis because of ambiguous genitalia. The phallus length was 1.2cm with a normal urethral opening and a fistula at the base. The right testicle was palpable in the scrotal fold but there was no evidence of the left testicle. Ultrasound examination showed urogenital sinus, vagina and uterine structures. Cytogenetic analysis of 50 cells revealed 33 cells with a normal female chromosome complement and 17 cells with a normal male chromosome complement. Fetal derivation of the blood was confirmed by hemoglobin isoelectric focusing. Molecular analysis of polymorphic microsatellite loci from twelve different chromosomes revealed a maternal and a paternal allele at all informative loci. Each of these highly polymorphic loci showed a maximum of two alleles consistent with a single zygotic origin of the infant. Therefore, genotype identical 46, XX and 46, XY cell lines observed in the infant most likely originated by two separate non-disjunctions from a 47, XXY embryo with subsequent loss of XXY cells. Maternal and paternal X chromosome alleles were also apparent at all X chromosome loci examined that will rule out origin of 46,XX cells from 46,XY cells by loss of Y chromosome and gain of X chromosome. These results are consistent with true mosaicism in the hermaphrodite infant rather than chimera.

**Utility of an Interphase FISH Panel to Screen for Common Chromosome Aneuploidies in 178 Spontaneous Miscarriages.** *B.M. Shearer, R.A. Mota, K.R. Hammer, S.M. Jalal, R.P. Ketterling.* Cytogenetics, Mayo Clinic, Rochester, MN.

Approximately 50% of spontaneous miscarriages, which occur during the first trimester of pregnancy, are due to numeric chromosome abnormalities. The most common chromosome anomalies observed include monosomy X, triploidy, and trisomies of chromosomes 13, 16, 18, 21 and 22. Unfortunately, approximately 20% of miscarriage tissues fail to produce a successful chromosome result due to a lack of viable dividing cells. Since interphase fluorescence in situ hybridization (FISH) analysis does not require dividing cells, we utilized a FISH panel of 7 probes (chromosomes 13, 16, 18, 21, 22, X and Y) to analyze each tissue for which standard chromosome analysis was unsuccessful. To implement this strategy, all miscarriage tissues referred for cytogenetic testing were simultaneously processed for both chromosome analysis (cultured) and FISH analysis (uncultured). A total of 178 miscarriage tissues were analyzed by the interphase FISH panel. The overall abnormality rate using the seven probe strategy was 22% (39 specimens) which included 3 samples with trisomy 13 (1.7%), 4 samples with trisomy 16 (2.2%), 5 samples with trisomy 18 (2.8%), 5 samples with trisomy 21 (2.8%), 3 samples with trisomy 22 (1.7%), 13 samples with triploidy (7.3%) and 6 samples with monosomy X (3.4%). Normal results were obtained for 122 samples (68%) while 17 samples (10%) were unsuccessful by FISH. The results of this study strongly suggest that FISH panel testing has proven efficacy for the detection of common chromosome aneuploidies associated with spontaneous miscarriages.

**45,X/46,XY mosaicism confined to amnion in a stillborn 46,XY male with IUGR.** *J. Bourgeois, J. Xu.* Pathology & Molecular Medicine, McMaster University, Hamilton, ON, Canada.

Confined placental mosaicism is found in 1-2% of CVS cytogenetics cases and is associated with an increased risk of spontaneous abortion, growth retardation, fetal demise, or uniparental disomy. We report a rare case with mosaic X/XY amnion in an unexplained stillbirth. This male was delivered at 25 weeks gestational age (GA) to a 40 year old G1P2 woman. The pregnancy was complicated by intrauterine growth restriction, oligohydramnios and intrauterine demise. Following delivery, the stillbirth showed symmetric growth restriction with measurements consistent with 22-23 weeks GA and minor external anomalies including low set ears and overlapping toes. The placenta was grossly and microscopically normal. A normal male karyotype 46,XY was found in all 14 in situ colonies from the amniocentesis at 15.2 weeks GA and 20 metaphases in cultured peripheral blood. However, mosaic 45,X[15]/46,XY[15] was observed in cultured amnion tissue taken at the time of fetopsy. While it is well documented that 90-95% of prenatally diagnosed mosaic X/XY cases give rise to a phenotypically normal live born male baby, our case seems to suggest that mosaic X/XY in amnion may be detrimental to fetal development. More cases of this kind are needed to confirm this hypothesis. This case emphasizes pathological significance of cytogenetics investigation of placental tissues in addition to routine studies of prenatal and fetal samples in a karyotypically normal stillbirth.

**FISH: an effective and less costly technique for genetic evaluation of products of conception in pregnancy losses.**

*A. Amiel<sup>1,3</sup>, M. Liberman<sup>3</sup>, M. Pomeranz<sup>2</sup>, A. Fishman<sup>2,3</sup>, M. Fejgin<sup>1,2,3</sup>.* 1) Genetic Institute, Kfar-Saba, Israel; 2) Department of Obstetrics & Gynecology, Meir Hospital, Israel; 3) Sackler School of Medicine, Tel Aviv University, Israel.

Fetal chromosomal abnormalities account for about 50 to 70% of first trimester pregnancy losses. Most of these are numerical abnormalities (86%) and the minority are structural abnormalities (6%) and mosaicism (8%). Since conventional cytogenetic analysis of the products of conception is costly and time consuming, it is not performed routinely, leaving a question mark on the cause of miscarriage. FISH technique for common numerical aberrations may uncover a major part of the genetic causes for pregnancy loss at a fraction of the cost. Also, bacterial contamination is not an issue. We evaluated the effectiveness of FISH in detection of numerical abnormalities in 59 cases of spontaneous abortion and used 61 electively terminated pregnancies as controls. The probes used were 13,21,16,18, X and Y which should identify in about 75% of the common aberrations in the spontaneous miscarriage. In 55.9% of the spontaneous miscarriage numerical aberrations were diagnosed compared to 8.2% in the cases of elective pregnancy termination ( $p < 10^{-5}$ ). The most common aberrations were: triploidy (16.9%), sex chromosome aberrations (13.6%), trisomy 21 (8.5%), trisomy 16 (6.8%), trisomy 13 (6.8%), trisomy 18 (3.4%). There risk of aneuploidy was in direct correlation to maternal age ( $p < 0.005$ ). We find FISH to be a reliable and rapid tool in detecting the frequent aneuploidies in cases of pregnancy loss. Based on the low cost of this test and the utmost importance of understanding the cause of pregnancy loss it may be feasible to offer it in all cases of pregnancy. Furthermore, it probably should replace the routine histological examination.

**Partial distal trisomy 12q in a father and daughter.** *L. Bao, E.K. Schorry.* Division and Program of Human Genetics, Cincinnati Child Hosp Med Ctr, Cincinnati, OH.

Partial trisomy 12q (q24.31qtel) was found in a girl and her father. The proband was a 19 month old white female referred for developmental delays and dysmorphic features. On examination, she had normal growth parameters, curly and kinky short hair, prominent forehead with frontal bossing, simplified helices of the ears, and a small mouth with thin lips. Both of her parents were mentally retarded. Her father was felt to function in the borderline or mild range of mental retardation, and had macrocephaly, broad forehead, simplified helices of the ears, and small mouth with thin lips. The mother had a more significant degree of mental retardation, and had dysmorphic features very similar to the daughter, with curly and kinky short hair, small deeply set eyes, and small mouth with thin lips. Standard and molecular cytogenetic analysis revealed that both the girl and her father had an unbalanced 12;16 translocation with a der(16)t(12;16)(q24.31;q24.3) while the mother had a normal karyotype. Most of the daughter's dysmorphic features were felt to be related to a possible dominantly inherited syndrome from the mother. Features in common with both the daughter and father which might be attributed to trisomy 12q24.31-q telomere include mild developmental delays, borderline or mild mental retardation, broad forehead, and small mouth with thin lips. Few partial trisomy 12q cases have been reported, and to our knowledge, this is the first reported case of familial transmission of this abnormality.

**Molecular and phenotypic characterization of 9p23-p24.3 deletions.** *S. Biton, C. Crowe, L. Christ, M. Eichenmiller, M. Graff, S. Schwartz.* Genetics, case western reserve universit, cleveland, OH.

The 9p deletion syndrome is a well-established deletion syndrome, but with a variable phenotype. A deletion involving a region on 9p22.3 (the "critical region") has been specifically implicated in the presence of hallmark clinical manifestations detected at birth including: trigonocephaly, upslanting palpebral fissures, wide flat nasal bridge, arched eyebrows, hypertelorism, long philtrum, anteverted nostrils, micrognathia, short and broad neck, long middle phalanges, and an increased number of dermatoglyphic whorls. To date, no study has investigated the correlation between karyotype and phenotypic presentation among individuals with smaller deletions, i.e., those deletions distal to and not including the delineated "critical region". This study's purpose was to better correlate phenotypic to karyotypic findings of patients that display abnormalities due to a deletion of the terminal region of 9p (outside the "critical region"). Fourteen patients with deletions of 9p23-p24.3, encompassing a region of approximately 15 Mb, represent the largest cohort of patients to be systematically studied. High resolution chromosome analysis, microsatellite and molecular cytogenetic (FISH) analysis were utilized to define the breakpoints, the extent of the deletions, and their parental origin. The results from this study yielded several interesting and important findings: 1) a lack of specific hotspots for breakpoint occurrence; 2) a statistically significant number of paternally derived deletions; 3) a preliminary phenotypic map of the investigated region; 4) delineation that all of the patients presented with hypotonia, developmental delay and behavioral abnormalities regardless of the deletion size; and 5) all of these patients had similar findings to patients with "classical" 9p deletion syndrome but with no dysmorphic facial features. Establishment of phenotypic maps should be useful to genetic counselors and medical geneticists both prenatally and postnatally. The results of this study will assist in diagnosis, provision of more accurate diagnosis and in facilitation of decision making.

**Cytogenetic studies of human lymphocytes exposed to sodium pertechnetate and its reducing agent stannous chloride, in vitro.** *I.P. Aranha*<sup>1</sup>, *V.R. Bomfim*<sup>2</sup>. 1) Inst Biol, PHLC S-525-6, Univ Estado Rio de Janeiro, Rio de Janeiro, RJ, Brasil; 2) Sociedade Universitária Augusto Motta, Rio de Janeiro, RJ, Brasil.

Technetium-99m (<sup>99m</sup>Tc) is a marker for molecules and cells widely used in the detection of inflammatory sites as well as in the diagnosis of the rejection of transplanted tissues. Its efficiency is increased by a reducing agent, stannous chloride (SnCl<sub>2</sub>·2H<sub>2</sub>O). Previous work in our laboratory has shown that the use of the reducing agent in the culture of whole blood lymphocytes neither decreased the mitotic rate nor caused any numerical or structural chromosomal abnormality. The goal of the present work was to observe if sodium pertechnetate combined with its reducing agent might cause chromosomal alterations in human lymphocytes in vitro. Peripheral whole blood cells, collected from healthy donors, 18 to 30 years old, were incubated at 37°C for 48h in the presence of <sup>99m</sup>Tc (3.7 MBq/100l) combined to SnCl<sub>2</sub>·2H<sub>2</sub>O (12g/ml). Cells not exposed to the radionuclide served as control for the experiment. Chromosomes were stained with Giemsa Gurr (2%) and observed under optical microscope. In the test group, 1469 metaphases were studied; 1073 were normal and 396 carried chromosomal alterations (242 gaps and 267 breaks). In the control group, 1102 metaphases were observed, being 1042 normal and 60 abnormal (42 gaps and 30 breaks). Our results were extremely significant ( $\chi^2$  with Yates correction = 198.24 p0.0001). They suggest that sodium pertechnetate combined with stannous chloride was responsible for the chromosomal alterations observed.

**Double balanced translocations t(5;22) and t(6;8) in a woman with recurrent miscarriages.** *Z. Chen<sup>1</sup>, D. Tang<sup>2</sup>, C.N. Huang<sup>1</sup>, X.M. Song<sup>1</sup>, J. Xu<sup>3,4</sup>.* 1) Medical Genetics, Zhongshan Medical College, Sun Yat-sen University, Guangzhou, PR China; 2) Medicine; 3) Pathology and Molecular Medicine; 4) Lab Medicine, Hamilton Health Sciences and McMaster University, ON, Canada.

Double balanced translocations are rare; only a few cases are documented in literature. Some of which are associated with clinical complications, possibly a result of submicroscopic aberrations in the breakpoints. Others are associated with a normal phenotype, but with significantly increased reproductive risk of miscarriages, stillbirths or liveborn children with anomalies. Here we present a case of a 27-year-old and phenotypically normal woman who had cytogenetics analysis done because of three recognized miscarriages over the period of 5 years and no liveborn children. The gestational age for the miscarriages is ~60 days for the 1st, ~40 days for the 2nd, and ~60 days for the 3rd. Routine G-banding analysis of the cultured peripheral bloods of the couple revealed that the husband had a normal male karyotype 46,XY and the woman had two independent and apparently balanced translocations 46,XX, t(5;22)(q15;q11),t(6;8)(q21;q22). The origin of the translocations remains unknown because the parents are not available for karyotyping. The double translocations in our patient are likely the cause of her repeated abortions.

**Telomeric FISH screening in population with mental retardation or reproductive failure.** *D. Giardino<sup>1</sup>, P. Finelli<sup>1,2</sup>, C. Corti<sup>1</sup>, G. Gottardi<sup>1</sup>, M.T. Bonati<sup>1,3</sup>, F. Natacci<sup>3,4</sup>, M. Della Monica<sup>5</sup>, G. Scarano<sup>5</sup>, L. Larizza<sup>1,2</sup>.* 1) Lab. Citogenetica, Istituto Auxologico, Milan, Italy; 2) Dip. Biologia e Genetica per le Scienze Mediche, Università di Milano, Milan, Italy; 3) Fondazione Istituto Sacra Famiglia, Cesano Boscone, Italy; 4) Servizio di Genetica Medica, ICP, Milano, Italy; 5) U.O.C. di Genetica Medica, A.O.R.N. G. Rummo, Benevento, Italy.

Subtelomeric chromosome rearrangements are a cause of mild to moderate mental retardation (MR), particularly when associated with dysmorphism. They could also account for recurrent miscarriages or reproductive failures. Sets of commercially available subtelomeric fluorescent DNA probes have been used to detect subtelomeric anomalies in patients with MR, with or without dysmorphic features (DF), and individuals with a history of multiple miscarriages (MM) and/or reproductive failures (RF). All the patients were karyotypically normal by Q-banding technique. The group of subjects with MR was also negative for FRAXA and FRAXE expansion. 108 cases were analyzed, 73 with MR/DF and 35 with MM/RF. FISH was performed with Chromoprobe Multiprobe T System (Cytocell) and then with locus specific probes to characterize the observed abnormalities. In the MR group 10/73 anomalies were found, 7 were inherited from a phenotypically normal parent and interpreted as benign polymorphism, 2 were derivative chromosomes consequent to a parental balanced translocation and one was a 22qter cryptic deletion. Both the derivative chromosome determine a 2q subtelomeric deletion, with a concurrent trisomy of 16q and 6q, respectively. The extent of the 2q deleted regions in the two patients was determined by targeted FISH with BAC clones. The 2q deletion interval in one of our patients is smaller than that previously defined for Albright Hereditary Osteodystrophy-like syndrome, with the centromeric boundary moved >1.0 Mb towards the 2q telomere. No subtelomeric abnormalities were found in the MM/RF group, while two polymorphisms were detected. According to our experience telomeric FISH screening appears to be a useful tool for diagnostic and prognostic purposes in children with MR, but it does not seem such a targeted approach for couples with MM/RF.

**Definition of chromosomal abnormalities in children with multiple congenital anomalies, dysmorphic features and mental retardation using spectral karyotyping (SKY).** *S. Ben Shachar<sup>1</sup>, Y. Yaron<sup>1,2</sup>, D. Kunig<sup>1</sup>, M. Goldstein<sup>1,2</sup>, N. Furman<sup>1</sup>, R. Shomrat<sup>1</sup>, A. Orr-Urtreger<sup>1,2</sup>.* 1) Genetic Institute, Tel Aviv Sourasky Medical Cent, Tel Aviv, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Some chromosomal aberrations cannot be elucidated by standard cytogenetic techniques. Spectral karyotyping (SKY) is a molecular cytogenetic technique that allows the simultaneous and rapid identification of all 24 chromosomes in different colors. We hereby describe the use of spectral karyotyping technique in the identification of chromosomal aberrations that could not be interpreted by standard cytogenetic techniques. The study included four children with psychomotor delay and dysmorphic features. G-band staining revealed chromosomal aberrations in all cases. Spectral karyotyping analysis was performed to further define the nature of the abnormality. Patient 1, a 2-year old girl with recurrent infections, psychomotor delay and dysmorphic features was found to have additional material on the long arm of chromosome 11. Using SKY analysis we determined that this was a 11q24-25 duplication. Patient 2, a 3-year old girl with development delay, hemiparesis and dysmorphic features had an extra structurally abnormal chromosome (ESAC). The origin of this ESAC could not be determined by G-band staining. Spectral karyotyping demonstrated that the origin of this ESAC was chromosome 5. The chromosomal G-band analysis of patient 3, a 4-year old boy with psychomotor delay and dysmorphic features, showed an additional chromosomal material on chromosome 3. It was proved to be a 3q duplication by spectral karyotyping analysis. Patient 4 was a neonate with multi organ defects and dysmorphic features. A combination of SKY and FISH techniques demonstrated partial trisomy of 1qter and partial 11qter monosomy. We conclude that spectral karyotyping is a powerful adjunct tool to standard cytogenetic analysis in patients with multiple congenital anomalies, dysmorphic features and mental retardation.

**The molecular basis of terminal deletions.** *B.C. Ballif<sup>1</sup>, W. Yu<sup>1</sup>, C.D. Kashork<sup>1</sup>, C.A. Shaw<sup>1</sup>, M. Gajecka<sup>2</sup>, H.A. Heilstedt<sup>1</sup>, L.G. Shaffer<sup>1,2,3</sup>.* 1) Dept Molecular & Human Genet, Baylor Col Medicine, Houston, TX; 2) Health Res & Edu Ctr, Washington State Univ, Spokane; 3) Sacred Heart Med Ctr, Spokane.

Terminal deletions are one of the most commonly observed chromosome abnormalities and result in several well-known mental retardation syndromes. However, the molecular mechanisms that generate and stabilize terminal deletions are poorly understood. We developed a contig of the most distal 10.5 Mb of 1p36 and characterized the deletions in 60 subjects with monosomy 1p36. Deletion sizes varied widely, with no single common breakpoint. Terminal deletions, interstitial deletions, complex rearrangements, and derivative chromosomes were identified. Ten rearrangements of 1p36 were examined at the DNA sequence level. Seven were apparently terminal deletions and three were known derivative chromosomes, der(1)t(1;1)(p36;q44). Sequence analysis at the junctions indicated that one was a pure terminal truncation stabilized by telomeric repeat sequences. Analysis of two cell lines identified terminal deletions associated with cryptic interrupted inverted duplications. These junctions are identical in structure to those found in cell lines that have gone through breakage-fusion-bridge cycles where uncapped sister chromatids are fused by non-homologous end joining. In four subject cell lines, the breakpoints occurred in repetitive DNA sequence elements (LINEs, SINEs, etc.). Analysis of the der(1) chromosomes junctions did not identify low-copy repeats in the regions, suggesting that nonallelic homologous recombination did not mediate these rearrangements. These data are consistent with the mechanism of telomere capture by break-induced replication at the site of a double-strand break generating nonreciprocal translocations from terminally deleted chromosomes. The results of the molecular analyses of 10 terminal deletions of 1p36 are strikingly similar to recent observations in model systems where a variety of mechanisms compete to repair a double-strand break near a telomere and stabilize the end of a broken chromosome.

**Two interstitial deletions in a subject with a complex chromosomal rearrangement of 1p36.** *M. Gajicka<sup>1</sup>, B.C. Ballif<sup>2</sup>, S.K. Shapira<sup>3</sup>, W. Yu<sup>2</sup>, L.G. Shaffer<sup>1,2,4</sup>*. 1) Health Res & Edu Ctr, Washington State Univ, Spokane; 2) Dept Molecular & Human Genetics, Baylor Col Med, Houston, TX; 3) Dept of Pediatrics, Univ of Texas Health Sci Ctr, San Antonio; 4) Sacred Heart Med Ctr, Spokane, WA.

Although terminal deletions of 1p36 are relatively common (~1 in 5,000 live births), interstitial deletions of 1p are less frequent, and little is known about their mechanisms of formation. We studied a subject with two interstitial deletions within the 1p36 region that are present on the same chromosome 1. The complex rearrangement was detected using FISH, microsatellite analysis, and microarray-based comparative genomic hybridization (array CGH). Array CGH was performed using a 1p36 microarray constructed from a contig that consists of 97 large-insert BAC clones spanning 10.5 Mb of the most distal region of 1p36 and 41 subtelomere clones from all chromosomes except the acrocentric short arms. Four breakpoints in the subject's cell line were identified. Additionally, the cell line was fused to HPRT-deficient RJK88 hamster cells to generate somatic cell hybrids. Hybrid colonies containing the chromosome 1 with the 1p36 interstitial deletions segregated from the normal chromosome 1 homologue were identified. Each junction was further refined by PCR and STS marker walking on hybrid DNA. By this approach, we sequenced the proximal interstitial deletion junction. Sequence analysis of the junction revealed that each breakpoint is located within a repetitive DNA sequence element. Continued investigation of the distal deletion junction of this subject and other complex rearrangements of 1p36 may uncover the mechanism(s) resulting in interstitial deletions and rearrangements of telomeric regions.

**Unusual clinical presentation of a patient with ring chromosome 4: cytogenetic molecular characterization.** *D. Concolino<sup>1</sup>, R. Apa<sup>1</sup>, R. De Marco<sup>1</sup>, M.A. Iembo<sup>1</sup>, E. Rossi<sup>2</sup>, V. Pascale<sup>3</sup>, P. Strisciuglio<sup>1</sup>.* 1) Department of Pediatrics, University "Magna Graecia", Catanzaro, Italy; 2) Istituto di Patologia Umana ed Ereditaria, Universit di Pavia, Pavia, Italy; 3) Divisione di Neonatologia, Ospedale Pugliese, Catanzaro, Italy.

The ring chromosomes are cause of malformations, mental and growth retardation. The presence of a ring chromosome 4 is a rare event and usually shows a predominant loss of distal 4p including the Wolf-Hirschhorn region (WHS). Few cases of molecular characterization of ring 4 were reported in literature. We describe a newborn with a case with r(4) who presented without features of WHS; she had pre-postnatal growth retardation, microcephaly, minor dysmorphic signs and renal malformations. Cytogenetic studies were performed by QFQ and GTG banded metaphases from synchronised peripheral blood lymphocyte cultures using standard procedures. Probands karyotype was interpreted as 46,XX,r(4)(p16q35) in all metaphases observed. Parental karyotypes were normal. FISH analysis with telomeric 4p and 4q probes failed to detect 4q signal but there was no 4p ter fluorescent signal. A DNA probe corresponding to the Wolf-Hirschhorn region showed two copies of the signal. The ring breakpoints identified by FISH analysis were 46,XX,r(4)(p16.3;q35.2).ish r(4)(4ptel-,WHS+,4qtel+). The phenotype of our case seems different from previous patients for the presence of renal malformations and absence of psychomotor developmental delay probably due to a small deletion on the region 4p.

**Molecular and cytogenetic characterization of breakpoints by FISH in 14 cases of isodicentric Y chromosomes.**

*M. Beaulieu Bergeron*<sup>1,4</sup>, *M. DesGroseilliers*<sup>1,4</sup>, *R. Fetni*<sup>5</sup>, *P. Brochu*<sup>3</sup>, *E. Lemyre*<sup>2,4</sup>, *N. Lemieux*<sup>1,3,4</sup>. 1) Département de Pathologie et biologie cellulaire, Université de Montréal, Montréal, Québec, Canada; 2) Département de Pédiatrie; 3) Département de Pathologie et; 4) Centre de recherche de l'Hôpital Sainte-Justine, Montréal, Québec, Canada; 5) Department of Pathology, McGill University Health Center, Montreal, Quebec, Canada.

Infrastructural rearrangements of the Y chromosome are not rare, especially isodicentrics. These idic(Y) are greatly unstable during meiosis and mitosis, and patients having such rearrangement often present mosaicism. Most severe phenotypes, including Turner syndrome and sex reversal, are almost exclusively seen in females bearing an idic(Y). In male cases, clinical implications often include azoospermia and infertility. We present the FISH results of 14 cases of idic(Y) including 6 males, 7 females and one individual with sexual ambiguity. FISH analyses were performed using probes SRY (Yp11.3), 91H4.5 (Yp11.2), DYZ1 (Yq12), DYZ3 (Y centromere) and WCPY (whole chromosome painting of the Y). BACs (Bacterial Artificial Chromosomes) were used in some cases in order to refine the molecular breakpoints. Breakpoints were all localized in the Yq11.2-Yq12 region except for one case, a female with a 46,X,idic(Y)(p11.2)/45,X SRY- karyotype. Except for the latter and a male with a 47,X,idic(Y)(q12)x2/45,X karyotype, all other cases were negative for heterochromatin. Of the 14 cases, one male and 5 female patients show a 45,X cell line in addition to the idic(Y). Furthermore, 2 males show a 46,X,idic(Y)(q11.21) chromosomal constitution without any mosaicism, while 2 females, the individual with sexual ambiguity and 2 males were shown to have a deleted Y chromosome or two idic(Y) in addition to the idic(Y) cell line. When present, the 45,X cell line was found in variable proportions. Finally, one male presents a 47,XY,idic(Y)(q11.21)/46,XY karyotype. Thus, clinical implications of idic(Y) are greatly variable and depend not only on the percentage of cells showing a 45,X constitution or structurally abnormal Y chromosomes, but also on the sexual differentiation, since only females generally show severe clinical problems. *Supported by RMGA-FRSQ.*

**Ring 2 chromosome case report and cell cycle studies.** A. Corona-Rivera<sup>1,2,5</sup>, L. Bobadilla-Morales<sup>1,5</sup>, S. Mendoza-Becerra<sup>1</sup>, F. Carbajal-López<sup>1</sup>, P. Barros-Núñez<sup>4</sup>, J.R. Corona-Rivera<sup>1,3,5</sup>, *Cuerpo Académico Genética Médica y Clínica, CUCS, U. de G.* 1) Laboratorio de Genética Humana, Universidad de Guadalajara, CUCS, Guadalajara, Jalisco, México; 2) Unidad de Citogenética, OPD Hospital Civil de Belén, Guadalajara, Jal., México; 3) OPD, Hospital Civil Juan I. Menchaca, Guadalajara, Jal., México; 4) CIBO, IMSS, Guadalajara, Jal., México; 5) Doctorado en Genética Humana, CUCS, U. de G., México.

We are aware of ten previously reported cases of ring 2 chromosome (r(2)). Ring chromosomes without an important deletion share a common pattern of phenotypic anomalies, which occurs independently of the chromosome involved, named as General ring syndrome. Such common pattern exhibit Intrauterine Growth Retardation, postnatal growth failure, and a mild-to-moderate mental retardation. We report a patient concordant with General ring syndrome features, whose also showed severe microcephaly, obesity, hyperphagia, recurrent medial otitis and hyperkinesia. At birth, routine cytogenetic analysis showed karyotype 46,XY,r(2)(p25;q37) in all cells. At 6 years old, subsequent kayotypes showed mosaicism with increasing appearance, up to 30%, of normal cells and low frequency of ring variants such as dicentric or double rings, and tetraploidy. It has been proposed that the normal occurrence of sister chromatid exchanges within a ring constantly produces further chromosomal abnormalities resulting in a high cellular death rate in vivo and in vitro and to end with a decrease in the total number of viable cells present at any given interval of proliferation. Cellular proliferation kinetics was measured in our patient by differential sister chromatid stain evidencing lower proliferation rate in cells bearing r(2). Besides, r(2) frequency gradually decreased in three different culture times. Observed r(2) instability and clinical findings agree with the fact that ring size and ring behavior, rather than its genetic content, are involved and may be associated with the growth deficiency.

**CYTOGENETIC FINDINGS IN 780 COUPLES WITH RECURRENT ABORTION.** *R. Baez-Reyes, JL. Saucedo-Hernandez, DG. Mayen- Molina.* Genetica, Inst. Nac. de Perinatologia, Mexico, Edo.Mex.

Recurrent gestational loss is a very important reproductive health problem in our country since it affects 1% of the couples. It has an heterogeneous etiology, which means that the geneticists must face medical and psycho-social dilemmas and problems. It has been estimated that about 50 to 60% of the first trimester spontaneous abortions undergo chromosome anomalies. The latter may be either inherited or de novo. A sample of 1560 cytogenetic studies from 780 couples with two or more spontaneous abortions were analyzed from January, 1984 to June, 2003. Peripheral blood lymphocytes were cultured after the clinical evaluation of the patients. GTG bands were obtained and fifteen metaphases from two primary cultures were analyzed. If an altered cell was found, the mitotic count was increased up to 100 metaphases. The frequency of chromosome anomalies per couple observed in our sample was 7.3 %. Balanced reciprocal translocations ( 2.69 % ), robertsonian translocations ( 1.02 % ), sex chromosome mosaicism ( 2.43 % ), autosomal mosaicism ( 0.76 % ) and inversions ( 0.38 % ) were the alterations found. International papers report 4.8-5.5% of chromosome alterations in couples with recurrent abortions. The cytogenetic study in peripheral blood lymphocytes, as well as in fetal tissues and placental annexa, must be considered as a diagnostic tool in the evaluation of patients who have undergone one or more abortions in order to be able to give appropriate information and opportune genetic counseling. The forementioned will create the possibility to offer a better medical and psychological attention, as well as a prenatal diagnosis for the future pregnancies. On the other hand, this will help to detect fetal anomalies in good time.

**A de novo intrachromosomal inverted duplication of chromosome 18 with deletion of subtelomeric region in a newborn with severe congenital anomalies.** *D. Flannery<sup>1</sup>, S.M. DeLaney<sup>1</sup>, A.S. Kulharya<sup>1,2</sup>*. 1) Dept Pediatrics, Sect Genetics, Medical College of Georgia, Augusta, GA; 2) Dept Pathology, Medical College of Georgia, Augusta, GA.

Duplication deletion of chromosome 18 is rare; most result as recombinants from an inverted chromosome 18 in a carrier parent. Partial trisomy of chromosome 18 resulting from intrachromosomal duplication accompanied by a deletion has not been previously demonstrated. We present a patient with intrachromosomal duplication of chromosome 18 and a submicroscopic deletion of chromosome 18 demonstrated by FISH. The patient was a full term infant delivered to a 33-year old G3P1 mother and 29-year old father. At birth, he was noted to have large anterior fontanelle, hypertelorism, low set ears, wide spaced nipples and an absent kidney. He has bilateral arthrogryposis of the hands and feet. The tympanic membrane was abnormal with a hyper-dense area. At 6 months of age he underwent fundoplication to correct GE reflux. He is developmentally delayed. Chromosome analysis demonstrated additional material on the long arm of chromosome 18. FISH with subtelomeric probes for the short and long arm of chromosome 18 and whole chromosome paint (WCP) was performed. The hybridization pattern with WCP 18 is consistent with duplication of 18. The subtelomeric probe for 18p shows a normal hybridization pattern while the signal for 18q subtelomeric probe is deleted on the abnormal 18. The karyotype is: 46,XY,add(18)(q23). ish dup(18)(pter->q23::q23->q21.3)(wcp18+),del(18)(q23)(D18S1390-) The terminal deletion at 18q involves the region commonly deleted in the 18q-syndrome which has an incidence of 1/40,000 and a highly variable phenotype with mental retardation, short stature and foot anomalies as common features. Two critical regions of partial duplications of chromosome 18 have been identified that produce phenotypic features of trisomy 18. These regions lie within 18q12.1-18q21.2 and 18q21.3->qter. Our patient has duplication of the second of these critical regions and reflects some features of trisomy 18. This patient confirms the recent findings that intrachromosomal inverted duplications are accompanied by deletions.

**De Novo direct duplication of chromosome 11 (q13-qter) associated with dysmorphism - A case report and review.** *S. Abulhasan<sup>1</sup>, D.S. Krishna Murthy<sup>2</sup>, R. Al-Dabbus<sup>3</sup>, M. Abdul Rasool<sup>1</sup>, S.A. Al-Awadi<sup>3</sup>.* 1) MOLECULAR CYTOGENETICS and Cytogenetics laboratory, MEDICAL GENETICS CENTER, Kuwait; 2) Cytogenetics Laboratory,; 3) MEDICAL GENETICS CENTER, Kuwait.

Duplication of autosomal segments lead to less severe clinical manifestations and handicap than deletion of the same segments, some deletions are even lethal. Partial trisomy for autosomal segments result from translocations (de novo/inherited). However, segmental direct duplications are very rare. We report here a newborn female with minor dysmorphic features, congenital heart defect (PDA), bossing forehead, short nose, low set ears, prominent philtrum, Ultrasonography scan of skull and abdomen was normal. There is no consanguinity and family history is unremarkable. Proband's 10 sisters and a brother are all normal. Chromosome analysis of the peripheral blood metaphase chromosomes using G-banding technique showed an apparently large segment of chromosome 11 (duplication of 11q13-q23). Karyotype of the parents were normal. FISH studies were carried out using different probes specific for chromosome 11 (WCP11, CyclinD1 locus specific and Tel11qter), confirmed direct duplication of chromosome 11(q11-q23). In most of the patients reported the partial trisomy is familial, resulting from balanced translocation heterozygote carrier parent, de novo cases are very rare. The recurrence risk and the clinical manifestations is compared with other similar cases of trisomy 11q.

**Prenatal Overgrowth and Mosaic Trisomy 15q25-qter Including the IGF1 Receptor Gene.** *L. Faivre<sup>1</sup>, T. Rousseau<sup>2</sup>, N. Laurent<sup>3</sup>, P. Gosset<sup>4</sup>, C. Thauvin-Robinet<sup>1</sup>, S. Lionnais<sup>2</sup>, P. Callier<sup>5</sup>, P. Khau Van Kien<sup>1</sup>, F. Huet<sup>1</sup>, C. Turleau<sup>4</sup>, P. Sagot<sup>2</sup>, F. Mugneret<sup>5</sup>.* 1) Centre de Genetique, Hopital d'Enfants, Dijon, France; 2) Centre pluridisciplinaire de Medecine Foetale, Maternite du Bocage, Dijon, France; 3) Anatomopathologie, Faculte de Medecine, Dijon, France; 4) Cytogenetique, Hopital Necker-Enfants Malades, Paris, France; 5) Cytogenetique, CHU Le Bocage, Dijon, France.

Although chromosome imbalances are commonly associated with growth failure, the number of chromosomal abnormalities associated with overgrowth have started to emerge. In particular, todate, 12 cases of trisomy 15qter have been associated with overgrowth. Here we report on a male foetus presenting with overgrowth and additional material on the short arm of one of the chromosome 15 in 12% of lymphocytes and 50% of amniotic cells. Cytogenetic studies were indicated for elevated maternal age. Parents karyotypes were normal, indicating a de novo origin for this unbalanced rearrangement. Complementary studies using cytogenetic and FISH studies showed that this additional material resulted in a 15q25-qter trisomy and confirmed the presence of three copies of the insulin-like growth factor 1 receptor (IGF1R) gene, included in the trisomic region. Autopsy performed after termination of pregnancy revealed isolated overgrowth (90th centile) and absence of visceral malformations. The possible mechanisms and origins for the formation of this mosaic pure trisomy are complex. The present observation emphasises the hypothesis that the overgrowth phenotype, frequently reported in patients with a trisomic segment involving the 15q26 region, might be causally related to a dosage effect of the IGF1R gene, as well as the importance of chromosome analysis in patients with overgrowth. It also confirms that overgrowth is of prenatal onset in those observations. The present observation raise the question of the indication of a fetal karyotype in prenatal overgrowth when a maternal origin has been ruled out.

**Two cases of partial trisomy 21 resulting from a translocation involving chromosome 21 and a non-acrocentric chromosome initially identified by interphase FISH.** *J.A. Adkins<sup>1</sup>, L. Werhane<sup>1</sup>, D. Gore<sup>2</sup>, D.M. Main<sup>3</sup>, V.S. Tonk<sup>4</sup>, G.N. Wilson<sup>4</sup>, J.B. Ravnani<sup>1</sup>, S.A. Berend<sup>1</sup>.* 1) Genzyme Genetics, Santa Fe, NM; 2) Medical Center of Lewisville, Lewisville, TX; 3) California Pacific Medical Center, San Francisco, CA; 4) Texas Tech Medical Center, Lubbock, TX.

Fluorescence in situ hybridization (FISH) analysis of interphase cells is an effective, rapid method for screening amniocentesis specimens for the common aneuploidies. However, often the chromosome analysis provides additional cytogenetic information that is not obtainable by this test. Together these two tests provide complimentary information. We present two cases of partial trisomy 21 resulting from translocations involving chromosome 21 and a non-acrocentric autosome. Interphase FISH analysis showed three copies of the chromosome 21 probe in each of the two cases. Cytogenetic analysis revealed 46 chromosomes, including a derivative chromosome. Case 1 was referred for an amniocentesis due to abnormal ultrasound findings including agenesis of the corpus callosum, hydrocephalus, a heart defect, and clenched hands. Chromosome analysis showed a derivative chromosome 17. Because the interphase FISH analysis showed three copies of the chromosome 21 probe, it was apparent that the derivative chromosome 17 resulted from a translocation involving the short arm of chromosome 17 and the long arm of chromosome 21. Parental chromosome analyses were not done on this case. Case 2 was referred for an amniocentesis due to an abnormal maternal serum screen with increased risk for Down syndrome. Chromosome analysis showed a derivative chromosome 18. Utilizing the interphase FISH results and the chromosome analysis, it was apparent that the derivative chromosome 18 resulted from a translocation involving the short arm of chromosome 18 and the long arm of chromosome 21. Parental chromosome analyses showed that the mother carried a balanced translocation involving chromosomes 18 and 21. The rearrangement in each of these cases was confirmed by metaphase FISH analysis. These two cases show the importance of following all interphase FISH studies with conventional cytogenetics.

**An unusual case of mosaicism for a cryptic complex inversion duplication 8p and ring (inv dup 8p) demonstrates a novel mechanism of chromosome stabilization.** *J. Chernos*<sup>1,2</sup>, *M. Innes*<sup>2</sup>. 1) Cytogenetics Laboratory, Alberta Children's Hosp, Calgary, AB, Canada; 2) Dept Medical Genetics, University of Calgary, Calgary, AB, Canada.

Inversion duplication 8p is a relatively common chromosome rearrangement with a well-delineated clinical phenotype including severe mental retardation, dysmorphic features, agenesis of the corpus callosum, and malformations of the heart and kidneys. We report an unusual case of mosaicism for an inv dup 8p chromosome present in both a linear and a ring configuration that suggests a novel mechanism for stabilizing the inv dup 8p chromosome. Chromosome studies were initiated at 16 years of age due to agenesis of the corpus callosum, short stature, failure to thrive and dysmorphic features. G-banded karyotype was reported as 46,XY,dup(8)(p23p11.2){27}/46,XY,der(8)r(dup 8)(p23q24.3)[5]. This appeared to be the typical inverted duplication of the 8p21.3p23.3. In theory, no truly terminal deletion exists due to the loss of telomeres and resultant chromosome instability. Telomere healing or telomere capture have been proposed mechanisms to stabilize the terminal inv dup(8) (Giglio, et al, 2001). In this patient, the formation of a ring inv dup 8 represents an alternate stabilization of the rearranged chromosome. In contrast, the linear inv dup 8 must have been stabilized by an another, perhaps unrelated, mechanism. FISH using dual colour chromosome 8 telomere probes yielded surprising results. The linear inv dup 8 lacked the 8p telomere that was replaced by a second copy of the 8q telomere. The ring inv dup 8 similarly, showed no 8p signal but had a signal for 8q. The hypothesized mechanism for stabilizing the inv dup 8 chromosome in this patient is via a ring formation followed by breaking open to produce the linear chromosome that has been stabilizing through capturing some of the 8q telomeric sequences on the short arm. Therefore, the inv dup 8 is actually a cryptic derivative chromosome arising secondary to the ring inv dup 8 configuration.

**Maternal duplication of 15q11-q13 identified in one autism patient during linkage disequilibrium mapping.** *S.L. Christian<sup>1</sup>, L.A. Weiss<sup>2</sup>, H.L. Fritz<sup>1</sup>, C. Lord<sup>3</sup>, N. Akshoomoff<sup>4,6</sup>, E. Courchesne<sup>5,6</sup>, X. Wu<sup>1</sup>, B.L. Leventhal<sup>1,7</sup>, E.H. Cook Jr.<sup>1,2,7</sup>*. 1) Dept Psychiatry, Univ Chicago, Chicago, IL; 2) Dept Human Genetics, Univ Chicago, Chicago, IL; 3) Dept Psychology, Univ Michigan, Ann Arbor, MI; 4) Dept Psychiatry, Univ California, San Diego, La Jolla, CA; 5) Dept Neurosciences, Univ California, San Diego, La Jolla, CA; 6) Childrens Hosp Res Cntr, San Diego, CA; 7) Dept Pediatrics, Univ Chicago, Chicago, IL.

Autistic disorder is a neurodevelopmental disorder that affects ~1 in 500 with a 4:1 male to female ratio. One of the most common genetic mechanisms associated with autism is a ~4 Mb maternal duplication of the 15q11-q13 region that affects ~1-2% of autistic patients. These abnormalities are usually detected using routine cytogenetics and/or FISH. In a study of 92 trios comprised of one autistic child and both parents, linkage disequilibrium (LD) mapping was performed using 116 SNPs across this 4 Mb region. The data were analyzed using software developed by Dr. Wu to identify 3 clusters representing the 1/1, 1/2, and 2/2 genotypes. In one autistic patient the genotyping data for 54 SNPs was found to fall in between otherwise tight heterozygote and homozygote clusters relative to the other data. Examination of the other SNP data on this patient indicated 23 homozygous and 39 heterozygous genotypes. The possibility that this patient had a chromosomal duplication that shifted the SNP data was studied further. Examination of the parental data identified 15 fully informative SNPs that indicated a maternal origin for the shifted results in all cases. Additionally, 5 microsatellites located within this 4 Mb region were analyzed on this patient and both parents. Two markers, D15S541 and strp7, were fully informative and showed the presence of 2 maternal and 1 paternal alleles indicating the presence of a maternal duplication of the 15q11-q13 region and confirming the SNP data. This is the first reported case of a chromosomal duplication identified using SNP mapping data and indicates that careful interpretation of SNP data is needed to prevent overlooking the presence of a chromosomal abnormality.

**Synaptonemal complex analysis in infertile men.** *R. Martin*<sup>1,2</sup>, *F. Sun*<sup>1,2</sup>, *E. Ko*<sup>2</sup>, *L. Barclay*<sup>2</sup>, *G. Kozak*<sup>3</sup>, *K. Trpkov*<sup>4</sup>, *C. Greene*<sup>5</sup>. 1) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Department of Genetics, Alberta Children's Hospital, Calgary, AB, Canada; 3) Pathology Department, Rockyview Hospital, Calgary, AB, Canada; 4) Urology Department, Rockyview Hospital, Calgary, AB, Canada; 5) Department of Obstetrics and Gynecology, University of Calgary, Calgary, AB, Canada.

The purpose of this study was to analyze early stages of meiosis in infertile men to determine if any abnormalities in chromosome pairing or recombination could be discovered using new immunocytogenetic techniques. The stages of meiotic prophase, extent of chromosome pairing and the number of recombination foci were compared in men with nonobstructive azoospermia and controls. Immunofluorescence methods were used to identify the synaptonemal complex in various stages of prophase. Antibodies were used to identify the synaptonemal complex (SCP1/SCP3), the centromere (CREST) and sites of recombination (MLH1). Testicular samples from 5 men with nonobstructive azoospermia were studied. Two men had no meiotic cells. One man had an early arrest in meiosis with 13% of cells in leptotene, 87% of cells in zygotene and no pachytene cells. Control donors had 94% of cells in pachytene. One infertile man had a normal number of cells in pachytene, but a decreased number of recombination foci with a mean of 45 (range 2-54), compared to a mean of 48 (range 34-62) in control donors. He also had a large number of cells (25%) with at least one bivalent with no recombination foci, which was rare in controls (4% of cells). The last infertile man had very few meiotic cells (35) with 33% in a zygotene-like stage in which there appeared to be a block in pairing. Other cells (64%) reached pachytene, but with a greatly reduced frequency of recombination (mean 35, range 1-61); 52% of cells had unpaired regions, and 65% of cells had at least one bivalent with no recombination. The sex body was not formed in most cells. These studies in infertile men demonstrate a number of abnormalities in chromosome pairing and recombination associated with meiotic arrest.

**Prenatal level II mosaic marker representing true fetal mosaicism: What is the lesson?** *M. Nowaczyk, J. Xu.*  
Pathology & Molecular Medicine, Lab Medicine, Hamilton Health Sciences and McMaster University, Hamilton, ON, Canada.

We reported a case of a level II mosaic marker detected in amniocentesis that turned out to be a true fetal mosaicism. A 40-year-old woman had amniocentesis at 15.3 weeks gestation because of advanced maternal age. Routine G-banding analysis showed that 22 of the 23 in situ colonies had a normal male karyotype 46,XY. One colony had an extra small ring-like marker in 6/7 cells examined in that colony. A single abnormal colony is defined as level II mosaicism and is generally considered as pseudomosaicism, without significant clinical implications. Therefore, this finding was interpreted as a probable normal male karyotype; however, the possibility of fetal mosaicism could not be ruled out. A detailed fetal sonogram at 19 weeks gestation showed adequate fetal growth and no fetal anomalies. A normal male infant was born at term; there was a nuchal skin fold and a shawl scrotum. At 17 months of age he presented with a history of normal growth and normal gross and fine motor developmental milestones, however he had no intelligible speech. He never cooed or babbled as an infant. His hearing and understanding were normal; he would follow two-step commands. The follow-up cytogenetic analysis of cultured cord blood cells at birth showed a mosaic male karyotype with a marker in 14 (20%) of the 70 cells, 47,XY,+mar[14]/46,XY[56]. Both parents had a normal karyotype; thus it was a de novo marker. FISH revealed that the marker was negative for chromosome 15 probes specific for D15Z1 at 15q11.2, SNRPN at 15q11-q13 and PML at 15q22, and whole chromosome paint (wcp) 22. Spectral karyotyping using all 24 wcps did not produce a conclusive result likely due to the small size and makeup of the marker and/or a low proportion of the positive cells. This case suggests that while a sense of perspective should be kept, there exists a possibility of fetal mosaicism associated with a level II mosaicism found at the time of amniocentesis. Cytogenetic follow-up should be considered in such a case. Further case reports are needed for a better estimation of risks associated with level II mosaicism and for appropriate genetic counselling.

Program Nr: 786 from 2003 ASHG Annual Meeting

**Cytogenetic study of human lymphocytes under chloroquine treatment in vitro.** *C.V. Lopes, J.G. Frydman, I.P. Aranha.* Dept. de Bio Cel. e Genet., Univ. Est. do Rio de Janeiro, Rio de Janeiro, RJ , Brasil.

Chloroquine is a drug that was initially used for the treatment of malaria but that has also been successfully used for the treatment of arthritis and lupus eritematosus. The present study had the objective of studying the effect of chloroquine on chromosomes from human lymphocytes in vitro. Blood was collected from healthy donors 18 to 30 years old. Peripheral whole blood cells were incubated at 37C for 72h in enriched RPMI 1640 medium in the presence of chloroquine in the concentrations of 15, 30, 60 e 120 g/ml. Cells not exposed to the drug served as control for the experiment. A large amount of metaphases were obtained with the use of colchicine ( 16g/ml ). After fixation, chromosomes were stained with Giemsa Gurr ( 2% ) and analysed under optical microscope. Due to the low number of cells obtained in the 30 and 60g/ml concentrations and the lack of cells in the 120g/ml concentration, the groups were combined as exposed and not exposed to the drug. The low growth rate indicates that the drug had a cytotoxic effect. In 1416 metaphases analysed in the test group there were 704 with chromosomal alterations ( 1215 gaps and 545 breaks ). In the 1223 metaphases from the control group there were 24 abnormal ones ( 26gaps and 2 breaks ). The results were extremely significant (  $\chi^2$  with Yates correction = 746.78 ;  $p < 0.0001$  ) suggesting that chloroquine was responsible for the chromosomal alterations observed.

**Tertiary structure of cloned t(11;22) breakpoint DNA.** *H. Kurahashi*<sup>1,2,3</sup>, *B.S. Emanuel*<sup>2</sup>, *T. Toda*<sup>1</sup>. 1) Div Functional Genomics, Osaka Univ Grad Sch Med, Osaka, Japan; 2) Div Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 3) Div Molecular Genetics, Inst Compre Med Sci, Fujita Health Univ, Aichi, Japan.

The constitutional t(11;22)(q23;q11) is the only known recurrent non-Robertsonian translocation. We have previously demonstrated that the translocation breakpoints are located within palindromic AT-rich repeats (PATRR) located on chromosomes 11q23 and 22q11. As a mechanism for this translocation, we proposed that the PATRR forms a cruciform structure that induces genomic instability leading to the translocation. To test this hypothesis, we have analyzed the tertiary structure of the PATRR cloned from 11q23. A plasmid containing the 11q23 PATRR undergoes a mobility shift upon agarose gel electrophoresis in a temperature-dependent manner. Analysis using two-dimensional gel electrophoresis indicates that the mobility shift is due to the formation of a cruciform structure. S1 nuclease or T7 endonuclease can cut the PATRR-containing plasmid into a linear form, which also suggests the cruciform formation. To visualize the tertiary structure of the PATRR, atomic force microscopy has been applied. Cruciform extrusions from the plasmid DNA with hairpin arms of the expected size were visualized. These data imply that the susceptibility to translocation mediated by the PATRR is likely a result of its unstable tertiary DNA structure.

**Phenotypic effects and pregnancy outcome of an unbalanced familial 5;21 chromosome translocation. C.**

*McKenna<sup>1</sup>, L.S. Heckman<sup>1</sup>, R. Schmidt<sup>1</sup>, M. Moretti<sup>2</sup>, A. Yenamandra<sup>3</sup>, P. Koduru<sup>3</sup>, L. Mehta<sup>3</sup>.* 1) Genzyme Genetics, Yonkers, NY; 2) St. Vincent's Medical Center, Staten Island, NY; 3) Schneider Children's Hospital & North Shore University Hospital, Manhasset, NY.

We describe a family where three members were found to carry an unbalanced 5;21 chromosome translocation. A 29 y.o woman was referred for amniocentesis because of increased nuchal skin fold in the fetus. Fetal karyotype was designated 46,XX,der(5)t(5;21)(q35;q22), with partial trisomy for 21q, including the Down syndrome critical region. Peripheral blood chromosome analysis of the pt. revealed a karyotype of 45,XX,der(5)t(5;21)(q35;q22),-21. FISH analysis confirmed the karyotypic findings. The pt.'s brother was independently evaluated for learning disabilities with multiple psychiatric diagnoses. He had a history of malignant hyperthermia during orchidopexy for undescended testes. He was short and had bilateral temporomandibular joint (TMJ) ankylosis. He carried the same translocation as his sister. The translocation was present in their mother. All three individuals had a similar appearance with prominent nasal tip, large ears and short stature. The sister also had TMJ problems, malignant hyperthermia and learning disabilities, but the mother denied these problems. The proband delivered a full-term female infant with features of trisomy 21. Cardiac findings were persistent left superior vena cava and patent foramen ovale. Other features present in the mother were not detected in the infant. The child died at 2 years following a respiratory illness. The familial translocation in our family was unbalanced with monosomies for distal 5q35-ter and proximal 21q. Adjacent meiotic segregation and fertilization with a normal sperm resulted in the infant's partial trisomy 21. The phenotypic features of distal 5q deletions and monosomy 21q22 are not well defined. TMJ instability and malignant hyperthermia have not been reported in association with these deletions and genetic susceptibilities for these problems have not been mapped to either region. A subtle though variable phenotype was associated with the der(5) chromosome in our patients, but could not be correlated with reports in literature.

**Telomere abnormalities with variable presentation: cytogenetic variants or a window to epigenetics?** *J.J.D Morrissette, L. Medne, J. Ganesh, K. Russell, DM. McDonald McGinn, EC. Moore, EH. Zackai, NB. Spinner.* Div Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA.

Subtelomeric chromosomal rearrangements are emerging as an important cause of human malformations and neurodevelopmental disabilities. We have screened 1,297 patients using a subtelomeric probe set, and have identified 41 abnormalities that appear to correlate with clinical abnormalities (3.1%). In addition, we have identified 4 patients with a subtelomeric abnormality that was also found in one of their parents, raising the possibility that the finding may be a variant. Pt 1 had a PDA, VSD, ASD, TE fistula, duodenal atresia. Subtelomeric studies indicated a duplication of the 14q subtelomere probe (der(14)t(14;14)(p12;q32) which was found to be paternally inherited. There was no history of any medical problems in this patient's father. Pt 2 presented with clinical features of Goldenhar syndrome and subtelomeric testing revealed a deletion of 21q (46,XX,ishdel21q subtel(21qtel07-). Parental studies demonstrated that this deletion was maternally inherited. Pts 3 and 4 demonstrated the same subtelomeric deletion. The third patient presented with TOF, dysmorphic features and was found to have a deletion of 4q35 (46,XY, del(4)(q35).ishdel(4)(qtel)(4qtel11-). This deletion was visible as a subtle change on G-banding studies. Parental chromosomes demonstrated that the deletion was maternally inherited. The patient's mother demonstrated duplicated distal phalanges of the second toe and duplicated distal phalanges of the third toe on one foot, and small distal phalanges on the other foot, hearing loss, and learning differences with no identifiable syndrome. Pt 4 presented with IUGR, hypospadias and mild dysmorphic features. The deletion was not visible by G-banding, but subtelomeric studies demonstrated a deletion of 4q35, inherited from his healthy father. The significance of these subtelomeric abnormalities is not clear, but documentation of the frequency and clinical features associated with these abnormalities is needed. These may be normal variants, or they may represent abnormalities that show variable expressivity (possibly dependent on the genes associated with the other allele).

**Delineation of the clinical manifestations associated with an unbalanced familial chromosome abnormality:**

**46,XX,der(9)ins(9;11)(p23;??).** *J. Murphy*<sup>1</sup>, *E. Kolomietz*<sup>2</sup>, *I.E. Teshima*<sup>3</sup>, *D. Chitayat*<sup>1</sup>. 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto; 2) Department of Laboratory Medicine and Pathology, Mount Sinai Hospital, Toronto; 3) Department of Pediatric Laboratory Medicine, Hospital for Sick Children, Toronto.

Determining the clinical manifestations associated with abnormal karyotypes is an important tool for the identification of genetic disorders and the genes causing them. We present a family with microcephaly, mild to moderate mental retardation and mood disorder associated with duplication of a segment derived from chromosome 11. The proband was a 16-year-old girl in her second trimester of pregnancy who presented with a known 46,XX,9p+ karyotype, which was detected at the age of five when she, her sister and her mother were investigated for learning difficulties. Detailed assessment of the family members indicated that the proband and her mother have mild mental retardation, and her sibling has moderate mental retardation. All three have microcephaly and mood disorders, with the youngest age of presentation of depression being in the proband at age fourteen. A maternal aunt is described as having severe mental retardation and the maternal grandparents are described as having no learning difficulties. Chromosome analysis has not been performed to date on these individuals. Cytogenetic analysis done on the proband revealed a partial trisomy of chromosome 11 due to an unbalanced maternally inherited insertion: 46,XX,der(9)ins(9;11)(p23;??)mat. The insertion of chromosome 11 material into the chromosome 9 short arm was identified by SKY and confirmed by FISH using whole chromosome paint probes WCP9 and WCP11 (VYSIS) and a 9ptel FISH probe specific for the telomeric region of the short arm of chromosome 9 (Cytocell). Further molecular and cytogenetic investigations are underway to help define this region. This relatively large duplication of a segment from chromosome 11 is associated with a surprisingly little physical phenotypic effect in this family. The finding of the same mood disorder in all affected members of the family is important in determining genes associated with mood disorders.

**Selection of patients with idiopathic mental retardation for subtelomeric FISH analysis: Experience at Hospital for Sick Children, Toronto.** *R.E. Mueller<sup>1</sup>, G. Nie<sup>1</sup>, M.M. Nezarati<sup>3</sup>, L. Dupuis<sup>3</sup>, A. Teebi<sup>3</sup>, S. Kennedy<sup>3</sup>, D. Chitayat<sup>3</sup>, D. Stephens<sup>2</sup>, M. Shago<sup>1</sup>, I. Teshima<sup>1</sup>. 1) Cytogenetics, Department of Pediatric Laboratory Medicine; 2) Department of Population Health Sciences; 3) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Canada.*

**Background:** Subtle chromosomal rearrangements are a common cause of mental retardation (Knight et al 1999). DeVries et al (2001) have proposed a five item checklist to improve the diagnostic pick-up rate among mentally retarded patients. After one year of experience using the Vysis ToTelVysion Multi-colour FISH Probe Panel at the Hospital for Sick Children, a large, tertiary care centre, we reviewed our results of testing for subtelomeric FISH rearrangement. **Design:** Clinical geneticists at the Hospital for Sick Children selected patients with idiopathic mental retardation and multiple congenital abnormalities suggestive of a chromosomal abnormality using their own criteria and subsequently evaluated the same patients using the deVries et al checklist. No particular score was required for testing. **Results:** Of 95 patients who had apparently normal karyotypes, seven patients were identified with subtelomeric chromosomal rearrangements: del(1)(p36p36)(CEB108/T7-), der(1)t(1;9)(p36.3;p24)(CEB108/T7+,305J7/T7+), del(6)(6PTEL48-), del(10)(D10S2490-), der(12)t(9;12)(q34.3;p13.1)(D9S325+,8M16/SP6-), der(12)t(12;16)(p13.3;p13.3)(8M16/SP6-,D163399+)pat, del(22)(q13.3)(ARSA-,D22S1726-). The detection rate was 7/95 or 7.4% (95% CI=2.1-12.6%). Two abnormalities were later judged to be familial variants when they were also identified in unaffected family members. The patients with normal subtelomeric regions had a mean score on the deVries et al checklist of 5.16 (SD 1.80, n=88) while those with subtelomeric changes had a mean score of 5.29 (SD 2.29, n=7). No one category made a disproportionate contribution to the total scores. **Conclusions:** Our patient selection is appropriate based on our pick-up rate. However, in agreement with deVries et al, we found the phenotype associated with subtelomeric chromosome changes is variable.

**Examination of the origin and mechanism of the idic(X) chromosome in case of Turner Syndrome with a mosaic karyotype.** *N.B. Kardon<sup>1</sup>, J.B. Ravnán<sup>2</sup>, R. Rapaport<sup>3</sup>, D. Bowlby<sup>3</sup>, B. Levy<sup>1</sup>, L. Edelmann<sup>1</sup>.* 1) Dept Human Genetics, Mount Sinai Sch of Medicine, New York, NY; 2) Genzyme Genetics, Santa Fe, NM; 3) Division of Pediatric Endocrinology, Mount Sinai Sch of Medicine, New York, NY.

The i(Xq) chromosome is the most common isochromosome and is present in 30% of all Turner syndrome females. In these cases the genetic defect can be viewed as both a sex chromosome aneuploidy and a chromosomal rearrangement disorder. We present the cytogenetic and molecular analysis of a case of classic Turner syndrome in a young woman with the mosaic karyotype: 46,X,idic(X)(p11.2)[13]/46,X,+mar[8]/46,X,+2mar[1]. Although the initial chromosome analysis of this patient, performed in The Republic of Georgia, was reported as 46,XX, our analysis of more than 150 cells failed to identify a single cell with two normal X chromosomes. The marker chromosomes were positive for X centromere material by Fluorescence In Situ Hybridization (FISH) and the presence of 2 centromeres was confirmed on the idic(X) using the DXZ1 probe (Vysis). Microsatellite analysis revealed that the idic(X) resulted from an intra-chromosomal exchange and was paternal in origin. Several BACs spanning 6 Mb on Xp11 were used as probes to narrow the breakpoints on Xp11. We determined that the breakpoints on Xp were proximal to the BAC RP11 348F1 on Xp11.22 at position 49.8 Mb on genomic contig NT\_011638. In addition, there was no evidence of euchromatic material on the marker chromosomes. Interestingly, FISH analysis performed with BAC RP11 38O23, which maps to the SSX (Synovial Sarcoma X) gene cluster, containing SSX5 and SSX6 on Xp11.22, also hybridized to a second locus more proximal on the normal X chromosome. This BAC had two positive signals on the idic(X) chromosome, however, the signal corresponded to the second more proximal locus, most likely the region containing the SSX2, SSX7 and SSX8 genes. The SSX genes on Xp11 are involved in the reciprocal somatic t(X;18)(p11;q11) that is characteristic of synovial sarcomas and generates a fusion gene between an SSX gene and the SYT gene on chromosome 18. We are currently investigating whether this repeated gene cluster was involved in the generation of the idic(X) in this patient.

**A rare cytogenetic compliment with two abnormal cell lines in a new born female.** *C.N. Harris<sup>1</sup>, A. Babu<sup>2</sup>, S. Kleyman<sup>2</sup>, M.J. Macera<sup>2</sup>.* 1) Long Island College Hospital, Brooklyn, NY; 2) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

A 3555 gm baby girl was delivered by caesarian section at 39 weeks gestation of a 37 y. o. mother who refused amniocentesis. Remarkable features included low set ears, a large protruding tongue, symmetrical wide set nipples, shortened limbs, broad hands and a grade 1 to 2 systolic heart murmur. Chromosome analysis on peripheral blood lymphocytes, revealed two different abnormal cell lines. About 63% of her cells had a 45,X karyotype, while the remaining 37% cells had 46,XX,der(21;21)(q10;q10),+21. No normal cells were seen in 150 cells. Cytogenetic analysis of the father and a sibling showed normal karyotypes. Maternal specimen was not available for analysis. Considering the odds, based on the findings on the sibling and the family history, the mother is not likely to be a carrier of the der(21;21)(q10;q10). The occurrence of two unrelated abnormal cell lines, with no normal cells is very rare. There are only two previous reports of such cases with two abnormal cell lines, one with two aneusomic cell lines and the other the same as that seen in the present case. It is noteworthy that among such cases, two of these have a sex chromosome aneusomy coincident with an isochromosome 21. The most interesting is the mechanisms(s) giving rise to such a mosaic/chimera. The mechanism resulting in two aneusomic cell lines is obviously simpler than that required to produce an aneusomic cell line and a cell line with a structural rearrangement. One of the possible origins of such a chimera is a pre-zygotic event where two independent zygotes result from oocytes and/or a polar body, conjoined at early embryonic development. Alternatively, a series of post-zygotic events with concurrent loss of the normal cell line can explain the mosaic. Additional studies on DNA markers should enlighten the true mechanism involved in the present case.

**22q13.3 deletion syndrome : cryptic terminal rearrangements involving 22q13.3 is a significant cause of unspecified developmental delay and unexplained mental retardation.** *S.K. Murthy<sup>1</sup>, E. Lemyre<sup>2</sup>.* 1) Department of Pathology, Cytogenetic Laboratory, Hospital Sainte Justine, Montreal, PQ, Canada; 2) Departments of Pediatric and Medical Genetics, Hospital Sainte Justine, Montreal, PQ, Canada.

22q13.3 deletion, leading to a well recognized syndrome, is a subtle chromosomal change that may remain undetected by routine cytogenetic analysis. We report here a male child with global developmental delay, hypotonia, severe expressive language delay and minor dysmorphic features. Cytogenetic analysis showed a 47,XYY,rec(22)dup(22p)inv(22)(p11q13.2)mat.ish inv del(22)(TUPLE+, ARSA-,qtel-) karyotype. The abnormal chromosome 22 was inherited from his mother. She showed the presence of a pericentric inversion of chromosome 22 with no loss of the ARSA locus. The patient's normal younger brother carried the non recombined maternal inversion 22. One of the patient's maternal aunts with mental retardation also showed the same recombinant chromosome 22 with the 22q13.3 deletion. These clinical abnormalities in the patient and his aunt can be attributed to haploinsufficiency of genes in the deleted region of 22q13.3. Also to our knowledge, this is the first report of a recombinant 22 with 22q13.3 deletion in association with a sex chromosomal aneuploidy of XYY. The second case is a 10-month-old female with global developmental delay carrying a cryptic 22q13.3 deletion: 46,XX.ish del(22)(q13.3)(TUPLE+,ARSA-,qtel-). Her father showed an apparently balanced translocation between chromosomes 12 and 22 and the karyotype was interpreted as 46,XY.ish t(12;22)(q24;q13.3)(tel12q-,ARSA+,tel22q+;TUPLE+,ARSA-,tel22q-, tel12q+). FISH with 12q subtelomeric probe confirmed the paternal origin of the der(22) and trisomy for 12q subtelomere in the patient. The subtle nature of this chromosome change makes it difficult to detect the 22q13.3 microdeletion. Due to a non specific phenotype, this syndrome may be underdiagnosed clinically. Rigorous clinical assessment followed by high resolution chromosome analysis and FISH should be carried out to confirm this diagnosis, particularly in hypotonic children in whom other etiologies have been excluded especially in the presence of a major language delay.

**Developmental Genome Anatomy Project (DGAP): Identification of genes involved in human development.** *N.T. Leach*<sup>1,5</sup>, *G.A.P. Bruns*<sup>3,5</sup>, *R. Eisenman*<sup>3</sup>, *H.L. Ferguson*<sup>1</sup>, *J.F. Gusella*<sup>2,5</sup>, *D.J. Harris*<sup>1,3</sup>, *S.R. Herrick*<sup>1</sup>, *A.W. Higgins*<sup>1,5</sup>, *H.G. Kim*<sup>2,5</sup>, *A.H. Ligon*<sup>1,5</sup>, *W. Quintero-Rivera*<sup>2,5</sup>, *R.E. Williamson*<sup>5</sup>, *C.C. Morton*<sup>1,5</sup>. 1) Brigham & Women's Hospital, Boston, MA; 2) Massachusetts General Hospital, Charlestown, MA; 3) Children's Hospital, Boston, MA; 4) Howard Hughes Medical Institute; 5) Harvard Medical School, Boston, MA.

The Developmental Genome Anatomy Project (DGAP, <http://dgap.harvard.edu>) is a collaborative effort to identify genes important for human development. Breakpoints of balanced chromosomal rearrangements in individuals with congenital anomalies are analyzed in an attempt to uncover potential causal relationships between rearrangements and phenotypes. A benefit to the individual and geneticist alike is a possible explanation of a disorder that may be otherwise undefined. Our study takes a high-throughput approach by utilizing four groups expert in: (1) patient identification and sample collection, (2) FISH-based breakpoint localization, (3) breakpoint cloning and candidate gene identification, and (4) functional analysis in model organisms. More than 126 cases have been ascertained through collaborations with clinicians, cytogeneticists and genetic counselors. To date, 62 breakpoints have been FISH-mapped, 27 of which have been positioned on the human genome map within a single BAC clone. Fifteen breakpoints have been localized further to 0.5-36 kb, and 8 have been cloned. In 8 cases the breakpoints have been shown to disrupt sequences of known genes. Surprisingly, the presence of a microdeletion at the breakpoint was found in only 1/27 cases. Attractive candidate genes such as *DGKD* for a seizure phenotype, *MTAP* and *FLJ21820* for hearing loss, *FGFR1* for Kallman syndrome and several others, are under extensive molecular study. Knock-out mouse models for *FLJ21820* and *DGKD* orthologs are being created for functional testing. DGAP success in gene discovery is built on the selfless dedication of the medical genetics community and will continue to provide crucial insights into human development.

**Molecular Evaluation of Maternal Cell Contamination in Spontaneous Abortions Cultured Cells.** *S. Nazarenko, T. Nikitina, I. Lebedev, N. Sukhanova, E. Sazhenova, M. Nazarenko, A. Beljaeva.* Cytogenetics Lab, Inst Med Gen, Tomsk Science Ctr, Tomsk, Tomsk, Russia.

Estimation of the chromosome constitution of the fetus by long-term tissue cell cultures is prone to error due to contamination of such cultures by maternal cells. Only a few studies have been performed to discriminate between true confined placental mosaicism and maternal cell contamination (MCC) by molecular methods. In the present study, we examined the results of retrospective cytogenetic analysis of 478 first trimester spontaneous abortions. In 16% of the embryos with a 46,XX karyotype a molecular assay of the amelogenin locus revealed the presence of Y-chromosome DNA in non-cultured embryonic tissues. There was a significantly prolonged cell cultivation time prior to chromosome harvesting for these conceptions in comparison with abortions without a Y-chromosome. A mathematical model for estimation of MCC level, expected rates of different karyotypes in abortions with correction for MCC and diagnostic accuracy of conventional cytogenetic analysis is proposed. Taking MCC into account, the frequency of chromosomal abnormalities in the studied sample of spontaneous abortions rose from 54.6% to 60.3% and the sex ratio in abortions with normal karyotype increased from 0.66 to 1.02. The model allows to evaluate the diagnostic accuracy of cytogenetic analysis, which make up to 92.3%. The experimental validation of the proposed model was performed using several highly polymorphic microsatellite DNA markers for chromosomes 2, 11, 16, 19, 20 and 21 in 60 46,XX embryos and their parents. For 7 abortions (11.7%), including 4 without molecular evidence for a Y-chromosome, numerical chromosomal abnormalities were revealed and confirmed by FISH. This frequency corresponds well to the expected rate 8.3%, predicted by the model and study design. MCC clearly affects the rates of chromosomal abnormalities and sex ratios in spontaneous abortions. Thus, correction for MCC should be taken into account before invoking biological explanations of sex ratio bias, such as the effect of X-linked lethal genes or abnormal X-inactivation, and may be useful to include in diagnostic reporting.

**Meiotic 3:1 segregation outcome in POCs and livebirths.** *M. LeMieux, K. Reddy.* Genzyme Genetics, Orange, CA.

Our aim is to assess the empirical distribution of 3:1 segregants of balanced reciprocal translocations and the clinical impact. In 40 cases compatible with a 3:1 segregation, 15 were products of conception (POC) and 25 were livebirths. Parental chromosome(cs) studies showed maternal inheritance in 21(81%), paternal in 4(15%) and de novo in 1(4%) case. In POC and livebirths the 3:1 segregation outcomes were: tertiary trisomy (TT) with a supernumerary derivative cs in 60% [9/15] and 64% [16/25], interchange trisomy (IT) for a whole chromosome due to two translocation cs and a normal homolog segregation in 7% [1/15] and 28% [7/25], and tertiary monosomy (TM) for one of the derivative cs in 33% [5/15] and 8% [2/25]. The TT with supernumerary der(22)t(11;22), was seen in 5 cases. An acrocentric cs was involved in all livebirth cases and 47 % of POCs. The TT POCs had a derivative cs that was on average (2.2 fold) larger than in livebirths. IT usually involved non-viable trisomies (3, 10, 15, 9 & 21) in POC as compared to livebirths (21). TM had a loss of an acrocentric cs 22(50%), 21(25%), or 15(25%), which was involved in the translocation. The other derivative cs present was usually a nonacrocentric and in 7/8 cases the breakpoint was in the terminal band. Hence, the loss was minimal and the gain was partial long arm of 21, 22 or 15. In many cases FISH studies were necessary to characterize or confirm the origin of the derivative cs. The clinical spectrum ranged from mild to severe. The cases with apparently normal to mild phenotype were TT and TM found in mothers with an abnormal amniocentesis result. A TT found in a 37-year-old fertile woman whose mother carried a balanced translocation. Two siblings, one a 35-year old apparently normal female with TT and the other 37-year-old with TM resulting from 3:1 segregation of maternal t(6;21) (q27;q21.2). A 39-year-old patient with premature menopause and TM, 45,XX,der(18)t(18;22) (p11.3;q11.2),-22.ish der(18)(ARSA+,TUPLE+,D14Z1/D22Z1-,D18S552-,D18Z1+,MBP+) karyotype. All other cases had congenital abnormalities. Included in this group, was a newborn with TM, 45,XY, der(13)t(13;15)(p11.2;q15),-15 pat.ish der(13) (GABRB3-,PML+,D13Z1/D21Z1+) karyotype and Prader-Willi syndrome.

Program Nr: 798 from 2003 ASHG Annual Meeting

**The double minutes chromosomes in workers exposed to densely-ionising (high-LET) radiation.** *N. Popova, V. Puzyrev, S. Nazarenko.* Institute of Medical Genetics, Tomsk, Russia.

The analysis of peripheral blood lymphocytes was performed in the 60 healthy workers of Nuclear-Chemical Plant (NCP) who have various internal Pu-239 burdens (I group - 1,5-11 nCi; II group - 13-25 nCi and III group - more 40 nCi). As control 36 unexposed persons from ecologically clean village were observed. In average 300 cells per individual were analyzed. Double minutes chromosomes (DMs) have been found only in plutonium workers of II and III groups. In II group 10 from 22 studied individuals and in III group 7 from 24 persons had cells with DMs. It was found 23 (II group) and 10 (III group) cells with DMs per 5778 and 6560 metaphases (0.350.10 and 0.150.05 percent) respectively. Differences between II and III groups of plutonium workers and control individuals were statistically significant ( $P < 0.01$ ). We believe, that DMs in peripheral blood lymphocytes of plutonium workers may be a biomarker of densely-ionising internal irradiation and can display an initial stage of cell transformation. Plutonium workers who have cells with DMs should be periodically to undergo cytogenetic testing and frequent clinical monitoring for early detection of possible oncological pathology.

**Novel X:Y translocation in a female habitus with dysmorphic features and implications for sex reversal. A.**

*Maleki*<sup>1,2,3</sup>, *D. Manchester*<sup>1,3</sup>, *C. Donovan*<sup>2</sup>, *N. Parker*<sup>2</sup>, *J. Kennaugh*<sup>4</sup>, *L. McGavran*<sup>1,2,3</sup>. 1) University of Colorado Health Sciences Center-Department of Pathology; 2) Colorado Genetics Laboratory; 3) The Children's Hospital-Department of Pediatrics; 4) Presbyterian/St. Luke's Hospital, Denver, CO.

We report the case of a novel X;Y translocation female habitus newborn referred for standard cytogenetic testing and a FISH trisomy panel to rule out an abnormality consistent with Trisomy 18 features. Although preliminary FISH findings were negative for trisomy 13, 18 and 21, she had the presence of a Y chromosome [Ycen (DYZ3)]. Clinical findings at birth included intrauterine growth retardation, agenesis of the corpus callosum, a Dandy Walker variant, telecanthus, mild retrognathia, overlapping fingers, an atrial septal defect, seizures, incomplete formation of the labia majora superiorly, and a prominent clitoris. The distal vagina appeared normal. A well formed uterus was seen on ultrasound and renal ultrasound was normal. Standard cytogenetic analysis revealed a 46,X,der(Y)t(X;Y)(p11.23;q11.222) karyotype as the sole abnormality found in all cells examined. To further characterize the der(Y), additional FISH studies were performed which confirmed the presence of the SRY locus, absence of sat III Yqh, presence of both Xp and Yp subtelomeric sequences, presence of the Kallman locus, and normal 9ps. This confirmed the presence of an abnormal sex chromosome including the p arms of both the X and Y chromosomes. There are few cases of female der(Y)t(X;Y) in the literature. Bardoni et al.,(1993) describe a dosage sensitive sex reversal gene (DSS) on Xp21 which, when duplicated, or present without an XIST gene, can result in a phenotypic female, even in the presence of SRY. The case presented here results in a novel der(Y), including Y short arm with minimal Yq, and whole X short arm with the lack of an Xq, which results in functional disomy of the majority of the genes present on Xp, and three copies of the pseudoautosomal region Xp/Yp. The more involved phenotype of this child is most likely due to deletion of the X-inactivation center and the resultant lack of dosage compensation of the genes present on Xp.

**Analysis of a translocation breakpoint by FISH and PRINS: a molecular cytogenetic approach.** *M. Nimmakayalu<sup>1</sup>, A.L. Gotter<sup>1</sup>, B.S. Emanuel<sup>1,2</sup>*. 1) Human Genetics & Molecular Biology, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, University of Pennsylvania. School of Medicine, Philadelphia, PA.

Low copy repeats (LCRs) located in 22q11.2, especially LCR-B, are susceptible to rearrangements associated with several common constitutional disorders. These include DiGeorge syndrome, Velocardiofacial syndrome, and recurrent translocations of 22q11 including the constitutional t(11;22) and t(17;22). The presence of palindromic AT rich repeats (PATRRs) within LCR-B of 22q11.2, as well as within the 11q23 and 17q11 regions, has suggested a palindrome-mediated, stem loop mechanism for the generation of recurrent constitutional 22q11 translocations. Several additional autosomes and the X chromosome, are involved in non-recurrent rearrangements with the PATRR of LCR-B of 22q11.2. We have adapted a molecular cytogenetic approach in the form of fluorescence in-situ hybridization (FISH) and Primed in-situ hybridization (PRINS) to rapidly localize the BP of one of these sporadic 22q11.2 translocations, a t(4;22). This is the first time PRINS has been used to fine-map a translocation breakpoint (BP). Our approach localized the t(4;22) BPs within 4q36 and 22q11.2, and permitted cloning and analysis of translocation junction fragments. By FISH, a 200 kb BAC clone crossing the translocation BP was identified on chromosome 4. Multiple primer pairs were designed from the sequence of the BP-spanning BAC to use for PRINS reactions. Amplification of adjacent primer pairs, labeled in two colors, allowed us to narrow the t(4;22) BP to a 6.7 kb clonable region. Identical primer pairs were used for PCR mapping of t(4;22) somatic cell hybrid DNA, confirming the PRINS localization results. The PRINS approach allowed rapid BP cloning and demonstrated the presence of a 270 bp palindromic sequence at the chromosome 4 BP. Analysis of this BP further supports a stem loop secondary structure mechanism for the formation of other, non-recurrent translocations with 22q11.

**Tandem duplication of Xq13->q22 in a newborn female with hydrocephalus.** *P. Mowrey<sup>1</sup>, L. Bason<sup>2</sup>, E. Arch<sup>2</sup>, I. Gadi<sup>1</sup>, L. Wisniewski<sup>1</sup>, J. Tepperberg<sup>1</sup>, P. Singh-Kahlon<sup>1</sup>, P. Papenhausen<sup>1</sup>.* 1) Diagnostic Genetics, Laboratory Corp of America, Res Triangle Pk, NC; 2) Division of Medical Genetics, A.I. DuPont Hospital for Children, Wilmington, DE.

A 6 month old female presented at birth with hydrocephalus and later with decreased muscle tone, DD and FTT. Shunting was performed at one month. Standard cytogenetics at 6 months revealed an extra band segment within one of the X chromosomes at Xq13. Chromosome paint confirmed an X derivation and high resolution analysis suggested direct tandem duplication of X(q13->q22). Interestingly, the abnormal X appeared to be active in most cells by virtue of scoring inactivation folding, suggesting partial functional disomy in a significant proportion of cells. Replication studies and parental karyotyping are in process. In general, short stature, hypotonia, and in some cases MR, are characteristic of Xq duplications in females. However, no previous case was apparently associated with hydrocephalus nor did any of these appear to involve the q13->q22 region. The abnormal X in previous studies in the literature has not always been inactive so that functional partial disomy was present. It is likely that functional nullosomy present in X deletions results in much faster and complete inactivation skewing due to strong selective disadvantage early in embryonic development which may account for the milder deletion phenotypes compared to duplications.

**De Novo 46,XX,del(4)(q12q13.3) in a 3 year-old with piebald trait.** *D. LaGrave<sup>1</sup>, M.S. Eswara<sup>2</sup>, S.P. Yang<sup>2</sup>, M. Tomlinson<sup>1</sup>, N. Qin<sup>1</sup>.* 1) Cytogenetics Department, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA; 2) GenetiCare Medical Associates, Davis, CA.

We describe a 3 year-old girl born at term to a 24 year-old gravida 5, para 2, SAB 3, phenotypically normal mother. Amniocentesis was performed due to two previous pregnancies with neural tube defects that resulted in intrauterine fetal demise at 32 and 37 weeks, respectively. Chromosome studies on the amniocytes revealed an interstitial deletion in the long arm of one chromosome 4. However, a series of ultrasounds were negative for any adverse findings. At birth, the infant weighed 6 lb, 15 oz, was 20 inches in length, and had an OFC of 33cm. No neonatal problems were reported. Findings from a CT scan of the head and an echocardiogram were reportedly negative. Hearing and vision were normal at birth, although esotropia was diagnosed at 18 months. The patient shows delay in all milestones. She is estimated to be functioning at a 6-month level for speech and communication and at a one-year level socially. She cannot yet eat solid foods. Her weight is at the 97<sup>th</sup> percentile, her height is at the 75<sup>th</sup> percentile and her OFC is at the 50<sup>th</sup> percentile. She displays subtle dysmorphic features including a high forehead, hypertelorism, a short nose, and a small midface. Her ears are low-set and posteriorly rotated, but with normal morphology. Her teeth were late in erupting, are yellowish in color and seem to have abnormal enamel. She has a midline white forelock and several large hypopigmented areas on her trunk and lower extremities. A few smaller areas of hyperpigmentation are present as well. She has had no significant medical problems or surgeries. Repeat karyotype of peripheral blood lymphocytes was performed at 3 years of age. This confirmed the previous finding of an interstitial deletion on 4q and identified the breakpoints as 4q12q13.3. FISH analysis using a whole chromosome paint probe specific for chromosome 4 revealed that the missing segment from 4 was not present on any other chromosome. Parental chromosome studies were normal. In summary, we discuss a rare deletion on 4q that resulted in developmental delay, mild dysmorphic features, and piebald trait.

**Quantification of aneuploid fetal cells in peripheral blood of pregnant women using molecular cytogenetic techniques.** *K. Krabchi<sup>1</sup>, M. Gadjji<sup>1</sup>, L.G. Jackson<sup>3</sup>, M. Ferland<sup>1</sup>, S. Roy<sup>1</sup>, M. Bronsard<sup>1</sup>, J.C. Forest<sup>2</sup>, R. Drouin<sup>1</sup>.* 1) Human & Molecular Genetics Unit, Medical Biol, St Francois d'Assise Hosp, Laval Univ, Quebec, PQ, Canada; 2) Perinatal Unit, St Francois d'Assise Hosp, Laval Univ, Quebec, PQ, Canada; 3) Dept Obstetrics & Gynecology, Drexel Univ College of medicine, Philadelphia, PA, USA.

Background: Fetal nucleated cells circulating in the peripheral blood during pregnancy are potential targets for noninvasive genetic testing. Molecular cytogenetic techniques have provided definitive evidence of their presence. In a previous study, we have shown that it is possible to reliably and reproducibly identify fetal cells in maternal blood of all pregnant women and to quantify all fetal nucleated cells (Krabchi K. et al Clin Genet 60:145, 2001). This number fluctuated between 2 to 6 cells per mL of maternal blood between 18th and 22nd weeks of gestation in euploid pregnancies. Objective: The aim of our study is to determine, using the same approach, the total number of fetal nucleated cells in maternal blood of pregnant women bearing an aneuploid conceptus. Methods: In order to achieve maximum recovery of fetal cells, we used a simple and rapid harvesting method without any enrichment procedures, followed by either Fluorescent in situ hybridization (FISH) or Primed IN Situ (PRINS) labeling technique. Detection of fetal cells was carried out using chromosome-centromeric or locus specific probes directly coupled to fluorochromes for FISH (CEP-X a-sat, CEP-Y sat III, CEP-18 a-sat, LSI-21, Vysis Inc.) or specific primers for chromosomes X, Y, 18, 7 and 8, for PRINS reaction. PRINS or FISH techniques were performed on blood specimens provided by 39 healthy pregnant women carrying an aneuploid fetus: 47,XY,+21 (12 cases); 47,XX,+21 (9); 47,XY,+18 (6); 47,XX,+18 (2); 47,XY,+13 (1); 47,XXX (2); 47,XXY (2); 47,XYY(1); 45,X (1); 69,XXX (1) and 69,XXY (2). Results: Between 4 and 32 fetal cells per mL were detected. These numbers are on the average 5-fold higher than the number of fetal cells observed in euploid pregnancies. Conclusion: The number of fetal cells in maternal circulation is remarkably higher in aneuploid pregnancies.

**Loss of abnormal cell line in chromosomal mosaic syndromes is due to increased cell death.** *S.L. Wenger, W. Tang.*  
Pathology, West Virginia University, Morgantown, WV.

Chromosomal mosaic syndromes, such as i(12p), i(9p) and trisomy 8 mosaicism, are characterized by a decrease of the abnormal cell line with age of patient, in vivo, or passaging of cells, in vitro. It has been thought that this is due to selective growth advantage of the normal cell line. We have shown previously that the cell cycle kinetics is similar for normal and trisomy 8 cells within the same tissues from an individual with trisomy 8 mosaicism (Hulley BJ et al. *Am J Med Genet* 2003;116A:144-6). Cell cycle kinetics was performed on i(9p) peripheral blood cells, which showed a similar rate of cell division for the normal and abnormal cells. In addition, amniocytes from an i(12p) fetus were examined for cell death using annexin V stain. A normal diploid control and i(12p) cultured cells showed annexin V fluorescent staining in the cytoplasm of 9% and 7% of cells, respectively. Additional cells were fixed with formalin and processed for FISH using a probe for the centromere of chromosome 12. These same cells were then stained with annexin V. In the normal control, 29% amniocytes stained positive for annexin V, suggesting the fixative process affected the cell membrane, thereby increasing the annexin V staining. In the mosaic amniocytes, cells with 2 signals (normal) had 28% annexin V positive cells, similar to the control cells. However, cells with 3 signals (i(12p)) had 43% annexin V positive cells, which is 50% higher than normal diploid cells ( $p < 0.1$ ). Although not statistically significant due to fewer aneuploid cells than diploid, the results suggest that the abnormal cell line in chromosomal mosaic syndromes decrease over time due to a higher rate of cell death, and therefore a growth disadvantage of the abnormal cell line.

**Mosaic sex chromosome anomalies in a normal appearing male newborn: prenatal and postnatal molecular cytogenetics studies.** *J. Xu<sup>1,2</sup>, M.J. Huggins<sup>3</sup>, T. Heshka<sup>1,2</sup>, S.A. Farrell<sup>4</sup>, M.J.M. Nowaczyk<sup>1,2</sup>.* 1) Pathology and Molecular Medicine; 2) Lab Medicine; 3) Obstetrics and Gynecology, Hamilton Health Sciences and McMaster University; 4) Lab Medicine, Credit Valley Hosp, Mississauga, ON, Canada.

A 40-year-old mother at 15.1 weeks gestation had amniocentesis for advanced maternal age. G-banding showed 11 of 12 in situ colonies had a marker, 46,X,+mar and 1 colony had 45,X. FISH of 37 subculture cells from 6 colonies, using centromere X (CEPX) and Y (CEPY) probes, and SRY at Yp11.3 showed 4 cell lines and 2 types of marker, both being of Y origin. One marker had single CEPY (12 cells) or SRY signal (14 cells), which was interpreted as deletion Yq, del(Y)(q11). Another marker had double CEPY signals in the proximal region (2 cells) or double SRY signals, one at each end (1 cell). This was interpreted as isodicentric Y, idic(Y)(q11). Two of the 4 cell lines were male; 46,X,del(Y)(q11)(26/37, 70%) and 47,XX,idic(Y)(q11)(3/37; 8%), and 2 were female; 45,X (2/37, 5%) and 46,XX (6/37, 16%). Presence of Y material (especially SRY) in most of the 37 subculture cells and 12 colonies was consistent with the ultrasound finding of a male fetus with no evidence of malformations. The couple was informed that such a prenatal finding could be associated with a wide phenotypic range, with a phenotypically normal male baby being likely, and with a significant risk of a male being infertile. After counseling, the couple chose to continue the pregnancy. The male infant was born at term and was normal in appearance. At birth, G-banding of the cultured cord blood cells showed 3 cell lines: 46,XX[2/50,4%], 46,X,del(Y)(q11)[33/50, 66%], and 46,X with a small ring[15/50,30%]. FISH confirmed the presence of SRY or CEPY signals in the marker. G-banding of the cultured cord tissue cells also showed 3 cell lines: 46,X,del(Y)(q11)[37/50, 74%], 47, XX, idic(Y)(q11)[4/50, 8%], and 45,X[8/50,16%]. In addition, 1 cell was 46,X with a large ring. This case suggests that a prenatal finding of multiple sex chromosome anomalies involving del(Y)(q11), idic(Y)(q11), r(?Y), or 45,X might not have external phenotypic effects in a male baby when the majority of the cells have 46,X, del(Y)(q11) and intact SRY.

**The 10q telomere region is a common site mediating polymorphic and pathogenic telomere rearrangements. D.**

*Waggoner<sup>1</sup>, D. Eash<sup>1</sup>, Y. Ilkin<sup>1</sup>, U. Surti<sup>2</sup>, E. McPherson<sup>2</sup>, M. Siegler<sup>3</sup>, J. Tepperberg<sup>4</sup>, C. Lese-Martin<sup>1</sup>.* 1) Dept Human Genetics, The Univ Chicago, Chicago, IL; 2) Pathol Gen, Magee Women's Hosp, Univ Pittsburgh, Pittsburgh, PA; 3) Clinical Genetics Center, Univ of Wisconsin, Madison, WI; 4) Cytogenetics Lab, LabCorp, RTP, NC.

With the increased utilization of genome-wide telomere screening it has become evident that as many as 5% of patients with previously unexplained mental retardation and/or birth defects have subtle rearrangements involving the telomeres. During the course of these studies, telomere rearrangements have been identified in normal individuals, suggesting that not all rearrangements are associated with a clinical phenotype. For example, deletions of the 2q and X/Yp telomere regions are typically inherited from a normal parent and are well described common polymorphisms. We report 6 patients with either a partial deletion, complete deletion or duplication of the 10q telomere probe, BAC 261B16. Family studies revealed that three of the four deletion cases and both duplication cases were inherited from unaffected parents. The fourth deletion case, a partial deletion, was *de novo*. Extended family mapping studies of the two families with complete deletions of the 10q telomere probe revealed that the deletions were not the same size, one was 1.4 Mb and the other 1.5 Mb, and that these deletions do not appear to correlate with the phenotypic features found in the families. This data suggests that 10q telomere deletions or duplications are often inherited and most likely represent polymorphisms. In addition, we have also observed that the 10q telomere region seems to be a common site for more complex balanced and unbalanced rearrangements. The combined experience of the two labs show that of 113 abnormal telomere cases, 12 (10.6%) involved abnormalities of 10q (including partial deletions, full deletions, duplications, reciprocal chromosomes and unbalanced translocations). Taken together, these data suggest that the 10q telomere region is a common site mediating telomere rearrangements leading to both inherited polymorphisms and unbalanced rearrangements associated with clinical perturbations.

**Prenatal diagnosis of a complex de novo translocation leading to sex reversal in a fetus.** *G.V.N. Velagaleti<sup>1,2</sup>, J.K. Northup<sup>2</sup>, S. Surendran<sup>1</sup>, M.R. Grafe<sup>2</sup>, J.M. McKee<sup>3</sup>, L.H. Lockhart<sup>1</sup>, S.M. Jalal<sup>4</sup>.* 1) Departments of Pediatrics; 2) Pathology; 3) Family Medicine, University of Texas Medical Branch, Galveston, TX; 4) Department of Pathology, Mayo Clinic, Rochester, MN.

A 15-year-old, G1P0 Caucasian female was referred for chromosome analysis at 12 weeks gestation due to family history of Down syndrome. Ultrasound examination showed multiple abnormalities including, increased nuchal fold, prominent cisterna magna, micrognathia, deviation of cardiac axis and hypoplasia of middle phalanx of the fifth digit. Chromosome analysis from amniocytes showed a complex balanced translocation, 46,XY,t(4;7;8;17)(4qter->4p15.2::17q25->17qter;7qter->7p15::4p15.2->4pter;8pter->8q12.2::7p21.2->7pter;17pter->17q25::8q12.2->8qter). Additional FISH with painting, subtelomeric probes and M-FISH studies confirmed the complex nature of the translocation. The patient elected to continue the pregnancy. A baby girl was delivered at 38 weeks of gestation. The infant had several congenital anomalies including a cleft palate, micrognathia, small mouth, posteriorly rotated ears, nail and digital abnormalities. Due to severe respiratory complications the baby died after 3 weeks. The autopsy results indicated several skeletal anomalies including 11 pairs of short and wavy ribs with deficient cartilage anteriorly. Though the infant had normal female external genitalia, the ovaries under microscopic examination were devoid of oocytes. The congenital anomalies seen in this infant are consistent with acampomelic campomelic dysplasia (acampomelic CMPD). Acampomelic CMPD is known to be caused by haploinsufficiency of SOX9 gene mapped to chromosome 17q25 which is one of the breakpoints seen in our case. There have been reports of balanced chromosome translocations involving 17q25 leading to ACMD with sex reversal, but this is the first report of Acampomelic CMPD caused by a complex de novo translocation diagnosed prenatally. Additional studies to determine the involvement of SOX9 are in progress.

**Bivalent chiasma frequencies in individual chromosomes using cenM-FISH analysis of human pachytene cells. F.**

*Sun*<sup>1</sup>, *M. Oliver-Bonet*<sup>2</sup>, *T. Liehr*<sup>3</sup>, *K. Trpkov*<sup>4</sup>, *E. Ko*<sup>5</sup>, *J. Navarro*<sup>2</sup>, *J. Benet*<sup>2</sup>, *R.H. Martin*<sup>1,5</sup>. 1) Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Unitat de Biologia, Universitat Autònoma de Barcelona, Bellaterra, Spain; 3) Institute of Human Genetics and Anthropology, Jena, Germany; 4) Pathology, Rockyview Hospital, Calgary, AB, Canada; 5) Alberta Children's Hospital, Calgary, AB, Canada.

There is very little information on the number of chiasmata in individual human germ cells. Chiasmata in individual human chromosomes have been assessed from diakinesis preparations using conventional cytogenetics. However, diakinesis preparations are very difficult to analyze as chromosome morphology and banding are poor, making identification of individual chromosomes and chiasma sites challenging. Nevertheless, these studies on a small number of men are widely cited to give estimates on recombination frequencies of individual chromosomes. A new immunocytological approach allows analysis of pachytene cells by using antibodies to detect the synaptonemal complex (SCP1/SCP3), the centromere (CREST) and sites of recombination (MLH1). We have used this approach in combination with centromere-specific multicolour (cenM-)FISH to identify chiasma sites in individual chromosomes in normal men for the first time. The men had a mean of 48 recombination foci (range 34-62) in all autosomes. For individual chromosomes, the mean number of chiasmata for chromosomes 1 to 22, respectively, was 3.85 (1), 3.60 (2), 2.90 (3), 2.45 (4), 2.75 (5), 2.65 (6), 2.60 (7), 2.20 (8), 2.40 (9), 2.30 (10), 2.40 (11), 2.55 (12), 2.00 (13), 2.05 (14), 1.90 (15), 2.15 (16), 2.25 (17), 1.90 (18), 2.00 (19), 1.85 (20), 1.00 (21), and 1.15 (22). This method allows precise identification of the number and position of recombination foci in individual chromosomes.

**Cytogenetic Study of Human Lymphocytes Exposed to Methylparaoxon *in vitro*.** P.B. Souza, E.D. Sodr , I.P. Aranha. Dept. de Bio Cel e Genet., Univ. Est. do Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brasil.

Methylparaoxon is an organophosphate pesticide largely used in agriculture. In order to exert its biological effect it must be biotransformed into its corresponding oxon-analogous, methylparaoxon, in the liver. The objective of the present work was to study the effect of methylparaoxon on chromosomes of human lymphocytes *in vitro*. Blood was collected from healthy donors 18 to 30 years old. Cells were exposed to the drug at the concentrations of 0.1, 0.25 and 0.5 ppm. Cells not exposed to the drug served as control for the experiment. Peripheral whole blood cells were incubated at 37 C for 72h in enriched RPMI 1640 medium. A larger number of metaphases were obtained with the use of colchicine (16 g/ml). Chromosomes were stained with Giemsa Gurr (2%) and analysed under optical microscope. At the 0.1 ppm concentration, in 549 metaphases, there were 343 normal ones and 206 with chromosomal abnormalities (264 gaps and 113 breaks). At the 0.25 ppm concentration 500 metaphases were analysed. Of those, 215 were normal and 285 abnormal (438 gaps and 133 breaks). At the 0.5 ppm concentration, 439 metaphases were observed. Of those, 205 were normal and 234 showed chromosomal abnormalities (353 gaps and 66 breaks). In the control group, in 500 metaphases studied, 472 were normal and 28 were abnormal (32 gaps and 7 breaks). The results obtained were extremely significant ( $\chi^2=343.5$ , p 0.0001). They suggest that methylparaoxon was responsible for the chromosomal abnormalities observed.

**Familial case of duplication 10p without phenotypic effects.** *D. Saxe*<sup>1</sup>, *K. Coleman*<sup>2</sup>, *D. Miley*<sup>1</sup>, *A. Yearall*<sup>1</sup>, *T. Sanders*<sup>1</sup>, *K. May*<sup>1</sup>. 1) Human Genetics, Emory Univ Sch of Medicine, Decatur, GA; 2) Children's Hospital of Atlanta, Atlanta, GA.

We describe a family with a history of congenital heart defects and an unrelated inherited duplication of the short arm of chromosome 10 (pterp13::p14qter). The first family member, a 19 yr. old female, was referred for amniocentesis due to low serum screen at 19.5 weeks gestation. Chromosome studies revealed extra material at 10p13. The mother's blood revealed the same abnormal 10 with no other chromosome abnormality. FISH with Coatosome 10 paint demonstrated the material to be chromosome 10 in origin. This pregnancy, and a second, with normal chromosomes, had normal outcomes. A third child had no prenatal diagnosis, but was born with tetralogy of Fallot. Cytogenetic studies at birth determined that this child carried the dup(10)(p13). FISH for DiGeorge syndrome (DGS) I and II on chromosomes 22 and 10 were negative. A family history revealing multiple relatives with either tetralogy of Fallot or other congenital heart defects prompted three other family members to have chromosome studies. These studies showed that the heart defects were unrelated to the abnormal 10p. Comparative genomic hybridization showed that the abnormal 10p is due to a duplication rather than an inversion. Therefore, this area of 10p appears to be a region which can be duplicated without phenotypic effect.

**Familial duplication, dup(11)(p14p15), in a mother and 9-year-old son confirmed by high resolution CGH.** *H.E. Wyandt*<sup>1,2</sup>, *X.L. Huang*<sup>1</sup>, *J.M. Milunsky*<sup>1,3,4</sup>. 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Dept of Pathology; 3) Dept of Pediatrics; 4) Dept of Genetics and Genomics.

A 9-year-old African-American male has been followed since 2 years of age due to his mental retardation, severe behavioral problems and dysmorphism. Initial cytogenetic analysis and chromosome painting revealed an apparent duplication in the short arm of a chromosome 11, seen also in his mentally retarded mother. The proband has moderate to severe mental retardation, a history of IUGR, infantile hypotonia, FTT, exotropia, inguinal hernia repair, and several dysmorphic features. His mother has mild mental retardation, a history of impulsivity, assaultive outbursts, and similar dysmorphism.

Although G-banding and FISH indicated a duplication, the precise origin of extra material in 11p would have required considerable trial and error in growing, labeling and hybridizing multiple BAC clones to find those specific to the area of interest. CGH, on the other hand, has the advantage of narrowing the origin of the extra material and localized it to specific bands, 11p14-11p15. Further characterization of the region with locus-specific BAC clones or probes is in progress. To our knowledge, this is the first example of a familial, cytogenetically visible duplication of euchromatin in 11p.

**Chromosome-specific variation in telomere lengths & somatic cell aneuploidy acquired with age: A twin study.** C. Rehder, L. Corey, C. Jackson-Cook. VCU, Richmond, VA.

While we know that telomeres shorten and aneuploidy increases with age, little is known about the relationship between these two phenomena, their tissue and chromosome-specific profiles in normal (non-cancerous) cells, and the influence of genetic and environmental factors on these traits. Thus, to date, we have scored aneuploidy levels in uncultured lymphocytes & buccal mucosa cells using interphase FISH and measured chromosome arm-specific telomere lengths in metaphase chromosomes (using a Q-FISH method) in 38 females [10 MZ & 6 DZ twin pairs] (ages 52-77). In lymphocytes, for all chromosomes examined, loss exceeded gain, with chromosomes 16 (4.7%); 17, 9, 2 & 1 (3.0%) showing the highest loss frequencies. These chromosomes (as well as 7, 12 & X) had significantly lower levels of loss in buccal smears ( $p < 0.001$ ). Interestingly, chromosome 7 showed significantly higher frequencies of gain (up to 6.8%) in buccal mucosa cells compared to lymphocytes ( $p < 0.0001$ ). Although average hypoploidy frequencies were not correlated between tissues, losses of chromosomes 2 and 17 were significantly correlated. Only loss of the X chromosome in lymphocytes showed a significant correlation with age ( $p < 0.01$ ). MZ twin pairs were significantly correlated for aneuploidy frequencies involving chromosomes 9, 16, 17 & X, suggesting an additive genetic effect. For chromosome-specific telomere lengths, differences were seen between females and chromosomes ( $p < 0.0001$ ) with the acrocentric chromosomes (p arms) and 2q having the longest and shortest telomeres, respectively. As expected, mean telomere length decreased with advancing age. For those females having the highest mean levels of hypoploidy ( $> 3.5\%$ ), a significant correlation was seen between increased acquired aneuploidy levels and shortened telomeres ( $p < 0.05$ ). In summary, we determined that acquired aneuploidy frequencies in females are influenced by age, heterochromatin content, and telomere length. Further study of these traits and the genetic and environmental factors that contribute to them will be helpful in understanding susceptibility to change in the human genome, as well as disease onset and progression.

**Familial 6q27 microdeletion detected by high resolution cytogenetics: Report on a family without an MCA/MR syndrome.** *L. Rong*<sup>2,1</sup>, *D. Wolff*<sup>1</sup>, *M. Kral*<sup>1</sup>, *A. LaRosa*<sup>1</sup>, *S. Pai*<sup>1</sup>. 1) Medical University of SC, Charleston; 2) Children's Hospital of Zhejiang University School of Medicine, People's Republic of China.

We evaluated a 14-month-old male for mild developmental delay, hypotonia and subtle facial dysmorphism. He was born by repeat C-section at term weighing 3240 gm. History was negative except for otitis media. Family history showed father with reading difficulty, uncle with hydrocephalus and aunt with congenital hip dysplasia. On physical examination height and weight were normal and the OFC was at the 5th centile. He had large, broad pinnae, broad nasal tip, well developed nasal bridge, mild hypotonia and otherwise normal examination. A consultant found no ocular or retinal abnormalities. CAT/CLAMS tests showed DQ of 83 and 70 for visual motor and speech and language skills, respectively. Diagnostic studies including urine organic acids, metabolic screen, serum amino acids, 7-dehydrocholesterol, very long chain fatty acids, FMR1 gene and abdominal ultrasound were normal. Brain MRI showed subependymal heterotopia in the lateral wall of the right occipital horn and mild hypointensities in the white matter suggestive of periventricular leukomalacia. High resolution chromosomal analysis showed a karyotype 46,XY del(6)(q27). Telomere FISH revealed absence of signal on one #6 homologue. No other structural abnormality was found by FISH with a whole chromosome 6 paint probe. Karyotypic analysis of his parents showed an apparently identical 6q deletion for the father. A del(6)(qTEL) was found by FISH in the father, father's brother and sister. Patient's mother and sister had normal karyotypes. All three adults with deletion 6q27 are high school graduates and gainfully employed. Proband's father achieved a full scale IQ score of 96(90 % confidence interval 93-100) on the Wechsler Abbreviated Scale for Intelligence(WASI). More extensive studies are planned. A review of 38 cases of 6q terminal deletions encompassing band 6q27 showed high incidence of CNS anomalies and mild to severe MR in all cases. The family reported here suggests that microdeletions within 6q27 only may have a more subtle phenotype that does not always include mental retardation.

**Characterization of Novel 4 and 6 Mb LCR-mediated Microduplications Involving the 22q11.2**

**DiGeorge/Velocardiofacial Syndrome Region.** *E.C. Thorland<sup>1</sup>, R.E. Ensenauer<sup>2</sup>, A. Adayinka<sup>1</sup>, H.C. Flynn<sup>1</sup>, D.B. Dawson<sup>1</sup>, J.L. Goldstein<sup>3</sup>, M.T. McDonald<sup>3</sup>, S.M. Jalal<sup>1</sup>.* 1) Lab Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Medical Genetics, Mayo Clinic, Rochester, MN; 3) Pediatrics, Duke University, Durham, NC.

Greater than 88% of patients with DiGeorge/velocardiofacial (DG/VCFS) syndrome share a common 3 megabase (Mb) deletion of 22q11.2. Low copy repeats (LCRs) have been implicated as mediators of non-allelic homologous recombination which is expected to produce both deletions and duplications of this region in equal proportions. However, although microdeletion occurs with a frequency of 1/4,000 live births, carriers of duplication of 22q11.2 are rarely reported. Utilizing interphase FISH, we have identified 13 cases of 22q11.2 microduplication that were suspected to have DG/VCFS. Clinical features vary widely with some overlap with DG/VCFS. The sizes of the microduplications have been characterized using a combination of overlapping FISH probes and STR (short tandem repeats) markers. These analyses have demonstrated that in addition to the common 3 Mb duplication (the reciprocal event of the common 3 Mb deletion), 4 Mb and 6 Mb duplications are also present in 4/13 and 2/13 patients, respectively. The origin of a 4 Mb duplication in one family with 4 affected members was determined to have occurred in the germline of the maternal grandfather. All of the duplications have a common centromeric boundary in an interval containing an LCR. Similarly, the telomeric boundaries of the 3, 4 and 6 Mb duplications are located within intervals that also contain LCRs. Deletions larger than 3 Mb have not been observed in DG/VCFS patients. Thus, larger deletions corresponding to the reciprocal of the 4 and 6 Mb duplications may not be compatible with life. Since patients were tested based on suspicion of DG/VCFS, the clinical spectrum of this newly recognized syndrome may actually be broader than presently recognized. In addition, the frequency of duplication of 22q11.2 may actually be greater than that of the deletion since there is no apparent selection against duplications that are larger than 3 Mb in size.

**Familial duplication dup(1)(p36.3) with minimal dysmorphism.** *V.S. Tonk<sup>1</sup>, G.N. Wilson<sup>1</sup>, G.V.N. Velagaleti<sup>2</sup>.* 1) Dept Pediatrics, Texas Tech Univ, Lubbock, TX; 2) Dept of Pediatrics, University of Texas Medical Branch, Galveston, TX.

Isolated duplication of the short arm of chromosome 1 are extremely rare with only 11 cases reported, most of them involve proximal and interstitial regions. Duplications of the terminal 1p are even rare with only 1 case reported. Here we report on a family where in an isolated duplication of 1p is observed in three members. The proband is a 15-year-old Caucasian female referred for seizures and mental handicap. Her height and weight were below the 5th percentile. She had difficult temperament and was diagnosed with ADHD. She has minimal dysmorphic features like hypertelorism and malformed ears. She had muscular hypotonia. Chromosome analysis revealed a karyotype 46,XX, dup(1)(p36.3). Her brother, an 8-year-old has similar problems with difficult temperament and ADHD. His height and weight were at the 25th percentile. Other than a down-turned mouth, he had no other dysmorphic features. Chromosome analysis showed similar karyotype 46,XY,dup(1)(p36.3). Subsequent chromosome analysis on the parents showed that the probands mother also has the same chromosome rearrangement. FISH studies with painting, locus specific and sub telomere probes confirmed the duplication. This is the first report of a terminal dup(1)(p36.3) segregating in a family with minimal phenotypic consequences. A complementary deletion involving the same p36.3 region is known to result in a clinically recognizable syndrome with features such as late closing anterior fontanel. Metopic synostosis is reported in duplication of 1p36.3. Such opposing phenotypes associated with deletion and duplication of 1p36.3 prompted speculation that this region contains genes that are involved in suture closure. Interestingly, chromosome 1p36.2 is known to harbor an intriguing gene cluster of about 1 MB including the constitutional neuroblastoma translocation breakpoint. This region consists of locally repeated sequences, thus recombination and unequal crossing over between these repeats can lead to both duplication and deletions. This might be one explanation for the complementary deletion and duplication of 1p36.3 region.

**3:1 segregation of reciprocal translocations: Examples and frequency.** *G.D. Wenger<sup>1,2</sup>, M. Springer<sup>1,3</sup>, Y. Syed<sup>1</sup>, J.F. Atkin<sup>3,4</sup>, J.M. Gastier-Foster<sup>1,2</sup>.* 1) Laboratory Medicine/Cytogenetics, Columbus Children's Hosp, Columbus, OH; 2) Dept. of Pathology, OSU College of Medicine and Public Health, Columbus, OH; 3) Human and Molecular Genetics, Columbus Children's Hosp, Columbus, OH; 4) Dept. of Pediatrics, OSU College of Medicine and Public Health, Columbus, OH.

Unlike single gene disorders, for which the calculation of recurrence risk is generally a straightforward exercise, determination of risk figures for chromosome rearrangements requires characterization of the specific rearrangement and prediction of the mode of segregation for each rearrangement. Balanced autosomal reciprocal translocations are relatively common. While most reciprocal translocations are unique to individual families, empiric data does exist for some situations, notably Robertsonian translocations and the recurring constitutional translocation t(11;22)(q23.3;q11.2). For most others, inspection of the breakpoints and the pachytene configuration which allows maximal alignment of homologous segments is needed for prediction of the mode of segregation. In 3:1 segregation, the unbalanced karyotype includes a supernumerary small derivative chromosome. This type of malsegregation, such as is seen with the recurring constitutional translocation t(11;22), occurs more rarely. In this laboratory, 6 families with t(11;22) were identified during the time period 1993-2002. In addition, 5 families with supernumerary chromosomes due to 3:1 malsegregation were identified; 4/5 of these were maternal in origin. This is in agreement with recent literature suggesting an excess of maternal origin for all unbalanced forms, particularly those resulting from 3:1 segregation. Additional cases were judged to have the potential for 3:1 segregation. An unusual case with t(13;18) is presented. In the ten year period, 201 balanced and 109 unbalanced translocations were identified in this laboratory; 31 of these cases involved 3:1 segregation or indicated a tendency for 3:1 segregation. The cytogenetic mechanism of 3:1 segregation that results in tertiary trisomy is an interesting and relatively uncommon event which should be considered when one of the derivative chromosomes of a reciprocal translocation is very small.

**Submicroscopic Chromosomal Gains and Losses in Patients with Idiopathic Mental Retardation Assessed Using Whole Genome CGH MicroArrays.** *C. Tyson<sup>1</sup>, C. Harvard<sup>1</sup>, JM. Friedman<sup>2</sup>, S. Langlois<sup>2</sup>, SL. Yong<sup>2</sup>, M. Hrynychak<sup>3</sup>, E. Rajcan-Separovic<sup>1</sup>.* 1) Pathology, University of British Columbia, Vancouver, Canada; 2) Medical Genetics, University of British Columbia, Vancouver, Canada; 3) Cytogenetics, Royal Columbian Hospital, New Westminster, Canada.

Idiopathic mental retardation (IMR) is present in 1-1.5% of the population. Many cases of IMR are believed to be caused by small chromosomal deletions or duplications. The resolution of standard cytogenetic techniques is 5-10 Mb, so smaller imbalances remain undetected. We used whole genome microarray CGH with a resolution of 2-4 Mb (Spectral Genomics, Inc.) to investigate potential sub-microscopic chromosomal deletions and duplications in children with IMR and normal karyotypes. A preliminary study was performed to assess the accuracy of the arrays. One normal individual and 5 cases with known chromosomal imbalances were tested. These included: one case with an interstitial deletion of 5q, two siblings with partial monosomy 2q and partial trisomy 17q, one case with a sub-telomeric deletion of 14q and one case of Wilms tumor with multiple chromosomal abnormalities. In all cases the known chromosomal rearrangements were detected with the arrays; 3 of the 5 abnormal cases were tested blindly. Previously-reported polymorphic copy number variants were found for single clones on 6q, 1q, and 17q. No abnormalities were seen in the normal individual. To date, 2 patients with IMR and an apparently normal karyotype at 500-550 band resolution have been tested with microarray CGH. Case 1 - a patient with IMR, microcephaly, mild dysmorphism and hirsutism. A deletion of two adjacent, terminal clones, RP11-58F7 and RP1-3K23, from 7q was demonstrated by CGH array analysis. The size of this deletion is estimated to be 2-4Mb. Case 2 : A duplication of one clone, RP11-143E20, from Xp22.2 was found in a patient with IMR, dysmorphic features and severe constipation. The observed changes will be further assessed using FISH. These preliminary data demonstrate that the 2-4 Mb CGH microarray can confirm visible chromosomal changes as well as detect sub-microscopic abnormalities in mentally-retarded individuals with apparently normal karyotypes.

**Chromosome 2 interstitial deletion [del(2)(q13q21)] associated with hypotonia, mild dysmorphism and hyperviscosity syndrome.** *S. Patel*<sup>1</sup>, *M.J. Macera*<sup>2</sup>, *S. Razvi*<sup>1</sup>, *A. Parekh*<sup>1</sup>, *E. Koenig*<sup>1</sup>, *S. Kleyman*<sup>2</sup>, *A. Babu*<sup>2</sup>. 1) Department of Pediatrics, Long Island College Hospital, Brooklyn, NY; 2) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center.

A male child was born at 39 weeks gestation by normal vaginal delivery to a 28-year-old mother. His birth weight 2440 gm, length 49.5 cm and head circumference of 33 cm were small for the gestational age parameters. Physical examination demonstrated increased anteroposterior diameter of the skull with molding of the cranial sutures and overriding of the sagittal suture. Mild dysmorphic features included a small bridge of the nose, a thin lower lip with down turned angles of the mouth and a long philtrum. The chest showed widely spaced nipples. There was hypotonia especially of the trunkal muscles with moderate head lag, poor sucking and rooting reflexes and a weak high-pitched cry. MRI revealed symmetric hyperintense T1 weighted extra-axial posterior fossa signal corresponding to a slow flow within the transverse and sigmoid sinuses versus thrombosis. MVR of the intracranial circulation was suggestive of partial thrombosis. The clinical features were also consistent with a hyperviscosity syndrome, with elevated hematocrit and thrombocytopenia. A 6 month follow-up revealed mild developmental delay and a catch up in the physical parameters. Chromosome analysis of peripheral blood at birth, revealed an abnormal 46,XY,del(2)(q13q21) karyotype. Parental chromosome analysis revealed normal karyotypes establishing the de novo origin of the del(2) in the child. Two cases with similar chromosome breakpoints have been reported in the literature (Schinzel 2001). It is hypothesized that both of those cases arose from balanced translocations involving chromosome 2 in one of the parents. It is interesting to note that all three cases expressed very different phenotypes. This case appears to be the first reported case of a del(2)(q13q21) having a de novo origin. Sumption and Barber (2001) have described a case of transmitted deletion (2q13-q14.1) with no phenotype. Based on this, it is possible the major clinical findings in our patient may be contributed by the distal region of the deleted segments i.e. 2q21.

**Detection of a submicroscopic interstitial deletion on 7q31 in a patient with a complex, apparently balanced, t(5;7;6) using CGH arrays.** *E. Rajcan-Separovic*<sup>1</sup>, *B. McGillivray*<sup>2</sup>, *C. Chijiwa*<sup>2</sup>, *C. Tyson*<sup>1</sup>. 1) Dept Cytogenetics, (Pathology), BC Children's Hosp, Vancouver, BC, Canada; 2) Department of Medical Genetics, University of British Columbia, Vancouver, Canada.

We describe the application of CGH array technology to elucidate a complex, apparently balanced translocation in a patient with idiopathic mental retardation (IMR). We used a commercial human CGH array (Spectral Genomics, Inc.), with a 2-4Mb resolution. The patient is a 13 year old male with bilateral cleft lip and palate, hearing loss and IMR. His mother and older sister had learning disabilities. G-banding and multicolor FISH revealed an apparently balanced 3-way translocation involving chromosomes 5, 6 and 7. Chromosomal CGH was performed to investigate whether there was any net loss of DNA as a result of the rearrangement. No abnormality was detected at any of the translocation breakpoints (5p13.2, 6p24, 7q21.1 and 7q21.3), although a deviation of the profile towards loss was seen at band 7q31. However, this deviation fell short of the laboratory's cut off level of 0.8, and was outside the region involved in the translocation breakpoint. CGH array analysis was initiated to clarify this finding and showed a deletion of two adjacent clones, CTB-133K23 and RP11-112P4, mapping to 7q31 and 7q31.3, respectively. These two deleted clones are 4.4Mb apart. FISH with these two clones performed on metaphase chromosomes from the patient confirmed the deletion. In light of this data from the CGH array experiment, the chromosomal CGH experiment was repeated. Once again there was a deviation at band 7q31; however, this time the loss fell above the requisite cut-off level for chromosomal loss, confirming that a very small deletion had occurred at band 7q31. FISH was performed with the two deleted clones on the patient's mother and no evidence of a deletion of either clone was found. This study has demonstrated that the CGH array technique can detect and precisely delineate sub-microscopic chromosome imbalances in patients with complex, apparently balanced chromosomal rearrangements. The new information provided by the CGH array technique will assist in genetic counseling of this family.

**Reproducibility and performance of Vysis GSA300 platform for pre- and post-natal array-based CGH diagnostics.** *E. Pestova, T. Ruffalo, T. Marble, M. Lucas, K. Wilber, W. King.* R&D, Vysis, Downers Grove, IL.

Genosensor<sup>TM</sup>Array 300 (GSA300) is a multiplex platform for array-based comparative genomic hybridization that detects unbalanced genomic aberrations including whole chromosome gains/losses, microdeletions, duplication, and unbalanced sub-telomeric rearrangements. In pre- and post- natal diagnostics, multiplex technologies such as CGH microarrays permit the simultaneous measurement of copy number changes across many genomic loci in a single experiment and require relatively small amount of specimen for analysis. Because of its greater resolution over conventional cytogenetics, it is ideally suited for the detection of small chromosomal aberrations that are associated with multiple disorders ranging from idiopathic mental retardation to micro-deletions syndromes. In the present study, we assessed the analytical performance, reproducibility, and utility of GSA300 arrays for potential application in pre- and post-natal diagnostics. We evaluated the performance of the arrays using DNA extracted from 1 microdeletion cell line (46,XX,del(22)(q11.2q11.2) Di-George) and 4 trisomic cell lines (47, XY, +13, 47, XY, +21, 47,XY,+18, and 47,XY,+2), blood samples from eight apparently normal donors, and amniotic cells obtained from apparently normal male and female pregnancies. In our studies, using DNA isolated from cell lines and normal reference DNA we were able to reliably detect each of the known genomic abnormalities, and achieved an analytical sensitivity of 90%, specificity of 99%, and low user-to-user variation. Using normal blood samples, we demonstrated specificity of 99% and an average CV for the replicate chips for the same specimen of 10%. Amniotic cells grown in culture allowed for accurate and reproducible identification of fetal gender. We have also demonstrated the ability to detect a 14qtel microduplication in one of the amniotic specimens.

**Familial cryptic chromosomal imbalances: assessment by FISH, CGH, m-FISH and array CGH.** *JC. Wang<sup>1</sup>, C. Tyson<sup>1</sup>, B. McGillivray<sup>2</sup>, H. Bruyere<sup>3</sup>, E. Rajcan-Separovic<sup>1</sup>.* 1) Department of Pathology, University of British Columbia, Vancouver, Canada; 2) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 3) Cytogenetics Laboratory, Vancouver General Hospital, Vancouver, Canada.

We describe two families with two individuals in each family showing an apparently identical chromosomal imbalance and different clinical outcomes. To test the possibility that this may be due to subtle differences in the extent of the chromosomal imbalance we are using a panel of molecular cytogenetic methods including the 2-4Mb resolution array (Spectral Genomics, Inc). Family A includes a baby-boy with multiple congenital anomalies-MCA (right radial and thumb aplasia, dysmorphic features, low sacral dimples, simian crease on left hand) and his father who, apart from autism and developmental delay, has no other clinical features. G banding, chromosomal CGH, sub-telomere testing and m-FISH demonstrated a gain of 2p25.3-ter and loss of the subtelomeric end of 10q in both family members. The CGH array analysis is in process. Family B: Two pregnancy losses from the same patient showed a loss of 2q37.2-qter and gain of 17q25-qter by chromosomal CGH. The pregnancies were terminated at different stages of development- pregnancy 1 terminated spontaneously at 12 weeks, while pregnancy 2 continued until week 34 and resulted in a baby with MCA who died at 24h of life. The mother was found to have a balanced, sub-telomeric t(2;17). The 2-4 Mb resolution array analysis did not demonstrate a difference in the extent of the 2qter loss and 17qter gain between the pregnancies: 7 clones from 2qter were lost and 7 clones from 17qter were gained in both pregnancies. However, the array study delineated the extent of the gain/loss more precisely and indicated that the breakpoint on 2q is more proximal than determined by chromosomal CGH. This suggests that if genomic alternations responsible for the phenotypical differences between these two pregnancy losses exist, they are most likely beyond the resolution of the CGH array we use now. The development of genomic arrays of higher resolution will help in further assessment of these patients.

**Interstitial deletions of proximal chromosome 6q: contribution to the phenotype.** *L. Turner<sup>1</sup>, J.-C. Wang<sup>2</sup>, S.-L. Yong<sup>1</sup>, J. Siegel-Bartelt<sup>1</sup>, E.R. Separovic<sup>2</sup>, P. Eydoux<sup>2</sup>.* 1) Department of Medical Genetics; 2) Department of Pathology, University of British Columbia, Vancouver, Canada.

Interstitial deletions of chromosome 6q have been rarely reported. Three phenotypic groups associated with 6q deletions have been described: group A (q11-q16), group B (q15-q25) and group C (q25-qter). We report on three new cases of proximal deletion of chromosome 6q (group A), further delineating the phenotype of these rare chromosome abnormalities. Case 1 was a newborn female with multiple minor abnormalities, including upslanting palpebral features, abnormal palmar creases, joint laxity and kidney abnormalities. Cytogenetic analysis showed an interstitial deletion of chromosome 6q11-q13, confirmed by CGH analysis. Case 2 shared similar features as case 1, but also had hypotonia, umbilical hernia. Chromosomal analysis allowed the detection of a deletion 6q13-q15. Case 3 was a 6 year-old female with developmental delay, mild hypertelorism, prominent eyebrows and obesity. A small deletion of 6q16.2 was seen on the blood karyotype. Deletions of chromosome 6q11-q16 are characterized by a high incidence of upslanting palpebral fissures and hernias, whereas intra-uterine growth retardation, hypertelorism and upper limb malformations have been described in more distal deletions. A Prader-Willi-like phenotype has also been reported with a deletion 6q15-q21. Our patients, carrying relatively small deletions of chromosome 6q, will help delineate the phenotype of corresponding segmental deletions. Further characterization of the breakpoints using molecular technologies will help the identification of genes contributing to the phenotype of these chromosomal diseases.

**A double cryptic chromosome imbalance is the main factor to explain phenotypic variability in Wolf-Hirschhorn syndrome.** *M. Zollino<sup>1</sup>, R. Lecce<sup>1</sup>, M. Murdolo<sup>1</sup>, I. Mancuso<sup>1</sup>, A. Selicorni<sup>2</sup>, G. Zampino<sup>3</sup>, L. Garavelli<sup>4</sup>, G. Marangi<sup>1</sup>, A. Ferrarini<sup>2</sup>, J.M. Opitz<sup>5</sup>, G. Neri<sup>1</sup>.* 1) Dept Medical Genetics, Univ Catt Sacro Cuore, Rome, Italy; 2) Dept Pediatrics "G.andD.De Marchi, Univ Milano, Italy; 3) Dept Pediatrics, Univ Catt Sacro Cuore, Rome, Italy; 4) Pediatrics Arcispedale S.Maria Nuova, Reggio Emilia, Italy; 5) Division of Medical Genetics, University of Utah, Salt Lake City, USA.

WHS is a MCA/MR syndrome caused by a partial 4p deletion, with a critically deleted region (WHSCR-2) in 4p16.3. Although the severity of clinical presentation usually correlates with the size of the deletion, unexplained phenotypic variability represents an hallmark of this condition. A total of 5 WHS patients with apparent de novo microdeletions (normal chromosomes and hemizygoty of WHSCR-2) presented with a severe phenotype, including major malformations. On further FISH analyses, the actual deletion size resulted to be of 12 Mb (3 cases), 5 Mb and 20 Mb. Additional chromosome segments on the deleted 4p were inferred, and then searched by FISH with subtelomeric probes. A de novo unbalanced t(4;8) translocation was detected in 4 patients and a der(4p;4q) in the last. All the unbalanced t(4p;8p) were maternal in origin, der(4p;4q) was paternal. To verify frequency and specificity of this phenomenon, we investigated yet another group of 20 WHS patients with de novo large deletions (n 13) or microdeletions (n 7) and with straightforward genotype-phenotype correlations. We found that: a) 24% (6/25) of rearrangements were maternal in origin, 76% (19/25) were paternal; b) all the maternally derived rearrangements were de novo unbalanced translocations, which were t(4;8) in five cases, t(4;11) in one case; the 4p deletion interval was of 12 Mb in 4 cases, 5 Mb in one case, and 4 Mb in the last, giving rise to phenotypes of different severity; c) unbalanced translocations caused large deletions mistaken as microdeletions; d) paternally derived rearrangements were isolated deletions, with the only exception of a double intrachromosomal rearrangement. We conclude that a double cryptic chromosome imbalance is the main factor to explain phenotypic variability of WHS.

**AHO-like deletion syndrome: significant refinement of the minimal deleted region at 2q37.3.** *R.C. Trembath*<sup>1</sup>, *M.C. Bonaglia*<sup>2</sup>, *R.C.M. Hennekam*<sup>3</sup>, *M.A. Aldred*<sup>1</sup>. 1) Division of Medical Genetics, University of Leicester, UK; 2) IRCCS E. Medea, Bosisio Parini, Lecco, Italy; 3) Department of Pediatrics and Clinical Genetics, Academic Medical Centre, Amsterdam, The Netherlands.

Deletion of 2q37.3, the telomeric region of chromosome 2q, is associated with an Albright hereditary osteodystrophy-like syndrome. This is characterized by developmental delay, hypotonia, facial dysmorphism and shortening of the metacarpals and metatarsals. Additional features may include obesity, short stature, strabismus, eczema, sparse or coarse hair and autism or other behavioral disturbances. Such deletions have traditionally been studied by conventional cytogenetics, FISH and microsatellite analysis, but with limited resolution. To better define the commonly deleted region, we have developed new assays for systematic assessment of gene dosage across the 2q37.3 region by multiplex amplifiable probe hybridization (MAPH), quantitative real-time PCR and a panel of new microsatellites. The MAPH assay covers 20 known genes and 5 microsatellite loci from 2q37, together with 8 control loci, in two hybridizations. Using these methods, the breakpoints in two previously published cases, a complex duplication/deletion and a deletion patient with classical AHO-like phenotype, were both mapped within a ~0.5Mb region in the vicinity of the *HDAC4* gene. Furthermore, *DERMO-1*, a *TWIST*-related gene involved in bone development, was mapped proximal of these breakpoints and was thus excluded as a candidate for the brachydactyly phenotype. These results are of immediate clinical utility, representing a ~50% reduction of the minimal deleted region and confining it to the most telomeric ~3Mb of 2q. Additionally, MAPH offers a rapid means of high-resolution dosage analysis across the 2q37.3 region that has recently allowed us to exclude major deletion in a patient with an AHO-like phenotype where initial microsatellite analysis was uninformative. Analysis of a wider panel of patients is ongoing to further narrow the critical region and gene(s) responsible for this phenotype.

**Consanguinity and Familial Recurrent Abortion Due To Balanced Translocation (13q;17p) A case report and brief review.** *M.A. Redha, D.S. Krishna Murthy, L.A. Bastaki, S.A. Al-Awadi.* Cytogenetic Laboratory, Kuwait Medical Genetics Center, Maternity Hospital, Kuwait.

**INTRODUCTION AND OBJECTIVES:** Duplication or deletion of chromosomes due to balanced /unbalanced (sporadic/inherited) is one of the major causes leading to multiple congenital anomalies in newborn or to repeated miscarriage. A family (consanguineous) with repeated pregnancy losses in several members of the extended family were investigated to rule out possible chromosomal abnormalities in specific chromosome as the underlying cause for repeated pregnancy losses. **Methodology:** Two young healthy sisters married each to their first cousin were referred to the center with history of repeated pregnancy loss, plus each having healthy children. Metaphase chromosomes of both sisters and their husbands were prepared from short term peripheral blood culture and karyotype analysis was done after (G-banding) by using PS1 power gene karyotyping system. The same study was done for all the children of one family. The other family members were unavailable for study. **Results:** Analysis of 30 metaphases (G-banding) in both healthy sisters confirmed a balanced translocation 46,XX,t(13;17) in all the cells, the same karyotype showed in some of the healthy children suggesting deletion/ duplication of chromosome 13 and 17 is lethal, which confirms maternal origin of chromosomal unbalanced rearrangement. **Conclusion:** Prenatal diagnosis in families having repeated pregnancy losses is extremely important to understand etiology and parental origin very precisely to provide better genetic counseling.

**A patient with DiGeorge-like syndrome and interstitial deletion 10p12.1-p12.31: Refining the critical region responsible for cardiac abnormalities.** S.A. Yatsenko<sup>1</sup>, A.N. Yatsenko<sup>1</sup>, K. Szigeti<sup>1</sup>, P. Stankiewicz<sup>1</sup>, S.W. Cheung<sup>1</sup>, J.R. Lupski<sup>1,2,3</sup>. 1) Department of Molecular & Human Genetics and; 2) Pediatrics, Baylor College of Medicine; 3) Texas Children Hospital, Houston, TX.

DiGeorge syndrome/Velocardiofacial syndrome (DGS/VCFS) is a frequent congenital disorder resulting from abnormal development of the third and fourth pharyngeal pouches. Usually, the phenotype is characterized by a hypoplastic thymus with T-cell deficiency, hypoparathyroidism, conotruncal heart defects, craniofacial dysmorphism, and developmental delay; however, there can be tremendous clinical variability. The submicroscopic deletion within chromosome region 22q11.2 (DGS1/VCFS1) involving *TBX1* is a major cause of DGS/VCFS. A second DGS locus (DGS2) has been described in patients with cytogenetically visible deletions of chromosome 10p. DGS2 is also considered to be a contiguous gene syndrome. Haploinsufficiency of at least two different genes on 10p13-p14 contributes to the DGS2 phenotype. Deletions of 10p14 and mutations in *GATA3* gene are associated with a HDR syndrome (Hypoparathyroidism, sensorineural Deafness, and Renal defects). Deletions proximal to 10p14 are responsible for cardiac and T-cell abnormalities. Recently, the nebulin gene (*NEBL*) was shown to be deleted in two patients with cardiac and craniofacial abnormalities and deletions of 10p12-p13. We present a four-year-old boy with craniofacial dysmorphism and developmental delay. Echocardiogram revealed trivial mitral and tricuspid regurgitation without gross structural abnormalities. MRI of the head showed aqueductal stenosis, mild compensated hydrocephalus, and Chiari I malformation. High-resolution chromosome analysis at 850-band resolution revealed interstitial deletion del(10)(p12.1;p12.32). To characterize the deletion breakpoints we performed FISH analysis using 27 BAC clones. Our data demonstrate a ~5.5 Mb deletion, the smallest one reported to date. Interestingly, the BAC clone RP11-56H7, containing *NEBL* was deleted in our patient. We correlate the clinical manifestations with deletion size in our patient and compare it with previously reported cases. Our data potentially narrow down the DGS2 critical region.

**Paternal balanced translocation, t(6;7)(p21.3;q34) in a couple with recurrent abortions: last of them with trisomy**

**16.** *C. Uria Gomez*<sup>1, 2, 4</sup>, *G. Arteaga Ontiveros*<sup>2</sup>, *E. Blanco Aguirre*<sup>3</sup>, *R. Garcia Cavazos*<sup>1</sup>, *D. Mayen Molina*<sup>1</sup>. 1) Depto de Genetica Inst. Nal. de Perinatologia, Mexico DF, Mexico; 2) Genecon Diagnostico Laboratorio, Toluca, Mexico; 3) Hosp. General Adolfo Lopez Mateos Toluca, Mexico; 4) Fac. de Quimica UAEM, Toluca Mexico.

The rate of spontaneous abortions in balanced translocation carriers was found to be 25-50%, and is a consequence of formation of gametes with unbalanced chromosomes. A healthy non consanguineous young couple was referred for cytogenetic analysis. They had four recognized spontaneous abortions and no live-born children. First, a sample specimen from a 9 weeks gestation abortion (last one out of four) was received for chromosome analysis. Twenty metaphases from four primary cultures were analyzed and the results showed trisomy 16 in all of them. There is not cytogenetic information about three previous abortions. Chromosomal analysis in the wife showed 46,XX. The Karyotype in the husband surprisingly showed 46,XY,t(6;7)(p21.3;q34). The translocation was further confirmed by FISH using whole chromosome paints for 6 and 7. We ignore the trisomy 16 parental origin in the last abortion, but trisomies are generally due to a maternal meiosis error. We observed again trisomy 16 metaphases and translocation was not present. This is an unusual translocation associated with fetal loss and aneuploidy. To our knowledge there is only one report about translocation (6;7), but this is (6q;7q). We ignore if some kind of segregation is preferential for this paternal translocation, but the fact that no malformed live births and no living child were observed, implies that the offspring gametes should have an unbalanced chromosomes. Genetic counseling such as prenatal diagnosis including FISH on interphase spermatozoa, should also be considered in a future pregnancy.

**An association between meiotic recombination and advancing maternal age for trisomy 21.** *S.L Sherman<sup>1</sup>, E. Feingold<sup>2</sup>, N.E. Lamb<sup>1</sup>*. 1) Human Genetics, Emory Univ., Atlanta, GA; 2) Human Genetics, Univ. of Pittsburgh, Pittsburgh, PA.

Advancing maternal age has long been identified as the primary risk factor for human chromosome trisomy. For specific chromosomes, altered patterns of meiotic recombination have also been associated with an increased risk of trisomy. For trisomy 21, these susceptible patterns include exchange near the centromere or single, telomeric exchanges. To date, however, no relationship has been found between these patterns on chromosome 21 and maternal age. As part of an ongoing study of trisomy 21 (ts21) we examined the recombination status of 562 ts21 cases, all of maternal origin. The cases were genotyped at STR markers spanning chromosome 21 and divided into groups based upon maternal age at the time of the trisomic birth (<29, 29-34, >34 years of age). Tetrad analysis was used to infer the meiotic exchange patterns for each group. Achiasmate tetrads accounted for 39%, 21% and 28%, respectively, of each age population. For those tetrads that participated in exchange, the inferred location of the exchanges varied between the groups in an age-dependent manner. Among the youngest group, 62% of nondisjoining oocytes with exchange had susceptible exchange patterns. These patterns were less frequent in the mid (44%) and older (33%) age groups, which instead contained increased proportions of stable, medially located exchange. These data support theories that suggest the fidelity of meiotic processes may be age-dependent. Oocytes of younger women, with fully functional meiotic apparatus and/or robust ovarian environment, are able to properly resolve all but the most susceptible exchange patterns. As women age, however, meiotic mechanisms erode, making it difficult to resolve even stable exchange events. As a result, nondisjunction rates would increase among older women, regardless of the location or stability of meiotic exchanges. These studies provide the first link between maternal age and the molecular events of meiosis, and suggest that stable chiasmate patterns can provide some initial protection for the tetrad against maternal-age related factors that cause the meiotic degradation and lead to nondisjunction.

**Application of array CGH in clinical genetics.** *M.R. Speicher<sup>1</sup>, H. Fiegler<sup>2</sup>, C. Fauth<sup>1</sup>, P. Carr<sup>2</sup>, J. Kraus<sup>1</sup>, N.P. Carter<sup>2</sup>.* 1) Institute of Human Genetics, Technical University Munich and GSF Neuherberg, Munich, Germany; 2) Wellcome Trust Sanger Institute/Cancer Research UK Genomic Microarray Group, Hinxton, Cambridge, CB10 1SA, United Kingdom.

High-resolution screening tools, such as array-CGH, for detecting small imbalances will become an indispensable tool in clinical genetics. Here, we report several cases, which were analyzed with array-CGH. Array CGH was performed on the recently developed 1 Mb large insert clone array (Fiegler et al. [2003] *Genes Chrom Cancer* 36:361-374). This array consists of about 3,500 clones selected from the published Golden Path which are spaced at approximately 1-Mb intervals across the genome. In one case with an additional marker chromosome derived from chromosome 21, array-CGH readily pinpointed the breakpoint to chromosome band 21q21.1. Array-CGH was also applied to two cases with complex translocations. In the first case, a complex translocation involving four chromosomes and 9 breakpoints was identified in both a mother and her daughter. While the mother has a normal phenotype, the daughter has a moderate mental retardation. To facilitate breakpoint mapping the translocation chromosomes were isolated by flow sorting and hybridized to the 1 Mb BAC array. This provided localization of all breakpoints to within a resolution of 1 Mb. Furthermore, array-CGH of the DNA from the mother and the daughter revealed unexpectedly a deletion on a chromosome which was not involved in the complex translocation. In another case, 7-fluorochrome M-FISH unraveled in a two year old child with multiple dysmorphic features the karyotype: 46,XX,der(5)t(5;14),der(6)t(6;8),der(8)t(5;8;5;8;6;2),der(14)t(8;14). However, we were unable to identify any genomic imbalance, which was expected because of the phenotype of the patient. Array-CGH readily identified 4 different deletions, each with a size of smaller than 7 Mb. These deleted fragments contain 14 different known genes which probably contribute to the patient's phenotype. In conclusion, the application of these novel technologies will unravel the cause of many currently unexplained cases with mental retardation and dysmorphic features.

**Meiotic recombination in the 22q11.2 deletion syndrome.** *S.C. Saitta, S.E. Harris, D.A. Driscoll, D. Conforto, T.H. Shaikh, M.K. Maisenbacher, D.M. McDonald-McGinn, E.H. Zackai, J.M. Yersak, P.K. Chakraborty, B.S. Emanuel.*  
Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA.

Detectable deletions of chromosome 22q11.2 are found in almost 90% of patients with DiGeorge/velocardiofacial syndrome (DGS/VCFS). The deletion is estimated to occur at a frequency of 1/3,000 live births, indicating a high de novo mutation rate. Approximately 10% of the deletions are transmitted from an affected parent. The presence of chromosome-specific low copy repeats (LCRs) in the 22q11 deletion interval predisposes the area to non-homologous recombination that could lead to the frequent occurrence of this microdeletion syndrome. To further examine such a mechanism, we traced the grandparental origin of regions flanking the deletion in 20 three-generation families. By FISH the size of these de novo deletions was determined to be the most commonly occurring, standard 3 Mb deletion. Haplotype reconstruction was consistent with an interchromosomal recombination event in 19/20 families. In contrast, the normal allele transmitted in these same families showed crossovers in 2/15 informative meioses, consistent with the rate expected for the physical distance. We also examined the parental origin of the deletion in 62 de novo standard deletions (including these patients) and found no bias. Further, we examined 22 patients and their parents by FISH for evidence of an inversion of chromosomal material around the LCRs flanking the standard 3 Mb deletion and the smaller 1.5 Mb deletion and found none. Eight non-deleted patients with a DGS/VCFS phenotype were also shown to not have an inversion. Our data are consistent with significant interchromosomal exchange events in the 22q11 genomic region that likely relates to the frequency of its deletion. This type of exchange occurs more often than those seen for chromosomes 7q11, 17p11, and 17q11 implying a difference in the meiotic behavior of chromosome 22.

**Paracentric inversions (PAI) and associated risks: A case report of a PAI carrier with two recombinant offspring.** *M.A. Springer<sup>1,2</sup>, J.M. Gastier-Foster<sup>1,3</sup>, L. Erdman<sup>1</sup>, J. Gordon<sup>1</sup>, B. Hamelberg<sup>1</sup>, C. Kulmer<sup>1</sup>, C. Deeg<sup>1</sup>, J. Labanowska<sup>1</sup>, R. O'Shaughnessy<sup>4</sup>, G.D. Wenger<sup>1,3</sup>.* 1) Laboratory Medicine, Columbus Children's Hosp, Columbus, OH; 2) Human and Molecular Genetics, Columbus Children's Hosp, Columbus, OH; 3) Dept. of Pathology, OSU College of Medicine, Columbus, OH; 4) Division of Maternal-Fetal Medicine, The Ohio State University.

Chromosome rearrangements occur commonly in humans, with an estimated incidence of 1/500-1/1,000 liveborns. Inversions are commonly observed and result from two independent breaks in one chromosome, with subsequent inversion of the interstitial segment. While pericentric inversions (PEI) are associated with a greater risk for viable recombinants, paracentric inversions (PAI) have generally been believed to be associated with a lower risk, with the majority of carriers identified incidentally. Recent reviews in the literature, however, have reported viable recombinant offspring from PAI carriers, suggesting that PAI may be associated with an increased risk for abnormal recombinants. We present a case of a 31-year old G3P1 female who presented at 25 weeks gestation with dilated renal pelvises in the fetus. Family history was significant for a 5-year old daughter with developmental delay, significant speech delay, growth hormone deficiency, severe hypotonia, and borderline microcephaly. Amniocentesis revealed an interstitial deletion in the short arm of chromosome 8. Parental karyotypes were obtained, demonstrating a paracentric inversion involving the short arm of chromosome 8 in the mother. Chromosome analysis was subsequently performed on the 5-year old sibling and revealed the same interstitial deletion of chromosome 8 as that found in the fetus. This case represents a rare report of a PAI carrier with two recombinant offspring.

**Unusual inverted duplication of 4p in conjunction with a balanced translocation in a 15-year-old girl with a mildly affected phenotype.** *J. Winters*<sup>1</sup>, *J. Cordell*<sup>2</sup>, *A. Grix*<sup>2</sup>. 1) Kaiser Permanente Northern California, Regional Cytogenetics Laboratory, San Jose; 2) Department of Genetics, Sacramento.

A 15-year-old girl was seen for a genetics evaluation because of her learning handicaps. Prenatal, birth, and family histories were unremarkable. She walked at 19 months and had delayed language development. At birth, she was noted to have bilateral inguinal hernias, which were repaired at 7 weeks of age. Her IQ is reported to be 81. During this evaluation, she was found to be non-dysmorphic with several nevi and learning disabilities. Karyotype analysis was ordered to rule out XXX syndrome. Routine chromosome analysis revealed two apparently independent rearrangements. One chromosome 4 had an abnormal short arm, with extra material inserted interstitially. This same chromosome 4 was also involved in an apparently balanced reciprocal translocation with a chromosome 10. The 4p rearrangement was most compatible with an intra-arm (or paracentric) inverted insertion, resulting in trisomy for the p15.2->p16 segment. FISH was performed with probes for the Wolf-Hirshhorn critical region at 4p16 and the 4p subtelomeric region (WHS and D4S3359, respectively, both from Vysis, Inc.). Both displayed two signals on the der(4) (one in the middle of the short arm and one at the p terminus). The karyotype was determined to be 46,XX,der(4)ins(4)(p15.2p16p15.2)t(4;10)(q25;q23.2),der(10)t(4;10).ish der(4)(4ptel++,WHS++). The mother's karyotype was studied and found to be normal; the father was not available for analysis. Duplications of the terminal regions of chromosomes are usually inverted duplications, thought to arise from a terminal two-strand break, followed by a U-type exchange and breakage between the centromeres (Hoo et al, 1995), leading to both partial trisomy and partial monosomy. In contrast, this case involves a same-arm inverted insertion, leading only to partial trisomy. The presence of two breakpoints on chromosome 4 raises the question of a possible interchromosomal effect.

**Identification of additional cryptic rearrangements in cytogenetically abnormal patients by a CGH microarray chip designed for clinical diagnosis.** A. Patel<sup>1</sup>, W. Yu<sup>1</sup>, C.A. Shaw<sup>1</sup>, L. Cooper<sup>1</sup>, M. Patel<sup>1</sup>, M. Fishman<sup>2</sup>, C. Bacino<sup>1</sup>, S.W. Cheung<sup>1</sup>, A. Beaudet<sup>1</sup>. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics-Neurology, Texas Children Hospital, Houston, TX.

Preliminary validation of a CGH microarray chip designed for clinical diagnosis of genetic disorders that can be routinely screened by FISH analysis found additional cryptic rearrangements while confirming the original cytogenetic abnormality in 2 out of 11 patients studied thus far. Patient 8 had an inv dup(8)(p11.23p23.1) cytogenetically and was confirmed to be all chromosome 8 material by whole chromosome 8 paint, and to be deleted for the 8p telomere by FISH analysis. Array CGH analysis confirmed loss of the 8p telomere and found a gain of the 18q telomere. Subsequent FISH analysis with the 18q telomere found the inv dup 8 chromosome to have captured the 18q telomere. This is a second case where an inv dup 8 chromosome has been stabilized by the 18q telomere. Patient 6 had a del(13)(q33.2) karyotype and all telomere FISH analysis with the Vysis telomere probe panel found no other abnormalities. Array CGH analysis confirmed the 13q telomere deletion but also identified a 22q telomere loss. The array 22q telomere clone is distal to the Vysis 22q telomere probe and again FISH analysis confirmed the 22q telomere deletion. Our preliminary data suggests that cytogenetically abnormal karyotypes may also harbor cryptic rearrangements that could go undetected and therefore the use of array CGH together with classical cytogenetics can provide a more accurate and sensitive clinical diagnostic screen for genetic disorders.

Program Nr: 834 from 2003 ASHG Annual Meeting

**CONFLICTING RESULTS BETWEEN PRENATAL INTERPHASE FISH & G-BANDED CHROMOSOME DIAGNOSES;IMPLICATIONS FOR CLINICAL DECISIONS.** *PalD. Singh-Kahlon, I. Gadi, J. Tepperberg, P. Mowrey, L. Wisnewski, S.K. Griffin, C.J. Bullen, P. Papenhausen.* PAL D. SINGH-KAHLON, CYTOGENETICS, LabCorp Inc,1912 ALEXANDER DR,Res Triangle Park, NC.TEL:800-533-0567x3403.

**SUMMARY:**We report a PRENATAL INTERPHASE FISH study on amniotic fluid showing an apparent TRISOMY 18 hybridization pattern. Although ultrasound findings were normal, the couple was counseled for the possibility that their fetus had TRISOMY 18. The subsequent G-banded chromosomal study showed an apparently NORMAL KARYOTYPE. A possible mix up in tube labeling, culture set up, or in the prenatal FISH preparation were all ruled out. The subsequent CHROMOSOMAL FISH analysis showed an extra hybridization of pericentromeric alpha satellite DNA signal, inserted into the proximal long arm of chromosome 9. Parental FISH studies revealed the father to be the carrier of the same rearrangement observed in the fetus. These results emphasize that no clinical decisions regarding ongoing pregnancies should be made, unless an abnormal karyotype and/or abnormal ultrasound findings confirm the FISH results.

**Cloning of the breakpoints of a de novo inversion of chromosome 8 inv (8)(p11.2q22) in a patient with Ambras syndrome.**

*M. Tadin-Strapps*<sup>1</sup>, *D. Warburton*<sup>2,3</sup>, *F. Baumeister*<sup>6</sup>, *G. Swergold*<sup>4</sup>, *S.G. Fischer*<sup>5</sup>, *J. Yonan*<sup>5</sup>, *T.C. Gilliam*<sup>2,5</sup>, *A.M. Christiano*<sup>1,2</sup>. 1) Dermatology, Columbia Univ, New York, NY; 2) Genetics and Development, Columbia Univ, New York, NY; 3) Pediatrics, Columbia Univ, New York, NY; 4) Medicine, Columbia Univ, New York, NY; 5) Columbia Genome Center, Columbia Univ, New York, NY; 6) Dr. v. Haunersches Kinderspital der Universitat Munchen, Germany.

Ambras syndrome (AMS) is a unique form of universal congenital hypertrichosis. In patients with this syndrome the whole body is covered with fine, long hair except for the areas in which normally no hair grows. Minor facial dysmorphism and dental anomalies, including retarded first and second dentition and absence of teeth have been reported as well. Cytogenetic abnormalities of chromosome 8 have been reported in two isolated Ambras syndrome patients. The presence of a common breakpoint in 8q22 in both of these cases suggests the presence of a candidate gene(s) in this region of chromosome 8. In order to precisely determine the nature of the rearrangement in a case of Ambras syndrome, we have used Fluorescent In Situ Hybridisation (FISH) with YAC and BAC clones from 8q22-q24. We have generated a detailed physical map across the inversion breakpoint interval, cloned and sequenced inversion breakpoints in this patient, and identified transcripts in the vicinity of the breakpoints. Genomic sequence analysis of the breakpoint interval revealed that the inversion does not disrupt a gene and suggests that the phenotype is caused by a position effect. Interestingly, the breakpoints occurred within a Tigger1 element on the 8p arm, and the LINE1 element on the q arm. We are currently analysing expression of the genes that map in the vicinity of the inversion breakpoints.

**Cytogenetic and Hematologic investigations of patients with severe chemical injuries after exposure to Mustard Gas during Iran-Iraq conflict.** *M. Shafa Shariat Panahi*<sup>1,3</sup>, *M. Khazab*<sup>2</sup>, *Y. Seyedena*<sup>3</sup>. 1) Genetics Clinic, NRCGEB, Tehran, Iran; 2) Genetics Research Center, Razi Institute, Karaj, Iran; 3) Biology Department, Shahid Beheshti University, Tehran, Iran.

Sulfur mustard (SM) is a potent alkylating agent with mutagenic properties. It has been widely used in Iran-Iraq conflict. This study assessed the impact of this agent on the hematologic parameters and chromosomal aberrations (CA) in the peripheral blood of severely-injured Iranian combatants. Twenty five patients with severe lung and eye injuries and ten controls were included in the study. The subjects of control group were healthy volunteers matched for sex and age. The lymphocytes were cultured by conventional culture methods. Hematologic parameters including CBC, Platelets, Blood index and peripheral blood films were studied. Twenty five well-spread metaphases were scored for each sample for any chromosomal aberrations. Two groups were compared with statistical methods including t-test and chi square test. We found that the mean Hb, HCT, WBC, Platelets, MCV and lymphocyte numbers were different in two groups ( $P < 0.001$ ). Patients and control group showed differences in the percentage of metaphases containing at least one chromosomal aberration. This study showed that there is a direct correlation between SM exposure and hematological as well as cytogenetic anomalies in these patients.

**Is Telomere Length Associated with Trisomy Risk in Humans?** *J. Gair<sup>1</sup>, E. Chavez<sup>3</sup>, M. Stephenson<sup>4</sup>, S. Langlois<sup>1</sup>, P. Lansdorp<sup>2,3</sup>, W. Robinson<sup>1</sup>*. 1) Department of Medical Genetics; 2) Division of Hematology, Faculty of Medicine, University of British Columbia; 3) BC Cancer Agency, Terry Fox Laboratory; 4) Department of Obstetrics and Gynaecology, BC Children's and Women's Hospital, Vancouver, BC, Canada.

Trisomy is a major cause of reproductive failure in humans and is generally due to an error in maternal meiosis. Little is known of its etiology other than it is strongly associated with maternal age. Structural aspects of chromosomes, such as telomeres, may also be important risk factors. Telomeres are important in chromosome pairing and decreased length is associated with increased somatic nondisjunction. We hypothesize that individuals starting life with relatively short telomeres or with lower levels of telomerase activity in early development may have relatively short telomeres in both germ cells and somatic cells and be at increased risk of meiotic nondisjunction. To determine whether shorter telomere length is associated with increased risk of trisomy, telomere length was evaluated in 10 women who had experienced at least one trisomic pregnancy and 9 similarly aged controls with no history of trisomy. Quantitative FISH was performed on metaphase chromosomes from peripheral lymphocytes, using peptide nucleic acid (PNA) probes to the telomeres of all chromosomes. The fluorescence signal from the probes was quantified. The average telomere length of 3.35kb (2.48 - 4.27 kb) in the patient group (N=10) was significantly shorter than the 4.04kb (2.72 - 6.17 kb) observed in controls (N=9) (p-value = 0.05, t-test). Although these preliminary results support our hypothesis, additional studies are underway to confirm this association with a much larger sample size and determine whether this is a primary cause for the increased risk of meiotic nondisjunction or simply an indicator of premature ovarian aging in women presenting with a trisomic pregnancy.

**Reconstruction of 3D-spatial structure of mammalian centromere.** *Y.C. Li<sup>1</sup>, S.J. Liao<sup>2</sup>, L.J. Hsieh<sup>2</sup>, C.C. Lin<sup>1,2</sup>.* 1) Department of Life Sciences, Chung Shan Medical University, Taichung, Taiwan; 2) Department of Medical Research, China Medical University Hospital, Taichung, Taiwan.

Centromere plays a pivotal role during mitosis and meiosis. Malfunctioned centromere would result in aneuploidy that is associated with disorders such as spontaneous abortion, birth defect and some neoplasia. In order to unveil the enigma of aneuploidy, it is an important and necessary to understanding the molecular architecture and composition of centromere. Interestingly, a functional conserved centromeric domain is made up of the diverse repetitive centromeric DNAs and highly conserved kinetochore proteins. Does a various centromeric satellite DNA be organized into a specific structure to associate with conserved kinetochore proteins in mammals? The simultaneous immunofluorescence and FISH study showed that the satellite II and IV were found to co-localize in muntjac centromere and to associate with kinetochore. Furthermore, the 3D- FISH and immunofluorescence were carried out on the polyacrylamide embedded, formaldehyde fixed cells using either biotinylated satellite II probe and digoxigenin-labeled satellite IV probe or one of them and CREST serum. The images acquired from the different Z-axial sections were deconvolved and reconstructed. The reconstructed 3D image showed that the CENP immunofluorescence signals parallels along with centromere whereas both satellite II and IV signals of X+3 centromere are organized into a spiral structure with four turns, each of which showed six fluorescence signals. The spiral structure may be to present centromeric chromatin to the exterior of the chromosome, where it can mediate kinetochore assembly and interactions with the spindle. This study was supported by grants from National Science Council (NSC 91-2320-B-040-037) and National Health Research institute (NHRI-EX92-9207 SI).

**Early-Replicating Human Centromeres.** *Y. Zou, W. Wright, J. Shay.* Cell Biology and Neuroscience, UT Southwestern Medical Center, Dallas, TX.

Heterochromatin, which has a condensed structure and rarely transcribed, usually replicates in late S phase. Here, we found that human heterochromatic centromeres replicate in early S phase. Human BJ fibroblasts had been labeled with 5-bromodeoxyuridine (BrdU) at hourly intervals before they approached to G2 phase, then they were arrested at metaphase with colcemid, and examined the centromere replication profile by strand-specific fluorescence in situ hybridization. Since BrdU labeled DNA strands become selectively labile to UV light and ExoIII treatment, they can be gotten rid of by a six-step treatments. Based on the principle of strand-specific in situ hybridization, a single-stranded centromeric probe can only bind to one of the two sister chromatids of a metaphase chromosome at a centromere locus. If the time point of centromere replication matches BrdU being made available to a replicating chromosome, the strand-specific FISH pattern will be observed. Conversely, if centromere replication is early or late when BrdU is made available to a replicating chromosome, the typical FISH labeling pattern will be observed. Therefore, the timing of centromere replication can be determined by chromosome orientation fluorescence in situ hybridization using dual color labeled strand-specific centromeric probes. This is the first report demonstrating that the majority human centromeres (>90%) are replicating in early S phase. Thus, early-replicating, rather than late-replicating, is a fundamental property of replication timing of human centromeres.

**The donor chromosome breakpoint for a jumping translocation is associated with large low-copy repeats in 21q21.3.** *P. Stankiewicz<sup>1</sup>, S.W. Cheung<sup>1</sup>, C.J. Shaw<sup>1</sup>, R. Saleki<sup>1</sup>, K. Szigeti<sup>1</sup>, J.R. Lupski<sup>1,2,3</sup>.* 1) Depts of Molecular & Human Genetics; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children Hospital, Houston, TX.

Jumping translocations (JTs) are very rare chromosome aberrations, usually identified in tumors. We report a constitutional JT between donor chromosome 21q21.3-qter and recipients 13qter and 18qter, resulting in an ~ 15.5 Mb proximal deletion 21q in a girl with mild developmental delay and minor dysmorphic features. Using fluorescence in situ hybridization (FISH) studies, we identified an ~ 550 kb complex inter- and intra-chromosomal low-copy repeat (LCR) adjacent to the 21q21.3 translocation breakpoint. On the recipient chromosomes 13qter and 18qter, the telomeric sequences TTAGGG were retained. Genotyping revealed the deletion was of maternal origin. We propose that genome architecture involving LCRs may be a major mechanism responsible for the origin of jumping translocations.

**Trisomy 3q secondary to a terminal deletion/generation of a mirror-image analphoid marker in a neonate. P.**

*Papenhausen<sup>1</sup>, I. Gadi<sup>1</sup>, J. Tepperberg<sup>1</sup>, P. Mowrey<sup>1</sup>, P. Singh-Kahlon<sup>1</sup>, L. Wisniewski<sup>1</sup>, D. Goodwin<sup>2</sup>.* 1) Dept Cytogenetics, Labcorp of America, Res Triangle Pk, NC; 2) Naval Medical Center, Portsmouth, VA.

A 23 day old female was referred to rule out Turner syndrome by cytogenetics and FISH. The phenotype included venticulomegaly with a VSD and a bicuspid aortic valve. There was a prominent forehead, large fontanelles, broad nasal bridge, and retrognathia. Cytogenetic results from lymphocytes revealed 47,XX,del(3)(q23),+mar in all cells. Although there was an apparent centromeric constriction near one end of the marker, high resolution suggested mirror-image duplication of the deleted 3q23->qter region. An analphoid marker was anticipated due to the frequent inverted duplication structure of that class of marker. The acentric nature was confirmed by FISH. Two distal subtelomere 3q FISH signals confirmed the duplication and the net trisomy for 3q23->qter. The neocentromere constriction was estimated at band 3q27 on one side of the duplicate. Analphoid markers with neocentromeres have tended to originate from limited regions of the genome with frequent hot spots on 3q and 13q. Those that are generated from terminal deletions form isochromosomes while those that are interstitially excised form rings. The isochromosomes are often asymmetric due to off center positioning of the neocentromere. The mechanism of formation of active kinetochores and the necessary molecular sequence remains largely unknown. This is the first such report of an excision based analphoid marker from the long arm chromosome 3 hot spot region.

**An innovative molecular cytogenetics method: Fluorescence in Situ Hybridization of chromosomes in suspension applied to medical genetics.** *Z. Chen*<sup>1</sup>, *J. Kaminsky*<sup>2</sup>, *J.N. Lucas*<sup>2</sup>. 1) Dept Pediatrics/Cytogenetics, Univ Utah Sch Medicine, Salt Lake City, UT; 2) A. L. Tech Biomedical, Inc., Arlington, VA.

Classical FISH is performed on slides and has a detection sensitivity of 1 in 100-1000 cells. PCR is very sensitive, but lack of very accurate quantitation still is a problem. By contrast, an innovative approach, which we have been developing, will greatly enhance accurate and quantitative detection of chromosomal aberrations and has a potential detection sensitivity of 1 in 1,000,000 cells. Our techniques include a novel approach of hybridizing chromosomes in suspension with fluorescently-labeled regular DNA probes or repetitive sequences depleted DNA probes, in combination with a flow cytometric method of analysis or magnetic sorting, in order to sensitively, precisely and rapidly quantify chromosomal translocations and rearrangements. The repetitive sequences depleted DNA probes are generated through our novel two-step method that includes subtracting hybridized biotin-labeled repetitive-sequence DNA complex with phenol and chloroform and a second subtraction using avidin labeled magnetic beads. The unique sequences are then recovered using our dual unique sequence primers. Our pilot experiments have demonstrated the great efficacy of the method in depleting repetitive sequences. In suspension hybridization, our method allows recovery of large numbers (46-73%) of isolated individual chromosomes post hybridization. The well-preserved morphology of hybridized chromosomes allowed rapid detection of exchange chromosome aberrations and counting of chromosomes. The utility of our method for cancer genetics was demonstrated using a probe for the C-MYC oncogene on 8q24. After hybridization in suspension, free floating interphase cells showed two distinct signals and suspended metaphase chromosomes showed bright signals on 8q. Our revolutionary methods offer a new tool to assay chromosomes and DNA and provide the possibility to develop new techniques for sorting chromosomes based on FISH signals, for early detection and screening of genetic diseases and cancer, and for bulk measurement of both balanced and unbalanced chromosomal rearrangements post exposure to mutagens.

**A Strategy for Detecting Submicroscopic Deletions in Patients with Holoprosencephaly using FISH.** *C. Bendavid*<sup>1</sup>, *B. Haddad*<sup>2</sup>, *M. Muenke*<sup>1</sup>. 1) Medical Genetics Branch, NHGRI/NIH/DHHS, Bethesda, MD; 2) Georgetown University Medical Center, Washington, DC.

Holoprosencephaly (HPE) is the most common structural anomaly of the developing forebrain in humans (1:250 during early embryogenesis and 1:10,000 at birth). The etiology of HPE is extremely heterogeneous with known teratogens and genetic factors such as visible cytogenetic anomalies (in 25-50% of newborns) and gene mutations (in 20-25% of chromosomally normal infants). Cytogenetic deletions have helped define HPE minimal critical regions and identify HPE genes: 7q36 (Sonic Hedgehog: *SHH*, 13q32 (*ZIC2*, 2p21 (*SIX3*), and 18p11.3 (TG Interacting Factor: *TGIF*). *DISPATCHED* in 1q14 and *HNF3beta* in 20p11.21 are currently studied as HPE candidate genes. Based on the known HPE-associated cytogenetic anomalies we hypothesize that submicroscopic deletions can lead to HPE. To test this hypothesis we have initiated a study of 100 lymphoblastoid cell lines from unrelated HPE patients without detectable chromosomal alterations by conventional cytogenetic karyotyping and no known mutations in the six previously identified and/or putative HPE genes. We developed a panel of six BAC probes for FISH analysis including the genes for *SHH*, *ZIC2*, *TGIF*, *SIX3*, *HNF3beta*, and *DISPATCHED* from the human RP11 and RP4 libraries (CHORI), using public databases (NCBI, ensembl! and UCSC genome browsers). Each probe was individually mapped to normal human chromosomes to confirm its correct location. The presence of the gene of interest in the BAC clone was confirmed by PCR with primers flanking 2 known gene exonic amplicons. Finally, we set up a multilocus FISH panel to visualize all six probes in a single hybridization. We have validated this panel by using samples from HPE patients with known deletions for the genes in this panel and samples from normal donors in a blinded fashion. To date, we have completed the analysis in 30 HPE patients. This preliminary study did not show any abnormalities using this HPE FISH panel. FISH analysis of additional HPE patients is now in progress, to determine if submicroscopic deletions in known HPE genes contribute to the etiology of HPE.

**Two unrelated cases of Xp21 contiguous gene deletion syndrome: rapid characterization of the deletion using**

**QMPSF.** A. Goldenberg<sup>1</sup>, V. Drouin-Garraud<sup>1</sup>, S. Baert<sup>1</sup>, S. Marret<sup>2</sup>, C. Kolly<sup>3</sup>, C. Vanhulle<sup>2</sup>, C. Forget<sup>4</sup>, E. Bessenay<sup>1</sup>, D. Recan<sup>5</sup>, M-A. Gougerot-Pocidal<sup>6</sup>, T. Frebourg<sup>1</sup>, P. Saugier-veber<sup>1</sup>. 1) Department of Medical Genetics, Rouen University Hospital, France; 2) Department of Neonatology, Rouen University Hospital, France; 3) Department of Paediatrics, Rouen University Hospital, France; 4) Department of Paediatrics, CHG d'Elbeuf, France; 5) Laboratory of Biochemistry and Molecular Genetics, Hpital Cochin, Paris; 6) Laboratory of Haematology and Biologic Immunology, CHU Bichat-Claude Bernard, Paris, France.

The Xp21 contiguous gene deletion syndrome includes Duchenne muscular dystrophy, congenital adrenal hypoplasia, glycerol kinase deficiency, MacLeod syndrome, and X-linked chronic granulomatous disease, involving the DMD, DAX/NROB1, GK, XK and CYBB genes, respectively. We report here on two unrelated cases of Xp21 deletions. The first patient presented at birth with hypotonia and salt wasting syndrome. Polyhydramnios was noted during pregnancy. Elevated CPK and hypertriglyceridemia prompted us to consider the diagnosis of glycerol kinase deficiency associated with Duchenne muscular dystrophy. The clinical follow-up included developmental delay, short stature and mild dysmorphic features. The second patient presented at the age of 10 months, with severe hypotonia and recurrent subcutaneous staphylococcus infections, failure to thrive and mild dysmorphism. Elevation of CPK led us to suspect the diagnosis of DMD. NBT test and phagocytic functions studies confirmed a chronic granulomatous disease, suggesting therefore a large Xp21 deletion. QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments) was performed to identify and characterize the deletion in both cases. In patient 1, a 5 Mb deletion removed exons 53-79 of DMD and the entire GK, DAX1 / NROB1 and IL1RAPL1 genes. In patient 2, a 7 Mb deletion encompassed exons 1-52 of DMD and the entire XK and CYBB genes. In both cases, QMPSF easily allowed the determination of the mother's carrier status and therefore facilitated genetic counseling. This report shows that QMPSF can be efficiently used to detect and map contiguous gene deletions.

**Ring 15 Syndrome: Clinical, Cytogenetic and Comparative Genomic Hybridization-Array Characterization of Two Discordant De Novo Cases.** *I.A. Glass<sup>1</sup>, E. Chen<sup>2</sup>, K.A. Rauen<sup>2</sup>, D.G. Albertson<sup>2</sup>, D. Pinkel<sup>2</sup>, P.D. Cotter<sup>2</sup>.* 1) University of Washington, Seattle, WA, USA; 2) University of California San Francisco, CA, USA.

Ring chromosome 15 is an unusual finding with less than 50 patients reported. Despite this rarity a wide range of outcomes resultant from the ring is evident, ranging from a near-normal outcome to prenatally recognizable birth defects. However, precise genotype-phenotype correlations are problematic because of the difficulties determining the extent of euchromatic loss, the extent of mosaicism, and the timing of ascertainment/characterization coupled with the potential loss of the ring during mitosis. We report, two discordant examples of a chromosome ring 15. In the first case, prenatal diagnosis of a case of a de novo ring 15 manifesting IUGR, single umbilical artery and a thickened nuchal fold was made, following amniocentesis at mid-trimester: 46,XX,r(15)(p13q26). Post-natal follow-up confirmed growth retardation, mild microcephaly, triangular facies, cafe au lait macules, brachydactyly, congenital heart disease, neonatal seizures, microphthalmia and developmental delay. The second patient, a 31 year old female was karyotyped because of her short stature and dilated cardiomyopathy; 46,XX,r(15)(p11q26). Although, mild intellectual disability (requiring special education) was present she was living and working independently. There was disproportionate short stature (-4 HT-SDS;US:LS = 0.91), small hands and feet and a unilateral blue iris heterchromia present. To investigate the discordance in phenotypes between the two patients, we undertook further molecular cytogenetic evaluations of both cases, including FISH and array CGH analyses in order to more fully characterize the extent of the deletions associated with these r(15) chromosomes. Case 1, manifesting the more severe phenotype showed deletion of multiple clones, consistent with approximately a 6Mb deletion of distal 15q. By contrast, case 2 with the milder phenotype, only revealed loss of the 15q subtelomere clone by array CGH.

**High resolution CGH in the characterization of cryptic and non-cryptic chromosome imbalances.** *X.L. Huang<sup>1</sup>, H.E. Wyandt<sup>1,2</sup>, J.M. Milunsky<sup>1,3,4</sup>*. 1) Center for Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Dept of Pathology; 3) Dept of Pediatrics; 4) Dept of Genetics and Genomics.

High-resolution comparative genomic hybridization (HRCGH), using Cytovision Hi-resolution CGH software, Version 2.77 (Applied Imaging, Santa Clara, CA), was done to further characterize several structural chromosome abnormalities previously identified by conventional cytogenetics (CC) and/or FISH. These included: 1) dup(3)(p?21p?25)de novo; 2) rec(2)dup(2q)inv(2)(p25.3q32.2)mat; 3) add(11)(p15)mat; 4) add(X).ish der(X)t(X;15)(q?26;q?24)de novo; 5) +der(9)t(8;9)(p23;q?13)mat; 6) r(22)(p11.1q13)de novo; 7) ish del(9)(q34.3)de novo; 8) ish +i(18)(p10)de novo; 9) ish +r(2)(p?12q?12)de novo. The above abnormalities, except for case 9, were confirmed by HRCGH. The +r(2), with euchromatin identified by chromosome painting, was present in only 55% of cells. This imbalance most likely was not detected by HRCGH, due to the mosaicism. Generally, imbalances of segments in or near centromeres and the ends of chromosome arms (e.g. cases 5,7 and 8) were not detected, although they were clearly involved. In cases 2-4, breakpoints obtained by HRCGH revised or clarified those estimated by CC. In case 2 with rec(2), detectable loss in the terminal band of 2p extended more proximal by HRCGH than was determined by CC. Similarly, breakpoints in 11p (case 3) and Xq (case 4) were revised to more proximal bands by HRCGH. An extra copy of distal 15q in der(X)t(X;15) (case 4) was not identified by CC, but was readily detected by HRCGH. In case 5, a small piece of distal 8q on der(9)t(8;9)mat was not initially identified by CC, but was detected by HRCGH. A cryptic del(9q) detected by subtelomeric FISH (case 7) was confirmed by HRCGH. Regions in or near centromeres and telomeres, dosages of segments <3Mb, or mosaicism <60% are reportedly not reliably detected by HRCGH. Nevertheless, three of our cases (3, 5, and 7) with deletion or duplication in terminal bands were detected by HRCGH. The benefits and limitations of HRCGH as an alternative to other FISH techniques for identifying euchromatic imbalances are demonstrated.

**Subtelomeric FISH Analysis in 108 Autistic Patients as Adjunct to Chromosome Analysis and Fragile X Testing.**

*L. Medne, K. Russell, J. Ming, I.D. Krantz, M. Souders, S. Levy, A. Gupta, N.B. Spinner, E.H. Zackai, J.J.D. Morrissette.* Div Hum Gen & Molec Biol, Clin, The Children's Hospital of Philadelphia, Philadelphia, PA.

The recent development of molecular probes that allow for detection of subtelomeric chromosomal rearrangements by FISH has led to the emergence of submicroscopic telomeric rearrangements as an important cause of human malformations and neurodevelopmental disabilities. Autistic spectrum disorder (ASD) represents a broad range of cognitive and neurobehavioral impairments that cause qualitative deficits in socialization, communication and behavior. ASD can be associated with various genetic syndromes and chromosomal abnormalities. In the vast majority of patients, ASD is non-syndromic without an identifiable genetic etiology. In addition to standard karyotyping and Fragile X testing, we performed subtelomeric FISH analysis in 108 patients with ASD. A clinically recognizable syndrome was ruled out. 8/108 (7.4%) had a chromosome rearrangement, only one of which was an unbalanced subtelomeric translocation not detectable cytogenetically. Of the seven cytogenetically detectable chromosomal rearrangements, two had an unbalanced translocation: 46,XX, der(8) t(4;8)(q34;q32); 46,XY, der(4) t(4;4)(p12q28); one had a terminal deletion 46,XY, del(21)(q22.1); three patients had cytogenetically balanced rearrangements and their clinical significance was unknown as they were inherited from an unaffected parent: 46,XY, t(3;4)(q25;q27) mat, 45,XY, t(13;14)(q10;q10) pat and 46,XX, inv(7)(q22.1q34) mat. The last patient had 46,XY, 15p+ (ish.subtel x 2) and the clinical correlation is also not known. The patient with the subtelomeric unbalanced subtelomeric translocation had 46,XY.ish der(18) t(13;18)(q34;q23). Based on the findings of this study, the utility of subtelomeric FISH analysis remains to be further clarified.

**Utilization of FISH analysis to identify mosaicism in Ullrich-Turner syndrome patients.** *A. Wiktor, D.L. Van Dyke.*  
Medical Genetics, Henry Ford Health System, Detroit, MI.

Ullrich-Turner syndrome (UTS) is most commonly associated with a 45,X karyotype, but is seen in patients with a variety of X-chromosome abnormalities or 45,X/46,XY mosaicism. The phenotype of UTS patients is highly variable, and depends largely on the karyotype. Patients are at an increased risk of gonadoblastoma when a Y-derived chromosome is present. Since constitutional mosaicism is present in approximately 50% of UTS patients, the identification of minor cell populations is clinically important and a challenge to laboratories. We reviewed our cytogenetic data on 55 females with a 45,X karyotype as the sole abnormality or as part of a more complex karyotype. Seventeen (31%) revealed a 45,X karyotype. There was X/XX/XXX or X/XXX mosaicism in 20 (36%) samples, four (7%) patients had an iso(Xq), two (4%) had deletions of the X chromosome (Xq21.1 and Xp11.2), and five (9%) had a ring X chromosome. Mosaicism with a structurally normal Y chromosome was seen in three (5%) cases, two (4%) patients had a dicentric Y, and one (2%) case had a small marker that was determined to be derived from the Y. One (2%) patient showed mosaicism for a marker chromosome that was derived from neither the X nor Y chromosomes. To further investigate the possibility of Y chromosome material in the 17 patients with an apparently non-mosaic 45,X karyotype, we performed FISH using centromere probes for the X and Y chromosomes. A 45,X result was confirmed in 11 cases, and a minor XX cell line was identified in 6 patients. Two of the six samples were found to have a second structurally abnormal X chromosome when metaphase cells were analyzed by FISH or G-banded slides were re-examined. One patient had an i(X)(q10) and the other had an idic(X)(q25). No samples with a XY mosaicism were identified. While several publications have documented the use of PCR-based assays to identify mosaicism in UTS patients, the incidence of false positives using PCR testing has raised concern with these assays. We believe the use of FISH as an adjunct to karyotype analysis provides a sensitive and cost-effective technique to identify sex chromosome mosaicism in UTS patients with a 45,X karyotype.

**Use of telomere and specific locus FISH probes to detect deletions within duplications.** *J. Panella<sup>1</sup>, M. Williams<sup>4</sup>, C. Miller<sup>1</sup>, J. Johnson<sup>1</sup>, W. Wells<sup>1</sup>, Z. Qi<sup>2</sup>, L. Meisner<sup>1,3</sup>, J. Yu<sup>1,2,3</sup>.* 1) Wisconsin State Laboratory of Hygiene; 2) The Waisman Center; 3) Department of Pathology and Lab Medicine, University of Wisconsin-Madison, Madison, WI; 4) Gunderson Lutheran Hospital, La Crosse, WI.

We present an 18 month old child who is the product of an uncomplicated pregnancy with a non-contributory family history. Concerns relating to delayed development were raised at 3 months, and by 17 months neurological testing showed that both gross and fine motor skills were at the 10-11 month level. Physical examination demonstrated mild to moderate facial dysmorphic features but a normal neurological exam except for the developmental delay. MRI of the brain showed a thin anterior corpus callosum and apparently absent splenium, with focal areas of abnormal high signal in the periventricular white matter. High resolution cytogenetic analysis with G-banding demonstrated an extra dark band in the 8p23 region that was similar in appearance to band 8p22, suggesting a duplication of the 8p22-23 region. Since both parents were cytogenetically normal, we used a chromosome 8 painting probe with fluorescence in situ hybridization (FISH) to establish that the duplicated material derived from chromosome 8. We then microdissected the 8p23.1 band, and made a probe for this region. Since this probe yielded two signals of different sizes, we used an 8p sub-telomere probe to better evaluate the distance between the telomere and the duplicated region. The telomere and specific locus FISH signals, combined with inverted DAPI banding, suggested an inverted duplication of part of 8p21, all of p22, and part of 23.1. In addition, the 8p terminal region distal to the breakpoint within 8p23.1 was deleted. Therefore, the karyotype of the patient is 46,XX,der(8)del(8)(p23.1)dup(8)(p23.1p21). The FISH studies enabled obtaining more detailed genetic information for the clinical assessment of the patient, and for genotype/phenotype association studies. This study also demonstrated the necessity of using molecular cytogenetic techniques to more precisely analyze de novo chromosome aberrations that cannot be interpreted by standard prometaphase banding alone.

**A Case of Twin Pregnancy: a Coexisting of 46, XY Heterozygous Complete mole; and a Normal 46, XX Fetus.** *O. Samura, N. Miharu, Y. Nakashima, N. Fujito, M. Hyodo, N. Honda, K. Ohama.* Dept OB/GYN, Hiroshima Univ Sch Medicine, Hiroshima, Japan.

Hydatidiform moles with a coexisting live fetus are rare; the incidence is estimated at from 1:22000 to 1:100,000 pregnancies. Three variants of the condition are known: (1) twin pregnancy with a complete hydatidiform mole and coexistent normal fetus (CMCF); (2) twin pregnancy with a partial hydatidiform mole and coexistent normal fetus; and (3) a partial hydatidiform mole. Of the three variants, CMCF has the highest potential for developing persistent trophoblastic disease (PTD); thus, it must be differentiated from the other types. Especially CMCF with the 46,XY heterozygous mole is very rare, only three cases have been reported. We report the case which had a normal infant without developing persistent trophoblastic disease (PTD). A 30-year-old pregnant woman delivered a normal female infant and the molar tissue at 28 weeks of gestation. Cytogenetic analyses of the mole and fetus were performed. We analyzed the genetic origin by quantitative fluorescent PCR (QF-PCR) with short tandem repeat markers. Chromosomal analysis revealed that the karyotype of the molar tissue was 46, XY, and the fetus was 46, XX. The molar tissue showed a 46,XY heterozygous complete mole using QF-PCR. This case indicates that a patient can achieve a good pregnancy outcome even if the pregnancy consists of CMCF with a 46, XY heterozygous mole. In addition, QF-PCR is useful method for the determination of the genetic origin of the mole and the infant.

**Delineation of the origin and structure of chromosomal duplications: analysis of 136 cases.** *R. Tarvin, L. Christ, C. Curtis, S. Schwartz.* Case Western Reserve University and University Hospitals of Cleveland.

The routine use of FISH analysis in the cytogenetic laboratory has identified chromosomal duplications arising from either duplication of material from the same chromosome (intrachromosomal) or from another chromosome (interchromosomal). They may be a simple duplication of material or they may involve the loss or rearrangement of other material. In order to better understand the structure, origin and nature of duplications, we have undertaken a systematic study of 136 duplications, which were not due to the malsegregation of parental rearrangements. These have been analyzed using high-resolution chromosome analysis, FISH with chromosomal libraries, in many cases, analysis with microsatellite markers and lastly, employing data from the Human Genome Project, the utilization of over 250 BACs to fully characterize many of the duplications.

This is the most comprehensive study of duplications to date and results from this work have lead to a number of findings regarding this abnormality. (1) The majority of duplications are intrachromosomal although 39% are interchromosomal; (2) the structure of these abnormalities is easily determined by FISH and in 94% of the cases only one library needed to be used to delineate the chromosomal origin of the extra material; (3) chromosomes 8, 9, 15, 18 and X are preferentially involved; (4) the abnormalities can originate in either paternal (37%) or maternal meiosis (67%); (5) overall 93% were de novo duplications, but in 7% of the cases a parent had the same duplication; the majority of these were intrachromosomal; (6) approximately 14% of these were ascertained serendipitously without an associated phenotype; (7) in 29% of the cases the structure was more complex than just that of a simple duplication; most of these involved a deletion in addition to the duplication; (8) approximately 20% of these duplications were associated with a specific syndrome and in 5% of the cases a duplication of a specific gene was diagnostic; and (9) in 10% of the cases cryptic telomeric duplications, most, which did not involve the subtelomere, were delineated by this work.

**Constitutional abnormalities of chromosome 20: Report of 2 rare new cases and review.** *J. Garcia-Heras, R.A. Kilani, K. Grange, R. Martin, S. Lamp, J. Ivanovich.* Dept Pediatrics, Washington Univ Sch of Med, St Louis, MO.

We report 2 unbalanced rearrangements of chromosome 20 in newborns and review the literature to establish genotype-phenotype correlations. Case A is a male born at 37 wks by vaginal delivery to a 33-year-old G5P2 mother. The APGAR score was 2, 6 and 7 at 1, 5 and 10 minutes respectively. The birth weight was 2,400 GM (40th centile), the length was 47 cm (25th centile) and the OFC was 32 cm (25th centile). The child had craniofacial dysmorphism, normal male genitalia, a small phallus with a semibifid scrotum, and bilateral widely separated 1st and 2nd toes, A hypoglycemia since birth and the small phallus were due to panhypopituitarism. GTW banding in lymphocytes detected an interstitial deletion of band 20p11.2. The paternal karyotype was normal. The mother carried in lymphocytes the same deletion of 20p11.2 in mosaicism so this case would be the 2nd deletion of 20p inherited from a mosaic carrier parent. Our case and a deletion of 20p11.22-p11.23 with autism, minor facial anomalies and Hirschprung disease suggest that monosomies of 20p11.2 have a mildly affected phenotype. Case B is a female born at 40 wks by C-section to a G1P1 27-year-old mother. At birth the weight was 3,507 GM (75th centile), the length was 51.5 cm (75th-90th centile), and the OFC was 33 cm (25th centile). The APGAR score was 6 at 1' and 7 at 5'. The child had craniofacial dysmorphism, bilateral 5th finger clinodactyly, broad thumbs and mildly broad great toes. An echocardiogram showed a complex cardiac defect. Multiple thoracic vertebral anomalies, 12 pairs of ribs and 6 lumbar vertebrae were seen by a chest X-ray. GTW banding in lymphocytes demonstrated a rec(20) dup 20q with a deletion of 20p13->pter and a trisomy of 20q13.1->qter. The maternal karyotype was normal. The rec(20) was inherited from the father carrier of an inv(20)(p12q13.11). This first report of a rec(20) dup 20q and 3 other trisomies 20q13->qter have a normal intrauterine growth, a congenital cardiac defect, craniofacial dysmorphism and hand, feet, rib and spine anomalies. Subtelomeric deletions in the chromosomes involved in the translocations or the 20p deletion in the rec(20) explain their clinical differences.

**Cleft palate, polydactyly and mild mental retardation in a girl with a balanced chromosome 7;9 translocation.** *P. Gustavsson, E. Gourgouvelis, E. Blennow, A. Ilicki, M. Nordenskjöld.* Department of Molecular Medicine, Karolinska Hospital, Stockholm, Sweden.

We have identified a girl carrying a chromosomal translocation associated with cleft palate, polydactyly and learning difficulties. The girl is the only child of healthy parents. Chromosome banding revealed an apparently balanced translocation involving chromosomes 7p and 9p. The karyotype is defined as 46,XX,t(7;9)(p21;p21).

Previous studies have shown that patients carrying mutations in the TWIST gene located on chromosome 7p21 present with Saethre-Chotzen syndrome characterized by multiple anomalies such as facial malformations, craniosynostosis, hand and foot abnormalities. Also, microdeletions spanning the TWIST locus are associated with mild mental retardation suggesting a contiguous gene syndrome.

We have used fluorescent in situ hybridization (FISH) to metaphase chromosomes in order to map the translocation breakpoints on chromosome 7p and 9p. Our results revealed that no known gene was disrupted by the chromosome 9p breakpoint. FISH analysis show that the chromosome 7p breakpoint is located 3' of the TWIST gene. In addition, the breakpoint on chromosome 7p is located close to a gene encoding histone deacetylase 9 (HDAC9). HDAC9 is predominantly expressed in the brain and the gene product is involved in histone deacetylation that regulates gene expression.

We suggest that the chromosome 7p breakpoint is involved in the aetiology of malformations and learning difficulties in the patient. The mechanism might be explained by a positional effect on adjacent genes caused by the translocation breakpoint. Further FISH and molecular analysis is in progress in order to refine the chromosome 7p breakpoint in relation to known and unknown genes.

**22q11.2 deletions in familial DiGeorge/Velocardiofacial syndrome are predominantly smaller than the commonly observed 3Mb.** *A. Adeyinka<sup>1</sup>, K.J. Stockero<sup>1</sup>, H.C. Flynn<sup>1</sup>, L.K. Courteau<sup>2</sup>, C.P. Lorentz<sup>1</sup>, R.P. Ketterling<sup>1</sup>, D.B. Dawson<sup>2</sup>, S.M. Jalal<sup>1</sup>.* 1) Cytogenetics Laboratory, Pathology and Laboratory Med, Mayo Clinic, Rochester, MN; 2) Molecular Genetics Laboratory, Pathology and Laboratory Med, Mayo Clinic, Rochester, MN.

DiGeorge/Velocardiofacial syndrome (DG/VCFS), cytogenetically characterized by deletion of 22q11.2, is the most common microdeletion syndrome with an incidence of about 1: 4000. In over 88% of patients, the deletion size is 3 Mb while the remaining have deletions between 1.5 Mb and 2.5 Mb. Recently, we described a number of patients with duplication of 22q11.2 which is the reciprocal recombinant product of the 22q11.2 deletion. The duplication sizes observed ranged from 3 Mb to 6 Mb, and included a family of 3 affected siblings who inherited a 4 Mb duplication from their mother. Interestingly, of approximately 250 well-characterized microdeletion cases in the literature, no deletion sizes over 3 Mb was reported. This observation supports the notion that large duplications of the genome are better tolerated than large deletions and has led us to hypothesize that small deletions may be tolerated in a familial fashion more easily than large deletions. To test this hypothesis, FISH probes designed from bacterial artificial chromosomes (BACs) and P1 artificial chromosomes (PACs) mapped to 22q11.2 were used to determine the deletion sizes in 13 individuals from six families with cytogenetically proven 22q11.2 deletion. Three families (7 individuals) had deletions of less than 3 Mb (1.5 Mb to 2 Mb) and 3 families (6 individuals) had 3 Mb deletions. Molecular analysis based on a panel of 15 STR markers is underway to confirm these findings. The 50% frequency of smaller deletions among this group of patients with familial del(22)(q11.2) is significantly higher than that reported (upper limit of 22%) in the general population. These preliminary findings support the hypothesis that smaller sized del(22)(q11.2) are more common in a familial setting and underscores the need to exclude a familial basis in all cases of del(22)(q11.2) smaller than 3 Mb.

**Segregation of a novel euchromatic expansion of 8p22 in three generations with no associated phenotypic abnormalities.** *S. Chan*<sup>1</sup>, *F.J. Dill*<sup>1,2</sup>, *S. Langlois*<sup>1,2</sup>, *J.T. Pantzar*<sup>1</sup>, *B. Lomax*<sup>1</sup>, *E. Rajcan-Separovic*<sup>1</sup>. 1) Pathology and Laboratory Medicine; 2) Medical Genetics, Children's and Women's Health Centre of British Columbia, University of British Columbia, Vancouver, Canada.

Rearrangements of the short arm of chromosome 8 encompass a wide variety of cytogenetic abnormalities, many of which are recurrent. Recent studies have suggested that the presence of two olfactory receptor gene clusters in 8p may be involved in the generation of some of these rearrangements. We present the first report of a euchromatic expansion of 8p22 which segregates in three generations of a family with no associated phenotypic abnormalities.

A 30 year-old, G<sub>2</sub>P<sub>1</sub> woman presented with an increased risk of Down syndrome on triple maternal serum screen. Amniocentesis was performed and cytogenetic studies on G-banding preparations showed an expansion of the G-positive band 8p22 in all cells examined. FISH with chromosome 8 paint indicated that the extra genetic material was chromosome 8 in origin. CGH using DNA extracted from the cultured amniocytes revealed a small gain in the distal portion of 8p22. Investigations on the family members showed identical findings in the phenotypically normal mother and maternal grandfather. C-banding performed on maternal blood lymphocytes revealed no C-band positive material in the 8p22 region, providing evidence that the extra genetic material was euchromatin. Given the results, the couple was counseled that this cytogenetic finding was a familial variant unlikely to be associated with an increased risk of developmental anomalies. Despite this, the family elected to terminate the pregnancy. Autopsy revealed no fetal anomalies.

As 8p22 is a G-positive band and likely to be gene-poor, this may explain the absence of phenotypic abnormalities in association with the cytogenetic finding observed in this family. Given that the location of 8p22 expansion in this case is in close proximity to that of an olfactory receptor gene cluster reported in the literature, it likely represents a rearrangement originating from or in association with these repetitive sequences, the exact nature of which is to be determined by further studies.

**Infant with maternal UPD14 heterodisomy arising through a de novo dic(14:14)(p12;p12) formed during maternal meiosis I.** *C. Curtis<sup>1</sup>, M. Falk<sup>1</sup>, A. Zinn<sup>1</sup>, N. Bass<sup>2</sup>, S. Schwartz<sup>1</sup>.* 1) Center for Human Genetics; 2) Dept Pediatric Neurology, Case Western Reserve University and University Hospitals of Cleveland, Cleveland, OH.

A 9-month-old infant was referred for genetic evaluation of his hypotonia, hypoactive reflexes and small size. Testing provided no evidence of a metabolic disorder or Prader-Willi syndrome. Cytogenetic analysis, however, revealed a male karyotype with 45 chromosomes including a dicentric chromosome composed of two long arms of chromosome 14 [45,XY,dic(14;14)(p12;p12)]. Parental karyotypes were normal. Molecular analysis of chromosome 14 DNA markers revealed a pattern of inheritance in the patient consistent with maternal disomy, without inheritance of any paternal alleles at informative loci. Most interestingly, DNA marker D14S990, located in G-band region 14q11.2 and the most proximal marker tested, exhibited maternal heterodisomy. This suggests that both maternal chromosome 14 homologues participated in the formation of the de novo dic(14;14). D14S48, a more distal marker in 14q31-q32, exhibited maternal isodisomy. This study revealed that: (1) Because maternal heterodisomy was present in the most proximal markers analyzed while maternal isodisomy was present in distal markers, the dicentric most likely formed between non-sister chromatids after completion of crossing-over. (2) The infant's UPD14mat most likely resulted from post-zygotic trisomy rescue of a 46,XY,+14,dic(14;14)(p12;p12) conceptus through loss of the normal paternal chromosome 14, though such a 46 chromosome cell-line was not detected in the patient's peripheral blood. (3) The infant's phenotype of small size and hypotonia correlates with previously reported cases of i(14q) isodisomy and normal karyotypes (46,XX or 46,XY) with UPD14 heterodisomy. (4) UPD14 testing should be considered in infants with hypotonia, normal methylation of 15q11.2-15q12 and no evidence of a metabolic disorder, since the remaining common features of UPD14mat (precocious puberty, short stature, developmental delay and/or mental retardation) may not become evident until some time later.

**Prenatal cytogenetic detection of an unbalanced karyotype involving 9p- and 18q duplication in a fetus with apparently normal phenotype.** *C.C. Lin<sup>1,3</sup>, L.J. Hsieh<sup>1</sup>, Y.J. Pan<sup>2</sup>, Y.C. Li<sup>3</sup>.* 1) Department of Medical Research, China Medical University Hospital, Taichung, Taiwan; 2) Department of Obstetrics and Gynecology, Lin Shin Hospital, Taichung, Taiwan; 3) Department of Life Sciences, Chung Shan Medical University, Taichung, Taiwan.

A 26-year-old woman was referred for prenatal diagnosis of chromosomal disorders at 17 weeks gestation due to a maternal serum triple screen resulting in a Down syndrome risk estimate of 1 in 162. A fetus sonogram did not show any structural abnormality. The pregnancy was uneventful up to the time the test was performed. G-banding and SKY analyses revealed the fetus had a female sex with a derivative chromosome 9 that was resulted from a translocation of the chromosome 18 segment distal to 18q11.2 to the short arm of chromosome 9 at band 9p22. In addition, FISH study showed the presence of a chromosome 18q sub-telomeric sequence in the short arm of the derivative chromosome, thus verified the translocated segment containing 18qter. Chromosome studies on the parents of the fetus were also performed and found both parents have normal chromosome complement. Therefore, the fetus was identified of having an unbalanced karyotype, 46,XX,der(9)t(9;18) (p22;q11.2) de novo. The pregnancy was terminated at 21 weeks and other than the slightly low-set ears, the fetus appeared as having a normal phenotype. Follow up chromosome studies on a cord blood sample and a skin sample confirmed early cytogenetic findings. To our knowledge, this is the first reported case of an apparent normal fetus with an unbalanced karyotype involving 9p- syndrome and 18q duplication syndrome. The study was supported by grants from National Health Research Institute (NHRI-EX92-9207 SI) and National Science Council (NSC 91-2320-B-040-037).

**Terminal deletions of 4q in phenotypically normal individuals.** *J.T. Mascarello<sup>1</sup>, B.R. Ravnan<sup>1</sup>, C.L. Martin<sup>2</sup>, M. Verp<sup>2</sup>, E. Weber<sup>2</sup>.* 1) Genetics, Santa Fe, NM; 2) University of Chicago, Chicago IL.

We report five families with at least one phenotypically normal carrier of a terminal deletion of the chromosome 4 long arm. In four families, the deletion involved the microscopically-detectable loss of chromatin from band q35. In all four cases, the terminal nature of the deletion was demonstrable by subtelomere FISH analysis. In the fifth, the deletion was detected by subtelomere FISH. Results of G-band analyses in this family were not available but, presumably, would have shown no deletion because the deletion removed the Vysis subtelomere target but not the CytoCell subtelomere target. These cases, in conjunction with previous reports of satellited chromosome 4 long arms demonstrate that the loss of distal 4q often produces no clinical consequences. Moreover, such cases point to a need for caution in interpreting results of subtelomere studies that show a deletion of terminal 4q.

**Infant with homozygous premature chromatid separation trait: Autopsy findings of bilateral Wilms tumors and rhabdomyosarcoma of the bladder.** *H. Numabe*<sup>1, 2</sup>, *T. Ikeuchi*<sup>3</sup>, *T. Kajii*<sup>4</sup>, *M. Tachibana*<sup>2</sup>, *K. Iso*<sup>5</sup>, *E. Arai*<sup>6</sup>, *T. Ishida*<sup>6</sup>, *K. Mukai*<sup>6</sup>. 1) Dpt of Medical Informatics, Tokyo Medical Univ, Tokyo, Japan; 2) Dpt of Pediatrics, Tokyo Medical Univ Hosp, Tokyo, Japan; 3) Dpt of Molecular Cytogenetics, Medical Research Institute, Tokyo Medical and Dental Univ, Tokyo, Japan; 4) Hachioji, Tokyo, Japan; 5) Dpt of Obstetrics and Gynecology, Tokyo Medical Univ Hosp, Tokyo, Japan; 6) First Dpt of Pathology, Tokyo Medical Univ, Tokyo, Japan.

We report a girl with homozygous premature chromatid separation (PCS) trait, chromosomally characterized by PCS and mosaic variegated aneuploidy (MVA). She had pre- and postnatal growth retardation, microcephaly, Dandy-Walker malformation, and minor facial abnormalities; and at age 22 weeks developed generalized seizures controllable with phenobarbital. At age 4 months, bilateral multicystic Wilms tumors and rhabdomyosarcoma of the bladder were detected. She died of renal failure at age 9 months. Autopsy findings will be described. All tissues and cells from the infant analyzed showed a high frequency of PCS and MVS. They included amniotic fluid cells at 34 weeks of gestation; placental chorionic villous cells and cord blood lymphocytes at delivery; neonatal peripheral blood lymphocytes; and lung fibroblasts, kidney fibroblasts, and Wilms tumor cells obtained on autopsy.

**Molecular characterization of a (14)(q23q24) deletion in a patient with features of Holt-Oram syndrome. C.**

*Michel-Adde<sup>1</sup>, N. Le Meur<sup>1</sup>, A. Goldenberg<sup>1</sup>, V. Drouin-Garraud<sup>1</sup>, G. Blaysat<sup>2</sup>, S. Marret<sup>2</sup>, S. Abu Amara<sup>3</sup>, H. Moiro<sup>1</sup>, P. Saugier-veber<sup>1</sup>, T. Frebourg<sup>1</sup>, A. Rossi<sup>4</sup>.* 1) Department of Genetics, Rouen University Hospital, France; 2) Department of Paediatrics, Rouen University Hospital, France; 3) Department of Paediatric Surgery, Rouen University Hospital, France; 4) Department of Genetics, EFS-Normandie, Bois-Guillaume, France.

Holt-Oram syndrome, the major "hand-heart" syndrome, is defined by the association of radial defects or triphalangeal thumb and atrial septal defect. The transmission is autosomal dominant and the causative gene has been shown to be TBX5 located on 12q24.1 which encodes a transcription factor. The genetic heterogeneity of this syndrome has been suggested by several reports. We report here on a 14q23q24 deletion in a boy presenting with severe bilateral asymmetrical radial aplasia, congenital heart defect and poor neurological outcome. This deletion was shown to be inherited from the mother who carried a balanced interchromosomal insertion (46, XX, ins(4;14)(q31.1;q23q24)). This is the second report a 14q23q24 deletion associated with features of Holt-Oram syndrome. In our case, molecular cytogenetic analysis demonstrated that the deleted 14q material encompassed several genes encoding transcription factors potentially involved in heart and bone development. This observation strongly suggests the implication of a new "heart-hand" locus on chromosome 14q.

Program Nr: 861 from 2003 ASHG Annual Meeting

**Molecular characterization of an atypical 5p microdeletion in a child with dysmorphic features and developmental delay.** *M.D. Speevak, D. Cushing, M. Wood, S.A. Farrell.* Dept Genetics, Credit Valley Hosp, Mississauga, ON, Canada.

Cri du chat syndrome is a contiguous gene disorder associated with a partial short arm deletion of chromosome 5 and typical clinical features including a cat-like cry, distinct facies and severe global delay. The relevant breakpoint begins at 5p15 and extends through to the short arm terminus. We report a case of a four year old boy with a small interstitial deletion detected by G-banding, at band 5p15.2; however, FISH using the Cri du chat probe (Vysis) failed to confirm the deletion. The child had mild developmental delay and subtle dysmorphic features with a small lower jaw and slightly prominent ears but none typical of Cri du chat syndrome. Because the clinical features and FISH analysis were not consistent with a diagnosis of Cri du chat syndrome, chromosome band walking was performed using fluorescent probes generated from BAC clones labeled by degenerate oligomer primed (DOP) PCR. An atypical deletion involving bands 5p14.2 and 5p15.1 was revealed. These results demonstrate that unique custom probes are valuable tools for the confirmation of suspected rearrangements when commercial probes are uninformative.

Program Nr: 862 from 2003 ASHG Annual Meeting

**Prenatal diagnosis of a fetus with trisomy for the 16p subtelomere.** *G. Sekhon, N. Agan, J. Branson, A. Salvador.*  
Cytogenetics Lab, St John's Mercy Medical Ctr, St Louis, MO.

Routine analysis for abnormal ultrasound led to the prenatal diagnosis of a fetus with additional euchromatic material on the short arm of chromosome 20. Ultrasound on a 24 week fetus showed the presence of multicystic left kidney and right kidney hydronephrosis. Additional material on the short arm of chromosome 20 and multicystic kidney disease prompted us to use the whole arm painting probe for chromosome 16. This and further FISH mapping studies with probes from the polycystic kidney gene PKD1 confirmed our suspicion that the extra material is from chromosome 16 ; hence, the cytogenetic diagnosis was given as 46,XX,der(20)t(16;20)(p13.2;p13).ish der(20) (D16S3400x3,D20S1157x2). The breakpoint on the short arm of chromosome 20 occurred distal to the short arm specific telomere probe and did not result in any monosomy of chromosome 20. Parental chromosomes were normal. Only by supplementing conventional cytogenetic methods with molecular cytogenetic techniques could the true karyotype be unequivocally determined.

**Cytogenetic mapping of PKD2 gene to 4q21 within the critical region for the 4q- macrocephaly phenotype.** *M. Velinov*<sup>1,2</sup>, *M.J. Macera*<sup>3</sup>, *J. Kupferman*<sup>2</sup>, *H. Gu*<sup>1</sup>, *A. Babu*<sup>3</sup>, *E.C. Jenkins*<sup>1</sup>, *G. Kupchik*<sup>2</sup>. 1) Dept Cytogenetics, IBRDD, Staten Island, NY; 2) Maimonides Medical Center, Brooklyn, NY; 3) Wyckoff Heights Medical Center, Brooklyn.

A 3-year-old boy presented with growth and developmental delay, hypotonia, relative macrocephaly, dysmorphic features and polycystic kidneys. He had a small interstitial deletion of chromosome 4q (karyotype 46,XY,del (4)(q21.1q21.3). This patient's phenotypic findings were consistent with the previously reported deletion 4q21/4q22 macrocephaly phenotype (Nowaczyk M.J.M et al., Am J Med Genet 68:400-405, 1997). Previous linkage studies have localized the gene for type II polycystic kidney disease, PKD2, to bands 4q21-q23. FISH analysis, with a BAC probe containing the PKD2 gene, demonstrated hemizyosity for this locus in our patient since no signal was detected over the del (4) chromosome. This provided a more precise cytogenetic localization for PKD2. Cytogenetic findings in our patient appear to limit the deletion to 4q21.1-4q21.3. Band 4q22 was cytogenetically present. The reported deletion also better defines the minimal critical region for the 4q- macrocephaly phenotype. The absence of one of the PKD2 alleles in our patient had likely contributed to the early bilateral development of renal cysts. For comparison, previously reported patients with non-PKD1 (most likely PKD2) mutations had ultrasound - identifiable renal cysts before the age of 30 in only 11% of cases. Thus in our patient PKD2 hemizyosity is associated with a more severe variant of type II polycystic kidney disease. *This work was supported in part by the new York State Office of Mental Retardation and Developmental Disabilities.*

**Understanding placental mosaicism: two unusual cases of apparently confined placental mosaicism found in the neonate.** *G. Stetten, C.S. Escallon, J.L. McMichael, D.O. Saul, K.J. Blakemore.* Johns Hopkins University, Baltimore, MD.

Confined placental mosaicism (CPM) is a tissue specific mosaicism, often involving an aneuploid cell line identified in the placenta and apparently absent from the fetus. When mosaicism is identified through chorionic villus sampling (CVS) patients are counseled about options including follow-up ultrasound, amniotic fluid (AF) analysis, fetal blood and/or skin biopsy as well as possible uniparental disomy (UPD) studies. If these studies are normal, then it is highly likely that the fetus has a normal, non-mosaic karyotype. In 4000 CVS we have identified placental mosaicism in 38 cases. In 29 of these a normal karyotype was obtained from AF. In 28 the pregnancy progressed to a live birth with a normal phenotype. In 18 cases cord blood was karyotyped and found to be normal. UPD testing was offered as indicated, and in four cases showed normal, biparental inheritance of the given chromosome. In two of the 28 cases the abnormal karyotype thought to be confined to the placenta was found in the baby. In one case the CVS showed three cell lines 48,XX,+18,+mar[19]/47,XX,+18[12]/46,XX[5]. The AF was 46,XX in 33 colonies. However, cord blood at birth showed 3/100 cells with the trisomy 18 karyotype, 47,XX,+18[3]/46,XX[97]. In the second case an accessory derivative chromosome 10 was seen in the CVS, 47,XY,+der(10)[15]. Because the cytogenetic abnormality was inconsistent with a normally developing fetus, an amniocentesis was recommended. The AF was 46,XY in 80 colonies. At birth cord blood showed 20/20 cells with the normal karyotype. Mosaicism was confirmed in the placenta as expected, 47,XY,+der(10)[33]/46,XY[4], but surprisingly found in the skin as well, 47,XY,+der(10)[3]/46,XY[16]. The difficulties encountered when what was thought to be CPM is found in a neonate present a new diagnostic dilemma. We recommend follow-up at birth because it is important to know the degree of mosaicism in the population and its association with both normal and abnormal phenotype. However, the information must be presented to patients with great care, since a low level, mosaic chromosomal abnormality may or may not be benign.

**Development of Genomic Resources and Cytogenetic Databases for Patient Sample Characterization and Disease Gene Discovery.** *J.S. Herbrick<sup>1</sup>, E. Kanematsu<sup>1</sup>, L.R. Osborne<sup>2</sup>, P.N. Ray<sup>1,2</sup>, J.M. Rommens<sup>1,2</sup>, A.D. Paterson<sup>1</sup>, D.E. Bulman<sup>3</sup>, S.W. Scherer<sup>1,2</sup>.* 1) The Centre for Applied Genomics and Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Ottawa Health Research Institute, Ottawa, Ontario, Canada.

The Centre for Applied Genomics (TCAG; [www.tcag.bioinfo.sickkids.on.ca](http://www.tcag.bioinfo.sickkids.on.ca)) at The Hospital for Sick Children (Toronto) is a Canadian infrastructure established to facilitate innovative research and development in genetics and genomic biology. With the objective of providing core resources and technologies to support large-scale research projects, as well as for service-related research, five (unrestricted and not-for-profit) infrastructures operate. They are (i) Genome Resource Facility, (ii) Genetic Analysis Facility, (iii) Gene Expression Facility, (iv) DNA Sequencing and Synthesis Core, and (v) the Bioinformatics and Statistical Analysis Facility. Over the past year, 435 investigators from around the world used one or more of the facilities. To maximize application of these resources for the medical genetics community we have initiated a pilot project to integrate all cytogenetic breakpoint information with associated phenotypes into the human DNA sequence map. As a starting point we have collected and collated clinical records of over 1570 breakpoints and phenotypes from individuals with chromosome 7 rearrangements (850 constitutional and 720 malignancy-associated) and already localized over 500 of these to defined sites on the sequence map (see <http://www.chr7.org/>). Integrating this data with the DNA sequence and gene map has already led to the identification of candidate genes or mechanisms of disease for autism, split-hand split-foot syndrome, Williams-Beuren syndrome, cavernous malformation syndrome, splenic lymphoma, acute myeloid leukemia (see *Science* 300; 767-772, 2003); additional diseases will also be discussed. We are continuing to expand these studies by incorporating new chromosome 7 data sent from molecular and medical geneticists worldwide and are now considering a similar strategy to annotate the rest of the human genome.

**Subtelomeric FISH analysis of 1363 patients: A high frequency of subtle familial deletions and translocations.**  
S.A. Adams, A. Adeyinka, C.P. Lorentz, S.M. Jalal. Division of Laboratory Genetics, Mayo Clinic, Rochester, MN.

Subtelomeric DNA fluorescence *in situ* hybridization (FISH) probe panel is an effective tool for the investigation of children with developmental delay, idiopathic mental retardation, and nonspecific congenital anomalies. Of 1363 consecutive patients studied, one hundred eleven (111), or 8.14%, were abnormal. Of the abnormal results, 40 were derivative chromosomes, 53 were deletions, and 18 were balanced rearrangements or numeric abnormalities. The most common subtelomere abnormalities were those of 2p, 4p, 5p, 8p, and 10q. Cryptic subtelomere abnormalities of 12q, 15q, and 20q were observed and have not been previously reported. In addition, a high rate of familial abnormalities involving deletion and derivative chromosomes was identified. Among the patients with derivative chromosomes, 15 had family members tested. Of these, 10 (66.7%) inherited the abnormality from a parent who had a balanced translocation, while 5 (33.3%) were *de novo*. Among the deletion group, 21 had family members tested, and in 9 cases (42.8%) the deletion was inherited, whereas 12 (57.2%) were *de novo*. The most common familial abnormalities involved 3p, 4q, 7p, 8p, and 13q. In several families, the parent with the deletion had either normal clinical features or milder phenotype than the affected child. This chromosomal anticipation may be explained by several potential mechanisms, including unmasking of an autosomal recessive allele, imprinting effect, or expansion of the deletion in subsequent generations. To further elucidate this mechanism and to differentiate between normal variants and pathogenetic subtelomeric deletions, larger family studies need to be performed. The present findings underscore the need for parental FISH studies as part of the investigation of abnormal results, particularly because the rate of familial subtelomeric anomalies appears to be significantly higher than familial microdeletion syndromes and larger abnormalities detectable by banded chromosome analysis.

**Unbalanced Familial Subtelomeric Rearrangement Detected by FISH.** *S.A. Ebrahim<sup>1</sup>, A. Al Saadi<sup>2</sup>, K.S. Puder<sup>1</sup>, L. Gardner<sup>1</sup>, A. Johnson<sup>1</sup>.* 1) Dept Pathology, Cytogenetics, Wayne State Univ, Detroit Medical Center Detroit, MI; 2) Dept Anatomical Pathology, Beaumont Hospital, Royal Oak MI.

A subtle familial unbalanced rearrangement involving the short arm of chromosome 18 was identified in a woman, her son and unborn fetus. Standard chromosome analysis revealed a subtle 18p11.3 deletion that was later diagnosed by subtelomeric FISH probes as a cryptic unbalanced 5;18 translocation. The proband, a 3 year old Caucasian male, was referred for chromosome analysis due to multiple anomalies. Lymphocyte chromosome analysis revealed a male karyotype with a subtle distal 18p deletion. FISH analysis using a probe for the 18p subtelomeric region confirmed the loss of 18p11.3-pter region. Testing of the mother during her next pregnancy confirmed that she was a carrier of the same 18p deletion. High-resolution ultrasound at 19 weeks of gestation showed no apparent fetal anomalies, however, cytogenetic and FISH analysis of amniocytes revealed the same subtle distal 18p deletion. The patient was counseled regarding these findings, and opted to continue the pregnancy. The maternal grandparents were unavailable for testing. To further evaluate the familial deletion, analysis with a subtelomeric FISH probes was performed. The proband and his mother were found to have a previously undetected gain of 5p subtelomeric material translocated distal to 18p. The mother and her sibs are therefore monosomic for 18p11.32 and trisomic for 5p15.33. Deletion of 18p has been reported, with a wide range of phenotypic variability. The majority of cases are sporadic, however, about 15% are familial. It is likely that a subset of cases reported as familial deletion are cryptic rearrangements involving other subtelomeric regions. For proper genetic counseling, a careful evaluation of subtelomeric FISH probes assay should be included in the diagnostic work-up of patients with apparent familial chromosome deletion syndromes.

**Subtelomeric rearrangements and mental retardation: further phenotypic definition.** *K. Anyane-Yeboah<sup>1</sup>, T. Jancelewicz<sup>1</sup>, W. Chung<sup>1</sup>, E. Cox<sup>1</sup>, E. Guzman<sup>1</sup>, L. Tambini<sup>2</sup>, D. Warburton<sup>1</sup>.* 1) Division of Genetics -BHN6-601A, New York Presbyterian Hospital(Columbia University), New York, NY; 2) Dept of Obstetrics and Gynecology, St Luke's-Roosevelt Hospital, New York, NY.

Cryptic subtelomeric rearrangements have been reported in 4-7% of moderate to severely retarded individuals with apparent normal chromosomes(Knight et al,1999;deVries et al,2001). We present phenotypic information on 12 children from 11 families with cryptic subtelomeric chromosome rearrangements detected by FISH in our clinic population of moderate to severely retarded children with apparently normal chromosomes. The rearrangements were made up of the following deletions: 1p(2 cases), 3q, 9p, 9q(1), 22q(2 cases) and unbalanced translocations: der(4)t(4;5)(p;p), (8)t(8;10)(p;p), (9)t(9;1)(q;p), (9)t(9;16)(q;p), (22)t(22;16)(q;q). 3 balanced translocation carrier parents were identified in 8 families studied(37.5%). 41% of deliveries were via C-section and 33% of the pregnancies were associated with complications. Ten pregnancies were term, 1 preterm and 1 postdated. Apgar scores were normal in all cases. 33% were IUGR and 42% were born microcephalic. 50% overall subsequently became microcephalic. Feeding difficulty in infancy was present in 72%. Cognitive deficits were present in all, but was severe to profound in 83%. 33% had no speech and in an additional 50% speech was severely delayed. Muscle tone was abnormal in 75% and behavior was aggressive or hyperactive in 42%. There was history of seizures in 33%, congenital heart disease in 66%, hypertelorism in 66% and hypothyroidism in 16%. Abnormalities of skin including wrinkled palms and soles, hemangiomas, nevi and cutis marmorata were present in 42%. Abnormalities of the hand and feet, generally minor were present in 66% and included persistent fetal pads, small hands and feet, clinodactyly and minor overlap of the toes. This analysis is an attempt to define a phenotype that will be helpful to clinicians in the selection of suitable patients for subtelomeric FISH analysis in order to maximize yield of positive results and minimize costs.

**High resolution FISH analysis of NF1 REP and non-REP microdeletions evidences nonhomologous end joining mediated rearrangements.** *P. Riva<sup>1</sup>, M. Venturin<sup>1</sup>, C. Gervasini<sup>1</sup>, F. Orzan<sup>1</sup>, A. Bentivegna<sup>1</sup>, L. Corrado<sup>1</sup>, P.*

*Colapietro<sup>1</sup>, A. Friso<sup>2</sup>, R. Tenconi<sup>2</sup>, M. Upadhyaya<sup>3</sup>, L. Larizza<sup>1</sup>.* 1) Dept of Biology & Genetics, Medical Faculty University of Milan, Italy; 2) Clinical Genetics and Epidemiology Unit, Dept of Pediatrics, University of Padua, Italy; 3) Inst of Medical Genetics, University of Wales College of Medicine, Cardiff UK.

NF1 microdeletion syndrome is caused by haploinsufficiency of the NF1 gene and its flanking regions. NF1 patients carrying gross deletion, often displaying complex phenotype, account for 5-10% of all NF1 mutations. Most of the NF1 deletions (80%) originate by unequal homologous recombination of repeated sequences (REP-P and M) mapped to 17q11.2, while the remaining show unusual breakpoints. We performed high-resolution FISH analysis of 20 NF1 microdeleted patients with the aim of mapping non recurrent deletion breakpoints and verifying the presence of other recombination-prone genome architectural motifs. Conventional FISH analysis allowed us to identify 17 REP-deleted patients, and three patients carrying atypical deletions of 1.3 Mb, 1.5 Mb and 3 Mb respectively. By fiber-FISH, we identified genomic intervals of ~100 Kb comprising the breakpoint regions, which proved to be affected by reported deletions and translocation. The generation of several locus-specific FISH probes allowed us to restrict the critical deletion endpoint intervals to a few Kb. This approach led us to hypothesize that small blocks of REPs cluster around the 1.3 Mb deletion breakpoints and LPA1 repeats may be involved in the 1.5 Mb deletion breakpoints. The precise restriction of the deletion interval, by locus-specific probe, allowed us to isolate the 3 Mb deletion junction fragment by long-range PCR. Sequencing of the novel junction fragment indicated that the deletion is likely caused by non homologous end joining. We also established the exact deletion gene content in non-REP deletions which, by comparison with the REP deletion gene content, will contribute to carrying out genotype-phenotype correlation studies.

**De novo 14q subtelomere deletion and 15q subtelomere duplication in a child: detection by FISH subtelomere analysis.** *N. Qin<sup>1</sup>, M.G. Bialer<sup>2</sup>, I. Taff<sup>3</sup>, S. Hahn<sup>2</sup>, D. LaGrave<sup>1</sup>, B.J. White<sup>1</sup>.* 1) Cytogenetics, Quest Diagnostics Nichols Ins, San Juan Capistrano, CA; 2) Div of Med Genetics and; 3) Ped Neurology, North Shore Univ Hosp/NYU Med Center, Manhasset, NY.

An 8 yr old white girl presented with hypotonia, developmental delay, and dysmorphic features. She had been delivered by C-section at 37 wk gestation because of fetal bradycardia and failure to progress. Her birth weight was 3040 g. She was polycythemic at birth and severely constipated as a neonate. Mild hypotonia, epicanthal folds, a narrow palate, and retrognathia were noted at 6 mo. At 12-15 mo, speech and motor development were delayed. A DNA methylation test for Prader-Willi syndrome was normal, as were metabolic studies and a DNA test for myotonic dystrophy. She has been diagnosed with ADD and probably has mild mental retardation. She has fractured or lost 4 teeth and her extremities sometimes turn red or blue. At 8 yr, her height was 129.1 cm (25-50th percentile), weight 22.5 kg (10th percentile), and OFC 50 cm (~10th percentile). She had dysmorphic features including a long, thin face, medial flaring of the eyebrows, a high, narrow nasal bridge, malar hypoplasia, a narrow, high arched palate, a long, recessed jaw, dental crowding, a long philtrum and prominent triangular anhelices. Mild joint limitation, tapered fingers, and soft neurological signs were evident. High-resolution chromosome analysis and a FISH microdeletion syndromes panel were normal. However, on FISH subtelomere analysis, one 14q subtelomere signal was absent, replaced by an additional 15q subtelomere signal; the resulting imbalance consists of a 14q subtelomeric deletion and a 15q subtelomeric duplication. Parental 14q and 15q FISH subtelomeric probe findings were normal, suggesting a de novo rearrangement. To our knowledge, coexistence of these chromosome abnormalities has not been reported before. However, this patient's presentation is more consistent with 14q deletion than with 15q duplication. Our results add to knowledge on clinical findings in subtelomeric deletions and duplications and demonstrate the value of FISH subtelomere screening in children with unexplained dysmorphisms and developmental delay.

**Subtelomere FISH: Identification of Familial Variants.** *J.H. Tepperberg, I.K. Gadi, P.N. Mowrey, S.K. Griffin, C.J. Bullen, P.J. Schupp, P.D. Singh-Kahlon, L. Wisniewski, P.R. Papenhausen.* Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC.

Unbalanced subtelomere alterations have generally been associated with developmental delay, minor dysmorphic features and mild mental retardation. In over 2500 cases, we have observed 10 familial unbalanced autosomal subtelomere alterations. The proband in each case was referred because of phenotypic abnormalities, developmental delay and/or mental retardation. Three cases showed a 2qter deletion detected with the CytoCell multiprobe subtelomere panel. In each case, a parent was found to have the same deletion using the same DNA probe. Analysis with a slightly more proximal subtelomere DNA probe (Vysis, Inc.) showed this region to be present in all individuals. Three unrelated cases showed partial trisomy 4pter from a der(22)t(4;22)(pter;pter) translocation. Follow-up parental studies showed the same unbalanced alteration. Two cases showed diminished subtelomere DNA hybridization signals. The first case showed a diminished hybridization signal for distal 4p and the second case showed a reduced signal for 10q. Subsequent paternal analyses showed a diminished hybridization signal, for the respective chromosome, in both cases. An alteration of chromosome 17pter with an unexplained green (FITC) hybridization fluorochrome color was observed in both the proband and mother. A rearrangement involving chromosome 8p, which has a FITC fluorochrome in the Vysis mix with 17p, was ruled out with a specific chromosome 8p subtelomere probe. Finally, a 21q subtelomere deletion was observed in a young girl and her phenotypically normal mother. The presence of the same alteration in the proband and parent would suggest that the specific DNA probes are targeting non-coding DNA sequences. Alternatively, it is conceivable that an abnormal recessive gene is unmasked by a knockout of the normal allele in the proband consequently leading to an abnormal phenotype. Therefore, conclusions based strictly on subtelomere studies should only be interpreted within the context of a parental subtelomere analysis.

**Detection of trisomy 21 and other aneuploidies by Paralogous gene quantification.** *S. Deutsch*<sup>1</sup>, *U. Choudhury*<sup>1</sup>, *A. Sylvan*<sup>2</sup>, *S.E. Antonarakis*<sup>1</sup>. 1) Division of Medical Genetics, University of Geneva, Geneva, Switzerland; 2) Pyrosequencing AB, Uppsala, Sweden.

The link between Down Syndrome and trisomy of human chromosome 21 was established in 1959, and since then diagnosis of aneuploidies has been performed mostly by Karyotyping and later FISH, two methods that are based on counting the number of chromosomes present in human cells. These approaches are highly accurate but costly and labour intensive. The development of alternative methods for faster, higher throughput, accurate and semi-automated diagnosis of common cytogenetic abnormalities would be highly desirable. We have developed a simple method for the detection of chromosome number abnormalities based on the use of paralogous genes. These are genes that have a common evolutionary origin but have been duplicated over time in the human genome. They are in many cases located on different chromosomes, and show a high degree of sequence similarity. We exploit this sequence similarity in order to co-amplify paralogous sequences located on different chromosomes with identical primer pairs. Single nucleotide differences between the paralogue sequences which we call "Paralogous sequence differences" or PSDs, are then quantified using the Pyrosequencing technology, and the ratio of the PSDs reflects the relative copy-number of the chromosomes tested. We have now developed and validated tests for trisomies of chromosomes 21, 13 and 18, as well as all X and Y chromosome abnormalities in over 100 patients. At least two independent tests have been developed for each chromosomal abnormality. In addition we have used the same principle to detect common deletions such as those in DiGeorge and Williams-Beuren syndromes. For all tests, the correct diagnosis for each DNA was unambiguously assigned. This method has advantages over the microsatellite-based detection of aneuploidies, since the tests work on all DNAs (irrespective of informativeness of polymorphisms), and the detection of deletions does not require the parental DNAs.

**PHENOTYPE AND BEHAVIOR IN PATIENTS WITH ANGELMAN SYNDROME: COMPARISONS BETWEEN THE DIFFERENT CLASSES OF DELETIONS AND BETWEEN PATIENTS WITH A**

**DELETION AND WITH UPD.** *M.C. Varela<sup>1</sup>, F. Kok<sup>2</sup>, I. Kohl<sup>1</sup>, C.I.E. Castro<sup>1</sup>, C.P. Koiffmann<sup>1</sup>.* 1) Dept of Biology, Bioscience Institute, University of Sao Paulo; 2) Child Neurology Service, Dept of Neurology, Hospital das Clinicas, University of Sao Paulo, Sao Paulo, Brazil. email: [mcvarela@ib.usp.br](mailto:mcvarela@ib.usp.br). Support: FAPESP, CNPq.

The Angelman syndrome (AS - developmental delay, severe mental retardation, speech impairment, ataxia, outbursts of laughter, seizures) can result from either a 15q11-q13 deletion (del), paternal uniparental disomy (UPD), imprinting, or UBE3A mutations. We describe here the phenotypic and behavioral variability in 48 patients with different classes of deletions (11 BP1-BP3, 14 BP2-BP3, 2 BP2-BP4, 1 BP2-BP5, 20 inconclusive) and 9 patients with UPD. The diagnosis was made by methylation pattern analysis of the SNRPN-SNURF gene (exon1) and microsatellite analysis of loci within and outside the PWS/AS region. The clinical pictures of the patients with different classes of deletions showed no major phenotypic differences. Frequent swallowing disorders, brachycephaly, some capacity of communication and hyperactivity were more prevalent in BP2-BP3, while absence of speech was more common in BP1-BP3 patients. Previous reports have indicated that in patients with UPD the AS phenotype was milder than in patients with deletions, children with UPD had a better physical growth, fewer or no seizures, less ataxia and higher cognitive skills. Here in deletion patients presented a higher incidence of swallowing disorders (in centile) (73.9del;40UPD), hypotonia (71del;16.6UPD), absence of speech (91.3del;66.6UPD), microcephaly (57.7del;11.1UPD), and outbursts of laughter (95.74del;77.7UPD). Besides the abnormalities already described, weight (55.5UPD;17.9del), height (44.5UPD;11.4del), and OFC (33.3UPD;2.22del) above the 75th centile were more frequent among the UPD patients. These findings confirm the hypothesis that the severe phenotype of deleted patients is caused by haploinsufficiency of other genes in the deleted region. The frequency of UPD in AS patients reported in the literature is 2-3% of all AS cases, and, since these children may present a less typical phenotype, we suggest that AS patients with UPD may remain undiagnosed.

**Commercial FISH probes for Smith-Magenis syndrome do not contain the *RAII* gene and fail to diagnose all cases.** *C.N. Vlangos*<sup>1</sup>, *J. Blancato*<sup>4</sup>, *M. Wilson*<sup>5</sup>, *A.C.M. Smith*<sup>6</sup>, *S.H. Elsea*<sup>1,2,3</sup>. 1) Genetics Graduate Program; 2) Dept of Zoology; 3) Dept of Pediatrics and Human Development, Michigan State Univ, East Lansing, MI; 4) Institute for Molecular and Human Genetics, Georgetown Univ, Washington, DC; 5) Dept of Clinical Genetics, The Children's Hospital at Westmead, Westmead, Australia; 6) National Human Genome Research Institute, NIH, Bethesda, MD.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies/mental retardation disorder usually associated with an interstitial deletion of chromosome 17p11.2. The SMS phenotype includes mental retardation, developmental delay, distinct facial anomalies, sleep disturbance, and behavioral abnormalities. The typical SMS deletion occurs in ~70% of deletion patients and spans ~4 Mb, while the critical SMS region spans ~900 kb and contains ~25 genes. SMS was thought to be a contiguous gene syndrome, though recently we determined that the core SMS features are due to haploinsufficiency of the *RAII* gene, which maps to the middle of the SMS critical region. All SMS patients carrying a deletion are deleted for *RAII*. Currently, diagnostic testing for the SMS deletion relies on commercial probes mapping to the proximal side of the SMS critical region and do not include *RAII*. We present here two patients with the typical SMS phenotype who carry a cytogenetically visible 17p11.2 deletion. An SMS deletion was not detected using commercially available FISH probes in these patients. Further analysis using FISH probes mapping to the central portion of the critical region show that these patients are deleted for *RAII*. These findings further narrow the SMS critical region and provide additional evidence that haploinsufficiency of the *RAII* gene is the cause of the core SMS phenotype. Current commercial FISH probes cover the proximal end of the SMS critical region and may provide false negative results for diagnosis of SMS. Diagnostic testing for SMS should utilize FISH probes containing the *RAII* gene in all new cases. Furthermore, patients testing negative with currently available FISH probes should be re-evaluated using an *RAII* containing probe. Patients negative for *RAII* FISH may be appropriate for mutation screening.

**Cryptic chromosomal rearrangement screening in 30 patients with mental retardation and dysmorphic features.**

*M. Mila<sup>1,2</sup>, L. Rodriguez-Revenga<sup>1,2</sup>, C. Badenas<sup>1,2</sup>, A. Sanchez<sup>1,2</sup>, J. Mallolas<sup>1</sup>, A. Carrio<sup>1,2</sup>, National Network on Mental Retardation.* 1) Serv Genetica, Hospital Clinic, Barcelona, Barcelona, Spain; 2) IDIBAPS (Institut d'Investigacions Biomediques Agusti Pi i Sunyer). Hospital Clinic. Barcelona. Spain.

Mental retardation affects 1-3% of the general population and the genetic causes in many cases are unknown. Cytogenetically invisible chromosomal imbalances have been indicated as an explanation for them. Nowadays, and due to the development of molecular cytogenetic techniques, it is possible to identify cryptic rearrangements involving the ends of chromosomes. Over 500 children with moderate to severe mental retardation have been screened for their telomeres and it has been established that 5-10% of these have subtle abnormalities of chromosome ends. The clinical consequences of different telomere alterations are mostly unknown and with this type of study new syndromes are being delineated. We report a screening using chromosome-specific telomere FISH probes in a group of 30 patients with a well-characterized phenotype including mental retardation, dysmorphic features and normal karyotype. Among them, two subtelomeric rearrangements have been detected and characterized, the frequency of imbalances is estimated to be 6.7%. One of them is a de novo deletion of 1p36, which has been previously described as a contiguous gene syndrome. The second one is an unbalanced product of a cryptic translocation involving chromosomes 1 and 13, which results in a partial 1q trisomy and partial 13q monosomy. It is interesting to define a genotype-phenotype correlation for telomere regions in order to identify dosage-sensitive genes involved in human genetic diseases. It is worth highlighting the importance of searching for cryptic subtelomeric rearrangements in nonsyndromic mentally retarded patients in order to determine the etiology of mental retardation. Acknowledgements: Red de Grupos V2003-redG098-O.

**Fast routine screening for subtelomeric deletions and duplications using Multiplex Ligation-dependent Probe Amplification (MLPA).** *E. Sijtermans, C. de Kovel, D. Smeets, C. van Ravenswaay, B. de Vries, H. Brunner, W. Nillesen.* Dept Human Genetics, Univ Medical Centre Nijmegen, PO-Box 9101, 6500 HB Nijmegen, The Netherlands.

Subtelomeric submicroscopic rearrangements are known to be the cause of mental retardation in ~5% of patients. As a result, there is a demanding need for a fast, inexpensive and reliable detection method in routine diagnostic labs. Several methods, such as multiprobe FISH analysis, Multiplex Amplifiable Probe Hybridization (MAPH), and array-CGH do not meet all the criteria stated above. Recently a new technique was developed to analyse copy-numbers of almost any given chromosomal segment. This technique, Multiplex Ligation-dependent Probe Amplification (MLPA) is based on the annealing and subsequent ligation of two adjacent primers, followed by a quantitative PCR step (for technical details see [www.mrc-holland.com](http://www.mrc-holland.com)). MLPA is now routinely used for the detection of exon deletions in several human genes, including *BRCA1*, *MSH2* and *MLH1*. Recently a first generation MLPA probe-set for the detection of subtelomeric deletions/duplications became available. We have validated this set and subsequently analyzed 180 patients suspected of chromosomal aberrations but with a normal karyotype. Although the kit is not yet optimal for all chromosome ends (at least 3 probes need to be replaced, until now ~60% could be validated on patients with known deletions), anomalies have been detected in almost 8% of the patients. We are now in the process of confirming these findings by FISH analysis or array-CGH. These results indicate that MLPA (upon further optimization of the probe-sets) is likely to become the method-of-choice for routine analysis to screen for subtelomeric deletions.

**Detection of cryptic subtelomeric rearrangements in idiopathic syndromic mental retardation using telomeric QMPSF, a new molecular genetics method.** *P. Saugier-veber<sup>1,2</sup>, C. La Rochebrochard<sup>1,2</sup>, N. Le Meur<sup>2</sup>, A. Rossi<sup>3</sup>, V. Layet<sup>4</sup>, V. Drouin-Garraud<sup>2</sup>, A. Goldenberg<sup>2</sup>, G. Joly-Hélas<sup>2,5</sup>, H. Moïrot<sup>2,5</sup>, M. Tosi<sup>1</sup>, T. Frebourg<sup>1,2</sup>.* 1) INSERM EMI-U 9906, Faculty of Medicine 76183 Rouen, France; 2) Department of Genetics, CHU de Rouen, 76031 Rouen, France; 3) Department of Genetics, Etablissement Français du Sang, 76235 Bois-Guillaume, France; 4) Cytogenetics, Centre Hospitalier du Havre, 76083 Rouen, France; 5) Cytogenetics, CHU de Rouen, 76031 Rouen, France.

It is estimated that 6 % of all cases of idiopathic syndromic mental retardation may result from cryptic subtelomeric rearrangements. Most laboratories use FISH with telomere specific probes, but this method remains difficult, expensive and time consuming for routine diagnostic tests. CGH, microarray-CGH or microsatellites studies have been described but remain incompatible with high-throughput diagnosis. We developed a new simple molecular genetics assay based on the QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments) method, based on the simultaneous amplification of short fluorescent genomic fragments. For each subtelomeric end, we choose an exonic amplicon of 160-300 bp within the BAC or PAC used for the FISH assay and, when possible, a second more telomeric amplicon. Thus, for the 41 telomere exploration, 46 amplicons were used and integrated into 9 multiplex PCR. This method was first validated with 25 samples with characterized subtelomeric rearrangements. We have initiated the screening of 500 patients presenting with idiopathic syndromic mental retardation, and of 150 normal controls in order to document the existence of polymorphic rearrangements. We already detected a 15qtel duplication and a 19qtel deletion in two patients as well as a 10qtel duplication in a control. Telomeric QMPSF may constitute a simple method for the detection of cryptic subtelomeric rearrangements in patients with idiopathic mental retardation. Furthermore, because of its flexibility, telomeric QMPSF may facilitate the cartography of the rearrangements, the molecular cloning of the breakpoints and the positional cloning of genes involved in mental retardation, or malformations.

**Molecular mechanisms in Xp22-p21 deletions among patients with complex glycerol kinase deficiency (GKD).** *Y.-H. Zhang<sup>1</sup>, J.C. Ho<sup>2</sup>, B.-L. Huang<sup>1</sup>, L.L. McCabe<sup>1,2</sup>, K.M. Dipple<sup>1,2,3</sup>, E.R.B. McCabe<sup>1,2,3</sup>.* 1) Department of Pediatrics, David Geffen School of Medicine at UCLA, LA, CA; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, LA, CA; 3) Mattel Children's Hospital at UCLA, LA, CA.

Chromosomal rearrangements in Xp22-p21 typically involve the adrenal hypoplasia congenital (AHC), glycerol kinase (GK) and/or Duchenne muscular dystrophy (DMD) loci. The deletion sizes and breakpoints are unique within each family. The purpose of our investigation was to sequence patients deletion breakpoints and to identify potential mechanisms responsible for these recombination events. The breakpoints were sequenced using an ABI 3700 automated sequencer, and the sequences were analyzed using the NCBI and UCSC websites. We sequenced the breakpoints in six affected males (A-F) and identified the following: A) 0.4Mb interstitial deletion involving AHC; B) 0.6Mb interstitial deletion involving AHC and GK; C) 0.7Mb interstitial deletion involving GK and DMD; D) 1.9 MB interstitial deletion involving AHC and GK; E) 3.2 Mb interstitial deletion involving GK and DMD; and F) 4.5 MB interstitial deletion involving AHC, GK and DMD. The patients phenotypes matched the observed deletions for all six patients. Among the six patients, the data showed one Alu-Alu recombination, and three nonhomologous end-joining (NHEJ) events with 2-3 bp micro-homologies. The remaining two involved Alu sequence insertions. Our data are consistent with previous results from rearrangements involving other chromosomes. Unequal crossing over may occur between repeat sequences and very short NHEJ overlaps of 1-5 bp have been described in recombinant chromosomes. The possibility of retrotransposition events remains for both of the deletions associated with Alu insertions. In summary, the recombination breakpoints in these six patients with Xp22-p21 rearrangements differ from each other and potential mechanisms are consistent with observations of similar events elsewhere in the human genome.

**Refined risk of UPD associated with prenatally-detected inv dup(15) chromosomes.** *B. Huang*<sup>1,2</sup>, *A.N. Lamb*<sup>3</sup>. 1) Genzyme Genetics, Orange, CA; 2) Division of Human Genetics, University of California Irvine; 3) Genzyme Genetics, Westborough, MA.

Marker chromosomes originating from chromosome 15, often referred to as inv dup(15), are the most common marker chromosomes found in humans. The large marker 15 chromosomes that contain the Prader-Willi syndrome (PWS)/Angelman syndrome (AS) critical region are usually associated with an abnormal phenotype and the small inv dup(15) chromosomes that do not contain the PWS/AS region are mostly associated with a normal phenotype. The observation of the PWS or AS phenotype in a small minority of these patients has been mainly due to the presence of uniparental disomy (UPD) for chromosome 15. The risk of UPD in prenatally-detected de novo inv dup(15) cases has been reported to be as high as 12% (2 in 17 cases) in a previous study. In this report, we attempt to further define the risk associated with the prenatally-detected inv dup(15)s.

A total of 37 cases of inv dup(15)s identified during prenatal diagnosis that did not contain the PWS/AS region were examined for the presence of UPD for chromosome 15. Among the 37 cases, the inv dup(15) chromosomes were de novo in 23 cases, familial in 11 cases, and inheritance was unknown in 3 cases. In 35 cases, UPD was ruled out prenatally by either methylation analysis or microsatellite analysis. UPD was excluded in the remaining 2 cases by the presence of a normal phenotype during postnatal follow-up. Therefore, UPD was not detected in these 37 cases. Combining the previous study with this study, the overall risk of UPD associated with the de novo inv dup(15) chromosomes identified during prenatal diagnosis is lowered to 5% (2 in a total of 40 de novo cases). Further study with a larger number of cases is necessary for more accurate risk assessment.

**Single-Tube Polymerase Chain Reaction Analysis of 14-Microsatellite Markers for the Detection of Uniparental Disomy of Chromosome 15.** *S. Wang, F. Quan, W. Sun, C.M. Strom.* Dept Molecular Genetics, Quest Diagnostics Nichols Inst, San Juan Capist, CA.

Both Prader-Willi (PWS) and Angelman (AS) Syndromes are complex genetic disorders with severe clinical manifestations, including developmental delay, mental retardation, and dysmorphic features. About 70% of PWS cases are caused by a microdeletion of paternal chromosome 15q11.2-q13. Approximately 25% of PWS cases are caused by maternal uniparental disomy for chromosome 15 (UPD 15). Approximately 70% of AS cases are caused by a microdeletion of maternal chromosome 15q11.2-q13, and 3-5% of AS cases are caused by paternal UPD 15. Here we report a single-tube multiplex PCR-based microsatellite assay to detect UPD 15. The single-tube PCR assay analyzes 14 microsatellites, including 6 FAM-labeled (D15S988, D15S205, D15S986, D15S118, D15S130 AND D16S515), 3 VIC-labeled (D16S423, D15S978 and D16S3103), and 5 NED-labeled (D15S1007, D15S120, D15S128, D16S516 and D15S994) microsatellites. The heterozygosity of these microsatellites ranges from 0.66 of 0.88. To analyze microsatellites, we employed a highly automated system for sizing fluorescent-tagged PCR products. This system consisted of 1) capillary electrophoresis of PCR products on an Applied Biosystems (ABI) 3100 Genetic Analyzer, 2) fragment sizing using an internal size standard (GS 500Liz) and Genescan Analysis Software, and 3) genotype determination using the Genotyper Software. This 14-plex PCR assay can successfully genotype DNA samples with 2 to 100 ng genomic DNA in a 15 l reaction. Due to the discriminatory power of the large number of highly polymorphic microsatellites analyzed, we believe this multiplex PCR assay can determine the parental origin of chromosome 15 for all patient samples and thus enable the detection of UPD 15 for the diagnosis of PWS and AS.

**Random X-inactivation in an SRY positive, XX male.** *A. Al Saadi.* Dept Anatomic Pathology, William Beaumont Hosp, Royal Oak, MI.

Inactivation of an X chromosome in females is usually random, with some exceptions. Genes from pseudoautosomal and other regions on the human X chromosome usually escape inactivation. We report here a case of a 13-year-old, who was diagnosed prenatally as a female, 46,XX, but was phenotypically male at birth. The patient has been monitored regularly from early childhood. On his last visit, he appeared normal for his age and showed no evidence of hormonal deficiencies. His pubertal development has been normal without assistance. DHEA - sulfate was 64, LH 1.0, FSH 0.8, testosterone 46, his bone age and all other clinical evaluations were normal. He was referred to our laboratory for chromosomal analysis, since none was done post-natally. Cytogenetic studies were performed on both blood leukocytes and skin fibroblasts. A mosaic karyotype 45,X/46,XX constitution was found in both tissues. Eighteen of 50 leukocytes and 12 of 50 skin fibroblasts were 45,X. FISH study, using SRY DNA probe revealed that one of the X chromosomes in the 46,XX line and the single X in the 45,X line had positive signals.

X-inactivation study revealed a random inactivation in the 46,XX cells, which were previously scored for the SRY signal in both tissues. Since there was no mention of mosaic karyotype in the prenatal diagnostic study, it is proposed that the normal X chromosome is selectively lost, and that with the SRY is conserved in the 45,X line. The random inactivation in the 46,XX line is unlikely to involve the pseudoautosomal region with SRY. Normal hormonal and physical development in the 46,XX males may require that the SRY region be active in all cells. Molecular studies are underway to evaluate the SRY expression in the active and inactivated X chromosomes of the 46,XX line in this patient.

**Functional disomy of Xp: prenatal findings and postnatal outcome.** *K. Godbole<sup>1</sup>, E. Kolomietz<sup>2</sup>, E.J.T. Winsor<sup>2</sup>, D. Chitayat<sup>1,3</sup>*. 1) Dept Clinical Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Department of Laboratory Medicine and Pathobiology, Mount Sinai Hospital, Toronto, ON, Canada; 3) Prenatal Diagnosis and Medical Genetics, Mount Sinai Hospital, Toronto, ON, Canada.

We report a trisomy of the short arm of X chromosome (Xp11.2-pter) due to a de novo unbalanced X;13 translocation diagnosed prenatally in a female fetus. Amniocentesis was performed at 20 weeks gestation following the finding of Dandy-Walker malformation on a prenatal ultrasound examination. The trisomy of Xp11.2-pter was confirmed with fluorescence in situ hybridization (FISH), using an X chromosome painting probe and telomeric FISH probes specific for the short arm of chromosome X. The karyotype was defined as 46,XX,der(13)t(X;13)(p11.2;p11.2). FISH analysis with an XIST probe showed that the derivative chromosome 13 does not include the XIST locus at the X-inactivation center. A guarded prognosis for growth and development was discussed with the couple and they chose to continue the pregnancy. A severe phenotype was seen at birth including macrosomia, facial dysmorphism with preauricular tag, congenital heart disease and structural brain malformations. Because the derivative chromosome was not subject to X inactivation, functional disomy of Xp11.2-pter most likely accounts for the abnormal phenotype in this patient.

**Skewed X-chromosome inactivation in Premature Ovarian Failure.** *K.L. Bretherick<sup>1</sup>, M.R. Fluker<sup>2</sup>, C.L. Beever<sup>1</sup>, C.L. Anderson<sup>1</sup>, C.J. Brown<sup>1</sup>, W.P. Robinson<sup>1</sup>.* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Genesis Fertility Centre, Vancouver, BC, Canada.

Although the average age of menopause in humans is 51 years, approximately 1% of women will experience menopause before the age of 40, a condition known as Premature Ovarian Failure (POF). Known genetic causes of POF include various X-chromosome mutations and deletions, however in most cases the genetic etiology remains unknown. In females, an X-chromosome carrying a disadvantageous mutation or deletion is often preferentially inactivated resulting in skewed X-chromosome inactivation (XCI). We therefore examined XCI skewing in women with idiopathic POF to determine if undetected X-chromosome mutations or microdeletions are a significant cause of POF. XCI skewing was assayed by methylation-sensitive restriction enzyme digestion and PCR amplification of the polymorphic X-chromosome markers, AR and FMR1. XCI skewing using the AR assay was similar in cases and controls; 3 of 36 (8.3%) women with POF and 7 of 94 (7.4%) control women had extremely (90%) skewed XCI ( $p=0.6$ ), suggesting that X-chromosome mutations and deletions causing skewed XCI do not account for the cases of POF in our population. However, women with POF were more skewed using the FMR1 assay than they were with the AR assay; of 7 POF cases with a difference in skewing of 10% between the FMR1 and AR assays, 6 (85%) were more skewed using FMR1 than AR. This was not seen in controls; of 33 controls that had a 10% difference in skewing between the assays, 14 (42%) were more skewed using the FMR1 assay ( $p=0.09$ ). The increase in skewing detected using the FMR1 assay may reflect the role of FMR1 in POF; FMR1 premutation size alleles have been associated with POF. Interestingly, the distribution of skewing in women with POF shows a bias towards demethylation of the larger FMR1 allele ( $N=27$ , skewness of distribution = -0.27), a trend that is not so apparent in controls ( $N = 70$ , skewness of distribution = -0.12). This may represent a tendency for women with POF to activate larger FMR1 alleles, a finding of potential importance in elucidating the etiology of the FMR1 association with POF.

**Chick neural tube electroporation for the analysis of Zic2 function in CNS development.** *L. Brown, S. Brown.*  
Ob/Gyn, Columbia Univeristy , New York, NY.

Loss-of-function mutations in *ZIC2* result in severe brain malformations in humans and mice, proving that the developing CNS is very sensitive to the level of *Zic2* gene product. Our own unpublished data show that ectopic expression of *Zic2* in the developing spinal cord of mice results in severe malformation, confirming this idea. In order to pursue this observation and to further investigate how *Zic2* acts at the molecular level, we have used chick neural tube electroporation as a rapid and inexpensive method for studying the mis-expression of genes in the developing spinal cord.

In this system, 48 hour chick embryos are exposed by un-roofing the egg and plasmid DNA is injected into the open neural tube using a fine glass micropipette. A train of pulses of DC current is then applied through platinum electrodes placed on either side of the neural tube. The egg is then allowed to incubate for up to 72 hours before it is sacrificed and prepared for either whole-mount analysis of gene expression or for serial sectioning. The use of green fluorescent protein (GFP) allows for a rapid assessment of electroporation efficiency. Because the DNA only enters one half of the neural tube, the contra-lateral side serves as a convenient control for all downstream gene expression studies.

We have used this system to express both normal and mutant mammalian alleles of *Zic2*. Interestingly, at 48 hours after electroporation, there is no discernable expression of *Zic2* although an inactive *Zic2* allele is expressed without problem as is GFP. By examining earlier time points, we were able to demonstrate that electroporation of *Zic2* results in rapid apoptosis as determined by TUNEL assay and staining for anti-phospho-histone H2AX. The use of mutant alleles of *Zic2* indicates that apoptosis depends on the presence of an intact DNA binding domain but not transactivation activity of the *Zic2* protein. These results point the possibility that *Zic2* has a very divergent roles in chick and mammalian development. Work is currently in progress to clone the full length *Zic2* protein.

**Expression profiles of regenerating avian hair cells.** *R.D. Hawkins<sup>1</sup>, S. Bashirdes<sup>1</sup>, M.E. Warchol<sup>2</sup>, M. Lovett<sup>1</sup>.* 1) Genetics, Washington Univ, St Louis, MO; 2) Central Institute for the Deaf, St Louis, MO.

Age-related hearing loss affects one-third of people over the age of 50, and fifty percent of those over the age of 60. While the environment and/or genetic predisposition are causative, a major physiological limitation is the inability to regenerate damaged hair cells in the inner ear. These specialized cells are necessary for hearing and balance. The avian inner ear, unlike that of mammals has the remarkable ability to regenerate damaged hair cells. After exposure to ototoxic drugs or oto-acoustic trauma, damaged hair cells re-grow by proliferation and differentiation of supporting epithelial cells. In the current study cultured utricular and cochlear sensory epithelial cells, hair cells and supporting cells, were treated with an ototoxic drug, neomycin, for 24 hours (hrs), and allowed to recover for 0hrs, 24hrs, and 48hrs. Each time point was profiled for changes in gene expression compared to time-matched controls. Earlier time points were also profiled from laser damaged utricular sensory epithelia at 30mins, 1, 2, and 3hrs. Due to the small number of cells, a micro-cDNA amplification method was employed to generate enough labeled target for expression profiling. Time point samples were hybridized to custom oligonucleotide arrays that interrogate ~1700 human transcription factor genes. Greater than 10 percent of these transcriptional regulators showed differential levels of expression across the time points, falling into various clusters or trends of expression. We observed a burst of transcription at 24hrs in both organs, but could discern differences between utricle and cochlea regeneration including changes in CEBPG, ETV1 and POU5F. We also observed commonalities in both organs, including upregulation of HES2, HSF1, and ERF. The laser ablation time course exhibited a reproducible burst of gene expression at 1hr followed by a second cycle of increased expression at 3hrs including HOXA13, and RORC. Identifying key transcriptional regulators in these processes should provide insights into the genetic programs necessary for hair cell regeneration in avians, and may provide clues to the differences between these mechanisms and those in mammals.

**Gene expression profiles of FAC sorted mouse inner ear cells.** S.A. Sajan<sup>1</sup>, R. Veile<sup>1</sup>, P. White<sup>2</sup>, A. Doetzlhofer<sup>2</sup>, A. Groves<sup>2</sup>, N. Segil<sup>2</sup>, M. Lovett<sup>1</sup>. 1) Genetics, Washington University, St. Louis, MO; 2) House Ear Institute, Los Angeles, CA.

Late onset hearing loss affects almost 30 million Americans and is primarily due to irreversible damage to the inner ear auditory sensory epithelium. This epithelium consists of hair cells and surrounding supporting cells. Hair cells are mechanoreceptors that initiate action potentials in response to sound (or in the case of the vestibular organ, movement). One route towards restoring auditory hair cell function is cell replacement therapy. This would require *in-vitro* hair cell differentiation. To decipher the genetic programming of mammalian hair cell development we used a human transcription factor custom microarray and created gene expression profiles of various purified cell types from the mouse inner ear. The mouse atonal homolog1 (*Math1*) and cyclin-dependent kinase inhibitor *p27<sup>Kip1</sup>* are two of the few known markers of hair cells and supporting cells, respectively. We obtained FAC-sorted cochlear and vestibular hair cells at post natal days 1-3 from a transgenic mouse strain expressing *GFP* downstream of the *Math1* regulatory elements. Cochlear supporting cells from the same stage were obtained from mice expressing *GFP* downstream of the *p27<sup>Kip1</sup>* regulatory elements. Unlabeled cochlear and vestibular cells were also obtained from these mice. Several pairwise microarray comparisons were conducted on these various cell populations. The microarray data-sets were analyzed, and lists compiled of differentially expressed genes. Over 60 TF genes were over-expressed in hair cells and approximately 50 genes were over-expressed in supporting cells. We are currently validating this data-set by quantitative-PCR, in-situ hybridizations and RNA-interference experiments. These observations provide new insights into the developmental programming of these important cell types, as well as potential new markers for lineage tracing. Finally, we have also constructed cDNA libraries from these sorted cell populations. These cDNA collections from purified cell types should be valuable resources for future EST analyses.

**Expression pattern of the gene responsible for Dyggve-Melchior-Clausen syndrome (*Dym*) during human development.** V. El Ghouzzi, G. Mattei, V. Paupe, T. Attie-Bitach, A. Munnich, M. Vekemans, V. Cormier-Daire. Department of Medical Genetics and INSERM U393, Recherches sur les Handicaps Génétiques de l'Enfant, Hôpital Necker-Enfants Malades, 149, rue de Sèvres, 75015 Paris, France. elghouzzi@necker.fr or cormier-daire@necker.fr.

Dyggve-Melchior-Clausen syndrome (DMC) is a rare autosomal recessive skeletal disorder characterized by spondylo-epi-metaphyseal dysplasia and mental retardation. Studying DMC, we have recently identified nonsense, frameshift and splice mutations in a novel evolutionarily conserved gene, *Dym* (*FLJ20071/FLJ90130*), which encodes Dymeclin, a 669 amino-acid product of unknown function. Electron microscopy analysis on skin biopsy from DMC patients strongly suggests a storage disease as the cytoplasm of all cells displayed an enlarged endoplasmic reticulum and a large number of membranous vacuoles containing amorphous material. However, the accumulated metabolite remained unidentified. In order to determine the expression pattern of *Dym* during human development, RT-PCR analyses, multiple tissue expression arrays and *in situ* hybridizations were performed on several human embryo-fetal and adult tissues. We found that *Dym* is widely expressed but particularly in germinative zones of brain, lung, gut epithelium, limb buds and orofacial structures of 7 and 8 weeks human embryos. Interestingly, *Dym* transcripts were not detected in bone and cartilage at these stages but later, in post-natal chondrocytes, osteoblasts and fibroblasts. In addition, RT-PCR experiments and Northern blot hybridizations indicated that the mutated transcripts were not or weakly expressed in patients fibroblasts, suggesting that a specific mRNA decay occurs in DMC. These data indicate that DMC results from a loss-of-function of *Dym* at the transcriptional level, which would trigger storage of an unidentified substrate and suggest that *Dym* exert a role in early brain patterning, but may act later in the growth plate. This work was supported by the European Skeletal Dysplasia Network (ESDN).

**Disruption of the gene encoding for E-Selectin Ligand 1 (ESL-1) in mouse causes a reduction of skeletal growth independent of the FGFR signaling.** *R. Mendoza-Londono*<sup>1</sup>, *K. Li*<sup>2</sup>, *M. Jiang*<sup>1</sup>, *H. Lu*<sup>3</sup>, *J. Hicks*<sup>4</sup>, *A. Beaudet*<sup>1</sup>, *B. Lee*<sup>1,5</sup>. 1) Depts. of Molecular and Human Genetics; 2) Surgery; 3) Medicine; 4) Pathology and; 5) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX.

E-Selectin ligand 1 (ESL-1) is expressed on the cell surface of multiple cell lines. It is highly homologous to the chicken cysteine-rich fibroblast growth factor receptor (CFR) and the rat and human golgi apparatus protein 1 (MG160 and GLG1). ESL-1 was first isolated based on its ability to bind E-selectin, but its role as a resident Golgi apparatus protein is still unclear. ESL-1 binds fibroblast growth factors (FGF) with high affinity, but unlike FGF receptors, it lacks the intracytoplasmatic tyrosine kinase domain required for signaling. Because of its homology to CFR, we asked whether ESL-1 regulates FGF signaling during development. We have generated an ESL-1 null mouse by targeted disruption of the ESL-1 locus. ESL-1 heterozygous mice are phenotypically normal. The homozygous mutant mice are viable but only 65% survive to weaning. Mutant mice are 30% smaller than their wildtype littermates and skeletal preparations show generalized shortening and thinning of the long bones, with no patterning defect. X-rays of the skeleton show shortening of all bony elements with an apparent decrease in bone mineral density. Histological analysis demonstrated shortening and minimal disorganization of the growth plates, with fewer cells in the proliferating and hypertrophic zones and moderate increase in bone trabeculae thickness. Immunohistochemical analyses for Stat-1, Stat5a and p21, which are downstream targets in the FGFR/Stat-1 pathway, did not show differences between (+/+) and (-/-) animals. To study the role of FGFR3 signaling in the ESL-1-null mice we generated ESL-1 (-/-) /FGFR3(-/-) double mutants. These mice did not show correction of the skeletal phenotype, further suggesting that ESL-1 acts independently of FGFR3 signaling. These in vivo data suggest that ESL1 regulates chondrogenesis in a pathway autonomous of FGF signaling and is a candidate gene for skeletal dysplasias with similar chondro-osseous features.

**A search for causative genes of split hand/foot malformation (SHFM3).** *H. Kano*<sup>1</sup>, *H. Kurahashi*<sup>1, 2</sup>, *T. Toda*<sup>1</sup>. 1) Division of Functional Genomics, Department of Post-Genomics and Diseases, Osaka University Graduate School of Medicine, Osaka, Japan; 2) Division of Molecular Genetics, Institute for Comprehensive Medical Science, Fujita Health University, Aichi, Japan.

Split hand/foot malformation (SHFM) is a limb malformation involving the central rays of the autopod and presenting with syndactyly and median clefts of the hands and feet. At least five loci for SHFM have been mapped. The Dactylaplasia (Dac) mouse is considered a model for human SHFM3 as the human 10q24 region is homologous to the Dac locus on mouse chromosome 19. Two independent Dac mutations in the mouse dactylin gene have been identified. Both mutations found in Dac mice were insertions. We first cloned these insertions of 7,486 bp for Dac1 and 7,473 bp for Dac2, respectively. The insertions were LTR transposons called ETn and they were 99.6% identical. However, one of the Dac alleles has been shown neither to affect the amount nor the size of the dactylin transcript. In addition, no mutations in the human dactylin gene have been reported. Therefore, these Dac alleles may cause long-range disruption of the regulation of one or more other genes, leading to the pathogenesis of Dac mice. With the aim to elucidate this hypothesis, we investigated the expression levels of genes mapped to the homologous region of human SHFM3-candidate locus. However, genes in the Krd deletion were excluded from the analysis, because the Krd mouse has no limb abnormality despite a deletion encompassing 5 cM on mouse chromosome 19. Hence, the remaining region which was 1 Mb long, including 30 transcripts was analyzed. We used quantitative real-time RT-PCR to measure the expression levels of these transcripts in Dac embryos at various stages. Results were normalized to -actin and compared to their expression levels in wild type embryos. Although most transcripts were expressed normally in Dac embryos, a few transcripts exhibited lower levels of expression. We are now searching for mutations in these genes, in 32 unrelated SHFM patients. To date no mutation has been found, however, we expect that the causative gene of SHFM3 is amongst these genes.

**Expression of Fibroblast Growth Factor Receptor 3 (FGFR3) in glial cells of a TDI fetus carrying a K650M mutation.** *L. Legeai-Mallet<sup>1</sup>, P. Loget<sup>2</sup>, J. Martinovic<sup>1</sup>, S. Heuertz<sup>1</sup>, C. Benoist-Lasselin<sup>1</sup>, A. Munnich<sup>1</sup>, J. Bonaventure<sup>1</sup>, F. Encha-Razavi<sup>1</sup>.* 1) Génétique INSERM U393, Hôpital Necker, Paris, France; 2) Service d'anatomopathologie CH Le Mans, France.

Thanatophoric Dysplasia (TD) is a neonatal lethal skeletal dysplasia caused by common FGFR3 mutations in different domains of the protein. Based on radiological, histological and molecular criteria, TD has been divided into type 1 (TDI) and type 2 (TDII). While TDII is caused by a single K650E mutation in the tyrosine kinase 2 (TK2) domain of the receptor, conversion of the same lysine residue into methionine (K650M) can produce either TDI or Severe Achondroplasia with Developmental Delay and Acanthosis Nigricans (SADDAN). Here we identified a K650M FGFR3 mutation in a 24-week fetus presenting with typical TDI features. Clinical and radiological analyses revealed that the fetus had rhizomelic shortening of the limbs, curved femora, platyspondyly and narrow thorax. At the histological level the femoral growth plate had reduced size, the chondrocyte columns were totally absent and the line of ossification was distorted. In keeping with previous studies, high level of the FGFR3 protein was found in the pre-hypertrophic zone of the growth-plate. Immunostaining showed an abnormally high amount of STAT1, STAT3 and STAT5 proteins in the pre-hypertrophic cells confirming constitutive activation of the receptor. Brain examination showed macrocephaly and classical abnormalities of the temporal lobes associated with severe hydrocephalus due to third ventricle atresia. Interestingly FGFR3 expression in the brain was restricted to glial components (ependymal periventricular cells and astrocytes). Comparison with an age-matched control showed a slightly higher expression of the receptor in the ependymal cells of the TDI fetus whereas neurons of the cortical plate and deep brain nuclei were negative. Since glial cells are involved in neuronal migration, our findings raise the question of whether abnormal gyration of the temporal lobes in TDI is directly related to defective neuronal migration. This work was supported by the European Skeletal Dysplasia Network (ESDN).

Program Nr: 891 from 2003 ASHG Annual Meeting

**Molecular and Biochemical analysis of Oligophrenin, a RhoGAP, in Fibroblasts.** *A.L. Gropman, B.W. Howell.*  
Neurogenetics Branch National Institutes of Health 10 Center Drive Building 10, Bethesda MD 20892.

Recently, interest has been generated in the members of the Rho GTPases which play a role in actin cytoskeleton dynamics. These small proteins have been shown to influence cell shape, migration, adhesion, and connectivity via regulation of actin stress fiber formation and extension of lamellipodia and filopodia. Several Rho family members and their effectors have been identified and believed to play a role in mental retardation, cancer progression, and neurodegenerative disorders. The oligophrenin gene, encoding a RhoGAP, has recently been implicated in X-linked mental retardation with associated cerebellar hypoplasia and seizures. It is up-regulated in several. Oligophrenin contains a pleksin homology domain, a RhoGAP domain, and is highly conserved between human and mouse; its function remains unknown. In order to investigate the function of oligophrenin as a potential mediator of neuronal migration/cytoskeletal changes, we performed a number of in vitro experiments. Using an antibody to the C-terminus of oligophrenin, we have observed oligophrenin expression in E16 cortical neurons with a diffuse cytoplasmic distribution. Histologic examination of E15 fetal mouse brain shows diffuse immunoreactivity. In adult tissue sections, expression is high in the rostral migratory stream, entorhinal cortex, septal area, hippocampus, and dentate gyrus. In transfection experiments, we have observed that fibroblast cell lines overexpressing oligophrenin have very few stress fibers, consistent with a role for oligophrenin in the suppression of Rho GTP levels. In yeast two hybrid screens, we have identified a panel of potential interactors. In vitro association studies with one candidate, VACM-1 (Vasopressin activated calcium mobilizing receptor-1), which is homologous with a member of the cullin family of proteins implicated in the regulation of cell cycle through the ubiquitin-mediated degradation of cyclin-dependent kinase inhibitors shows a positive association in co-immunoprecipitation studies. This suggests that oligophrenin may participate in a signaling pathway involved in ubiquitin mediated degradation.

***mage*: a MAGE/NDN-like gene in zebrafish.** *J.M. Bischof*<sup>1</sup>, *M. Ekker*<sup>2</sup>, *R. Wevrick*<sup>1</sup>. 1) Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Ottawa Health Research Institute and Department of Medicine, University of Ottawa, Canada.

The human necdin/MAGE gene family has over 50 members identified, but most of the proteins encoded by these genes are of unknown function. Two gene family members on chromosome 15q11, *NDN* (necdin) and *MAGEL2*, are inactivated in the neurobehavioral gene deletion syndrome Prader Willi Syndrome. *NRAGE/MAGED1* is an X-linked member of the same gene family that is implicated in neurotrophin signaling. We have now identified a single locus in *Danio rerio* that encodes a putative protein with significant coding sequence similarity the MAGE homology domain, a 165-171 amino acid motif of shared sequence similarity among members of the mammalian NDN/MAGE gene family. Highest similarity was found to *Mageg1* and *Maged1*, and like *Maged1*, zebrafish *mage* is multi-exonic within the open reading frame. The 1072 nucleotide cDNA has a 260 amino acid open reading frame and is represented by UniGene Dr.2185, which we placed at a single map position near the top of LG23. Analysis of the complete *Fugu ribripes* genome sequence also gives evidence for the existence of only a single MAGE-like gene in teleost fish. We show that *mage* is expressed in several regions of the larval and adult brain, specifically the retina, the medial region of the telencephalon, periventricular gray zone of the optic tectum, and most highly in the cerebellar corpus. Specific down-regulation of *mage* translation in early development using a morpholino oligonucleotide had no effect on embryonic development. At present there are no induced or naturally occurring zebrafish mutations genetically mapped in proximity to the location on LG23 containing *mage*. The identification and characterization of such a mutant and further investigation of the role of these proteins in neural development and function is important to resolve issues of parallel functions of MAGE genes in vertebrate species.

**Establishment of a tetracycline inducible system for the ectopic expression of Zic2 during brain development.** *S. Brown, L.Y. Brown.* Ob/Gyn, Columbia University, New York, NY.

Heterozygous null mutations in the transcription factor gene ZIC2 have been previously shown to result in holoprosencephaly (HPE) in humans, while diminished levels of the Zic2 protein cause HPE in mice. Thus, brain development is exquisitely sensitive to the level of Zic2 protein. Despite studies in several model systems, there is currently little understanding of how Zic2 functions during brain development. We have hypothesized that mis-expression of Zic2 during development may be a good system for attempting to understand Zic2 function, and to this end, we have used transient transgenic mice to mis-express Zic2 during brain development. Zic2 mis-expression indeed results in severe brain malformations, but for this reason, it is impossible to establish a stable transgenic line and detailed studies of how Zic2 acts to cause malformation have not been possible.

To circumvent this problem, we have used the tetracycline regulated system to establish a modular, inducible system for over-expressing and mis-expressing Zic2 during development in mice. In this system, a stable line harboring a Zic2 transgene under the regulation of the tetracycline response element (TRE) can be crossed with other transgenic lines that express the reverse tetracycline transactivator protein (rtTA). Maternal administration of tetracycline then results in expression of transgenic Zic2 in compound heterozygote embryos. Thus, transgene expression can be regulated with respect to location, developmental time and level.

We have developed TRE-Zic2 mouse lines and we have performed crosses between these and several rtTA expressing lines. These studies show the feasibility of this system and have allowed us to produce embryos with tetracycline inducible brain malformations. Studies of how ectopic expression of Zic2 alters the expression of other developmental genes and leads to malformation are ongoing and promise to lead to important insights into the role of Zic2 in brain development.

**Imprinting and the brain: Maternal influences on cognitive skills.** *L. Goos, I. Silverman.* Dept of Psychology, York Univ, Toronto, ON, Canada.

This study represents one of the first attempts to investigate the influence of genomic imprinting on normal brain development and adult behaviour. Animal experimentation and clinical studies have indicated that the maternal and paternal genomes play differential roles in the development of the mammalian brain. In particular, evidence suggests that the maternal genome makes a disproportionate contribution to the development of the neocortex, with increasing influence from the occipital to the frontal lobes. Numerous psychological and psychophysical tasks have been designed and validated for cortical localization of function and dysfunction in normal and clinical populations. Appropriate tasks were utilized in an intra-familial design to determine if parental influence on cognitive task performance could be discriminated. It was expected that children's scores would become more like their mothers' scores and less like their fathers' scores as the cortical region recruited by the task changed from the occipital to the frontal lobes. 65 biological families were recruited as participants, with members ranging in age from 17-70. Where significant correlations between parent and child scores exist, the predicted trend is obtained eight times out of twelve. Mother-child correlations were higher than father-child correlations in 12 out of 16 comparisons (75%), a frequency unlikely to occur by chance (binomial expansion,  $p=0.03$ ). Stepwise, hierarchical regression showed that maternal score was the sole predictor for mean child score for frontal, parietal and temporal tasks ( $F$ 's (1,63)=20.225, 12.632, 10.156 respectively,  $p$ 's 0.01). Paternal score for these locations did not account for any further reductions in variance. Paternal score was a significant predictor of mean child score for the occipital lobe tasks ( $F(1, 63)=15.276$ ,  $p<0.000$ ), with the influence of mothers approaching significance ( $F(2, 62)=3.63$ ,  $p=0.06$ ).

**Developmental instability and isolated sagittal craniosynostosis.** *K. Aldridge<sup>1</sup>, V.B. DeLeon<sup>2</sup>, J.T. Richtsmeier<sup>1</sup>.* 1) Department of Anthropology, Pennsylvania State University, University Park, PA; 2) Center for Functional Anatomy and Evolution, Johns Hopkins University School of Medicine, Baltimore, MD.

Developmental instability is defined as noise or disruption in the normal pathway of development. Previous research has demonstrated characteristic dysmorphology in the skulls and brains of children with isolated sagittal craniosynostosis. The purpose of this study is to determine whether these dysmorphologies are associated with developmental instability, as determined by the degree of fluctuating asymmetry in the skeletal and central nervous systems. We predict that perturbations in growth associated with the synostosed suture increase levels of fluctuating asymmetry.

A sample of children with premature midline fusion of the sagittal suture was compared to an age-matched sample of morphologically normal children. Three-dimensional landmark coordinate data from the skull and brain were collected using computer reconstructions of CT and MRI data. An application of Euclidean Distance Matrix Analysis (EDMA) was used to quantify and compare the degree of fluctuating asymmetry in the two groups.

Comparisons of fluctuating asymmetry levels in the brain produced inconclusive results, with the relative degree of asymmetry varying across different regions of the brain. Contrary to our prediction, the degree of fluctuating asymmetry in the skulls of individuals with craniosynostosis is less than that of the normal control sample, indicating a more stable developmental system in craniosynostosis. The differential effects of the constrained suture on developmental instability in the skeletal and nervous systems may be related to the sequential occurrence of developmental events in these systems.

This research was supported by NIDCR grant 1 P60 DE13078 (Project VI, PI: JTR).

**Good Babies Sleeping Poorly: Insufficient Sleep in Infants with Smith-Magenis Syndrome (SMS).** *W.C. Duncan*<sup>1</sup>, *A. Gropman*<sup>2</sup>, *R. Morse*<sup>3</sup>, *D. Krasnewich*<sup>3</sup>, *A.C.M. Smith*<sup>3</sup>. 1) NIMH; 2) NINDS; 3) MGB/NHGRI, NIH, HHS, Bethesda, MD.

Sleep disturbance in Smith-Magenis syndrome (SMS) has been described in early childhood through adulthood. To our knowledge there have not been any descriptions of sleep quality in SMS infants (1 year). While maladaptive behavior accompanies the sleep disturbance in young children with SMS (Dykens & Smith, 1998), happy complacency is often reported of SMS infants. The sleep disturbance in young children with SMS is partly attributed to deficient nighttime levels, and elevated daytime levels of melatonin. While many parents do not report unusual sleep patterns in undiagnosed SMS infants, anecdotal reports have suggested the possibility of sleep disturbance in this infant SMS population.

Actigraphy, a non-invasive technique used to measure rest and activity, was used to estimate home sleep behavior in twelve children with confirmed SMS. Four age groups were studied: infants (1y, n=3), preschool (3y, n=3), early school (5y, n=3) and later school (6-8y, n=3). All children were enrolled in the IRB-approved NIH natural history study and continued on their existing drug regimen during the study. All subjects wore a wrist or ankle Actiwatch for 2-4 weeks to quantify rest/activity patterns. Data were analyzed using Actiware-Sleep software (Mini Mitter Co, Inc.). Sleep estimates were derived for 24 hours (24H), daytime (L) and nighttime (N) and compared with previously reported values. Actigraphy-estimated sleep was reduced in the infant SMS group (24H=11.05 h; L=3.00 h; N=8.05h). Consistent with prior reports, estimated 24 hour and night time sleep in the three older age groups were also reduced: preschool (24H=9.5h, N=8.5h), early school (24H=8.6h, N=7.3h) and later school (24H=7.8h, N=7.5h). These results indicate the presence of a phenotypic sleep disturbance in SMS infancy, and document a progressive decline in estimated sleep from infancy to eight years.

**Dynamic expression and localization of MeCP2 in the developing mouse brain.** *J.M. LaSalle, D. Braunschweig, T. Simcox, R.C. Samaco.* Med Micro and Immuno and Rowe Program in Human Genetics, UC Davis Sch Med, Davis, CA.

Rett syndrome (RTT) is an X-linked neurodevelopmental disorder caused by mutations in *MECP2*, encoding the methyl-CpG-binding protein 2 (MeCP2). Despite ubiquitous expression of *MECP2*, the onset of symptoms in RTT is delayed until 6-18 months and limited to the CNS. MeCP2 protein expression shows cellular heterogeneity in the CNS and elevated MeCP2 expression is acquired in individual neurons during postnatal development. *Mecp2*-null mutations targeted to postmitotic neurons exhibit a similar phenotype as germline *Mecp2* mouse mutants. These combined results suggest that *MECP2* mutations are primarily manifested in mature MeCP2<sup>hi</sup> neurons. The onset of symptoms in the mouse is delayed until 3-6 weeks in males and 4-6 months in females, developmentally later than expected from female RTT patients. To further understand the developmental ontogeny of MeCP2, we have used laser scanning cytometry to perform quantitative localization of MeCP2 in individual cells within sagittal mouse brain sections during embryonic and postnatal development. While virtually all cells (>90%) were positive for MeCP2, heterogeneity in the level of expression was observed between different brain regions, developmental stages, and cellular subpopulations, resulting in >10-fold increases from embryonic (E10) to a 40-wk adult. Increases in MeCP2 expression were not completely linear throughout development as had been predicted from humans, but instead showed dynamic changes from embryonic to 3-wk postnatal. High MeCP2 expression in the cerebral cortex from 3-6 wks corresponded with the observance of a RTT phenotype in the *Mecp2*-null males. From 7-40 wks there was a positive correlation with age in the mean MeCP2 expression due to an increase in the MeCP2<sup>hi</sup> population from 31% to 47%. The continued increase in the %MeCP2<sup>hi</sup> cerebral neurons during normal mouse adulthood may help explain the delay of symptoms in heterozygous female mice. In conclusion, these results demonstrate dynamic developmental regulation of MeCP2 and provide support to the hypothesis that *MECP2* mutations are primarily manifested in the MeCP2<sup>hi</sup> population that emerges progressively during postnatal brain development.

**A microarray screen for genes involved in brain regionalization and morphogenesis.** Z. Luo<sup>1, 2</sup>, D. Tentler<sup>1, 2</sup>, L. Kudo<sup>3</sup>, C. Sabatti<sup>4</sup>, H.I. Kornblum<sup>5</sup>, D.H. Geschwind<sup>1,2</sup>. 1) Dept. of Neurology; 2) Program in Neurogenetics; 3) Neuroscience IDP; 4) Dept. of Human Genetics; 5) Dept. of Molecular & Medical Pharmacology, UCLA School of Medicine, Los Angeles, CA.

A large number of genes responsible for human neurodevelopmental disorders are likely to be also involved in brain patterning and regionalization. For example, the sonic hedgehog gene is involved in autosomal dominant holoprosencephaly type 3 and the paired box gene-6, which is responsible for aniridia type II, are known to play a key role in establishing of brain organization and morphology. We performed a large-scale microarray study in order to identify genes expressed in medial lateral gradients during the early stages of cerebral cortical regionalization, and therefore likely to be involved in cerebral axis formation and brain patterning. Messenger RNA was extracted separately from the left, right, and medial parts of mouse E10.5 telencephalon and Representational Differences Analysis (RDA) subtraction followed by microarray screening was performed, similar to previously published methods (Geschwind et al., Neuron 2001, 29: 325-339). We identified 33 known and 6 ESTs enriched in the medial cortical anlage and 80 known and 19 ESTs enriched in the lateral region. We confirmed differential expression of some known and novel genes by whole-mount in situ hybridization and by comparison with published literature. Gene ontology analysis and pathway analysis was performed to further categorize genes. A number of genes already known to be involved in human neurodevelopmental and neurodegenerative disorders, such as ZIC-3 and the multiple exostosis type 1 gene were identified. The chromosomal location of the known and unknown genes was determined to further investigate the candidacy of these brain patterning genes for producing mental retardation or other neurodevelopmental phenotypes.

**Tissue specific FGFR3 transgenic mouse models for Thanatophoric Dysplasia Type II.** *T. Lin*<sup>1</sup>, *S.B. Sandusky*<sup>1</sup>, *H. Xue*<sup>2</sup>, *K. Fishbein*<sup>3</sup>, *R. Spencer*<sup>3</sup>, *M. Rao*<sup>2</sup>, *C.A. Francomano*<sup>1</sup>. 1) Laboratory of Genetics, NIA, NIH, Baltimore, MD; 2) Laboratory of Clinical Investigation, NIA, NIH, Baltimore, MD; 3) Laboratory of Neurosciences, NIA, NIH, Baltimore, MD.

Neonates with thanatophoric dysplasia have profound skeletal manifestations and several reported CNS alterations as a result of mutations in fibroblast growth factor 3 (FGFR3). To investigate the effect of the FGFR3 K644E mutation on central nervous system (CNS) development, we have generated tissue specific thanatophoric dysplasia type II mice (TDII) by crossing *Fgfr3*<sup>+/*neo*-K644E</sup> transgenic mice with either CNS specific (Nestin-cre) or cartilage specific (Col2a1-cre) mice. TDII/Nestin-cre (TDII-N) neonates did not demonstrate a profound skeletal phenotype compared to TDII/Col2a1-cre (TDII-C). TDII-N pups were comparable to their wild type littermates in terms of tail length, fore and hindlimbs, and body weight, however, many pups did exhibit notably round heads. MRI and histochemical analysis illustrated asymmetrical changes in cortical thickness and cerebellar abnormalities in TDII-N mice, which correlate with brain abnormalities observed in human TDII patients. Such abnormalities were not seen in TDII-C mice. Overall, these data indicate that the tissue specific mouse model is an excellent system for studying the role of FGFR3 in the developing CNS and skeleton.

**Expression analysis of the LMX1B gene supports expansion of the Nail Patella Syndrome phenotype. I.**

*McIntosh<sup>1</sup>, J.A. Dunston<sup>1</sup>, T. Reimschisel<sup>1</sup>, R.L. Johnson<sup>2</sup>, E. Sweeney<sup>3</sup>.* 1) Inst Genetics Medicine, Johns Hopkins Medical Sch, Baltimore, MD; 2) Dept. of Biochemistry & Molecular Biology, M.D. Anderson Cancer center, Houston, TX; 3) Clinical Genetics, Royal Liverpool Childrens Hospital, Alder Hey, UK.

LMX1B is a member of the LIM-homeodomain family of transcription factors. Heterozygous loss-of-function mutations in LMX1B cause Nail Patella Syndrome (NPS). NPS is a pleiotropic phenotype, classically regarded as a connective tissue disorder, in which the cardinal features include dysplasia of the nails and hypoplasia/dysplasia of the patellae and elbow joints. Nephropathy and glaucoma have also been recognized as part of the syndrome. In parallel with transgenic mouse experiments to determine the elements responsible for the regulation of LMX1B expression during development, we have undertaken an analysis of the expression of the endogenous *lmx1b* gene. A lacZ reporter gene was inserted into the 3-UTR of the murine *lmx1b* gene via site-specific recombination in ES cells. Expression of *lmx1b* was monitored at E9.5 to E15.5 by -galactosidase staining. The expression of *lmx1b* in the dorsal limb mesenchyme, kidney and anterior chamber of the eye have been reported previously, and explain the defects in these structures/organs observed in NPS patients. LMX1B is unusual amongst members of the LIM-homeodomain family in being expressed abundantly outwith the CNS. Expression within the midbrain has also been reported (1) and *Lmx1b* expression has been used as a marker for the differentiation of dorsal interneurons within the spinal cord (e.g. ref. 2). We have confirmed these observations and also noted expression in the ventral floor plate and the primordial mammary glands, vibrissae and hair follicles. The CNS expression of *lmx1b* may explain the symptoms of Attention Deficit (Hyperactivity) Disorder (ADHD), peripheral neuropathy, Reynauds phenomenon and epilepsy observed in a large cohort of NPS patients (3).

**Abnormal expression of MAP1B in *fmr1* ko neurons during early neuritogenesis.** *R.R. Lu<sup>1</sup>, W. Li<sup>2</sup>, L. Ku<sup>2</sup>, H. Wang<sup>2</sup>, Y. Feng<sup>2</sup>.* 1) Medicine, Keck School of Medicine at USC, South Pasadena, CA; 2) Pharmacology, Emory University, Atlanta, GA.

Fragile X mental retardation results from the lack of FMRP, a selective RNA binding protein implicated in regulating protein synthesis by interaction with its bound mRNAs. More than 400 FMRP associated mRNAs in the adult mouse brain have been identified recently using microarray approaches. One mRNA ligand on the microarray showed sequence homology to the microtubule-associated proteins (MAPs) 1A and 1B, raising a hypothesis that FMRP may be involved in regulating microtubule stability via controlling translation of MAP1A/B, which in turn governs normal neuritogenesis and synapse development. Consistent with this hypothesis, delayed dendritic spine maturation has been reported in fragile X patients as well as in *fmr1* knockout mice. We directly tested the above hypothesis by examining FMRP's influence on MAP1A/B in early neuritogenesis, since the most severe abnormality observed in the neonatal brain of the *fmr1* knockout mice. We found that both MAP1A and MAP1B mRNAs were associated with FMRP in young mouse brain, with much higher quantity of MAP1B than MAP1A in immunoprecipitated FMRP complexes. Immunoblot analysis further revealed elevated MAP1B protein level in the developing hippocampus and early stages of primary cultures of cortical neurons derived from the *fmr1* knockout brain without increased MAP1B mRNA expression. Finally, linear sucrose gradient analysis indicated abnormally increased translation of MAP1B in the *fmr1* knockout neurons. These results support our hypothesis that FMRP is a translation suppressor that accurately regulates MAP1B expression during the early development of brain neurons. The lack of FMRP leads to elevated MAP1B, which in turn results in misregulation of microtubule dynamics in neuritogenesis as well as synapse maturation.

**Type III lissencephaly: a spectrum of neuro-ectodermal dysplasia?** *J. Martinovic<sup>1</sup>, F. Francis<sup>2</sup>, A. Benachi<sup>3</sup>, J. Roume<sup>4</sup>, M. Gonzales<sup>4</sup>, C. Fallet<sup>5</sup>, M. Vekemans<sup>1</sup>, J. Chelly<sup>2</sup>, F. Encha-Razavi<sup>1</sup>*. 1) Unit of Embryo-Fetal Development, Hosp Necker - Enfants Malades, Paris, France; 2) INSERM U129, Institut Cochin de Genetique Moleculaire; 3) Unit of Fetal Medicine, Hopital Necker-Enfants Malades; 4) Unit of Fetal Pathology, Hopital Saint-Antoine; 5) Dept. of Neuropathology, Hopital Saint-Anne, Paris, France.

Lissencephaly is defined by the absence or rarefaction of cerebral convolutions. Two major groups, type I and II are classically described. A third type (LIS III) with distinct neuropathological pattern was first reported in Neu-Laxova syndrome (NLS), and recently in an apparently different context of Fetal Akinesia Deformation Sequence (FADS) (OMIM N601160) with thick and/or fragile skin, but no ichthyosis. The purpose of this study is to describe a comparable family with four affected and two unaffected sibs in which the phenotypically healthy parents were first cousins of Turkish origin. Four affected fetuses terminated at 24, 18, 26, and 24 weeks respectively, presented severe growth delay with microcephaly, limb contractures with pterygia, and syndactyly. All presented microcephaly/lissencephaly, delayed cerebral cortex maturation, lack of callosal and cerebrospinal tracts, neuronal depletion of the germinal zones, basal ganglia, brain stem nuclei, and spinal cord. Viscreal exam showed bilateral adrenal agenesis. Thick and fragile skin without ichthyosis was noticed in all fetuses affected. Genetic analysis using homozygosity mapping was carried out with microsatellite markers evenly distributed over the whole genome. Homozygosity was observed for several regions of the genome. Currently, we are testing new set of markers for fine mapping, and assessing non excluded regions because of the non informativity of markers in the initial panel. Our hypothesis is that LIS III might be the common denominator in the neuroectodermal dysplasia spectrum including NLS and OMIM N 601160. The identification of the gene responsible for these disorders may shed further light on the frontier between these two entities, and possibility of a lesional continuum between them.

**Multiple pathways regulate MeCP2 in normal brain development and exhibit defects in non-*MECP2* mutant Rett and autism samples.** *R.C. Samaco, R.P. Nagarajan, D. Braunschweig, J.M. LaSalle.* Med Micro & Imm, UC Davis Sch Med, Davis, CA.

Mutations in *MECP2* cause Rett syndrome (RTT) but have also been found in other neurodevelopmental disorders, suggesting an important role for MeCP2 in normal brain development. Although *MECP2* is ubiquitously transcribed, MeCP2 protein expression is complex and developmentally regulated, involving alternatively polyadenylated transcripts and heterogeneous expression in the postnatal CNS. We hypothesized that MeCP2 expression changes may be defective in RTT, autism, and potentially other neurodevelopmental disorders that do not exhibit mutations in *MECP2*. We therefore performed a high-throughput analysis of MeCP2 expression on a tissue microarray containing 28 brain samples from RTT, autism, AS, PWS, PDD, and age-matched controls. Combined analyses of MeCP2 immunofluorescence plus FISH using riboprobes for the *MECP2* coding region (CDS) and alternative long transcript (3UTR) were performed. Negative controls included nonspecific IgG and sense strands of CDS and 3UTR riboprobes, while histone H1 and actin antisense controlled for variability of human brains. Combined quantitative analyses of MeCP2 protein and RNA were performed by laser scanning cytometry and tested for significant differences from age-matched controls. Normal cerebral samples showed an increase in total MeCP2 expression and %MeCP2<sup>hi</sup> cells and a decreased ratio of 3UTR to total CDS with age. The MeCP2<sup>hi</sup> cells had significantly higher CDS and 3UTR transcription, suggesting that the developmental switch in *MECP2* transcript usage is independent from the transcriptional increase that regulates the MeCP2<sup>lo</sup> to MeCP2<sup>hi</sup> transition. Several autism samples showed significant defects in MeCP2 protein levels, apparently by different transcriptional and posttranscriptional mechanisms. In contrast, the 3 RTT samples with *MECP2* mutations showed defects in MeCP2, but not CDS or 3UTR/CDS ratio. A RTT sample without a detectable *MECP2* mutation was deficient in the %MeCP2<sup>hi</sup> cells and the 3UTR/CDS ratio within the MeCP2<sup>hi</sup> population. These results suggest that defects in multiple pathways that regulate the complex developmental expression of MeCP2 may contribute to RTT and other autism-spectrum disorders.

**Sexually dimorphic expression of an X-linked deubiquitinating protease in mouse brain.** *J. Xu, A.P. Arnold.* Dept Physiological Sci, Univ California, Los Angeles, Los Angeles, CA.

Sexual differentiation of the brain and behavior is thought to be due largely to the direct action of gonadal steroid hormones on the brain. Recent evidence, however, indicates that some sex differences in brain cannot be easily explained as the result of steroid action. We hypothesize that genes on the sex chromosomes are expressed in the brain and cause sex-specific patterns of development. The X chromosome encodes a large number of genes essential for brain development. The dosage difference between males and females in expression of X genes is not entirely equalized by X-inactivation. Some X genes escape X-inactivation and X-inactivation may be a function of age and/or tissue type, therefore females may express specific X genes more highly than males do. We measured the expression of *Usp9x*, an X gene encoding a ubiquitin specific protease which regulates proteasome-mediated protein degradation. *Usp9x* has been found to be involved in neuronal differentiation and synaptic plasticity. Using northern and western blot analysis, we found *Usp9x* mRNA and protein are expressed higher in the whole brain of adult female mice than in males. *Usp9x* mRNA is also expressed higher in XX males and XX females than in XY males and XY females (sex defined by gonadal phenotype), therefore the sex difference in *Usp9x* expression is likely related to sex chromosome complement. The expression of Y homologous *Usp9y* is low or absent in adult brain and therefore cannot balance the sex difference in *Usp9x*. With immunohistology we localized *Usp9x* protein to cerebral cortex, hippocampus and cerebellum. In hippocampus *Usp9x* is found to be higher in CA3 than in CA1 or dentate gyrus. Cerebellar Purkinje cells *Usp9x* are labeled in a patchy pattern which is parallel to that of  $\beta$ -catenin, a putative substrate for *Usp9x* deubiquitinating activity. The sex difference in *Usp9x* expression suggests that sexually dimorphic gene expression could arise as a consequence of the complement of sex chromosomes, and raises the question whether the action of ubiquitinating/de-ubiquitinating attributes to sexual differentiation of the brain. Supported by MH59268, NS43196, HD43942.

**Down syndrome cell adhesion molecule (DSCAM): fetal heart expression is myocardial and mouse models provide clues to its role in cardiac development.** *G.M. Barlow<sup>1</sup>, K. Amano<sup>2</sup>, K. Yamakawa<sup>2</sup>, G. Lyons<sup>3</sup>, J.R.*

*Korenberg<sup>1</sup>*. 1) Med Genet, Cedars-Sinai Medical Center, UCLA, Los Angeles, CA; 2) Riken Brain Science Institute, Japan; 3) Dept. of Anatomy, Univ. of Wisconsin Medical School, Madison, WI.

Down syndrome (DS) is a major cause of congenital heart disease (CHD), particularly with defects of the endocardial cushions and AVSD (atrioventricular septal defect). We previously identified DSCAM as a candidate gene for DS-CHD, and identified a chromosome 11q gene homolog, DSCAML1 as a candidate gene contributing to the AVSD associated with Jacobsen syndrome caused by deletion of 11q. To examine the expression in the developing mouse heart, we found that both DSCAMs were expressed in the myocardium of the atria and ventricles from at least E10, but were not expressed in the endocardium or epicardium. Further, both DSCAM and DSCAML1 are excluded from the endocardial cushions prior to and during their fusion, and continue to be excluded from the cushion region until at least E16. We hypothesize that DSCAMs are involved in myocardial and cushion cell differentiation, and that its myocardial overexpression leads to decreased EC cell proliferation, premature differentiation, and defective cushion formation and contributes to cushion defects in both DS and del 11q.

To investigate the effects of altered DSCAM expression on heart development, we generated a putative dominant negative transgenic mouse model expressing a truncated DSCAM cDNA controlled by a 1.8 kb human DSCAM promoter region (Barlow et al., 2003) and a knockout for DSCAM. Previous analyses of our lacZ reporter models showed that this promoter drives expression in the developing brain and limb buds, but not in the developing heart. Analysis of hearts from the putative dominant negative and K/O mice revealed that they do not develop structural heart defects. Taken together, these results suggest that the elements required to drive DSCAM expression in the fetal heart lie outside of the 1.8 kb promoter region, and unusually, that the effects of DSCAM over expression may have more serious consequences, at least for cardiac development, than the effects of its deletion.

Program Nr: 906 from 2003 ASHG Annual Meeting

**Glomulin is Predominantly Expressed in Vascular Smooth Muscle Cells in the Embryonic and Adult Mouse.**

*B.A.S. McIntyre, P. Brouillard, V. Aerts, I. Gutierrez-Roelens, M. Vikkula.* Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology & Université catholique de Louvain, Brussels, Belgium.

Mutations in the glomulin gene result in dominantly inherited vascular lesions of the skin known as glomuvenous malformations (GVMs)(MIM#138000) (Brouillard et al., Am J Hum Genet 2002). These lesions are histologically distinguished by their distended vein-like channels containing characteristic "glomus cells", which appear to be incompletely or improperly differentiated vascular smooth muscle cells. The function of glomulin is currently unknown. We studied glomulin expression during murine development (E9.5 days post coitum until adulthood) by non-radioactive in situ hybridization. Glomulin was first detected at E10.5 dpc in cardiac outflow tracts. Later, it showed strong expression in vascular smooth muscle cells as well as a limited expression in the perichondrium. At E11.5-14.5 dpc glomulin RNA was most abundant in the walls of the large vessels. At E16.5 dpc expression was also detectable in smaller arteries and veins. The high expression of glomulin in murine vasculature suggests an important role for glomulin in blood vessel development and/or maintenance, which is supported by the vascular phenotype seen in GVM patients with mutations in this gene. (vikkula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

**Primary cilia in polycystin-2 knockout mice.** *J. Horst*<sup>1</sup>, *P. Pennekamp*<sup>1</sup>, *G. Lewandowski*<sup>2</sup>, *C. Rasch*<sup>3</sup>, *R. Reichelt*<sup>3</sup>, *B. Dworniczak*<sup>1</sup>. 1) Inst Human Genetics, WWU Muenster, Muenster, Germany; 2) HistoServe, Muenster, Germany; 3) Institut fuer Medizinische Physik und Biophysik, Universitaetsklinikum Muenster, Germany.

Autosomal dominant polycystic kidney disease (ADPKD) is a genetic disorder affecting 1 in 800 individuals. It is characterized by the formation of large, fluid-filled cysts in the kidney, the liver and other organs. Two genes have been identified which are mutated in 99% of ADPKD cases: PKD1, encoding polycystin-1 and PKD2, encoding polycystin-2. It has been shown that polycystins influence signalling pathways including the Wnt, G-protein and JAK/STAT pathways and that they are involved in Ca<sup>2+</sup> signalling. Both polycystins are imbedded in the kidney primary cilia membrane and recent data suggest that primary cilia function as cell antennae relaying environmental clues as calcium signals to the cell body. Primary cilia are found on a wide variety of cells in the body. The best known are cilia on the node a cellular structure that is involved in the development of normal left-right asymmetry in vertebrates. We have generated a *Pkd2* knockout mouse. Loss of *Pkd2* cause recessive embryonic lethality. *Pkd2*<sup>-/-</sup>*LacZ*<sup>+/+</sup>-embryos develop whole body edema and cysts in the kidneys, pancreas and liver. Mutant hearts exhibit structural deformations with abnormalities in trabecularization and cardiac septation. *Pkd2* knockout mouse embryos display L-R axis defects: embryonic turning, heart looping and placement of abdominal organs are randomized and the lung shows right pulmonary isomerism. *Lefty1*, *Lefty2* and *nodal* are not expressed in the lateral plate mesoderm and *Pitx2* is absent from heart and lung primordia and bilaterally expressed. We suggest that in mouse the ion channel polycystin-2 acts upstream of the nodal cascade in L-R axis determination. We hypothesize that loss of polycystin-2 affects the function of the monocilia on ventral cells of the node which are required upstream of the nodal cascade. Currently we are analysing structure and function of these monocilia and data concerning these experiments will be presented.

**A model for genetic interaction- Severe abnormalities in double heterozygotes for Zic3 and Nodal genes.** *K.G Harutyunyan, S.M. Ware, J.W. Belmont.* Molec & Human Genetics, Baylor College Medicine, Houston, TX.

Mutations in the *Zic3* gene, a member of the opa/Gli transcription factor superfamily, causes a rare developmental disease, X-linked heterotaxy (HTX1). *Zic3* null mice demonstrate abnormal left-right patterning, neural tube defects, and congenital heart defects. *Zic3* null mice therefore recapitulate many of the defects seen in patients with X-linked heterotaxy and are thus an important model for studying the mechanistic basis of this disease. Nodal, a TGF-beta family related growth factor, is a critical component in the determination of left-right asymmetry. Examination of Nodal gene expression in *Zic3* null mice demonstrated a failure to maintain Nodal expression as well as randomized expression of Nodal at the node and left lateral plate mesoderm. To determine whether *Zic3* might genetically interact with the Nodal pathway, we have intercrossed *Zic3*<sup>+/-</sup> and *Nodal*<sup>+/-</sup> mice. *Zic3*<sup>+/-</sup>/*Nodal*<sup>+/-</sup> compound heterozygote mice are born in statistically significantly reduced numbers compared to either single heterozygote; no *Zic3*<sup>null</sup>/*Nodal*<sup>+/-</sup> mice are born, indicating embryonic lethality in these mutants. However, only 50% of *Zic3* null die in utero and approximately 30% are lost in perinatal period. Nodal haploinsufficiency in *Zic3* deficient mice may allow us to identify a new functional role of these genes. Analyses of embryos from *Zic3*<sup>+/-</sup> and *Nodal*<sup>+/-</sup> crosses did not show any discrete time point of lethality. This result suggests that embryonic losses may occur over an extended time. Embryonic defects in *Zic3*<sup>+/-</sup>/*Nodal*<sup>+/-</sup> compound heterozygotes are phenotypically similar to those found in *Zic3* null embryos and include caudal truncation, neural tube defects, failure to complete heart looping and dextrocardia. The defects in *Zic3*<sup>null</sup>/*Nodal*<sup>+/-</sup> embryos are generally more severe than those found in *Zic3* null embryos. All these data demonstrate strong evidence of genetic interaction between these two genes. To elucidate the specific stage and site of this genetic interaction, we are undertaking an investigation of the effect of *Zic3* deficiency on Nodal expression in vivo using Nodal promoter reporter transgenes.

**Expression of Optineurin (OPTN), an Adult Onset Primary Open Angle Glaucoma (POAG) Gene, During Early Stages of Mouse Eye Development.** *I. Stoilov, T. Rezaie, M. Sarfarazi.* Molecular Ophthalmic Genetics Laboratory, Surgical Research Center, Department of Surgery, University of Connecticut Health Center, Farmington, CT.

Primary open-angle glaucoma (POAG) affects 33 million individuals worldwide and is one of the leading causes of blindness. Recently, we identified OPTN as the defective gene for locus GLC1E on chromosome 10p15-p14. Optineurin interacts with Huntingtin, Ras-associated protein RAB8, and Transcription Factor IIIA and has been implicated in the Tumor Necrosis Factor- signaling pathway. After cloning the mouse Optn gene our objective was to investigate expression of this gene during early stages of mouse development by whole mount In Situ hybridization. Mouse embryos from FVB/NCrlBR strain were fixed with 4% paraformaldehyde and dehydrated through methanol series. An Optn cDNA fragment was amplified by PCR and subcloned into transcription vector pCRII-TOPO (Invitrogen). Antisense and sense RNA probes labeled with digoxigenin-UPT were generated by in vitro transcription of linearized plasmids with SP6 and T7 RNA polymerase. The digoxigenin-labeled RNA was localized using a Fab fragments from an anti-digoxigenin antibody conjugated with alkaline phosphatase. Colorimetric detection was performed with NBT/BCIP substrate solution. We studied FVB mouse embryos staged at 9.0, 9.5, 10.5 and 12.5 dpc (days post conception). A distinct Optn expression domain was observed in the developing eye of 9.5, 10.5 and 12.5 dpc embryos. The Optn expression domain was identical to areas of pigmentation observed in the developing eyes of non-albino strains (C57BL/6). Inspection of sections from cephalic region of the whole mounts revealed that during the period of 9.5-12.5 dpc, the expression of Optn is restricted to outer layers of the optic cup (future pigment layer of retina). In summary, our study indicates that: 1)-Optn expression is triggered early during the eye development; 2)-Optn expression is localized in tissues corresponding to future pigment layers of the retina and; 3)-eye is a major site of Optn expression in the developing embryo. Supported by AHAF National Glaucoma Research grant and NIH (EY-09947).

**Breakpoint mapping of a *de novo* 15p;16p translocation reveals a candidate gene for autism.** C.L. Martin<sup>1</sup>, Y. Ilkin<sup>1</sup>, C. Powell<sup>2</sup>, K. Rao<sup>2</sup>, A. Whichello<sup>3</sup>, E. Cook<sup>1,4</sup>. 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Division Genetics and Metabolism, Univ North Carolina, Chapel Hill, NC; 3) Duke University School of Nursing, Durham, NC; 4) Dept Psychiatry, Univ Chicago, Chicago, IL.

A *de novo* translocation between the short arms of chromosome 15 and 16 was identified by G-banding analysis in a female with autism, epilepsy, delayed walking with mild residual ataxia, a history of behavioral regression, fluctuating liver function tests and mild cerebellar atrophy (sample from the AGRE collection). Fluorescence *In Situ* Hybridization (FISH) analysis using a set of genomic clones spaced across the most distal 10 Mb of 16p was used to localize the translocation breakpoint between 5 and 7 Mb from the telomere. Additional targeted FISH mapping was carried out in this region and identified a cryptic deletion of approximately 160 kb at the site of the translocation breakpoint. The deletion is at the boundary of the first exon and the first intron of the 1.7 Mb ataxin-2 binding protein-1 (*A2BP1*) gene which binds to ataxin-2, implicated in Spinocerebellar Ataxia type 2 (SCA2). As a result of the translocation, exon 1 of the *A2BP1* gene is moved to 15p while the rest of the gene remains on 16p. The *A2BP1* gene encodes a 377 amino acid protein and is highly conserved in *C. elegans*, *D. melanogaster*, mouse and human. *A2BP1* has been previously characterized by another group and shown to code for an RNA-binding protein which is expressed in muscle and brain. Specifically in the brain, *A2BP1* is found in the cytoplasm of Purkinje cells and dentate neurons in a punctate pattern. In the mouse, *A2bp1* is expressed in the neurons of the cerebral cortex, cerebellum, hippocampus and brain stem. This expression pattern is similar to the pathological pattern observed in brain tissue of autism patients. Therefore, it is likely that the rearrangement involving *A2BP1* in this child is responsible for her phenotype. In addition, given the function and expression pattern of *A2BP1*, it could be a candidate gene for other cases of autism.

Program Nr: 911 from 2003 ASHG Annual Meeting

**Tissue and developmental specificity of chromosomal homolog positioning in the interphase nucleus.** *S.R. Rittling, M. Mamcarz, J.A. Tischfield.* Genetics, Rutgers University, Piscataway, NJ.

Chromosomes occupy distinct, non-overlapping territories in the interphase nucleus. Studies on mitotic recombination between homologous regions on the two chromosomes 8 in mouse tissues reveal that the frequency of mitotic recombination is tissue specific. Since recombination in this model requires physical interaction between the two chromosomes, we reasoned that differences in the interhomolog spacing in different tissues could partially account for the differences in the frequency of mitotic recombination. Chromosome 8 territories were labeled using chromosome paints in interphase nuclei in freshly explanted cells from spleen, ear and kidney as well as in cultured ES cells. The closest physical distance between the two territories was measured in three-dimensions, as well as the distance of each territory from the nuclear periphery. Initial results indicate that while the closest spacing of the two territories does not correlate with mitotic recombination frequency, there is tissue specificity in the arrangement of chromosome territories in the different tissues.

**Identification of KIAA1034 as the cleft palate gene on 2q32-q33.** *D.R. FitzPatrick<sup>1</sup>, J. Leek<sup>2</sup>, L. McLaren<sup>1</sup>, I. Carr<sup>2</sup>, N. McGill<sup>1</sup>, J. Fantes<sup>1</sup>, A. Markham<sup>2</sup>, P. Wightman<sup>1</sup>, K. Williamson<sup>1</sup>, P. Gautier<sup>1</sup>, D.T. Bonthron<sup>2</sup>.* 1) MRC Human Genetics Unit, Edinburgh, United Kingdom; 2) Molecular Medicine Unit, Leeds, United Kingdom.

Cytogenetic evidence, in the form of deletions and balanced translocations, points to the existence of a locus on 2q32-q33, for which haploinsufficiency results in isolated cleft palate (CPO). Here we show by high resolution FISH mapping of two de novo CPO-associated translocations involving 2q32-q33 that one breakpoint interrupts the transcription unit of the gene encoding the DNA-binding protein KIAA1034. The breakpoint in the other translocation is located 130 kb 3 prime to the KIAA1034 polyadenylation signal, within a conserved region of non-coding DNA. The KIAA1034 gene is transcribed in a telomeric to centromeric direction and lies in a gene-poor region of 2q32-q33; the nearest confirmed gene is 1.26 Mb centromeric to the KIAA1034 polyadenylation signal. KIAA1034-encoding transcripts are assembled from 11 exons that span 191 kb of genomic DNA. They encode a protein of 733 amino-acids that has two CUT domains and a homeodomain and shows a remarkable degree of evolutionary conservation, with only 3 amino acid substitutions between mouse and human. This protein belongs to the same family as SATB1, a nuclear matrix-attachment region binding protein implicated in transcriptional control and control of chromatin remodelling. There are also sequence similarities to the *Drosophila* protein DVE. Whole mount in situ hybridisation to mouse embryos shows site- and stage-specific expression of KIAA1034 in the developing palate. Despite the strong evidence supporting an important role for KIAA1034 in palate development, mutation analysis of 70 unrelated patients with CPO did not reveal any coding region variants.

**Developmental origin of cultured chorionic villi: implications for cytogenetics.** *P.J. Yong<sup>1</sup>, D.E. McFadden<sup>2</sup>, C.D. MacCalman<sup>3</sup>, W.P. Robinson<sup>4</sup>.* 1) MD/PhD program; 2) Departments of Pathology; 3) Obstetrics; 4) Medical Genetics, UBC, Vancouver, Canada.

Cytogenetic analysis of the placenta can be indicated for both pregnancy management (via CVS) and investigation of pregnancy loss. Placental karyotyping is performed on cell cultures of chorionic villi, which are composed of an inner mesenchyme and an outer epithelium (trophoblast) derived from the inner cell mass (ICM) and trophoblast of the early embryo, respectively. Cells from these cultures are generally thought to be from the ICM-derived mesenchyme. However, previous studies using the epithelial marker cytokeratin-18 (CK18) have shown some CK18-positive cells in such cultures. Recently, a tissue histological study showed some CK18 expression in the mesenchyme, but identified a second epithelial marker, cytokeratin-7 (CK7), that was expressed only in the trophoblast.

We have assessed CK7 and CK18 protein expression in cultures of chorionic villi from CVS (n = 6) and from miscarriages (n = 5) using standard immunocytochemistry. Cultures showed few or no CK7-positive cells (0.4%0.7% [s.d.]) but variable proportions of CK18-positive cells (19%17%) (p=0.0025). There were no significant differences in the proportion of CK7- or CK18-positive cells based on karyotype or ascertainment (CVS vs miscarriage). Interestingly, a culture with maternal contamination (shown by PCR), which was excluded from the analysis, showed a high level (27%) of CK7-positive cells.

Hence, the vast majority of cells from chorionic villi cultures were true mesenchymal cells expressing neither the CK7 nor CK18 epithelial markers, while CK7 expressing cells (trophoblast) were very rare. This confirms that karyotypes from such cultures are representative of the ICM. The subpopulation expressing CK18 but not CK7 is presumably also ICM-derived, but may be a group of epithelial-like cells with a unique developmental history. They may be significant when only a few cells are karyotyped or when mosaicism is evident. Furthermore, CK7 expression may serve as a marker of maternal contamination likely originating from endometrial gland epithelium.

**Allelic variations at the haploid TBX1 locus do not influence the cardiac phenotype of 22q11 microdeletion.** *N. Philip<sup>1</sup>, L. Girardot<sup>1</sup>, B. Giusiano<sup>2</sup>, N. Levy<sup>1</sup>, M.A. Voelckel<sup>1</sup>.* 1) Dept de Genetique Medicale, Hosp d'Enfants de la Timone, Marseille Cedex 5, France; 2) Service d'information Mdicale, Hospd'Enfants de la Timone, Marseille.

Microdeletion at the 22q11 locus is characterised by a high clinical variability. Congenital heart defects are the most life-threatening manifestations of the syndrome and affect approximately 50% of patients. The causes of this phenotype variability remain unknown although several hypothesis may be raised, including a potential role modifier genes, a specific genetic background, environmental factors and epigenetic modifications. It has been suggested that allelic variations at the haploid locus could modify the phenotypic expression. Regarding this hypothesis, TBX1 was thought to be a major candidate to the cardiac phenotype or its severity in patients carrying the 22q11 microdeletion. To further explore this hypothesis a mutational screening was performed in TBX1 coding exons and flanking intronic sequences, in a series of 39 patients with a 22q11 microdeletion, proved by FISH analysis. Two groups were delineated, according to the cardiac status. 23 had a congenital heart defect (5 interrupted aortic arch; 4 truncus arteriosus; 7 TOF, 7 VSD). 16 had a normal cardiac examination. TBX1 Gene analysis was performed by PCR-SSCP method followed by sequencing analysis of the PCR product. Our results did not show any significant mutation in the TBX1 gene, in our population of deleted patients. We identified 5 different nucleotide substitutions in 17 patients in the haploid TBX1 gene : 8 patients carried a single substitution, 8 patients carried 2 different changes on the non deleted chromosome and a single patient had 3. There were no differences in the distribution of these polymorphisms between the two groups of patients. Four of the sequence variations identified corresponded to polymorphisms previously reported by Gong et al (2002). Moreover, we carefully screened these nucleotides substitutions for putative donor splice sites and did not found any. These results are against a major role of TBX1 polymorphisms at the haploid locus, in the pathogenesis of cardiac defects in 22q11 microdeletion.

**Mutational analysis of the *TP63* gene in Mexican patients with syndromic and isolated ectrodactyly.** *G. Pozo-Molina*<sup>1</sup>, *V. Berdon-Zapata*<sup>1</sup>, *M. Granillo-Alvarez*<sup>1</sup>, *M. Valdes-Flores*<sup>2</sup>, *J.E. Garcia-Ortiz*<sup>3</sup>, *S. Canun*<sup>4</sup>, *N. Perez*<sup>4</sup>, *S. Kofman-Alfaro*<sup>1</sup>, *J.C. Zenteno*<sup>1</sup>. 1) Department of Genetics, General Hospital of Mexico-Faculty of Medicine UNAM, Mexico City, Mexico; 2) Department of Genetics, Centro Nacional de Rehabilitacion, Mexico City, Mexico; 3) Department of Molecular Immunobiology, CIB, UadeC, Torreon, Mexico; 4) Department of Genetics, Hospital "Manuel Gea Gonzalez", Mexico City, Mexico.

Ectrodactyly is a congenital limb malformation that involves a central reduction defect of the hands and/or feet which is frequently associated with other phenotypic abnormalities. The condition is genetically heterogeneous and recently it has been demonstrated that mutations in the *TP63* gene, a homologue of the archetypal tumor suppressor gene *TP53*, are the cause of four autosomal dominant syndromes which feature ectrodactyly: EEC (ectrodactyly, ectodermal dysplasia, and facial clefting), isolated SHFM (split-hand/split-foot malformation), LMS (limb-mammary syndrome), and ADULT (acro-dermato-ungual-lacrimal-tooth syndrome). In this study we report the results of genetic analysis of the *TP63* gene in 17 Mexican individuals with syndromic and isolated ectrodactyly. Four patients with syndromic ectrodactyly had *TP63* heterozygous point mutations: in a patient with EEC syndrome, we found a CGC to CAC mutation in exon 7 which predicted an arginine to histidine change at position 279 of TP63 (R279H), located in the DNA binding domain of the protein; in other two patients (a mother with an EE phenotype and her daughter with EEC syndrome), a change from CGG to TGG at codon 204 in exon 5 predicted a shift from arginine to tryptophan (R204W), also in the DNA binding domain; a third mutation was identified in another patient with an EE phenotype and was identical to that described in the first subject (R279H). Finally, a missense mutation located at exon 3 was found in a subject with isolated ectrodactyly; this mutation predicts a R97C shift in the transactivation (TA) domain of TP63 and is the first naturally occurring mutation described in the TA domain. We discuss on the phenotype-genotype correlation observed in this and previous studies.

**The human hairless protein interacts with the 20S proteasome.** A. Hillmer<sup>1</sup>, U. Heyn<sup>1</sup>, G.M. Beaudoin<sup>2</sup>, R.C. Betz<sup>3</sup>, C.C. Thompson<sup>2</sup>, S. Cichon<sup>3</sup>, M.M. Noethen<sup>3</sup>. 1) Inst. of Human Genetics, Univ. of Bonn, Bonn, Germany; 2) Dept. of Neuroscience, Johns Hopkins Univ. School of Medicine/Kennedy Krieger Institute, Baltimore, MD, USA; 3) Dept. of Medical Genetics, Univ. of Antwerp, Antwerp, Belgium.

Mutations in the human hairless gene are responsible for complete, congenital absence of hair in families with autosomal recessive universal congenital alopecia (MIM #203655) and autosomal recessive papular atrichia (MIM #209500). These findings clearly show that the hairless protein (HR) is essential and specific for the maintenance of human hair. Little is known about the functional and structural properties of HR. The rat hairless protein (Hr) functions as a transcriptional corepressor for thyroid hormone receptors. To shed light on the function of HR, we identified HR-interacting proteins using yeast two-hybrid screens of a keratinocyte cDNA library. We identified the 20S proteasome subunit -7 (Pro-7) as a potential interaction partner of HR. The existence of this interaction *in vivo* was confirmed by co-immunoprecipitation of HR and Pro-7 expressed in COS-1 extracts, and GST pulldown experiments indicate that the interaction is direct. The domain of Hr which is responsible for the interaction with Pro-7 has been mapped in yeast two-hybrid and co-immunoprecipitation assays, indicating that amino acids 180-200 of Hr (corresponding to aa 154-174 of the human protein HR) are responsible for the interaction. To establish the functional significance of HR:Pro-7 interaction, we determined whether Hr is degraded by the proteasome. To reduce protein degradation by the proteasome, Hr expressing COS-1 cells were treated with a proteasome inhibitor. We found that increasing time of incubation with the proteasome inhibitor results in an increase of Hr, indicating that Hr is more stable when proteasome activity is decreased, suggesting that Hr is normally degraded by the proteasome. Although the biological relevance of this Hr degradation is unclear, it is possible that cyclic degradation of Hr is required for maintaining the cyclic transformations of the hair follicle. Future studies are needed to clarify this issue.

**Analysis of gene expression patterns in myogenic cells from healthy subjects and Duchenne Muscular Dystrophy patients.** *J.T. den Dunnen<sup>1</sup>, E. Sterrenburg<sup>1</sup>, R. Turk<sup>1</sup>, J.M. Boer<sup>1</sup>, F. Baas<sup>2</sup>, J.C.T. van Deutekom<sup>1</sup>, G.J.B. van Ommen<sup>1</sup>, P.A.C. 't Hoen<sup>1</sup>.* 1) Human and Clinical Genetics, Leiden University Medical Center, Leiden, Nederland; 2) Department of Neurology, Academic Medical Center, Amsterdam, Nederland.

To study myogenesis in general and disturbances in this process caused by defects in the genes involved in neuromuscular disorders, we are determining genome-wide gene expression levels using array technology. Cultured human satellite cells of healthy controls and patients are induced to form myofibers through serum depletion. RNA is isolated at different time-points after induction. Gene expression levels are measured using a 5,000-feature muscle-expressed and a 20,000-feature general micro-array. In cells from healthy individuals, as expected, serum depletion downregulates genes involved in proliferation and DNA replication, while genes related to energy metabolism and cell cycle arrest are upregulated. Genes involved in muscle development show a gradual upregulation, with a distinct set of genes showing highest expression around the time the cells start to fuse. Clusters of potentially co-regulated transcripts that, over time, behave in the same way contain EST sequences encoding unknown functions, their clustering providing clear hints towards their potential role. To verify whether processes known to be disturbed in neuromuscular disorders could be visualised, we zoomed in on the expression of genes that encode parts of the Dystrophin-associated Glycoprotein Complex (DGC). Our results show a downregulation of several of these genes in cells from Duchenne muscular dystrophy (DMD) patients. Current analysis focuses on the identification of other disturbances and whether these can be used for diagnostic purposes. In addition we are analysing gene expression profiles of non-myogenic cells, with or without myoD-induced forced myogenesis, to determine whether these can be used to study the same processes.

**Folic acid suppression of nicotine-induced teratogenesis in zebrafish embryos .** *S. Beiraghi, M.A. Pickart, E. Beckman, D. Shiroma, S.C. Ekker.* The Arnold and Mabel Beckman Center for Transposon Research, University of Minnesota, Minneapolis, MN.

Children of mothers that smoke have an increased risk for developmental abnormalities such as low birth weight as well as specific craniofacial anomalies including cleft lip and palate (Romotti et al 1998). Previous reports describe the teratogenic potential of nicotine in developing mouse embryos. We have extended this observation to zebrafish embryos. Independent animal studies and human epidemiologic intervention trials have demonstrated the capacity of folic acid to decrease the incidence of neural tube defects and orofacial clefts. **Objective:** The objective of this work was to identify the minimal concentration of nicotine necessary to alter the morphology of developing zebrafish embryos and to characterize the phenotypes observed. Subsequent studies examined the hypothesis that folic acid can suppress the teratogenic effects of nicotine. **Methods:** Within 1.5 hours post-fertilization, zebrafish embryos were bathed in 1.25 mM or 1.5 mM L-nicotine in the absence or presence of folic acid (concentrations between 0.05 mM and 1.0 mM) for 24 hours. Control (untreated) embryos were bathed in egg water. After 24 hours of treatment, embryos were transferred to new dishes and bathed in egg water. Embryo morphology was assessed at 48 hours and 5 days. **Results:** Embryos exposed to 1.25 mM and 1.5 mM nicotine displayed a spectrum of developmental malformations in more than half of the 48 hour and 5 day old fish. Treatment of folic acid with nicotine displayed a dose dependent suppression of the teratogenic effects of nicotine, however, only 1.0 mM folic acid was effective at suppressing the effects of both 1.25 and 1.5 mM nicotine. **Conclusion:** Our preliminary data supports the view that nicotine is a potent teratogen, particularly affecting early vertebrate embryogenesis. Furthermore, it suggests that folic acid may be an effective agent to counteract the negative effects of nicotine during vertebrate.

**Dax1/Nr0b1 and network partners are expressed in embryonic development prior to previously established function in steroidogenic axis ontogenesis.** *R. Clipsham*<sup>1</sup>, *K. Niakan*<sup>2</sup>, *E.R.B. McCabe*<sup>1,2,3</sup>. 1) Molecular Biology Institute at UCLA, LA, CA; 2) Dept of Human Genetics, David Geffen Sch of Med at UCLA, LA, CA; 3) Dept of Pediatrics, David Geffen Sch of Med at UCLA and Mattel Children's Hosp, LA, CA.

Mutations in *NROB1*, the gene encoding DAX1, are responsible for X-linked adrenal hypoplasia congenita and hypogonadotropic hypogonadism. Duplication of the *NROB1* region results in 46,XY sex-reversal. Targeted deletion of *Nr0b1* is thought to be embryonic lethal and transgenic over-expression on a *Mus domesticus poschiavinus* (weak Sry) background results in XY sex-reversal. We hypothesized that DAX1/Dax1 functions in embryogenesis prior to steroidogenic axis ontogenesis. The purpose of this investigation was to determine expression of *Nr0b1* and its network partners in both cultured embryonic stem (ES) cells and preimplantation embryos. We analyzed expression of *Nr0b1* and its key associated network partners, steroidogenic factor 1 (*Nr5a1/Sf1*) and Wilms tumor 1 (*Wt1*), in cultured ES cells in the totipotent and differentiated states by northern blot hybridization and RT-PCR, as well as *in vivo* by immunohistochemistry (IHC) of preimplantation embryos. *Nr0b1*, *Sf1* and *Wt1* were highly expressed in totipotent ES cells, with reduced expression following induction toward individual germ layer fates. Expression of Dax1 and network partners was observed by whole-mount IHC analysis of preimplantation embryos flushed from the uterus at 4.5 days post coitum. These findings are consistent with the existence of a potentially functional network of transcription factors, including Dax1, very early in embryonic development. These results validate ES cells as a developmentally dynamic model for investigations into potential roles for this regulatory network early in embryogenesis preceding organogenesis. We speculate that DAX1/Dax1 and other members of this transcriptional network have novel and possibly pleiotropic functions in early embryonic development.

**Analysis of hypothalamic-pituitary-adrenal axis development in zebrafish.** Y. Zhao<sup>1</sup>, N. Liu<sup>2</sup>, J.K. Phelan<sup>3</sup>, Z. Yang<sup>4</sup>, S. Lin<sup>4</sup>, E.R.B. McCabe<sup>1,3,5</sup>. 1) Dept Hum Gen, David Geffen Sch Med at UCLA, LA, CA; 2) Dept Med, Cedars-Sinai Res Inst, LA, CA; 3) Dept Peds, David Geffen Sch Med at UCLA, LA, CA; 4) Dept Molec, Cell and Dev Bio, UCLA, LA, CA; 5) Mattel Children's Hospital at UCLA, LA, CA.

Molecular development of the hypothalamic-pituitary-adrenal axis (HPA) is only partially understood. The zebrafish is model for vertebrate development. Proopiomelanocortin (*pomc*), a pituitary prohormone, and *ff1b* (*nr5a4*), a homologue of the steroidogenic factor-1 (*SF1*, *NR5A1*), are essential for HPA development. Our purpose was to compare expression patterns of *ff1b* and *pomc* in zebrafish early development. *In situ* hybridization was performed on embryos at ten developmental stages with *ff1b* riboprobes. Expression of *ff1b* was first detected in two narrow strips of cells extending from rostral basal forebrain midline at 18-somites. Two separate groups of *ff1b* expressing cells were first observed in the mid-abdominal region at 22 hours post fertilization (hpf), and the two sites of expression coalesced by 28 hpf. To compare temporal and spatial expression patterns of *ff1b* and *pomc*, two-color *in situ* hybridization was performed at 24 and 36 hpf embryos with riboprobes labeled with fluorescein (*ff1b*) and digoxigenin (*pomc*). In rostral basal forebrain, *pomc* expression was caudal to *ff1b* within the same area, but without significant overlap, and the second *ff1b* expression domain was confirmed in the mid-abdominal region. Based on *ff1b* and *pomc* expression in fish, and extrapolating from their known expression patterns in mammals, these transcripts represent markers for HPA during development: *ff1b* for hypothalamus and adrenal cortex, and *pomc* for pituitary. To evaluate known candidate genes, and to identify additional genes involved in HPA development using forward genetic screens, we are in the process of generating transgenic zebrafish that express fluorescent protein markers under control of *ff1b* and *pomc* promoters. One line of fish (*ff1b-1*) expresses green fluorescent protein (GFP) in adrenal cortex, but interestingly not hypothalamus. Identification of genes involved in HPA development in zebrafish will inform our understanding of pathogenesis of developmental disorders involving human HPA.

**Regulation of progenitor cell fusion by ABCB5 P-glycoprotein, a novel human ATP-binding cassette transporter.**

*N.Y. Frank*<sup>1</sup>, *S. Pendse*<sup>2,3</sup>, *P.H. Lapchak*<sup>3</sup>, *D. Shlain*<sup>3</sup>, *C. Doeing*<sup>3</sup>, *M.H. Sayegh*<sup>2,3</sup>, *M.H. Frank*<sup>2,3</sup>. 1) Partners Center for Human Genetics, Harvard Medical School, Boston, MA; 2) Laboratory of Immunogenetics and Transplantation, Dept. of Medicine, Brigham & Women's Hospital, Boston, MA; 3) Division of Nephrology, Children's Hospital, Boston, MA.

Cell fusion involving progenitor cells is a newly recognized phenomenon thought to contribute to tissue differentiation and repair. The molecular mechanisms governing cell fusion are unknown. P-glycoprotein (P-gp) and related ATP-binding cassette (ABC) transporters are expressed by progenitor cells, but their physiological role in these cell types has not been defined. Here, we have cloned and characterized a novel, third member of the human P-gp family encoded on chromosome 7p21-15.3, designated ABCB5 P-gp, which marks CD133-expressing progenitor cells among human epidermal melanocytes and determines the capacity of this cell subset to undergo cell fusion. Vector-mediated ABCB5 gene transfection and expression in MCF-7 breast carcinoma cells, which at baseline do not express the molecule as determined by the polymerase chain reaction and flow cytometry, demonstrated that ABCB5 P-gp mediates rhodamine-123 transport, a hallmark P-gp function. Intriguingly, magnetic microbead-purified ABCB5 P-gp-positive cells contained from one to four nuclei by fluorescent microscopy and 2n, 4n, 6n or 8n amounts of DNA as determined by propidium iodide staining and flow cytometry. DiI/DiO membrane dye labeling studies revealed that polyploid ABCB5-positive cells are generated by cell fusion and that specific anti-ABCB5 P-gp monoclonal antibody (mAb)-mediated blockade, but not isotype control Ab or anti-ABCB1 (MDR1) mAb treatment, significantly enhanced this process (p0.05). Remarkably, multinucleated cell hybrids gave rise to mononucleated progeny during continued culture, demonstrating that fusion contributed to culture growth and differentiation. Thus, our results define a novel molecular mechanism for cell fusion involving progenitor cells and show that fusion and resultant growth and differentiation are not merely spontaneous events, but phenomena specifically regulated by ABCB5 P-gp function.

**EDA-A1 transgene-induced guard hair formation and sebaceous gland hyperplasia.** C. Cui<sup>1</sup>, T. Hashimoto<sup>1</sup>, M. Durmowicz<sup>1</sup>, C. Ottolenghi<sup>1</sup>, B. Griggs<sup>2</sup>, A.K. Srivastava<sup>2</sup>, D. Schlessinger<sup>1</sup>. 1) Laboratory Genetics, NIA/NIH, Baltimore, MD; 2) J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC.

Mutations in the X-linked EDA gene cause Anhidrotic Ectodermal Dysplasia (EDA), with lesions in skin appendage formation; and mutations in the equivalent mouse gene, Ta, give a similar Tabby phenotype. EDA splice isoforms EDA-A1 and EDA-A2 belong to the TNF ligand family and function by activating NF- $\kappa$ B- and JNK- based transcription, consistent with microarray analyses (HMG 2001). To analyze their action further, we expressed the isoforms conditionally as tetracycline-regulated transgenes in Tabby and wild-type mice. High levels of expression of an mEDA-A1 transgene during embryogenesis had both determinative and trophic effects. The determination of sweat glands and one type of hair follicle (guard hair) was fully restored, in agreement with reported comparable effects of free circulating chimeric mEDA-A1 ligand (Nat Med 2003). In contrast, zigzag hair formation was not restored in Tabby mice and was sharply inhibited in wild-type mice. As a major trophic effect, mEDA-A1 has now been found to provoke hyperplasia of sebaceous glands in Tabby mice, with correspondingly higher levels of sebum formation. The trophic effect, like the initiating effects, required the presence of the isoform during embryonic life; but in contrast to the determinative effects, it was reversed when the gene was repressed in adult animals. In addition, none of the effects seen with EDA-A1 were given by comparable expression of the mEDA-A2 isoform. The results thus reveal trophic as well as initiating action of the EDA gene, and suggest a possible balance of isoform interactions in skin appendage formation and maintenance.

**Split Hand Foot Malformation is associated with a reduced level of Dactylin gene expression.** *D. Basel*<sup>1</sup>, *A. DePaepe*<sup>2</sup>, *M.W. Kilpatrick*<sup>1</sup>, *P. Tsipouras*<sup>1</sup>. 1) Dept Pediatrics, UConn Health Ctr, Farmington, CT; 2) University of Gent, Belgium.

Split Hand Foot Malformation (SHFM) is a developmental defect of the distal extremity presenting with median clefting of the hands and feet, syndactyly, and occasionally polydactyly. If severe, all four extremities are involved but usually only the hands are affected. SHFM is genetically heterogeneous and at least four different loci have been identified: SHFM1 (7q21.2-22.1), SHFM2 (Xq26), SHFM3 (10q24-25), and SHFM4 (3q27). SHFM3 has been localized to the 10q24 region but comprehensive mutation screening of several candidate genes within the critical region failed to identify any causative coding sequence alterations. Dactylaplasia (Dac), a semi-dominant trait in the mouse, which phenotypically resembles SHFM, has been described in a region syntenic to 10q24. This phenotype is associated with reduced levels of dactylin, an F-box/WD40 repeat containing protein which acts as an adaptor for proteins destined for ubiquitination. Transcript levels were determined for Dactylin and seven genes in its proximity. A significant difference between the expression profiles of five affected individuals and control samples was detected for two gene transcripts, Dactylin ( $p=0.0001$ ) and LBX1 ( $p=0.0002$ ). However, no significant difference was detected for these transcripts in the remaining six samples from affected individuals, Dactylin ( $p=0.442$ ) and LBX1 ( $p=0.340$ ). For six transcripts TLX1, BTRC, FGF8, NFKB2, CHUK and SUFU, no significant difference was observed between affected and control samples ( $p=0.473$ ,  $p=0.284$ ,  $p=0.437$ ,  $p=0.126$ ,  $p=0.157$  and  $p=0.152$  respectively). However, the transcript levels for both BTRC and FGF8 were low. The two-fold decrease detected in the level of Dactylin gene transcript from five unrelated individuals affected with SHFM as compared to unaffected controls supports a central role for dactylin in the pathogenesis of the disease and the possibility of a common pathogenesis for SHFM3 and Dac. Reduced levels of dactylin expression could result in insufficient removal of a postulated suppressor of cell proliferation leading to a failure of proliferative function in the Apical Ectodermal Ridge.

**Gene Expression Profiling of Human Pharyngeal Arches.** *J. Cai*<sup>1</sup>, *D. Ash*<sup>1</sup>, *L. Kotch*<sup>1</sup>, *E.W. Jabs*<sup>1</sup>, *T. Attié-Bitach*<sup>2</sup>, *J. Augé*<sup>2</sup>, *S. Audollent*<sup>2</sup>, *M. Vekemans*<sup>2</sup>, *Y. Korshunova*<sup>3</sup>, *R. Tidwell*<sup>3</sup>, *R. Veile*<sup>3</sup>, *D. Messina*<sup>3</sup>, *C. Helms*<sup>3</sup>, *M. Lovett*<sup>3</sup>. 1) Johns Hopkins Univ, Balto, MD; 2) Hospital Necker Enfants Malades, Paris, France; 3) Washington Univ, St Louis, MO.

The COGENE consortium is profiling gene expression to study craniofacial development. Twelve microSAGE libraries, averaging 50,000 tags per library, were constructed from microdissected structures of 4 to 8.5 wks of human development, including pharyngeal arch 1 (PA1) that forms the majority of the upper and lower jaw. Ninety-six of the 130 genes known to be expressed in mouse PA1 were identified, validating this SAGE dataset. Pairwise comparison between SAGE libraries revealed that 173 tags, corresponding to unique mRNAs, were upregulated, and 129 tags were downregulated ( $p < 0.05$ ) from 4 to 5 wks PA1, many of which are involved in transcriptional regulation. By comparing these SAGE libraries, genes that are expressed higher in pharyngeal arches than in any other structures (e.g. PA3 and 4, frontonasal prominence, anterior and posterior rhombomeres) were found. Many of these genes were previously unknown to be expressed in PA1. Whole mount *in situ* hybridization was performed on mouse embryos at corresponding stages to confirm the expression pattern observed in humans. For example, the *Cct3* gene, a molecular chaperone, was expressed highly in PA1. The *Set* gene, which plays a role in cell proliferation, was highly expressed both in PA1 precursor cells at GD8.5 and in PA1 at GD9.5, while the expression was more restricted to the maxillary portion of PA1 at GD10.5, making it a candidate gene for cleft lip/palate. Many of the expression changes were confirmed by Affymetrix microarrays and real-time RT-PCR. These data show conservation of expression patterns in human and mouse PA1 development. Many genes expressed in PA1 were also expressed in limb buds. Since craniofacial disorders are often associated with limb abnormalities, these findings suggest that similar signaling molecules are involved in both pharyngeal arch and limb development. This dataset should provide useful information in identifying pathways and genes that contribute to common pharyngeal arch defects including cleft lip and palate.

**Downstream effector candidates of HOX proteins in mammals.** *J.W. Innis*<sup>1, 2</sup>, *T.M. Williams*<sup>1</sup>, *R. Kuick*<sup>2</sup>, *D. Misek*<sup>2</sup>, *M.E. Williams*<sup>1</sup>, *L. Privette*<sup>1</sup>, *K. McDonagh*<sup>3</sup>, *S. Hanash*<sup>2</sup>. 1) Department of Human Genetics, University of Michigan; 2) Department of Pediatrics; 3) Department of Internal Medicine.

*Hox* genes encode transcription factors that regulate the morphogenesis of developing embryos. Knowledge of the genes and cis-acting sequences through which these highly conserved proteins regulate development is limited. Cell adhesion molecules and their receptors are known effectors of *Hox* expression, yet few other genes regulated by HOX proteins have been identified in mammals despite the broad developmental effects HOX proteins exert on cells. To identify genes whose expression is regulated by posterior HOX proteins, we expressed HOXA13 in a mouse mesenchymal cell line (NIH3T3-GP+E86) that lacks expression of any group 13 paralogue using a bicistronic HOXA13/EGFP retroviral vector. We applied EGFP-based fluorescence activated cell sorting to cells stably expressing HOXA13 and EGFP or EGFP alone and prepared RNA from the enriched populations. Utilizing Affymetrix Mouse Gene Arrays, we identified 50 genes that exhibited significantly ( $p < .01$ ) increased or decreased expression of at least two-fold in HOXA13-expressing cells. Among these, genes involved in BMP signaling, extracellular matrix and membrane metabolism, and numerous cell-surface molecules predominated. One zinc-finger transcription factor was upregulated 30-fold. Differences were confirmed for 10/11 selected candidates by semi-quantitative RT-PCR with independent RNA preparations, and RNA expression was demonstrated in the developing limb bud and mature cervix/vagina, two regions of known *Hoxa13* expression, for all 11 candidates. Additional whole mount *in situ* hybridization with *Hoxa13* mutants is being used to test whether *in vivo* expression of these candidate genes is altered in the mutant background. This work identifies specific genes involved in BMP signaling, extracellular matrix molecules and membrane/cell surface metabolism as strong candidates for regulation by posterior HOX proteins in morphogenesis.

**TGIF, a gene associated with holoprosencephaly, regulates neuronal gene expression.** *J.E. Ming<sup>1</sup>, A.C. James<sup>1</sup>, J.A. Golden<sup>2</sup>, J.L. Knepper<sup>1</sup>.* 1) Division of Human Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia and the University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Department of Pathology, The Children's Hospital of Philadelphia, Philadelphia, PA.

Holoprosencephaly (HPE) is a developmental disorder of the forebrain resulting in incomplete separation of the cerebral hemispheres into distinct right and left halves. Mutations in *TGIF*, which encodes TG-interacting factor, have been detected in patients with HPE. TGIF is an atypical homeodomain protein. In vitro studies have demonstrated that TGIF acts as a transcriptional co-repressor in TGF-beta signaling. TGIF can also bind to a retinoid X receptor response element and compete for binding with RXR. However, the role that TGIF plays in central nervous system development and its relationship to the pathogenesis of HPE are unknown. As an initial step in assessing its function, we determined its expression pattern during nervous system development. We find that TGIF is expressed in discrete domains in the forebrain and spinal cord, with highest levels of expression in dorsal regions. Using electroporation in the chick embryo model, we ectopically expressed TGIF in the neural tube. This caused a decrease in the expression of the dorsally expressed transcription factors Pax6, Cath1, and Lhx2b. In contrast, the expression of other transcription factors, including those necessary for ventral fate such as Nkx2.2, were not affected. Thus, TGIF specifically represses the expression of genes expressed in specific dorsal-ventral domains of the neural tube. Studies examining the functional effect of the *TGIF* mutations identified in patients with HPE are ongoing. Our data suggest that TGIF plays an important role in regulating gene expression in developing neurons and that altering TGIF activity results in defective nervous system development.

**Late-Gestation-Lung 1 (LGL1) Levels are Diminished in Animal Models of Bronchopulmonary Dysplasia (BPD) and Normalized During Recovery in Air.** *K. Nadeau<sup>1,2,3</sup>, R. Jankov<sup>4,5,6</sup>, L. Oyewumi<sup>5,6</sup>, K.A. Tanswell<sup>4,5,6</sup>, N.B.*

*Swezey<sup>5,6,7</sup>, F. Kaplan<sup>1,2,3,8</sup>.* 1) Dept Human Genetics; 2) Children's Res Inst, Montreal, PQ, Canada; 3) Mtl. Child. Hosp. Res. Inst, Montreal, QC, Can; 4) Lung Bio and Med. Res. Council Group in Lung Dev; 5) Hospital for Sick Children Res. Inst., Toronto, ON, Can; 6) University of Toronto, ON, Can; 7) Dept. of Pediatrics and Physiology; 8) Dept. of Pediatrics.

Malformation or destruction of alveoli characterize lung diseases of developmental origin (BPD). We cloned LGL1 (gene), a glucocorticoid induced and developmentally regulated gene in fetal and neonatal lung. The lg11 protein is a mesenchyme specific secreted glycoprotein. We showed that LGL1 regulates lung branching. However, maximal fetal LGL1 expression occurs in late gestation when branching of conducting airways is complete. Postnatally, lg11 (protein) is taken up by type II epithelial cells. These findings suggested that LGL1 also has a role in alveolarization. To test this hypothesis, we assessed postnatal LGL1 expression in two O<sub>2</sub> toxicity rat models of BPD. Reduced levels of LGL1 mRNA (northern analysis, n=2) and lg11 protein (immunohistochemistry (IHC), n=3) were observed in a rat model of BPD generated by exposing neonatal rats to 60% oxygen for 7, 10 or 14 days (n=4 litters/group). A second rat model was generated by exposing neonatal rats to 95% O<sub>2</sub> for 7 days. Exposure of these rats to air for 1, 2 or 3 weeks allowed us to study the expression of LGL1 both following hyperoxia and during the recovery period of accelerated growth in air, using IHC (n=3). Lg11 protein levels are greatly reduced after one week exposure to 95% O<sub>2</sub>, but were gradually increased to normal levels after 3 weeks of air exposure (n=2/group). Controls were exposed to air for the same time periods for both animal models. We speculate that deficiency of lg11 contributes to the arrested alveolar partitioning observed in BPD and that recovery is associated with normalization of lg11 levels. These findings support a role for LGL1 in the normal process of alveolarization.

**Mutations in wing 2 of the winged-helix transcription factor FOXC1 disrupt transactivation ability.** *T.C. Murphy, R.A. Saleem, M. Yu, M.A. Walter.* Ophthalmology/Med Genetics, Univ Alberta, Edmonton, AB, Canada.

*FOXC1*, mapping to chromosome 6p25, is a developmentally important winged-helix transcription factor characterized by the presence of the forkhead domain (FHD). The FHD is composed of a helix-turn-helix core of three-helix bundle, flanked by two loops or wings. Wing 1 is stabilized by a  $\alpha$ -sheet and makes contacts with the DNA while the function of wing 2 is largely unknown. Mutations in *FOXC1* lead to aberrant development of the anterior segment of the eye and increase the risk of early onset glaucoma. We have recently identified a novel mutation in wing 2 of the *FOXC1* forkhead domain (G165R). Together with the recently described M161K mutation in wing 2 we have investigated the effects of these *FOXC1* mutations on the ability of the *FOXC1* protein to bind DNA and activate gene expression. Site-directed mutagenesis was used to introduce these missense mutations into the *FOXC1* cDNA. Epitope-tagged *FOXC1* constructs were expressed in COS-7 cells, producing products of the correct size by Western analysis. The effect of each wing 2 mutation on *FOXC1*-DNA interactions was tested by electrophoretic mobility shift assays (EMSAs), while the effects of these missense mutations on the transactivation ability of *FOXC1* were tested using a dual luciferase reporter assay. Both the missense mutations localize to the nucleus at wildtype levels and EMSAs have revealed that *FOXC1* carrying M161K or G165R is still able to bind an in vitro derived *FOXC1* binding site at wildtype *FOXC1* levels. Interestingly, these mutations demonstrate reduced transactivation of a luciferase reporter gene in comparison to wild type *FOXC1*. Further analyses of the effects of these missense mutations on *FOXC1* binding specificity and the nature of the transactivation disruption are underway. These experiments show that these missense mutations in *FOXC1* do not perturb *FOXC1*-DNA interactions, but do disrupt the transactivation potential of *FOXC1*. The analyses of these two *FOXC1* missense mutations provide an understanding of how the wing 2 region of the forkhead domain is involved in *FOXC1* function. These analyses will also help define critical thresholds of *FOXC1* function.

**Gene expression profiles of human craniofacial structures in early embryogenesis.** *Y. Korshunova<sup>1</sup>, D. Messina<sup>1</sup>, R. Tidwell<sup>1</sup>, C. Helms<sup>1</sup>, M. Lovett<sup>1</sup>, T. Attie-Bitach<sup>2</sup>, J. Auge<sup>2</sup>, S. Audollent<sup>2</sup>, M. Vekemans<sup>2</sup>, J. Cai<sup>3</sup>, D. Ash<sup>3</sup>, E.W. Jabs<sup>3</sup>.* 1) Washington University, St. Louis, MO; 2) Hospital Necker Enfants Malades, Paris; 3) The John Hopkins University, Baltimore, MD.

Craniofacial defects are among the most common congenital abnormalities in humans. More than 20% of these defects appear to have a genetic component, but we know very little about the genetic programming of the complex structures that make up the human face. We have conducted the largest expression study to date on human embryonic structures that give rise to the head and face between the 4th and 8th weeks of human gestation. We employed four overlapping methodologies (EST generation from cDNA libraries, microSAGE, Affymetrix Genechips and microarray analysis) to derive a detailed picture of gene expression changes across 24 microdissected structures. Comparison of Genechip data with SAGE tag frequencies indicated that, in general, the results from both methods were highly consistent. Likewise, hierarchical clustering of expression data from over 50 separate Genechip experiments revealed that duplicate hybridizations from single dissected structures were highly reproducible. Self organizing maps were used to cluster expression data from all 24 tissues and resulted in the identification of 21 clusters of genes with similar expression patterns. These 21 clusters comprised a total of 405 genes that significantly vary during craniofacial development. In addition to this analysis, we used genes known to be involved in craniofacial development (such as EYA1, MSX2 and TWIST) as the basis of expression clustering. For example, clustering around MSX2 revealed coordinate changes in FoxG1B and a the gene encoding craniofacial development protein1. Likewise, clustering on the basis of EYA1 expression revealed two additional genes that may be important in craniofacial development: FOXF1 and MEOX2. Our very large set of >500,000 data points provides the base line for the identification of important pathways and for many future investigations of the effects of gene disruptions and environmental effects upon craniofacial development.

**COP9 signalosome subunit 3 (*Csn3*) is essential for maintenance of cell proliferation in the mouse embryonic epiblast.** J. Yan<sup>1</sup>, K. Walz<sup>1</sup>, H. Nakamura<sup>1</sup>, S. Carattini-Rivera<sup>1</sup>, Q. Zhao<sup>1</sup>, H. Vogel<sup>3</sup>, N. Wei<sup>4</sup>, M.J. Justice<sup>1</sup>, A. Bradley<sup>5</sup>, J.R. Lupski<sup>1, 2</sup>. 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Dept Pathology, Stanford University, CA; 4) Dept molecular, cellular, and developmental biology, Yale University, CT; 5) Sanger Centre, Cambridge, UK.

*Csn3*(*Cops3*) is located in the mouse chromosome 11 region syntenic to the common deletion interval for the Smith-Magenis Syndrome (SMS), a contiguous gene deletion syndrome manifested by anatomical and multi-developmental abnormalities and associated with a chromosome 17 deletion - del(17)(p11.2p11.2). It encodes the third subunit of the COP9 signalosome (CSN), that is an eight-subunit protein complex originally identified as a repressor of light mediated development in plants; mutants of this complex are lethal after the seedling stage. Disruption of two of the homologous subunits in *Drosophila* caused lethality at the late larval or pupal stages. To investigate CSN function in mammals, and its potential role in the SMS phenotype, we disrupted the murine *Csn3* gene in three independent ways using insertional vectors including constructing an ~ 3 Mb inversion balancer chromosome. The heterozygous mice appeared normal, although the protein level was reduced, and viable homozygous *Csn3* <sup>-/-</sup> mice were not obtained. Detailed analyses of 5.5 days postcoitum (dpc) to 11.5 dpc embryos revealed that homozygous *Csn3* <sup>-/-</sup> embryos arrested after 5.5 dpc and resorbed by 8.5 dpc. Mutant embryos form an abnormal egg cylinder which does not gastrulate. They have a reduced number of epiblast cells, mainly due to increased cell death. In the *Csn3* <sup>-/-</sup> mice, subunit 8 of the COP9 complex was not detected by immunohistochemical techniques suggesting the absence of *Csn3* may disrupt the entire COP9 complex. Therefore, *Csn3* is important for maintaining the integrity of COP9 signalosome and is crucial to the development of the postimplantation embryo in mice.

***Dby* expression and germ cell development.** *Q.P. Vong*<sup>1</sup>, *S.M. Wu*<sup>1</sup>, *M. Dym*<sup>2</sup>, *O.M. Rennert*<sup>1</sup>, *W.Y. Chan*<sup>1,2,3</sup>. 1) NICHD, National Institutes of Health, Bethesda, MD; 2) Department of Cell Biology, Georgetown University, Washington, DC; 3) Department of Pediatrics, Georgetown University, Washington, DC.

In mouse and human, deletion of the *AZFa* region of Y chromosome has been linked to early failure of spermatogenesis and consequent sterility. Molecular analysis identified six genes lying in that region: *Usp9y*, *Dby*, *Uty*, *Eif2s3y*, *Smcy*, and *Ube1y1*; all have closely similar X-encoded homologs. This interval is associated with the *Spy* spermatogenesis phenotype. Patients with deletion of *AZFa* frequently show Sertoli Cell Only syndrome; either low levels or no germ cells are present in seminiferous tubules. Of the Y-encoded genes which mediate the function of the Y chromosome in spermatogonial proliferation, *Dby* has been considered a strong candidate. Early studies using an indiscriminative probe showed that *Dby* was expressed primarily in testicular somatic cells. This observation implicated a regulatory role for *Dby* in spermatogonial proliferation during spermatogenesis. To understand the genetic regulation of spermatogenesis, we have profiled the transcriptome of type A spermatogonia (SgA) of the mouse using Serial Analysis of Gene Expression (SAGE) and found *Dby* expression in these cells. The full-length *Dby* gene was cloned from the same cell type. In mouse, as in human, the *Dby* gene gives rise to two alternative transcripts that differ only in the length of 3'untranslated region due to distinct polyadenylation signals. The long form was present in non-testicular tissues while the short form was found only in the testis. Both forms were shown to be present in SgA by molecular cloning and DNA sequencing. It is likely that the *Dby* signal previously observed in testicular somatic cells was contributed by the long transcript. Besides these two variants, two other types of alternatively spliced transcripts containing non-overlapping sequences of 48 and 120 nucleotides respectively, were found in SgA. Differential expression of these *Dby* variants in germ cells at different stages of spermatogenesis is being examined. The presence of *Dby* in SgA indicates that *Dby* has an intrinsic role in germ cell development and may explain the spermatogenic arrest observed in *AZFa* deletion patients.

**USING SAGE TO CONFIRM A TELOMERASE IMMORTALIZED SPERMATOGONIAL CELL LINE AS AN EXPERIMENTAL MODEL.** *N. Tayebi*<sup>1</sup>, *LX. feng*<sup>2</sup>, *V. Baxendale*<sup>1</sup>, *SM. Wu*<sup>1</sup>, *ALY. Pang*<sup>1</sup>, *M. Dym*<sup>2</sup>, *WY. Chan*<sup>1,2,3</sup>, *OM. Rennert*<sup>1</sup>. 1) Laboratory of Clinical Genomic, NICHD, NIH, Bethesda, MD; 2) Department of Cell Biology Georgetown University, Washington, DC; 3) Department of Pediatrics Georgetown University, Washington, DC.

The renewal and differentiation of spermatogonial stem cells into spermatozoa is a complex and continuous process. We are interested in identifying the genes and mechanisms of transcriptional control during spermatogenesis. To ascertain whether a Spermatogonial Cell Line (SCL) immortalized with mouse TERT (Feng et al, Science 2002) is an appropriate representation of Type A Spermatogonia (TAS) *in vivo*, we compared the Serial Analysis of Gene Expression (SAGE) profile of the SCL with that of isolated TAS. An SCL SAGE library was constructed from total RNA and 2,304 independent library clones were sequenced. SAGE 2000 analysis software and the SAGEmap data base were used to allocate UniGene cluster IDs to the tags. A total of 48,485 tags were identified, of which 17,042 were unique. Singleton tags not shared by both libraries were excluded. Comparison of SAGE tags from both libraries showed that 4,264 tags were SCL specific and 2,018 tags were expressed in both libraries. As the total number of tags in the SCL (48,485) and TAS (110,872) libraries was different, the percent of total for each tag was determined in each library. The ratio of the percentage of a tag in the two libraries was used as an indicator of its relative expression. Ratios between 0.5-2.5 were chosen for further analysis. Several known genes essential for spermatogenesis were identified in both libraries, including several growth factors and their receptors, Pumilio 2, MAD1, MAD2, RNA binding proteins, transcription factors, and SRY. *Daz1* was down-regulated in the TAS. The most abundantly expressed tags in the SCL which are shared or known to be expressed in TAS are candidates for further study using RT-PCR and/or Real Time PCR. The number of shared SAGE tags and genes identified shows that the SCL can be used as an *in vitro* experimental model to identify genes and transcriptional control systems involved in spermatogenesis *in vivo*.

**Expression of the *PAX8*, *TITF1*, *FOXE1* and *TSHR* genes during human development: new insights on human thyroid and kidney development.** S. SURA<sup>1,2</sup>, J. AUGÉ<sup>3</sup>, G. MATTEI<sup>3</sup>, H. ETCHEVERS<sup>3</sup>, J. MARTINOVIC<sup>3</sup>, P. CZERNICHOV<sup>1</sup>, M. VEKEMANS<sup>3</sup>, M. POLAK<sup>1,2</sup>, T. ATTIE-BITACH<sup>3</sup>. 1) INSERM U-457 et Service d'endocrinologie pédiatrique Hopital Robert Debre, Paris, FRANCE; 2) INSERM E0363 et Service d'Endocrinologie pédiatrique, Hopital Necker, Paris, FRANCE; 3) Departement de Genetique et INSERM U-393, Hopital Necker, Paris, FRANCE.

Congenital hypothyroidism affects about 1 in 3800 newborns. In most cases, it is linked to a defect in thyroid ontogeny. Inactivation of the *PAX8*, *TITF1*, *FOXE1* and *TSHR* genes in patients or mice produce thyroid dysgenesis. To better understand the phenotypes associated with human mutations of these genes, we decided to study their expression patterns at different stages of human development. *In situ* hybridization studies using specific [<sup>35</sup>S]UTP labeled probes were performed on 3 embryonic (CS14, CS15, CS19) and 2 fetal (9 and 11 developmental weeks) stages. *PAX8* and *TITF1* are the first genes expressed in the median thyroid primordium. *FOXE1* is detected later and *TSHR* is expressed only when the thyroid migration is completed. Interestingly, the *PAX8* gene is also expressed in the fourth pharyngeal arch ectoderm and later in an inner cell population corresponding presumably to the ultimobranchial body. Furthermore, the *PAX8* gene is expressed in ureteric bud and some of its derivatives in developing kidney. Finally, *FOXE1* is expressed in human thymus. In conclusion the expression patterns described here are distinct from those reported in animal models and correlate with the congenital anomalies observed in humans.

**Animal models for Amish lethal microcephaly.** *M.J. Lindhurst, T. Blake, A. Chen, P.P. Liu, L.G. Biesecker.* National Human Genome Research Institute, NIH, Bethesda, MD.

Amish lethal microcephaly (MCPHA) is an autosomal recessive disorder comprising severe microcephaly, a congenital malformation of the brain, increased urinary  $\alpha$ -ketoglutarate, and premature death. Previously we reported the discovery of a single nucleotide substitution in the *SLC25A19* gene encoding a mitochondrial membrane deoxynucleotide carrier, DNC, which segregates with the disease in affected individuals and alters an amino acid highly conserved in similar proteins. Functional analysis of the mutant protein revealed that normal transport activity was lost. We hypothesize that insufficient transport of dNTPs into mitochondria in the developing central nervous system interferes with mitochondrial DNA synthesis, causing abnormal brain growth and development. Zebrafish knockdown experiments confirm that this protein is necessary for normal development as two morpholinos targeted to DNC caused a range of CNS and cranial malformations in a dose-dependent fashion. The rostral portion of mutant embryos was smaller and more opaque than controls suggesting that tissues in this region have become necrotic. Histological examination of serial sections revealed the presence of a large vacuole in the dorsal region of the head. *In situ* hybridizations with *Wnt1* and *Krox20* showed expression patterns in mutant embryos that resembled those of earlier timepoints than those of control embryos indicating that DNC is necessary for proper formation of the zebrafish brain. We have also created a DNC knockout mouse and have begun breeding experiments to study the affects of the mutation in the homozygous state. These results show the critical relationship between energy metabolism and brain growth and development as well as suggest that perturbation of energy metabolism may explain other types of brain growth disorders.

**Evaluation of Zebrafish as a Model Organism for the Human Bardet-Biedl Syndrome.** *H.-j. Yen*<sup>1,2</sup>, *K. Mykytyn*<sup>1,2</sup>, *D.Y. Nishimura*<sup>1</sup>, *R.F. Mullins*<sup>3</sup>, *C.C. Searby*<sup>1,2</sup>, *T.A. Westfall*<sup>4</sup>, *D.C. Slusarski*<sup>4</sup>, *V.C. Sheffield*<sup>1,2</sup>. 1) Dept. of Pediatric, Division of Medical Genetics, University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute; 3) Dept. of Ophthalmology, University of Iowa, Iowa City, IA; 4) Dept. of Biological Sciences, University of Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) consists of the primary features of obesity, retinitis pigmentosa, polydactyly, renal and cardiac malformations, mental retardation and hypogonadism. Patients with BBS also have increased risk of developing hypertension and diabetes mellitus. BBS is an autosomal recessive disease that exhibits locus heterogeneity and is known to map to seven human loci: 11q13 (*BBS1*), 16q22 (*BBS2*), 3p13 (*BBS3*), 15q21 (*BBS4*), 2q31 (*BBS5*), 20p12 (*BBS6*) and 4q27 (*BBS7*). To date, 5 BBS genes (*BBS1*, *BBS2*, *BBS4*, *BBS6* and *BBS7*) have been identified. Complex inheritance of BBS has been proposed. In order to investigate complex inheritance of the disorder, we have used zebrafish as a model organism. We have identified putative zebrafish orthologs using bioinformatic approaches. Comparisons of the amino acid sequences of zebrafish and human BBS gene products show high homology (on average 70% identity and 80% similarity). We performed whole mount *in situ* hybridization in embryos between 0 to 24 hours post fertilization and determined that zBBS genes are ubiquitously expressed. We performed z*BBS4* morpholino antisense oligo gene knockdown experiments and observed retinal abnormalities in a dose-dependent manner. Furthermore, we performed functional vision assays and confirmed that the retinal abnormalities correlate with blindness. Histological analyses indicate that disrupting the expression of z*BBS4* results in ocular abnormalities including a failure of the retinal cell layers to form properly. In addition, we performed double knockdown experiments and preliminary results indicate that *BBS2* and *BBS6* interact genetically. This work supports the use of zebrafish as a model for the molecular pathogenesis of BBS.

**Microarray and functional analyses of primordial follicle formation and the etiology of premature ovarian failure.** *C. Ottolenghi<sup>1,3</sup>, M. Uda<sup>1,2</sup>, L. Herrera<sup>1</sup>, E. Garcia<sup>1</sup>, A. Forabosco<sup>3</sup>, D. Schlessinger<sup>1</sup>, L. Crisponi<sup>2</sup>, M. Deiana<sup>2</sup>, G. Pilia<sup>2</sup>.* 1) Laboratory of Genetics, GRC, NIA/NIH, IRP, Baltimore, MD; 2) Istituto di Ricerca sulle Talassemie ed Anemie Mediterranee CNR, and Dipartimento di Scienze Biomediche e Biotecnologie, Ospedale Regionale per le Microcitemie, University of Cagliari, Cagliari, Italy; 3) Genetica Medica, Department Mother and Child, University of Modena, Italy.

The stage of primordial follicle formation is critical for female fertility, correlated with selection of functional oocytes from a far larger fetal pool. In the mouse, this stage is restricted to the perinatal period, providing an opportunity to investigate critical factors. As complementary approaches, we have first applied expression profiling of gene expression in microarrays, and have found that over one hundred genes, including a number of transcription factors and novel transcripts, are differentially expressed between the first and later phases of follicle formation. Second, we have knocked out the FOXL2 gene (mutations in which are a cause of premature ovarian failure in humans), and are currently assaying its impact on fertility. Third, we are characterizing gene expression profiles in an embryonic stem cell-based in vitro model for the first stages of ovarian follicle development. These approaches provide a framework to identify genes and functions specifically involved in setting the level of functional oocytes.

**Identifying New Sex-Determining Loci Using a Congenic Mouse Model.** *G. Nikolova*<sup>1</sup>, *E. Vilain*<sup>1,2,3</sup>. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Dept of Pediatrics, UCLA, Los Angeles, CA; 3) Dept of Urology, UCLA, Los Angeles, CA.

In mice as well as humans, sex is determined by the presence or absence of Sry, a male specific gene found on the Y chromosome. Unlike humans however, the mouse Sry protein sequence differs among individual strains, especially between members of the *Mus musculus musculus*, and *domesticus* subspecies. Introducing a number of different *domesticus* Y chromosomes onto the inbred *musculus* C57Bl/6J genetic background results in varying degrees of XY sex reversal despite the fact that sexual development proceeds normally in the parental *domesticus* strain. Further investigations of the phenomenon have confirmed that the variability in Sry together with interacting factors from C57Bl/6J contribute to it, but neither specific Sry residues, nor C57Bl/6J polymorphisms have been implicated. Since many other *musculus* inbred strains, such as 129S1/Sv, are not subject to this form of sex reversal, mouse genetics can be used to investigate the C57Bl/6J components affecting the phenotype. 129S1/Sv males carrying a Y chromosome from the *domesticus* subgroup Poschiavinus, were mated with C57Bl/6J females, followed by repeated backcrossing of male offspring to C57Bl/6J females for 13 generations. Continuous selection for fully masculinized males resulted in generating a C57Bl/6J-XY<sup>POS</sup> congenic strain homozygous for the 129S1/Sv element(s) conferring protection against sex reversal. In order to identify the location of the congenic fragment(s) we have genotyped autosomal microsatellite markers spaced 15-20 cM apart in these C57Bl/6J-XY<sup>POS</sup> and control C57Bl/6J mice. Each inbred mouse strain has a characteristic PCR product size for a given marker, which can be used to distinguish the genetic background of origin at that locus. Markers for which the congenic does not match C57Bl/6J may thus potentially identify chromosomal segments containing genes involved in sex determination. Further analysis of such regions is being performed by creating a denser marker map, as well as by evaluating the sequence and expression pattern of candidate genes.

**Wnt4 signaling inhibits steroidogenesis by antagonizing Sf-1 and  $\beta$ -catenin.** *E. Vilain*<sup>1,2,3</sup>, *J.H.-C. Shen*<sup>4</sup>, *R. Olaso*<sup>4</sup>, *H.A. Ingraham*<sup>4</sup>, *B.K. Jordan*<sup>1</sup>. 1) Dept of Human Genetics, UCLA Sch of Medicine, Los Angeles, CA; 2) Dept of Pediatrics, UCLA Sch of Medicine, Los Angeles, CA; 3) Dept of Urology, UCLA Sch of Medicine, Los Angeles, CA; 4) Dept of Physiology, UCSF Sch of Medicine, San Francisco, CA.

In mammals, the genes of the sexual development pathway direct the cells of the bipotential gonad to organize in sexually-dimorphic ways including production of steroidogenic hormones. Genetic studies in mice have suggested that Wnt4 signaling suppresses the expression of enzymes controlling the biosynthesis of male hormones, thus effectively blocking their production in the female embryo. Recently, we identified an XY intersex patient carrying a duplication of the *WNT4* locus and demonstrated that overexpression of *WNT4* was the likely cause of this patient's feminization. To test this hypothesis, we generated a transgenic mouse model overexpressing *WNT4*. Although sexual development of transgenic females was unaffected by the increase in *WNT4* expression, transgenic males exhibited abnormal testis development with fewer germ cells and disorganization of the vascular system. Although a complete male-to-female sex reversal was not observed, testosterone levels were markedly reduced in transgenic males. This Wnt4-mediated repression of steroidogenesis was recapitulated in both Leydig and adrenocortical cell lines co-cultured with cells overexpressing *Wnt4*, which exhibited reduced progesterone secretion and 3-hydroxysteroid dehydrogenase activity, respectively. Further *in vitro* studies revealed that *Wnt4* antagonizes the functional synergy observed between  $\beta$ -catenin, the major effector of the Wnt signaling pathway, and Sf-1, the major regulatory factor of steroidogenesis. In addition, chromatin immunoprecipitation studies suggest that *Wnt4* attenuates recruitment of  $\beta$ -catenin to an Sf-1-target gene promoter. Taken together, these data provide evidence that *Wnt4* acts as an anti-male factor in sexual development. We propose a model in which Wnt4 signaling antagonizes steroid production by disrupting recruitment of  $\beta$ -catenin and Sf-1 to binding sites present in multiple steroidogenic target genes.

**Correlations between DNA, FMRP, and mRNA levels and ADOS-G and ADI-R scores in patients with Fragile X Syndrome.** *K. Herman<sup>1</sup>, S. Nowicki<sup>1</sup>, F. Tassone<sup>3</sup>, K. Koldewyn<sup>1</sup>, S. Bacalman<sup>1</sup>, S. Jacquemont<sup>1</sup>, I. Barboto<sup>1</sup>, R. Levine<sup>2</sup>, P. Hagerman<sup>3</sup>, R. Hagerman<sup>1</sup>.* 1) M.I.N.D. Institute, UC Davis Health System, Sacramento, CA; 2) Department of Mathematics and Statistics, San Diego State University, San Diego, CA; 3) Department of Biological Chemistry, UC Davis, Davis, CA.

Several papers have looked at the involvement of CGG repeat number, methylation status, and FMRP levels on the clinical phenotype of Fragile X Syndrome. However, mRNA levels have not been studied with regard to the Fragile X phenotype. In older male carriers of the premutation, we have documented the presence of a Fragile X Associated Tremor/Ataxia Syndrome (FXTAS), which is thought to be related to a toxic effect of elevated mRNA levels. In addition, we have seen autism in children with the premutation that may also be related to elevated message, low FMRP, or additional genetic effects. Since 33 percent of Fragile X patients have autistic spectrum disorders, we decided to examine the relationship between molecular measures and autism diagnostic measures (ADOS-G and ADI-R). We studied 66 patients with either Fragile X Syndrome (58 patients) or affected premutation carriers (8 patients), both with (31 patients) and without (35 patients) autistic spectrum disorders.

Neither ADI nor ADOS scores correlated with CGG repeat number. FMRP levels correlated only marginally with ADOS and ADI scores ( $p=0.08$ ). ADOS total scores had a strong correlation with mRNA levels ( $p=0.018$ ), even with controlling for IQ ( $p=0.029$ ). When the ADOS subscores were analyzed, it was found that mRNA levels correlated with the ADOS Communication scores at a significant level ( $p=0.0063$ ), but did not correlate with the ADOS Social scores ( $p=0.13$ ). In addition, the results showed a U shaped distribution, with both high and low mRNA levels correlating with high ADOS Communication scores.

The presence of autism in Fragile X Syndrome may be related to a number of factors including background gene effects, lowered FMRP, and elevated mRNA. These results suggest that elevated message may have the strongest effect, particularly on communication.

**Genome wide expression profile in trophoblastic disease.** *S. Jasani*<sup>1</sup>, *Y. Lin*<sup>2</sup>, *E. Feingold*<sup>2</sup>, *U. Surti*<sup>1</sup>. 1) Pathology, University of Pittsburgh, Pittsburgh, PA; 2) Biostatistics, GSPH, University of Pittsburgh, Pittsburgh, PA.

Affymetrix U113A oligonucleotide microarray chips were used to obtain genome wide expression profiles of fibroblasts from 3 androgenetic complete hydatidiform moles(CHM-PP), 3 normal biparental chorionic villus samples (NML-MP), 5 triploid partial hydatidiform moles(PHM-MPP) and 3 nonmolar triploids(NMT-MMP). The CEL files obtained after hybridization were used to scale and normalize the data using dCHIP software. Modified t-test that uses empirical Bayesian methods was used to obtain a list of most differentially expressed genes between NML-MP and CHM-PP as well as PHM-MPP and NMT-MMP. In addition, expression profiles of 2 choriocarcinoma cell lines were also obtained. Several genes constituting cell growth pathways such as the MAP kinase pathway, and/or cell death pathways are differentially expressed. Due to the androgenetic nature of a complete mole, special emphasis was placed on the expression of imprinted genes, most of which are expressed in the placenta and are important to growth and regulation of the fetus and placenta. Two important cell growth and regulatory pathways were explored in detail. These are the IGFII pathway and the TGF pathway. Several genes involved in these pathways are differentially expressed. IGFII, one of the major imprinted, placental growth promoters, is upregulated in complete moles, along with IRS-1, while IGF2R is downregulated, indicating an increased signaling through either the insulin or IGFIR, contributing to the increased size of the placenta in complete moles. This pathway is interconnected to the TGF pathway, which also has an independent function in the placenta. TIMP1 and PAII are genes directly controlled by TGF, and that are downregulated in complete moles. PEG1/MEST, PEG3, PEG10, SGCE, SNRPN, NOEY2 and TSSC3 were among differentially expressed genes in CHM-PP when compared to NML-MP as expected. Most of these genes were also among differentially expressed when PHM-MPP results were compared to NMT-MMP. These and other differentially expressed genes observed contribute to the peculiar phenotypes of complete mole, as well as type-1(large placenta) and type-2(small placenta, macrocephaly) triploids.

**Genome-wide gene expression comparison of forelimb versus hindlimb development by microarray technique.** S. Shou<sup>1, 2</sup>, H.S. Stadler<sup>1, 2</sup>, *Genomics, Development*. 1) Research Center, Shriners Hospital, 3101 SW Sam Jackson Park Road, Portland, OR 97239; 2) Oregon Health and Science University, Department of Molecular & Medical Genetics, 3181 SW Sam Jackson Park Road, Portland, OR 97239.

Analysis of gene expression profiles in limb tissues is an important approach to elucidate molecular mechanisms of limb development. The expression profiles of the developing forelimb and hindlimb were assessed using the Affymetrix mouse expression 430A/B GeneChips and total RNAs isolated from E 12.5 forelimb or hindlimb autopods. A transcriptome of the expressed genes in the autopod was generated detecting expression of approximately 24907 genes in the forelimb or hindlimb samples, 14748 genes representing 65% of the probe sets on MOE-430A GeneChip, and 10159 genes or ESTs representing 45% of the probe sets on MOE-430B GeneChip. Among the genes detected in the forelimb and hindlimb samples, 4.44% or 1105 genes and ESTs were differentially expressed between the forelimb and hindlimb samples as measured by the Affymetrix MAS 5.0 algorithm ( $|\text{Changed P value}| < .0006$ ,  $|\log_2 \text{Ratio}| > 0.2$ ). A greater than 2-fold expression difference between forelimb and hindlimb samples ( $|\log_2 \text{Ratio}| > 1$ ,  $|\text{Changed P}| < 0.006$ ) was detected for 136 genes or ESTs including *Tbx4*, *Tbx5*, and *Pitx1* which were previously shown by SAGE to be differentially expressed in the forelimb or hindlimb (Margulies 2001). Similarly, genes such as members of the BMP, FGF, EPHA, WNT, CASPASE, HSP, and HOX gene families were also found to be highly expressed or differentially expressed in developing autopods, suggesting that the differential expression and differential combinations of gene expression in the developing limbs contribute to differences in forelimb versus hindlimb patterning required for morphological diversification of these structures. **CONGENITAL PULMONARY LYMPHANGIECTASIA AND CONGENITAL CHYLOTHORAX ARE CLOSELY RELATED ENTITIES.** *C. Bellini<sup>1</sup>, F. Boccardo<sup>2</sup>, C. Campisi<sup>2</sup>, G. Taddei<sup>3</sup>, E. Bonioli<sup>1</sup>, M. Baldi<sup>1</sup>, C. Arioni<sup>1</sup>, R. Sacchi<sup>1</sup>, S. Ciotti<sup>1</sup>, G. Serra<sup>1</sup>.* 1) Servizio Patologia Neonatale, Gaslini Inst, Univ, Genoa, Italy; 2) Dipartimento Scienze Chirurgiche, Univ, Genoa, Italy; 3) Dipartimento Medicina Interna Univ, Genoa, Italy.

**Purpose.** To evaluate correlation between congenital pulmonary lymphangiectasia (CPL) and congenital chylothorax (CC). Congenital pulmonary lymphangiectasia (CPL) is a rare developmental disorder of the pulmonary lymphatics. CPL is characterized by numerous dilated lymphatic channels in the sub-pleural connective tissue, in the interlobular septa, and along bronchovascular axes. Chylothorax is defined as an accumulation of chyle in the pleural space. The term congenital chylothorax (CC) is usually limited to congenital abnormalities of the lymphatic system, and CC is present at birth. **Methods.** We report on three infants with congenital chylothorax (CC) and congenital pulmonary lymphangiectasia (CPL). **Results.** Clinical course, imaging and lymphoscintigraphic studies demonstrated the occurrence of CPL and CC, as well as lymphatic dysplasia. **Conclusion.** CPL and CC are often described as separate entities. This is mainly due to the low number of existing reports on CPL that include biochemical and cytological analysis of the pleural effusion, as well as to the limited number of cases of both CPL and CC, whose diagnoses had been prevented by lack of adequate diagnostic studies. CPL appears to be a constant pathological finding in CC. This study suggests that CC and CPL are strongly correlated entities and that the dysplasia of the lymphatic system results in a pulmonary lymphatic obstruction sequence. The initial, microscopic dilatation of the lymph channels leads to progressive weeping of lymphatics and, consequently, to pleural effusion. Non-Immune Hydrops Fetalis (NIHF) may be the final consequence of impaired systemic venous return and may help to explain pleural-pulmonary involvement of this generalized lymph-vessel malformation syndrome. This report focuses on CPL-CC-NIHF in neonates. On the basis of radiological and lymphoscintigraphic evaluation, it is suggested that there is a strong correlation among these entities.

**CONGENITAL CHYLOTHORAX IN NEWBORNS.** *F. Boccardo*<sup>1</sup>, *C. Bellini*<sup>2</sup>, *C. Arioni*<sup>2</sup>, *M. Baldi*<sup>2</sup>, *R. Sacchi*<sup>2</sup>, *S. Ciotti*<sup>2</sup>, *E. Bonioli*<sup>2</sup>, *C. Campisi*<sup>1</sup>, *G. Serra*<sup>2</sup>. 1) Dip Scienze Chirurgiche, Univ Genoa, Italy, Genoa, Genoa, Italy; 2) Servizio Patologia Neonatale, Univ Genoa, Gaslini Inst, Genoa, Italy.

Chylothorax is defined as an accumulation of chyle in the pleural space. The term congenital chylothorax (CC) is usually reserved for congenital abnormalities of the lymphatic system. Establishing the diagnosis and selecting the most appropriate therapy may be challenging. We report our experience in managing chylothorax of the neonatal age and discuss various congenital malformed condition that can be associated with chylothorax. Four cases of premature newborns born with CC and various degree of non-immune hydrops fetalis have been observed. CC is a rare cause of respiratory distress in the newborn and is the most common form of pleural effusion in the neonatal period. The real incidence of congenital chylothorax is not known, ranging from 1:1,000 to 1:15,000 pregnancies. The actual incidence is probably higher, and intrauterine fetal death as well as stillbirth might be underestimated. Lymphangiomas and lymphangiectasia are the two major abnormalities of lymphatic development that cause chylothorax. Abnormal prominence of subpleural and interlobular lymphatics typically occur in pulmonary lymphangiectasia. Obstructed, dilated lymphatics are unable to drain lymph appropriately (though an obstruction site has yet to be elucidated) and contribute to a non-physiologic stiffening of lung parenchyma. Thus, in some cases, chylothorax may occur. The exact mechanism through which chylothorax develops to a more generalized hydrops is poorly understood. Prognosis is unpredictable. Overall mortality for congenital chylothorax has been reported ranging 50-95%. The presence of hydrops fetalis has significant prognostic implications. (However, non immune hydrops caused by chylothorax may carry a better prognosis than non immune hydrops in general. The frequency of spontaneous resolution is unknown, occurring both antenatally and postnatally.

**Cholesterol supplementation does not appear to improve developmental progress in Smith-Lemli-Opitz syndrome.** *D.M. Sikora, M. Ruggiero, K. Pettit-Kekel, L.S. Merkens, W.E. Connor, R.D. Steiner.* Depts of Pediatrics & Medical and Molecular Genetics, Child Development & Rehabilitation Center, Oregon Health & Science Univ, Portland, OR.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive multiple malformation/mental retardation syndrome. Clinical manifestations, including motor delay with hypo/hypertonia, language delay, oral-motor dysfunction, and mental retardation, are caused by impaired conversion of 7-DHC to cholesterol in the final step of cholesterol biosynthesis, resulting in cholesterol deficiency and elevated and potentially toxic accumulation of 7-DHC throughout the body and brain.

There is anecdotal evidence from several investigators suggesting that cholesterol supplementation improves developmental progress and reduces atypical behavior in children with SLOS; however, none of these studies reported scores from standardized instruments to document changes over time. The purpose of the present study was to provide longitudinal data on the developmental progress of 14 children with SLOS.

Eight females and six males with SLOS participate in a prospective longitudinal study assessing developmental progress during cholesterol supplementation. All subjects completed at least two developmental assessments, scheduled at least one year apart, over a 6 year period. The duration of cholesterol supplementation averaged 8 months prior to the first assessment. Cholesterol supplementation has been continuous throughout participation in the study.

Scores from standardized tests in the areas of motor, cognitive, and adaptive skill development did not improve over time for these subjects, based on statistical analyses using a repeated measures design. In addition, baseline cholesterol levels, rather than age when supplementation began or increase in cholesterol levels, best predicted developmental outcome using multiple t-tests. These results suggest that cholesterol supplementation in its current form does not improve the developmental progress of children with SLOS.

**Phenotypic characterization and positional cloning of two recessive ENU-induced mouse models of cleft palate.**

*B.C. Bjork*<sup>1</sup>, *B.J. Herron*<sup>2</sup>, *A.R. Vieira*<sup>3</sup>, *J.C. Murray*<sup>3</sup>, *D.R. Beier*<sup>1</sup>. 1) Div. Genetics, Brigham & Women's Hospital, Boston, MA; 2) Wadsworth Genomics Institute, Albany, NY; 3) Dept. Pediatrics, The Univ. of Iowa, Iowa City, IA.

We are screening E18.5 embryos from ENU-treated mice for recessive phenotypes that resemble human congenital disorders. Among the large spectrum of phenotypic abnormalities we have identified are a significant number of cleft secondary palate. Non-syndromic orofacial clefting occurs in about 1 in 1000 live births. Many known mutant mouse phenotypes include orofacial clefts, but the best models for human clefting are those with isolated clefts. The *cleft palate only 1* (*cpo1*; isolated cleft secondary palate) and *curly tail/cleft palate* (*ctcp*; cleft secondary palate and/or a curly or kinked tail) mutations are excellent models of cleft secondary palate. Genetic fine-mapping defined critical regions of 500 kb on distal chr 4 and 3.5 Mb on proximal chr 3 for the *cpo1* and *ctcp* mutations, respectively.

We report the genetic localization, fine-mapping, developmental characterization and candidate gene screening for these ENU-induced recessive mutations. Most recently, we determined that *cpo1* mutant mice carry a mutation that affects splicing efficiency of a zinc finger transcription factor gene. We performed a histological evaluation of *cpo1* mutant embryos to identify a specific defect in palatal shelf elevation. RNA probes and polyclonal antibodies were generated to determine the developmental expression pattern of this zinc finger gene and its protein product and to begin to elucidate its function during craniofacial development, including identification of interacting proteins and downstream target genes. Finally, four potential etiologic missense mutations were identified in a screen of 100 individuals each from non-syndromic cleft populations from Iowa and the Philippines. These sequence variants have not yet been identified in control populations, thereby supporting a minor contribution by this gene to the complex etiology of non-syndromic clefting.

Program Nr: 946 from 2003 ASHG Annual Meeting

**Expression of Steroidogenic Acute Regulatory(StAR) Protein during Oocyte Apoptosis in the Gonadotropin-Stimulated Human Ovary.** *S.K. Kim<sup>1</sup>, H.W. Yang<sup>2</sup>, S.W. Bai<sup>1</sup>, K.H. Park<sup>1</sup>, D.J. Cho<sup>1</sup>, C.H. Song<sup>1</sup>.* 1) Dept. of OB/GYN College of MedicineYonsei Univ. CPO Box 8044 Seoul,Korea; 2) Dept.of OB/GYN College of MedicineUlji Univ. Seoul,Korea.

To determine the distribution and expression of steroid acute regulatory(StAR) protein in human oocyte and embryo in relation to apoptosis. Immuno-labelling and confocal microscopy were applied to examine the localization of StAR protein in human oocytes and embryos. Western blot analysis was also used for qualitative and quantitative assessment of StAR protein expression. There were lipid droplet accumulation in fragmented human oocytes and embryos. StAR protein (30 kDa) expression was detected in human oocytes and embryos. The level of StAR protein expression was lower in the fragmented group than the normal group. The present study provides evidence for involvement of StAR protein in the apoptosis of fragmented oocytes and embryos during in vitro fertilization (IVF) program as well as in the normal development of human oocytes and embryos.

**Vision defects and incomplete cone bipolar interneuron differentiation due to loss of function of the *Vsx1* homeobox gene.** *R.R. McInnes*<sup>1</sup>, *R.L. Chow*<sup>1</sup>, *B. Vogyi*<sup>3</sup>, *R.K. Szilard*<sup>1</sup>, *D. Ng*<sup>1</sup>, *C. McKerlie*<sup>2</sup>, *S.A. Bloomfield*<sup>3</sup>, *D.G. Birch*<sup>4</sup>. 1) Progs in Dev Biol, Genetics &; 2) Integrative Biology, The Research Institute, Hosp for Sick Children, Toronto, ON, Canada; 3) Depts of Ophthalmology and Physiology & Neuroscience, New York University School of Medicine, New York, NY, USA; 4) Retina Foundation of the Southwest, Dallas, TX, USA.

Bipolar interneurons of the vertebrate retina are essential for receiving and transmitting visual signals to retinal ganglion cells. One major class of bipolar interneurons, cone bipolar (CB) cells, are a molecularly and physiologically heterogeneous population that express the homeobox gene, *Vsx1*. *Vsx1* is a rapidly evolving *paired*-like homeo- and CVC-domain transcription factor whose homologues in vertebrates and worms play essential roles in interneuron development. In the retina, *Vsx1* is expressed in CB cells as they differentiate, suggesting it may play a critical role in CB cell formation. To examine this possibility, we targeted the *Vsx1* gene in mice. In *Vsx1*<sup>-/-</sup> mice, the specification, number and gross morphology of CB cells in the retina was normal, but great reductions were identified in the expression of at least four proteins (recoverin, NK3R, Neto1, and CaB5) characteristically expressed in OFF-CB cells. These defects in CB differentiation were accompanied by a reduced mixed rod-cone electroretinogram b-wave similar to that observed in human patients with dominant *VSX1* missense mutations (Heon et al. *HMG* 11, 1-8, 2002). This defect in visual transduction was also manifest by a general reduction in the light-evoked activity of OFF- but not ON-ganglion cells in the mesopic range. Importantly, *Vsx1*<sup>-/-</sup> mice had no corneal abnormalities, in contrast to humans carrying a single *VSX1* missense allele. Moreover, no expression of *Vsx1* was detected in the developing or mature mouse cornea, or adult human cornea. Our findings establish that *Vsx1* is essential for OFF-CB differentiation and visual signal transduction, and elucidate the basis of the abnormalities in visual transduction in humans with *VSX1* mutations. The pathogenesis of autosomal dominant human *VSX1*-associated corneal dystrophies, however, remains unclear.

**T cell clones as a tool for examining discrete FMR1 alleles in a common genetic background.** *D.H. Yasui<sup>1</sup>, F. Tassone<sup>1</sup>, P.K. Sahota<sup>1</sup>, A.K. Taylor<sup>2</sup>, R.J. Hagerman<sup>3</sup>, P.J. Hagerman<sup>1</sup>*. 1) Dept. of Medical Biochemistry, UC Davis School of Medicine, Davis, CA; 2) Kimball Genetics, Salt Lake City, UT; 3) MIND Institute, UC Davis School of Medicine, Sacramento, CA.

Southern and PCR analyses of whole blood from a high functioning, male, fragile X patient revealed genetic mosaicism in that 81% of *FMR1* alleles were in either the normal (5-54 CGG repeats) or premutation (55-200 CGG repeats) range and 19% were full mutation alleles (>200 CGG repeats). In order to examine individual *FMR1* alleles, T lymphocyte cloning was performed from peripheral blood mononuclear cells (PBMCs). Southern blot analysis showed that each T cell clone exhibited a discrete allele size that was stable throughout culture. Surprisingly, the preponderance (70%) of discrete *FMR1* alleles in the individual clones harbored full mutation alleles, with only 30% falling within the normal or premutation ranges. In contrast, previous studies in fibroblasts suggested that cells bearing full mutation *FMR1* alleles were negatively selected in vitro. Furthermore, 6% of the T cell clones contained intermediate *FMR1* alleles that were not detected in whole blood. Consistent with previous studies, quantitative RT-PCR analysis of RNA from individual T cell clones revealed that full mutation alleles produce virtually no *FMR1* transcripts while normal and premutation alleles produce normal or elevated levels of transcripts. These results suggest that: (1) there is no selection bias against cells with fully expanded *FMR1* alleles, (2) *FMR1* alleles are mitotically stable in adult tissues, (3) *FMR1* allele diversity in mosaic individuals is greater than what is revealed by Southern analysis of the pool of heterogeneous cell populations found in blood. T cell clones derived from \* mosaic patients are therefore a powerful tool for examining the molecular basis of fragile X syndrome.

**Narcolepsy: involvement of imprinted, differentially-methylated promotor haplotypes of vesicular monoamine transporter 2 (VMAT2).** *T. Drgon*<sup>1</sup>, *M. Takahashi*<sup>1</sup>, *D. Walther*<sup>1</sup>, *Z. Lin*<sup>1</sup>, *L. Lin*<sup>2</sup>, *M. Tafti*<sup>3</sup>, *M. Billiard*<sup>3</sup>, *M. Thorpy*<sup>5</sup>, *H. Temple*<sup>5</sup>, *J. Montplaisir*<sup>4</sup>, *E. Mignot*<sup>2</sup>, *G.R. Uhl*<sup>1</sup>. 1) Molecular Neurobiology, NIDA/NIH, Baltimore, MD; 2) Stanford Med. Ctr, CA; 3) Neurol. B, Montpellier, France; 4) Hopital du Sacre-Coeur, Montreal, Canada; 5) Montefiore Med. Ctr, New York, NY.

Narcolepsy is a familial sleep disorder with dysregulated REM sleep often accompanied by sleep paralysis and cataplexy. Since stimulants treat narcoleptic symptoms, genes implicated in stimulant actions including VMAT2 (SLC18A2) are candidates to harbor narcolepsy-predisposing variants. VMAT2 accumulates monoamine neurotransmitters into synaptic vesicles, while stimulants such as amphetamines release the same neurotransmitters from these vesicles and reduce the amounts released when neurons are depolarized. We now describe VMAT2 "B" haplotypes that are differentially transmitted from mothers to narcoleptic offspring in trio samples. Since these findings suggested imprinting, we examined methylation patterns of CpG sites located in VMAT2 5 flanking/promoter region. Allele-specific differences in methylation in the vicinity of specific transcription factor binding sites supported this mechanism. Maternally-inherited, imprinted VMAT2 haplotypes thus represent the second identified genetic contributor to vulnerability to this sleep disorder, providing effects more modest than those exerted by HLA haplotypes. The VMAT2 haplotypes identified in these studies are also likely to play pleiotropic roles in other disorders in which monoaminergic mechanisms play central roles.

**A *Drosophila* Model to Investigate MeCP2 Function and Interactions.** H. Cukier<sup>1</sup>, H.Y. Zoghbi<sup>1,2,3,4,5</sup>, J. Botas<sup>1,4,6</sup>.  
1) Human and Molecular Genetics; 2) Pediatrics; 3) Division of Neuroscience; 4) Program in Developmental Biology;  
5) Howard Hughes Medical Institute; 6) Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX.

The neurodevelopmental disorder Rett syndrome is caused by the loss of function of methyl-CpG-binding protein 2 (MeCP2), a protein implicated in chromatin remodeling. To gain insight about the *in vivo* function of MeCP2, we rationalized that a *Drosophila* model would be an ideal approach. *Drosophila* has proven to be an excellent organism to study *in vivo* function, interactions and modifiers of human disease genes. If MeCP2 can produce a phenotype in *Drosophila*, then large scale modifier screens can be performed to gain insight about the wild type protein and its *in vivo* interactions. Using the Gal4-UAS system, we have created eight independent lines which overexpress the full length human MeCP2. When these lines were crossed to flies carrying both elav-Gal4 (drives expression in neurons) and GMR-Gal4 (drives expression in the eye), all lines showed disorganized eyes. In addition, six of the lines demonstrated a variable crumpled wing phenotype and lethality. These stronger phenotypes correlated with higher levels of MeCP2 protein. To determine if these gain of function phenotypes require binding of the methyl-CpG-binding domain to *Drosophila* DNA or are due to interaction with the transcription repression domain, we are generating more transgenic strains using various alleles of MeCP2. Genetic screens are also currently being performed with the full length transgenic lines to identify modifiers and additional pathways in which MeCP2 may play a role. We identified one modifier that suppresses the eye- and wing-specific phenotypes. Further studies are ongoing to understand how this suppressor modulates MeCP2's function. Through investigation of MeCP2's molecular function in the *Drosophila* model system, we hope to gain insight into Rett syndrome pathogenesis.

**Targeted disruption of *Ube3a* alters the expression levels of *Ube3a-ATS* in *trans*.** M. Landers<sup>1</sup>, H. Glatt-Deeley<sup>1</sup>, J. Wagstaff<sup>2</sup>, M. Lalande<sup>1</sup>. 1) Dept of Genetics & Dev Biology, Univ of Connecticut Health Center, Farmington, CT 06030; 2) Dept of Pediatrics & Dept of Biochemistry & Molecular Genetics, University of Virginia Health System, Charlottesville, VA 22908-0733.

Angelman syndrome (AS) is a neurogenetic disorder characterized by severe mental retardation, 'puppet-like' ataxic gait with jerky arm movements, seizures, EEG abnormalities, hyperactivity and bouts of inappropriate laughter. Individuals with AS fail to inherit a normal maternal copy of chromosome 15q11-q13 usually (65-70% of all AS cases) as a result of de novo deletion of the maternal 15q11-q13 region. A small number (5-10%) of AS cases result from paternal uniparental disomy (UPD) for chromosome 15 or imprinting defects. Mutations of the gene encoding ubiquitin protein ligase E3A (UBE3A) are detected in AS cases not resulting from maternal deletion of 15q11-q13, paternal UPD or imprinting defect. UBE3A is transcribed predominantly from the maternal allele in brain but is expressed from both alleles in most other tissues. We have proposed that silencing of the paternal UBE3A allele is mediated by a brain-specific paternal noncoding antisense transcript (UBE3A-ATS). We show here that, in a mouse model of AS, maternal transmission of the *Ube3a* mutation leads to increased expression of the paternal *Ube3a-ATS*. Although it has been demonstrated in other cases of epigenetic regulation that antisense transcripts function in *cis* to silence target genes such as *Xist* and *Igf2r*, this is the first report to indicate that the putative target of antisense silencing can function to modulate the antisense transcript. Moreover, the observation that *Ube3a* modulates expression of *Ube3a-ATS* in *trans* is in contrast to the other examples of sense-antisense *cis* interactions. We are currently studying the potential mechanism associated with the *trans*-interaction and determining whether the expression of transcripts other than *Ube3a-ATS* are affected by mutation of *Ube3a*.

**Imprinting of the 5HT<sub>2A</sub> receptor in schizophrenia.** *M.S. Sodhi<sup>1,2</sup>, D. Ansari<sup>2</sup>, E. Sanders Bush<sup>1</sup>, P.J. Harrison<sup>2</sup>.* 1) Department of Pharmacology, Vanderbilt University, Nashville, TN, USA; 2) University Dept of Psychiatry, Warneford Hospital, Oxford UK.

The 5HT<sub>2A</sub> receptor (5HT<sub>2A</sub>R) is widely expressed in the human brain and evidence suggests that 5HT<sub>2A</sub>R may play a role in the aetiology and treatment of psychiatric disorders. Epigenetic factors such as imprinting, mRNA splicing and mRNA editing<sup>1</sup> can produce phenotypic variation, thus confounding the assumed relationship between genotype and phenotype. Imprinting of the 5HT<sub>2A</sub>R gene has been reported in 4 out of 18 individuals tested<sup>2</sup> and subsequently, partial imprinting of 5HT<sub>2A</sub>R has been detected in a larger sample<sup>3</sup>. Meta-analysis has demonstrated 5HT<sub>2A</sub>R allelic association with schizophrenia<sup>4,5</sup> but there are many studies contradicting these findings, which is common with association data. Therefore we have tested the hypothesis that imprinting of the 5HT<sub>2A</sub>R gene is polymorphic, and that this phenomenon explains the contradictory results of genetic association studies. The relative expression of the 5HT<sub>2A</sub>R T102 and C102 alleles was compared in post-mortem brain tissue in regions shown to be altered in schizophrenia, the dorsolateral prefrontal cortex (BA46) and hippocampus. 5HT<sub>2A</sub> T/C heterozygote individuals were identified by genotyping, revealing 9 schizophrenia cases and 8 controls, for which prefrontal cortex tissue was available and 6 cases and 6 controls with available hippocampal tissue. Results showed neither partial nor complete imprinting in any of the individuals tested. Moreover, no significant differences were detected between schizophrenia and control subjects in either BA46 (ANOVA F=0.44, ns.) or in hippocampus (ANOVA F=0.40, ns.) Therefore, imprinting of the 5HT<sub>2A</sub>R gene was not demonstrated in this study and if it does occur, it is probably too infrequent to alter the interpretation of genetic association data.

**Family History of Diabetes Mellitus (DM) and Turner Syndrome (TS).** *V.K. Bakalov, M.M. Cooley, C.A. Bondy.*  
Developmental Endocrinology , NICHD-NIH, Bethesda, MD.

Previous studies reported an increased prevalence of DM in parents of individuals with X-chromosomal aneuploidies such as Turners and Klinefelters syndromes, leading to the hypothesis that abnormal glucose metabolism may increase the risk of offspring having sex chromosomal aneuploidy (Nature 221;175, 1969). We have revisited this question recently in 58 women with Turner Syndrome participating in an NIH clinical study. They were in good general health, without DM and highly functional with mean age of 39.1 years (range 25-59). Most were Caucasian, with 2 Hispanics and 1 Asian in the group. We found that 14/58 or ~24% of the women with TS had a parent with diabetes. We interviewed a control group of age- and race-matched normal women (n=82, 40.1 yrs) and found 21% had a parent with DM, not significantly different from the TS group. In both groups, the parent with DM was maternal ~ 50% of the time, not supportive of a paternal preponderance noted in previous studies. Finally, the theoretical chance of a 40 yr old in the U.S. having a parent with DM may be estimated based upon CDC data on the prevalence of DM in the 65-74 yr old population, which is 16% for Caucasian men and 12.5 for women. Assuming that mother and father get DM independently, the predicted chance that either parent has DM, using the CDC figures above, is 26.5%. Taken together, these observations tend to refute the notion that DM or impaired glucose metabolism contributes to generation of offspring with X-chromosomal aneuploidy.

**X;autosome balanced translocations and premature ovarian failure: chromatin organization around the breakpoints.** *F. Rizzolio<sup>1</sup>, F. Rossetti<sup>1</sup>, C. Sala<sup>1</sup>, S. Bione<sup>2</sup>, T. Pramparo<sup>3</sup>, E. Rossi<sup>3</sup>, M. Goegan<sup>1</sup>, R. Ricotti<sup>2</sup>, L. DalPra<sup>4</sup>, A. Marozzi<sup>5</sup>, W. Vegetti<sup>5</sup>, F. Torricelli<sup>6</sup>, O. Zuffardi<sup>3</sup>, D. Toniolo<sup>1,2</sup>.* 1) DIBIT, San Raffaele Scientific Inst., Milano, Italy; 2) IGM-CNR, Pavia, Italy; 3) Dept of Human Genetics, University of Pavia, Italy; 4) Dept of Human Genetics, University of Milano Bicocca, Milano, Italy; 5) Dept of Human Genetics, University of Milano, Milano, Italy; 6) Dept of Human Genetics, University of Firenze, Firenze, Italy.

Monosomies and rearrangements of the X chromosome are often associated to premature ovarian failure (POF), but no molecular explanation has been found for the observation. Several independent studies have mapped the breakpoints of X; autosomes balanced translocations associated with POF and have confirmed the critical region for POF between Xq21 and Xq26. We have analyzed 22 such translocations. Our study seems to exclude that rearrangements of the critical region are responsible for alterations in meiotic pairing as a small number of chromosomal rearrangements found in normal females have been mapped in close vicinity and in between rearrangements causing POF. They have however also failed to definitively identify genes for ovulation along the X. Only three genes have been found interrupted but for only one statistical evidence indicates that it may be a risk factor for POF. Moreover, the majority of the breakpoints was found in intergenic regions or in very gene poor regions. An alternative explanation for the phenomenon is a position effect of the breakpoint on gene(s), X linked or more likely autosomal, found in the vicinity of the breakpoints. To this aim we are mapping the autosomal breakpoints in some of the patients and we are studying the pattern of expression of the genes as well as the organization of the chromatin in the DNA surrounding the breakpoints. We have evidence that, in a number of the cases studied to date, the autosomal breakpoint is in gene rich regions and of the presence of characteristic chromatin organization in the region of the breakpoints.

**A new diagnostic method for functional chromosome abnormalities based on RNA-FISH.** *T. Kubota*<sup>1, 2</sup>, *M. Matsumura*<sup>2</sup>, *S. Morita*<sup>3</sup>, *I. Hatada*<sup>3</sup>, *K. Okumura*<sup>4</sup>, *T. Sado*<sup>5</sup>, *H. Sasaki*<sup>5</sup>, *Y. Goto*<sup>2</sup>. 1) Environment Health/Epigenetic, Faculty Med, Yamanashi Univ, Yamanashi, Japan; 2) Birth Def/Mental Retard, Natl Inst Neuroscience, NCNP, Tokyo, Japan; 3) Gene Research Center, Gunma Univ, Maebashi, Japan; 4) Life Science, Faculty of Bioresources, Mie Univ, Tsu, Japan; 5) Human Genet, Natl Inst Genet, Mishima, Japan.

Functional, not structural, abnormalities of chromosomes can cause genetic diseases. However, conventional cytogenetic assays cannot detect these abnormalities such as uniparental disomy in imprinted diseases, although molecular methods have been used in some diagnostic laboratories for this purpose. Therefore, we have developed a new cytogenetic method based on RNA-FISH, in which gene expression can be visualized on chromosomes. In this study, we prepared slides according to a standard interphase DNA-FISH protocol, in which cells were fixed in 3:1 methanol-acetic acid (Carnoy's fixative), except that solutions used were treated with an RNase inhibitor and denature steps were eliminated. Using a 1.6-kb *XIST* gene cDNA probe, we detected clear *XIST*-RNA signals on the nuclei of fresh human peripheral lymphocytes and EB virus-transformed lymphoblast cells. When RNA-FISH was performed followed by DNA-FISH with an X-centromere DNA probe, a single *XIST*-RNA signal was detected adjacent to one of two X-centromere DNA signals in female cells. These results were consistent with normal X-chromosome inactivation. Furthermore, we could detect distinct *XIST*-RNA signals in the peripheral blood samples that had been drawn 3 days earlier when these samples had been collected in the tubes containing a culture medium. These findings suggest that RNA-FISH can be performed in standard cytogenetic laboratories, and imply that it could be used as an alternative diagnostic method for diseases with functional chromosome abnormalities, such as imprinted diseases and diseases with a failure of X-chromosome inactivation.

**Epigenetic marks of tissue-specific and imprinted regulation of the human NDN gene.** *M.L. Hanel<sup>1</sup>, J.C.Y. Lau<sup>1</sup>, I. Paradis<sup>2</sup>, R. Drouin<sup>2</sup>, R. Wevrick<sup>1</sup>*. 1) Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Unité de Recherche en Génétique Humaine et Moléculaire, Centre de Recherche, Hôpital Saint-François d'Assise, CHUQ, Québec, Québec, Canada.

Allele-specific DNA methylation, histone acetylation and chromatin structure are recognized as epigenetic characteristics of imprinted genes and imprinting centers (ICs) and are also used to regulate tissue-specific gene expression of imprinted and non-imprinted genes. Overlapping signals modulating allele-specific and tissue specific expression exist at imprinted loci. We have now examined the epigenetic characteristics of NDN, a target gene of the cis-acting Prader-Willi syndrome IC, using sodium bisulfite sequencing to analyze DNA methylation and in vivo DNA footprinting to identify sites of DNA-protein interaction and altered chromatin configuration. We found that NDN lies in a domain of paternal allele-specific histone hyperacetylation and paternal allele-specific DNaseI sensitivity, in *necdin*-active cells. We observed a bias towards maternal allele-specific DNA hypermethylation of the promoter CpG island of NDN, independent of tissue-specific transcriptional activity. Sites of modified chromatin mark the parental alleles in expressing *necdin*, and in cells in which NDN is not expressed. Our results suggest that a layering of epigenetic information controls allele- and tissue-specific gene expression.

**MECP2 mutations in 217 patients with RTT syndrome.** *I. Kondo<sup>1</sup>, I. Ishihara<sup>2</sup>, M. Miyamoto<sup>1</sup>, T. Matsuishi<sup>3</sup>, Y. Yamashita<sup>3</sup>, K. Kuwajima<sup>4</sup>, T. Iwai<sup>5</sup>, S. Endo<sup>5</sup>, M. Sone<sup>5</sup>, H. Yamagata<sup>1</sup>, Y. Tabara<sup>1</sup>, I. Ohmori<sup>6</sup>, E. Oka<sup>6</sup>.* 1) Dept. of Med. Genet., Ehime Univ. Sch. of Med., Ehime, Japan; 2) Faculty of Nursing, Univ. of Occupat. and Env. Health, Japan, Fukuoka, Japan; 3) Dept. of Pediatr. and Child Health, Kurume Univ. Sch. of Med., Fukuoka, Japan; 4) Dept. of Pediatr., Ibaraki Pref. Handicapped Children's Hosp., Ibaraki, Japan; 5) Dept. of Pediatr., National Kagawa Children's Hosp. Kagawa, Japan; 6) Dept. of Child Neurol., Okayama Univ. Sch. of Med., Okayama, Japan.

Numerous mutations in the methyl-CpG-binding protein 2 gene (MECP2) have been reported in patients with Rett syndrome (RTT) and X-linked mental retardation (XLMR). A wide spectrum of phenotypic variability in patients with MECP2 mutation has been considered to be correlated with the pattern of X-inactivation and mutation type and location in the gene. However, some mutations reported in patients with RTT and XLMR might be rare DNA variations. To study phenotype-genotype correlations in MECP2 mutations in RTT, a total 217 patients with classic and atypical RTT were studied for mutations of the MECP2 by using DGGE and direct sequencing. Patterns of X-inactivation were determined using PCR analysis of the androgen receptor gene. A total 61 different mutations were identified in 137 (63.1%) patients with RTT. The most common mutations is T158M, identified in 21(15.3%) patients, following by R168X (11.1%), R270X(8.9%), R255X (8.1%) and R294X (7.4%) in 138 patients with classic RTT. Two missense mutations, R133C (8.8%) and R306C (5.2%), were also common in our study, but clinical phenotypes in these patients were atypical RTT including preserved speech variant and milder form of classic RTT. Almost all patients showed random X inactivation pattern, suggesting clinical phenotypes did not depend on skewed X inactivation. Three missense mutations, P176R, A201V, and G232A, were identified in patients with RTT, but these mutations were also detected in healthy Japanese, indicating non-pathogenic variations in Japanese. Then, rare polymorphic variations should be carefully distinguished for the detection of distinct DNA mutations responsible for clinical conditions.

**Beckwith-Wiedemann syndrome and isolated hemihyperplasia following ART: Association with paternal UPD of**

**11p15.** C. Clericuzio<sup>1</sup>, C. Shuman<sup>2,3,4</sup>, L. Steele<sup>3,5</sup>, J. Milisa<sup>1</sup>, P. Ray<sup>3,4,5</sup>, R. Weksberg<sup>2,3,4,6</sup>. 1) Ped-Div Dysmorph/Clinical Gen, Univ New Mexico Sch Medicine, Albuquerque, NM; 2) Div Clin & Metab Genetics, Hosp Sick Children, Toronto; 3) Dept Mol & Med Genetics, Univ Toronto, Toronto; 4) Research Inst, Hosp Sick Children, Toronto; 5) Dept Paed Lab Med, Hosp Sick Children, Toronto; 6) Dept of Paed, Hosp Sick Children, Toronto.

Beckwith-Wiedemann syndrome (BWS) is a prototypical imprinting disorder, caused largely by epigenetic alterations of imprinted genes in the chromosomal region 11p15.5. Fifteen infants with BWS have been reported following conceptions with assisted reproductive technology (ART). Molecular genetic analysis of 7 of these cases has identified imprinting defects involving hypomethylation of KvDMR1. These data taken together with a report of 3 cases of ART-associated Angelman syndrome due to imprinting defects supports an association between ART and imprinting disorders. Here, we report 1 child with BWS and another with isolated hemihyperplasia (HH) who were conceived by ART (IVF) and who were found to have uniparental disomy (UPD) of chromosome 11p15.

Pt 1: A 36 week gestation male twin was diagnosed with BWS and later developed a Wilms tumor. Genetic studies on foreskin fibroblasts from the patient and parental blood DNA showed somatic mosaicism for paternal UPD of 11p15. Pt 2: A term female twin was diagnosed with right HH at 6 mo, following presentation with Stage 3 hepatoblastoma. Genetic studies of the patient's blood DNA revealed likely paternal UPD 11p15; parental samples have been requested for confirmation.

The finding of UPD 11p15 in these 2 cases suggests that errors in post-zygotic recombination that lead to UPD may be associated with ART. The development of tumors in these cases is not surprising, as BWS with UPD 11p15 is known to have a significant cancer risk. Moreover, the clinical spectrum associated with UPD 11p15 is now believed to encompass HH in addition to BWS. Hence, ART may be associated not only with epigenetic imprinting errors, but may also influence the risk of somatic mitotic recombination.

**Identification of acquired somatic mutations in the chromatin remodelling factor ATRX in the thalassemia myelodysplasia syndrome (ATMDS).** *R.J. Gibbons<sup>1</sup>, A. Pellagatti<sup>2</sup>, D. Garrick<sup>1</sup>, W.G. Wood<sup>1</sup>, N. Malik<sup>1</sup>, H. Ayyub<sup>1</sup>, C. Langford<sup>3</sup>, J. Boulwood<sup>2</sup>, J.S. Wainscoat<sup>2</sup>, D.R. Higgs<sup>1</sup>.* 1) MRC Molecular Haematology Unit, WIMM, John Radcliffe Hospital, Oxford, UK; 2) LRF Molecular Haematology Unit, NDCLS, John Radcliffe Hospital, Oxford, UK; 3) Sanger Centre, Hinxton, Cambridge, UK.

Thalassemia myelodysplasia syndrome (ATMDS) is a rare hematological disorder of clonal origin, associated with hypochromic microcytic anemia. Myeloid rather than lymphoid progenitors are affected. Therefore to obtain a population of cells affected by an acquired mutation in ATMDS, purified (>95%) granulocytes were isolated from the peripheral blood of a newly diagnosed ATMDS patient. Using microarray analysis to identify genes whose expression might be perturbed, ATRX expression was found to be reduced to 3% of normal. Sequence analysis of the ATRX gene revealed a G>A mutation in the canonical splice donor site (GT) of intron 1. This mutation, though present in granulocytes, was absent from buccal cells and a lymphoblastoid cell line from this patient. Using archival bone marrow samples, the ATRX gene was sequenced from cDNA in other ATMDS cases. A C>G (S79X) mutation in exon 4 was identified in one other patient. A mixture of mutant and wildtype sequence was detected in DNA from bone marrow and peripheral blood and this was confirmed by subcloning the two species.

Whereas the hematological phenotype in patients with inherited mutations affecting this gene (ATR-X syndrome) is subtle, in ATMDS the anemia is profound and is associated with the virtual absence of globin expression. To date, none of the constitutive ATRX mutations appears to be null. It seems likely, however, that mutations seen in ATMDS cases are true nulls and represent a tissue specific knockout. These findings cast new light on this pleiotropic co-factor which appears to be essential rather than merely a facilitator of globin gene expression.

**The parental origin of the normal X chromosome affects blood pressure in Turner Syndrome.** *C.A. Bondy<sup>1</sup>, M. Cooley<sup>1</sup>, V.K. Bakalov<sup>1</sup>, A.R. Zinn<sup>2</sup>.* 1) Developmental Endocrinology, National Institute of Child Health, NIH, Bethesda, MD; 2) McDermott Center and Dept. of Internal Medicine Univ. Texas Southwestern Medical School, Dallas, TX.

Turner syndrome (TS) arises from partial or complete X monosomy and is characterized by short stature, ovarian failure, distinct neurobehavioral traits, and cardiovascular problems including essential hypertension. Skuse et al. (1997) reported that individuals retaining the paternal X chromosome (Xp) had better psychosocial functioning than individuals whose normal X chromosome was maternal (Xm), suggesting that a gene or genes situated on the X-chromosome and involved in brain development might be subject to genomic imprinting. In the present study we investigated the possibility that the expression of certain cardiovascular features of TS might be dependent upon the parental source of the normal X. Thus we performed 24-hr ambulatory blood pressure (BP) monitoring on women with TS aged 18-42 participating in an NIH study of Turner syndrome. Women with coarctation of the aorta or any other known cause of hypertension, and those taking blood pressure lowering drugs were excluded. Genetic material was obtained from study subjects and parents under an IRB-approved protocol, and all participants signed informed consents. Conclusive data concerning parental origin of the single normal X-chromosome was obtained for 31 subjects; of these, 23 were maternal and 8 paternal in origin. Ages and body mass index were similar in the two groups. However, the mean arterial blood pressure (MABP) was significantly higher in the Xm group: Xm 892 vs. Xp 792 mm Hg ( $P=0.007$ ). An ANCOVA analysis assessing the impact of age and body mass in addition to X origin on MABP variation confirmed statistical significance for the elevation of blood pressure related to Xm ( $P=0.04$ ). These observations suggest that there is genomic imprinting of X-chromosome genes involved in BP regulation, with moderating effects active from paternal allele(s) or, alternatively, hypertensive effects from maternal allele(s).

**Identification and Functional Analysis of Human LIT1 (KCNQ1OT1) Promoter.** *M. Du<sup>1</sup>, W. Zhou<sup>1</sup>, L. Beatty<sup>1</sup>, R. Weksberg<sup>2</sup>, P. Sadowski<sup>1</sup>.* 1) Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, CANADA; 2) Division of Clinical and Metabolic Genetics, Hospital for sick Children, Toronto.

KvDMR is a differentially methylated region (DMR) in intron 10 of the KCNQ1 gene. KvDMR acts as an imprinting control center that regulates the expression of several adjacent imprinted genes in cis on human chromosome 11p15.5. It is also thought to contain the promoter for the LIT1 (KCNQ1OT1) transcript, a long, maternally imprinted, antisense transcript of the KCNQ1 gene. Loss of imprinting of LIT1 and loss of methylation of the KvDMR are seen in about 50% of patients with Beckwith-Wiedemann syndrome. Our previous investigations showed that the KvDMR also possesses strong silencer activity, thereby supporting a possible regulatory function in control of the imprinting gene cluster. In the present study, we have identified and functionally analyzed the human LIT1 promoter. We tested a series of DNA fragments from the KvDMR using a luciferase reporter assay in HEK293, HepG2 and Hela cells. A 581bp fragment exhibits very strong promoter activity while larger fragments with additional upstream and/or downstream sequences show reduced activities, suggesting possible upstream or downstream inhibitory elements. Interestingly, promoter activity has been detected in the reverse orientation from a tested subfragment of the 581bp putative promoter, indicating the possibility of sense transcripts originating in intron 10 of the KCNQ1 gene. The putative LIT1 promoter lacks a TATA-box but contains 4 CAAT-box and 4 SP1 sites as well as other potential binding sites for transcription factors. When the putative promoter fragments were methylated in vitro before transfection, the luciferase activities in the transfectants were markedly reduced. This observation supports the hypothesis that the imprinting of the LIT1 transcript is due to methylation in the maternal LIT1 promoter. We are determining the initiation site of the LIT1 transcript and the CpG residues in the minimal promoter fragment that are critical for LIT1 promoter activity. Our study suggests that functional analysis of imprinted promoters will provide insight into the mechanisms of genomic imprinting and related diseases.

**Heritability and identification of quantitative traits loci in eye morphometry: evidence of imprinting.** *G. Biino<sup>1</sup>, M.A. Palmas<sup>2</sup>, C. Corona<sup>2</sup>, R. Sulis<sup>2</sup>, I. Zucca<sup>3</sup>, M. Fossarello<sup>3</sup>, A. Serra<sup>3</sup>, M. Pirastu<sup>1</sup>*. 1) Institute of Population Genetics, CNR - Shardna Life Sciences, Alghero, Italy; 2) Shardna Life Sciences, Cagliari, Italy; 3) Eye Clinic, University of Cagliari, Cagliari, Italy.

Our aim is to assess the heritability of biometric ocular traits and to perform a genome wide scan to identify the associated QTLs. This study was conducted in Talana, an isolated village in eastern Sardinia whose demographic history exhibits ancient origin, low number of founders, high inbreeding and genealogical trees reconstructable from 1640. Volunteers from Talana (N=789, aged 5-89 years) have undergone a complete eye examination including ocular biometry: axial length (AL), anterior chamber depth (ACD) and corneal curvature (CC) were measured. Heritability analysis was performed by means of two methods: parent-offspring regression models on 201 nuclear families and variance component models on 3-4 generations pedigrees. Two and multipoint linkage analysis were performed using 654 microsatellites. The heritability estimates obtained by means of parent offspring regressions and variance components were consistent and significant ( $p < 0.05$ ). CC (mean value 7.67 0.25) had an heritability estimate of 62%. AL (mean value 23.49 0.91) and ACD (mean value 3.45 0.34) were found to have significantly different variances ( $P < 0.01$ ) in males and females so that heritability had to be calculated separately for each sex in the parent offspring regression models. AL had an estimated heritability in females of 31% and in males of 60%, whereas ACD had an estimated heritability in females of 47% and of 44% in males. Suggestive evidences of linkage in multipoint analysis were identified on chromosomes 6, 7, 14 and 15 for ACD, on chromosomes 6 and 12 for CC and on chromosome 2 for AL. To further examine the observed differences in parental transmission we performed Haseman Elston regressions, extended to accommodate parent of origin effects, on a larger sample of 231 nuclear families for markers with evidence of linkage. Preliminary results for AL suggest a preferentially paternal expression. Subsequent findings on all morphometric traits will be discussed.

**A randomized therapeutic trial in Angelman syndrome using betaine and folic acid.** C.A. Bacino, S. Peters, J. Goddard-Finegold, O. Smith, W. O'Brien, N. Madduri, D. Glaze, L. Shinawi, A.L. Beaudet. Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Angelman syndrome (AS) is caused by maternal deficiency of UBE3A which encodes E6-AP ubiquitin-protein ligase. UBE3A is subject to genomic imprinting, and expression from the maternal chromosome is essential to prevent AS. The report of MTHFR deficiency in a patient with a typical AS phenotype in the absence of a known molecular defect causing AS raised the possibility that decreased folate effect might silence the maternal allele for UBE3A. This led to the reciprocal hypothesis that high folate effect might promote leaky expression of the paternal allele for UBE3A providing a therapeutic benefit in AS. A clinical trial was developed to test if high intake of folic acid and betaine might provide clinical benefit in AS. Twenty patients with AS were enrolled in the study for 1 year. The subjects were randomized with half receiving drugs and the other half placebo. A nutritional evaluation and hematologic and biochemical studies were performed. The study included developmental evaluations performed by the Bayley Scales of Infant Development and by the Preschool Language Scale-3 to assess expressive and receptive language skills. In addition the Vineland Adaptive Behavior Scales, Interview Edition was done to assess parent reports of adaptive behavior. Of the 20 children enrolled in the study, 8 met criteria for the diagnosis of autism according to the ADI-R and the ADOS-G. When medication and placebo groups were compared, there were no significant differences between the two groups. When the autistic and nonautistic patients were analyzed separately, there was a trend of improvement in some developmental parameters in the nonautistic medication group for the Preschool Language Scales Composite scores as well as Expressive Communication scores. Although not statistically significant, Bayley Mental Scale scores were higher in the nonautistic medication group compared to the nonautistic placebo group. This may indicate a beneficial effect of folic acid and betaine in a subset AS children. Further studies are underway to increase sample size and assess whether this trend persists.

**The use of Me-RDA to identify novel DMRs on mouse Chr 6 and 11.** *D. Monk*<sup>1</sup>, *L. Bentley*<sup>1</sup>, *C. Beechey*<sup>2</sup>, *R. Smith*<sup>3</sup>, *P. Arnaud*<sup>3</sup>, *J. Peters*<sup>2</sup>, *M. Preece*<sup>4</sup>, *P. Stanier*<sup>1</sup>, *G. Kelsey*<sup>3</sup>, *G. Moore*<sup>1</sup>. 1) IRDB, Imperial College, London, UK; 2) MRC Mammalian Genetics Unit, Harwell, UK; 3) Developmental Genetics Programme, The Babraham Institute, Cambridge, UK; 4) Institute of Child Health, UCL, London, UK.

Silver-Russell syndrome is characterised by pre- and postnatal growth restriction. Maternal uniparental disomy for Chr 7 (mUPD7) has been demonstrated in ~10% of cases, suggesting a role for genomic imprinting in its causation. Two candidate gene regions have been mapped on human Chr 7. The first, 7p11.2-p13 encompass the imprinted *GRB10* gene, whereas the second maps to 7q31-qter. This second region contains the imprinted gene cluster of *MEST*, *MEST1T1*, *CIT1/COPG2IT1* and *CPA4*. No coding or epigenetic mutations have been found for these genes in any SRS patients to date, suggesting that there are other imprinted genes which map to human Chr 7.

Approximately 50% of human Chr 7 maps to regions of the mouse genome that presents with imprinted phenotypes when uniparentally inherited. Interestingly both candidate regions on human Chr 7 map to imprinted regions in the mouse that show growth restriction when maternally duplicated (MatDp). Proximal mouse Chr 11 is orthologous to 7p11.2-p13, whereas the proximal mouse Chr 6 is orthologous to 7q32-qter.

In order to identify novel imprinted candidate genes responsible for the growth phenotypes, we have screened for unmethylated fragments from differentially methylated regions (DMRs) that are associated with imprinted genes. Methylation-sensitive representational difference analysis (Me-RDA) was performed on mice with uniparental duplication proximal to the T40(11:7)Ad breakpoint on mouse Chr11 and separately on distal 6 to the T(4:6)77H breakpoint on mouse Chr 6. Preliminary analysis has demonstrated recovery of *U2af-rs1* and *Grb10* confirming the successful application of the technique. We report here the methylation status of candidate loci isolated from these two screens.

**Investigation of parent of origin effects for Autism susceptibility loci on chromosomes 2, 7 and 15.** *J. Jaworski<sup>1</sup>, A.E. Ashley-Koch<sup>1</sup>, M. Menold<sup>1</sup>, R.K. Abramson<sup>2</sup>, G.R. DeLong<sup>1</sup>, H.H. Wright<sup>2</sup>, M.L. Cuccaro<sup>1</sup>, J.R. Gilbert<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Duke University Medical Center, Durham, NC; 2) University of South Carolina, Columbia, SC.

Genomic screen and cytogenetic data implicate loci on chromosomes (Ch) 2, 7, and 15 in susceptibility for autistic disorder (AD). We have previously shown the GABRB3 locus on Ch 15q11-q13 to be linked to AD in a subset of 23 families with a high degree of insistence on sameness as identified from Ordered Subset Analysis (OSA). To determine whether these loci exhibit signs of parent of origin effects, we examined the 23 OSA and an additional 187 multiplex AD families. Using ASPEX to examine parental-specific IBD sharing in affected siblings, we saw excess paternal sharing for three of our peak markers on Ch 2: D2S1776 ( $p=0.03$ ), D2S2261 ( $p=0.02$ ), and D2S425 ( $p=0.04$ ). Excess paternal sharing was also observed on Ch 7, with D7S2527 ( $p=0.02$ ), D7S496 ( $p=0.05$ ), D7S495 ( $p=0.03$ ), and D7S640 ( $p=0.02$ ), as we had previously reported. On Ch 15, in the OSA families, GABRB3 SNPs in intron 6 ( $p=0.03$ ) and the promoter region ( $p=0.01$ ) showed evidence for excess maternal sharing. GENEHUNTER-IMPRINTING was used to maximize the heterogeneity LOD score (hetlod) over five heterozygote penetrance models; dominant, co-dominant, recessive, paternal imprinting and maternal imprinting. For Ch 2, D2S1776 had a peak 2pt hetlod of 1.8, maximizing under the maternal imprinting model. For Ch 7, the peak marker was D7S496, which maximized under the dominant model (hetlod=1.12). For Ch 15, in the OSA subset, the maximum hetlod was observed with the GABRB3 promoter SNP, under the paternal imprinting model (hetlod=1.65). These results are intriguing, but do not provide definitive evidence for parent of origin effects in AD. Due to the complex mode of inheritance, it is likely that a much larger sample size will be needed for more conclusive evidence to emerge.

**Isolation of a mouse snoRNA host gene from the *Snurf-Snrpn* locus and association with imprint establishment.**

*K. Mapendano*<sup>1</sup>, *T. Kishino*<sup>1</sup>, *N. Niikawa*<sup>1</sup>, *R.D. Nicholls*<sup>2</sup>, *T. Ohta*<sup>1</sup>. 1) Department of Human Genetics, Nagasaki University, Nagasaki, Japan; 2) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA.

Prader-Willi (PWS) and Angelman syndromes are neurobehavioral disorders caused by loss of function of paternally or maternally expressed genes, respectively, at 15q11-q13. Five families of C/D box snoRNAs have been mapped between *SNURF-SNRPN* and *UBE3A* in this chromosome region. These snoRNAs are expressed predominantly from the brain and only from the paternal allele. Previous studies in mouse and human suggested that the snoRNA genes may be involved in the PWS phenotype. The human snoRNA host gene was previously identified as a large transcript extending from *SNRPN* 3'-alternatively spliced exons into *UBE3A*. This transcript was assumed to start from the *SNURF-SNRPN* promoter and has been proposed to control *UBE3A* imprinting in *cis* as an antisense transcript, although the latter may represent extended transcripts in the absence of paternal *UBE3A* transcription due to a *trans*-mechanism. To elucidate the mechanism associated with snoRNA expression, we have isolated the mouse snoRNAs and the host gene. Only four of the five human classes of snoRNA were found conserved in mouse. We then performed 5'- or 3'-RACE and nested RT-PCR with mouse *IC*, *Snurf-Snrpn* and *Ipw* primers. 5' RACE and nested RT-PCR showed that the mouse *IC* transcripts, *Snurf-Snrpn* and *Ipw* are continuous transcripts. RT-PCR and northern analyses using multiple tissues showed that these *IC-IPw* transcripts and the snoRNAs are expressed in mouse brain and ovary. High expression of the snoRNA host gene from the ovary suggests that the snoRNAs may be required in oocyte function. Further, the germline-specific snoRNA host gene expression suggests this derives from the 5' *IC* promoters and not the 3' *Snurf-Snrpn* promoter, based on a differential expression of these promoters in female and male germ cells. The different chromatin structure from the *IC* to *Ube3a* in female and male germlines as a consequence of the differential expression of the *IC-Snurf-Snrpn*-snoRNA host gene may play a role in establishment of the parental imprint in this region.

**The methylation status of imprinted genes in murine and human MTHFR deficiency.** *M. Shinawi, V.R. Sutton, A. Beaudet.* Molecular Human Genetics T617 , Baylor College of Medicine , Houston , TX.

MTHFR plays an important role in folate metabolism by catalyzing the reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate. Methionine is the immediate precursor of S-adenosyl-L-methionine, the major intracellular methyl donor for methylation reactions. Recently, it has been shown that *Mthfr* deficient mice have DNA hypomethylation and the C677T mutation in human *MTHFR* affects genomic DNA methylation. We hypothesized that MTHFR may be required for the regulation of differentially methylated regions (DMRs) of imprinted genes and a deficiency may disrupt this mechanism. We checked the differential methylation of 4 different imprinted genes (*Snrpn*, *Necdin*, *H19*, and *Rasgrf1*) in different tissues of the *Mthfr*<sup>-/-</sup> mice. We also examined the methylation of *SNRPN* and *UBE3A* in the lymphoblasts and fibroblasts from 2 children with MTHFR deficiency who have presented with severe psychomotor retardation and dysmorphic features. Furthermore, the DMR of *Snrpn* in *Mthfr*<sup>-/-</sup> mice was sequenced after bisulfite treatment to precisely evaluate the methylation of the different CpGs at this region compared to *Mthfr*<sup>+/-</sup> and wild type mice. The methylation pattern of the DMRs was examined by Southern blot analysis after double digestion with methylation sensitive enzymes, and no change was demonstrated in the methylation pattern of these imprinted genes in the different tissues of the *Mthfr*<sup>-/-</sup> mice compared to wild type and *Mthfr*<sup>+/-</sup> mice. Bisulfite sequencing of the *Snrpn* DMR didn't show hypomethylation in the homozygous and heterozygous *Mthfr* deficient mice. Treating fibroblast cell lines from normal controls with different concentrations of folate did not change the methylation status of the 3'-DMR of *UBE3A*, but results from MTHFR deficient patients and cell lines treated with other metabolites and drugs are still pending. In conclusion, our results do not support an essential role for MTHFR in the methylation of the regulatory elements of imprinted genes in mice and human. These results may also suggest an alternative pathway for methylation of these regions or their sparing from the general hypomethylation that was observed in MTHFR-deficient humans and mice.

**Identification and analysis of *cis*-acting elements associated with the PWS-IC.** *S. Rodriguez-Jato*<sup>1</sup>, *D.J. Driscoll*<sup>1</sup>, *R.D. Nicholls*<sup>2</sup>, *T.P. Yang*<sup>1</sup>. 1) Univ of Florida College of Medicine, Gainesville, FL; 2) Univ of Pennsylvania, Philadelphia, PA.

The Prader-Willi and Angelman syndrome (PWS/AS) region includes a cluster of imprinted genes that are coordinately regulated by an imprinting center (IC) that spans the 5' region of the *SNURF-SNRPN* locus. The IC has a bipartite structure where the PWS-IC is postulated to maintain the paternal imprint in early embryogenesis, while the AS-IC is responsible for maternal imprint establishment. The *SNURF-SNRPN* promoter is implicated in PWS-IC function, while both an uncharacterized genetic element and alternative upstream *SNURF-SNRPN* promoters have been implicated in the function of the AS-IC. The PWS-IC contains major nuclease hypersensitive sites (HS) associated with the *SNURF-SNRPN* promoter region and 1st intron (adjacent to the IC), both specific to the paternal allele. *In vivo* footprint analysis of the promoter region has identified multiple factor binding sites, 4 specific to the paternal allele and 1 specific to the maternal allele. The paternal sites have been shown previously by *in vitro* studies to bind the NRF-1 and CTCF transcription factors. We have now found that some, but not all, of these sites affect promoter function in transient expression assays. Further, we have identified a novel position-dependent and orientation-independent activator associated with the intronic HS. This enhancer element preferentially activates the *SNURF-SNRPN* promoter relative to the *UBE3A* or *MKRN3* promoters. It appears to be a complex regulatory unit from which we have mapped a subregion that sustains high levels of *SNURF-SNRPN* promoter activity. Sequence comparison of this intronic activator with the homologous region in mouse identified several highly conserved sites within the subregion, including potential binding sites for NRF-1, and for YY1, a transcription factor implicated in imprinted expression of the *Peg3* gene. We are investigating the effect of this intronic activator on upstream *SNURF-SNRPN* promoters. This activator, together with *cis*-acting elements of the *SNURF-SNRPN* 5' region and upstream promoters, respectively, may play a role in the function of the PWS-IC and the AS-IC.

**An Approach to the Epigenetics of a Complex Trait.** *H.T. Bjornsson*<sup>1,2</sup>, *A. Aina*<sup>3</sup>, *F. Witter*<sup>3</sup>, *A.P. Feinberg*<sup>1,2</sup>. 1) Program in Human Genetics, Johns Hopkins University, Baltimore, MD; 2) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Obstetrics and Gynecology, Johns Hopkins University School of Medicine.

Deciphering the genetic contribution of complex traits has turned out to be more of a challenge than previously thought. This might be because the epigenetic contribution has widely been disregarded in studies. We have selected birth weight as a well-defined candidate complex trait to define how epigenetics may contribute to complex traits. Birth weight was chosen because studies in mice show that imprinting plays a significant role in birth weight determination, and several human types of uniparental disomy suggest the same is true for humans. Indeed, the Haig Hypothesis states that genomic imprinting arose as an evolutionary mechanism to deal with the natural conflict between maternal and paternal genomes in prenatal growth. It predicts that birth weight is determined in part by the expression of imprinted genes.

As a first test of this idea, we have developed quantitative allele-specific expression ratio assays for a panel of imprinted genes including IGF2, MEG3, PEG3, and PLAGL1. We are analyzing placental, white cell and umbilical samples from human newborns, as well as neonatal weight, gestational age, and relevant maternal factors such as gestational diabetes. At this writing (06/03), we do not have data on the relationship between birth weight and allele-specific expression. A greater understanding of human birth weight determination may as well be important because of the link between several adult onset diseases and low birth weight.

**Evaluation of *MLH1* gene expression following reactivating treatments in colorectal cancer cell lines with hypermethylated *MLH1* promoter.** *M. Genuardi*<sup>1</sup>, *I. Zito*<sup>2</sup>, *E. Lucci-Cordisco*<sup>2</sup>, *L. Boccuto*<sup>2</sup>, *G. Chichierchia*<sup>2</sup>, *G. Neri*<sup>2</sup>. 1) Med Gen, Clin Pathophysiology, Univ Florence, Florence, Italy; 2) Medical Genetics, Catholic University School of Medicine, Rome, Italy.

Promoter hypermethylation is one of the leading mechanisms accounting for gene inactivation in human cancer. This holds true also for the human mismatch repair gene *MLH1*, which shows promoter hypemethylation in about 10-15% of sporadic colorectal cancers (CRCs). Our purpose was to establish the level of *MLH1* reactivation in HCA7 and RKO cell lines (both MMR-deficient due to *MLH1* promoter hypermethylation), following treatments with the demethylating agent 5-azadC alone and in combination with the histone deacetylase inhibitors (HDACIs) Na-butyrate (BA) and 4-phenyl-butyrate (PBA), and the probable histone acetylator acetyl-L-carnitine (ALC). By means of Real Time-PCR and Western Blotting we observed that 0.1 and 0.2 M 5-azadC resulted in reactivation of *MLH1* transcription within 3 days in HCA7 and RKO cells, respectively. Expression levels increased with increasing concentrations of the substance and with time of exposure and persisted for at least 2 weeks following treatment suspension. Combined 5-azadC/BA treatment resulted in a synergistic effect on *MLH1* expression only with low BA doses, whilst preliminary results with 5-azadC/PBA showed a synergistic effect with a maximum of *MLH1* expression after 16 h. The 5-azadC/ALC experiments gave little or no extra reactivation as compared to treatment with 5-azadC only. These data confirm that *MLH1* silencing can be overcome following treatments with demethylating agents and enhanced following combined treatments with HDACIs. They also show that the magnitude of this effect depends on dosage of each agent, especially for combined treatments, on time of exposure, and on the type of cell line. Such reactivated cells may now respond to drugs that are normally tolerated by MMR-deficient cell lines (e.g. alkylating agents). This work was supported by AIRC and MIUR grants to G. N. and M.G., respectively.

**Regulation of neural gene expression in the CNS by DNA methylation.** *S. Fouse, G. Fan.* Human Genetics, UCLA School of Medicine, Los Angeles, CA.

DNA cytosine methylation plays an important role in regulating gene expression during mammalian development. CpG methylation in the promoter region leads to the suppression of gene transcription whereas unmethylated promoter is usually correlated with open chromatin structure allowing for active gene transcription. We have previously generated a line of transgenic mice that exhibit significant DNA demethylation in the entire central nervous system (CNS) due to conditional deletion of the maintenance DNA methyltransferase I gene (*J. Neurosci.* 21, 788, 2001). To determine whether a reduction in DNA methylation affects gene expression in the CNS, we used DNA microarrays to compare gene expression profiles between control and demethylated CNS samples. Significant changes of mRNA levels were observed in approximately 45 genes (0.71%) in the mutant CNS at the embryonic (E) day 18. Among the known genes are signaling molecules and enzymes, cell death-related genes, and synaptic proteins. Surprisingly, ten up-regulated genes belong to class I MHC molecules, which are normally detected at very low levels in the CNS compared to other somatic tissues. We have confirmed the array results with Northern blots and RT-PCR analysis. Our results indicated that DNA methylation does suppress expression of a subset of genes in the CNS during development. We are currently addressing the molecular mechanism by which DNA methylation inhibits expression of MHC I molecules and other neural genes in the CNS.

**SLIT2 promoter methylation analysis in neuroblastoma, Wilms' tumours and renal cell carcinoma.** *D. Astuti<sup>1</sup>, N.F. da Silva<sup>2</sup>, A. Dallol<sup>1</sup>, D. Gentle<sup>2</sup>, T. Martinsson<sup>3</sup>, P. Kogner<sup>4</sup>, R. Grundy<sup>1, 5</sup>, T. Kishida<sup>6</sup>, M. Yao<sup>6</sup>, F. Latif<sup>1, 2</sup>, E.R. Maher<sup>1, 2</sup>.* 1) Section of Medical and Molecular Genetics, Department of Paediatrics and Child Health, University of Birmingham, The Medical School, Edgbaston, Birmingham, B15 2TT, UK; 2) Cancer Research UK Renal Molecular Oncology Research Group, University of Birmingham, The Medical School, Edgbaston, Birmingham, B15 2TT, UK; 3) Department of Clinical Genetics, Gothenburg University, Sahlgrenska University Hospital/Ostra, S-416 85 Gothenburg, Sweden; 4) Childhood Cancer Research Unit, Department of Women and Child Health, Karolinska Institute, Karolinska Hospital, S-171 76 Stockholm, Sweden; 5) Department of Paediatric Oncology, Birmingham Childrens Hospital, UK; 6) Yokohama City University School of Medicine, Yokohama, Japan.

The 3p21.3 RASSF1A tumour suppressor gene (TSG) provides a paradigm for TSGs inactivated by promoter methylation rather than somatic mutations. Recently we identified frequent promoter methylation without somatic mutations of SLIT2 in lung and breast cancers. These findings prompted us to investigate SLIT2 methylation in these three human cancers. We analysed 49 neuroblastoma (NB), 37 Wilms tumours and 48 RCC and detected SLIT2 promoter methylation in 29% of neuroblastoma, 38% of Wilms tumours and 25% of RCC. Previously we had demonstrated frequent RASSF1A methylation in the same tumour series and frequent CASP8 methylation in the neuroblastoma and Wilms tumour samples. However there was no significant association between SLIT2 promoter methylation and RASSF1A or CASP8 methylation in neuroblastoma and RCC. In Wilms tumour there was a trend for a negative association between RASSF1A and SLIT2 methylation although this did not reach statistical significance. No associations were detected between SLIT2 promoter methylation and specific clinicopathological features in the tumours analysed. These findings implicate SLIT2 promoter methylation in the pathogenesis of both paediatric and adult cancers and suggest that further investigations of SLIT2 in other tumour types should be pursued.

**Epigenetic inactivation of SLIT genes in human cancers and in sputum from lung cancer patients and ductal carcinoma in situ from breast cancer patients.** *R.E. DICKINSON, A. DALLOL, E.R. MAHER, F. LATIF.* Department of Paediatrics and child health, Section of Medical and Molecular Genetics, University of Birmingham, Birmingham, MIDLANDS, U.K.

In *Drosophila* the Slit gene product, a secreted glycoprotein acts as a midline repellent to guide axonal development during embryogenesis. Three human Slit gene orthologues have been characterized and recently we reported frequent promoter region hypermethylation and transcriptional silencing of SLIT2 in lung, breast, colorectal and glioma cell lines and primary tumors. Furthermore, re-expression of SLIT2 inhibited the growth of cancer cell lines so that SLIT2 appears to function as a novel tumor suppressor gene. We analyzed the 5' CpG island of the SLIT3 gene in tumor cell lines and primary tumors for hypermethylation. SLIT3 was found to be methylated in breast, lung, colorectal and in glioma tumor cell lines. Hypermethylation of SLIT3 in tumor cell lines correlated with loss of gene expression and treatment with a demethylating agent reactivated SLIT3 gene expression. In primary breast tumors SLIT3 was methylated in 16% of primary breast tumors, 35% of gliomas and in 38% of colorectal tumors. Direct sequencing of bisulfite modified DNA from methylated tumor cell lines and primary tumors demonstrated that majority of the CpG sites analyzed were heavily methylated. To determine the extent of SLIT2 promoter hypermethylation in early breast tumorigenesis, we analyzed ductal breast carcinoma and corresponding ductal carcinoma in situ (DCIS) from breast cancer patients and DCIS without invasive cancer. 8/12 (67%) tumors were methylated, there was 100% concordance between tumor and corresponding DCIS methylation. Furthermore 3 of 10 DCIS without invasive cancer also underwent SLIT2 methylation. We also analyzed sputum and bronchial lavage samples from lung cancer patients for SLIT2 promoter region hypermethylation. SLIT2 methylation was demonstrated in 67% of exfoliative material from lung cancer patients. These findings further implicate the slit-roundabout-semaphorin gene family in tumor development and suggests a novel, and common underlying theme for these molecules in tumor suppression.

**DNA methylation inhibits STAT signaling and prevents precocious astrogliogenesis during CNS development.** *G. Fan*<sup>1</sup>, *K. Martinowich*<sup>2</sup>, *M. Chin*<sup>1</sup>, *F. He*<sup>2</sup>, *S. Fouse*<sup>1</sup>, *K. Shuai*<sup>3</sup>, *Y.E. Sun*<sup>2</sup>. 1) Human Genetics, UCLA School of Medicine, Los Angeles, CA; 2) Psychiatry and Pharmacology, UCLA School of Medicine, Los Angeles, CA; 3) Medicine and Biological Chemistry, UCLA School of Medicine, Los Angeles, CA.

DNA methylation has been implicated in regulating gene transcription, genomic imprinting, and X-inactivation in mammalian development. We report here that DNA methylation plays a critical role in controlling the timing of glial cell differentiation in the central nervous system (CNS). A number of astroglial differentiation-related genes are methylated and silenced during the neurogenic period in the mouse CNS but become demethylated and activated when CNS progenitors gain competence for gliogenesis. To examine if such a demethylation is causally linked to the initiation of gliogenesis, we used the cre/loxP system to achieve conditional gene deletion of DNA methyltransferase I (Dnmt1) and accelerated demethylation in CNS neural progenitor cells (NPC) (Fan, et al. *J. Neurosci.* 21, 788, 2001). DNA hypomethylation in NPCs enhanced activation of the astroglial JAK-STAT pathway and caused precocious astroglial differentiation throughout the embryonic CNS in vivo and in vitro. Demethylation in the promoters of the STAT1 gene and astroglial marker genes is accompanied by the dissociation of transcription repressor proteins such as methyl-CpG binding protein MeCP2 and a shift of the chromatin structure from a silent state into a permissive configuration for active gene transcription. Our data demonstrates that DNA methylation is an important mechanism to control the activation of JAK/STAT signals and to regulate the onset of cell-type specification during mammalian CNS development.

**De novo DNA methylation in neuronal and glial differentiation.** *M.H. Chin<sup>1</sup>, H. Wu<sup>2</sup>, S. Yuan<sup>2</sup>, E. Li<sup>3</sup>, Y.E. Sun<sup>2</sup>, G. Fan<sup>1</sup>.* 1) Human Genetics, UCLA School of Medicine, Los Angeles, CA; 2) Psychiatry and Pharmacology, UCLA School of Medicine, LA, CA; 3) Cardiovascular Research Center, MGH East, Harvard Medical School, Charlestown, MA.

DNA cytosine methylation in vertebrates influences many cellular events including gene transcription, genomic imprinting, and genome stability. The specific methylation pattern in a differentiated somatic cell is established through dynamic interplays of demethylation and de novo methylation during embryogenesis. We have previously demonstrated that proper DNA methylation is critically important for maintaining vital CNS functions and neuronal survival postnatally (Fan, et al., *J. Neurosci.* 21:788, 2001). However, whether de novo DNA methylation is important for CNS development has not been investigated. To explore the role of de novo DNA methylation in neural development, we compared the timing of neuronal and glial differentiation from wild-type and mutant embryonic stem (ES) cells that are deficient of de novo DNA methyltransferases Dnmt3a and Dnmt3b (Okano, et al., *Cell* 99:247, 1999). We established an in vitro differentiation protocol by which ES cells can be induced to differentiate into neural precursor cells (NPCs) that sequentially give rise to neurons and astroglial cells at different passages. When compared to the same passage of wild-type NPCs, Dnmt3a<sup>-/-</sup> and 3b<sup>-/-</sup> NPCs precociously gave rise to neurons and astroglial cells in early and late passages, respectively. Promoter reporter assays showed that neuron-specific (NeuroD) and glial lineage promoters (GFAP) are more active in Dnmt3a<sup>-/-</sup> and 3b<sup>-/-</sup> NPCs than that in control NPCs, suggesting that neurogenic and gliogenic program are prematurely activated in Dnmt3a<sup>-/-</sup> and 3b<sup>-/-</sup> NPCs. How de novo DNA methylation influences neurogenic and gliogenic program in differentiating NPCs will be further discussed.\*The first two authors made equal contribution to this abstract.

**BRCA1 and epigenetics in breast cancer.** *V. Birgisdottir<sup>1,2</sup>, S.K. Bodvarsdottir<sup>1,2</sup>, H. Hilmarsdottir<sup>1</sup>, J.G. Jonasson<sup>1,2</sup>, J.E. Eyfjord<sup>1,2</sup>.* 1) Icelandic Cancer Society; 2) University of Iceland, Reykjavik, Iceland.

Alterations in the BRCA1 gene have been linked to risk of breast cancer. Disfunction of the gene can be traced to germline mutations along with loss of the normal gene in tumor tissue. BRCA1 germline mutations are rare in Iceland; one such mutation has been found that explains <1% of breast cancer cases. The aim of this study was to assess whether epigenetic events, i.e. methylation of the BRCA1 promoter, might be of importance in sporadic tumors. Methylation of the BRCA1 promoter, which leads to loss of gene expression, was assessed in 130 sporadic breast cancer cases, using Methylation Specific PCR and gel electrophoresis. All tumors that showed methylation were analysed for allelic imbalance (AI) at BRCA1 and BRCA2 loci. AI was detected by amplifying microsatellite regions of normal/tumor DNA pairs and comparing peak allele sizes in an ALFexpress sequencer using Fragment analyzer software and also by FISH (fluorescent in situ hybridization). It has been suggested that mutation in the p53 gene is a necessary step in tumorigenesis in BRCA1 germline mutation carriers. Second aim was to search for p53 mutations in tumor samples that show methylation at the BRCA1 promoter. P53 analysis was carried out by DNA sequencing. Methylation at the BRCA1 promoter was found in 7.7% (10/130) of tumors tested supporting the hypothesis that methylation plays a role in functional inactivation of BRCA1 in sporadic tumors. 7/10 methylated tumors show clear AI and 2 tumors show borderline AI at the BRCA1 locus. These will be analysed further using FISH. AI at the BRCA2 locus was detected in 4/10 tumors and all those also show AI at the BRCA1 locus. These results show that the normal BRCA1 gene is frequently lost in tumors that have BRCA1 promoter methylation. Loss of both BRCA genes in 40% of methylated tumors indicates that both genes may be induced by, or function in, overlapping pathways in breast tumorigenesis. 40% of the methylated tumors carry p53 mutation. Our findings support the hypothesis that increased instability due to inactivation of caretaker genes such as BRCA1 leads to inactivation of important checkpoint genes like p53, which directly regulate tumor growth.

**Demethylation of the murine myogenin promoter is closely associated with transcriptional activation during development.** *T. Haines, P. Ainsworth, S-P. Yee, P. Bialek, D. Rodenhiser.* London Regional Cancer Centre and The University of Western Ontario, London, ON, Canada.

In many tissue-specific genes promoter methylation is correlated with transcriptional activity. Transcriptional activation is associated with hypomethylation while transcriptional repression is linked to promoter hypermethylation. We have examined the relationship between promoter methylation and transcriptional activity for the muscle specific gene myogenin. Using sodium bisulfite sequencing we have generated a developmental map of cytosine methylation for the murine minimal myogenin promoter from gamete to adult. Demethylation of the myogenin promoter is associated with transcriptional activation during development. At 7.5 days post fertilization the myogenin promoter is heavily methylated prior to transcriptional activation of myogenin around 8.5 days. Complete demethylation of the promoter is found in the developing somites of the 10.5 day embryo concurrent with the expression of myogenin. We found minimal methylation of the myogenin promoter in both gametes and the 2-cell preimplantation embryo suggesting that the promoter remains unmethylated until the genomic wave of *de novo* methylation occurs at implantation. We have demonstrated that tissue-specific methylation of the myogenin promoter in the adult mouse correlates with expression, with muscle showing the lowest levels of methylation while tissues of non-expression show higher levels of methylation. We have also examined tissue-specific methylation of an exogenous myogenin promoter in a transgenic mouse model. Methylation of the transgenic myogenin promoter was evaluated in muscle and brain at two time points in a myogenin-LacZ transgenic mouse line, initially while the gene was actively expressed in muscle, and again after the transgene had undergone silencing. The transgenic myogenin promoter was found to be heavily methylated in all cases where the transgene was not expressed and unmethylated only in muscle when it was active. Our results demonstrate that methylation of the myogenin promoter is inversely correlated with transcriptional activity in both the endogenous myogenin promoter and the transgene model.

Program Nr: 978 from 2003 ASHG Annual Meeting

**Epigenetic Control of hTERT Expression and Telomerase Activity in Differentiating Leukemia HL60 Cells.** *L. Liu, J. Berletch, J. Green, L. Andrews, T. Tollefsbol.* Univ Alabama at Birmingham 1300 University Blvd., CH175, Birmingham, Alabama.

The human promyelocytic leukemia HL60 cells display high telomerase activity, a phenotype related to their immortal status. All-trans retinoic acid (ATRA) was applied to induce the differentiation of HL60 cells. CD11b expression was examined to confirm the differentiation status of the treated cells. Decreased telomerase activity was observed in ATRA-treated HL60 cells, which is coupled with down-regulation of the hTERT gene. Upregulation of DNMT3a gene was observed during ATRA treatment, whereas no significant increase of DNA methylation in hTERT promoter. Acetylation of H3 is, however, dramatically decreased in the promoter region of hTERT, suggesting that downregulation of hTERT expression occurred through higher order of chromatin remodeling process. Our findings suggest that differentiation of HL60 cells requires inactivation of telomerase activity, which was achieved through epigenetic mechanisms controlling the expression of the hTERT gene.

**Frequent Epigenetic Inactivation of RASSF1A and BLu Genes Located within the Critical 3p21.3 Region in**

**Gliomas.** *L.B. Hesson<sup>1</sup>, D. Krex<sup>2</sup>, K. Hoang-Xuan<sup>3</sup>, E.R. Maher<sup>1</sup>, F. Latif<sup>1</sup>.* 1) Section of Medical and Molecular Genetics, Department of Paediatrics and Child Health, University of Birmingham, Edgbaston, B15 2TT, UK; 2) Department of Neurosurgery, Universitätsklinikum Carl Gustav Carus, Technische Universität Dresden, Fetscherstrabe 74, 01307 Dresden, Germany; 3) Federation neurologique Mazarin and Unite INSERM U495, Hopital de la Salpetriere, Paris, France.

RASSF1A is a major tumour suppressor gene located at 3p21.3. We investigated the role of aberrant promoter region hypermethylation of RASSF1A in a large series of adult gliomas. RASSF1A was frequently methylated in both primary tumours (36/63; 57%) and tumour cell lines (7/7; 100%). Hypermethylation of RASSF1A in glioma cell lines correlated with loss of expression and treatment with a demethylating agent reactivated RASSF1A gene expression. Next we investigated whether other members of the RASSF gene family were also inactivated by methylation. NORE1B and RASSF3 were not methylated in gliomas, whilst NORE1A and RASSF5 demonstrated methylation in glioma cell lines but not in primary tumours. We then investigated the methylation status of three other candidate 3p21.3 TSGs. CACNA2D2 and SEMA3B were not frequently methylated, but the BLu gene located just centromeric to RASSF1, was frequently methylated in glioma cell lines (7/7) and in 80% (35/44) of glioma tumours. In these tumour cell lines, BLu expression was restored after treatment with a demethylating agent. There was no association between RASSF1A and BLu methylation. RASSF1A methylation increased with tumour grade whilst BLu methylation was seen at similar frequencies in all grades. Our data implicates RASSF1A and BLu promoter methylation in the pathogenesis of adult gliomas, whilst other RASSF family members and CACNA2D2 and SEMA3B appear to have only minor roles. In addition BLu methylation is an early event in glioma development and that RASSF1A and BLu methylation appear to be independent and specific events and not due to region-wide changes in DNA methylation. In vitro and in vivo growth suppression studies in glioma tumor cell lines are in progress for both RASSF1A and BLu genes.

**DNA hypomethylation induces postnatal neuronal degeneration in the central nervous system.** *L. Hutnick, G. Fan.*  
Human Genetics, UCLA School of Medicine, Los Angeles, CA.

DNA cytosine methylation is a major epigenetic factor involving in gene regulation, genomic imprinting, and X-inactivation in development. Aberrant methylation has been attributed to a variety of human neurological disorders such as ICF and Rett syndrome. To understand the role of DNA methylation in neuronal development and function, we have generated CNS-specific conditional knockouts for the maintenance enzyme DNA methyltransferase I (Dnmt1). We crossed transgenic mice harboring floxed Dnmt1 allele with the Emx1-cre transgenic mice in which the cre-recombinase expression is restricted in the pallial cortical precursors that give rise to neocortex and hippocampus. Cre-loxP mediated Dnmt1 gene deletion occurred in precursor cells between E9-12, resulting in hypomethylation in postmitotic cortical and hippocampal neurons from the mid-gestation stage. Histological examination showed that mutant animals exhibited only very mild structural defect in cortex and hippocampus during embryonic and early newborn stages, suggesting that hypomethylation did not disrupt prenatal neurogenesis and cell differentiation. However, massive neuronal degeneration was evident in 2 to 3 weeks old mutant mice with a dramatic reduction of cortical and hippocampal structures. The loss of neuronal cells was accompanied by gliosis in these brain regions with a great increase in reactive astrocytes and activated microglial cells. Immunocytochemical analysis demonstrated that the remaining residual neurons in the mutant cortex and hippocampus were positive for parvalbumin, a marker of inhibitory interneurons that are not targeted by the Emx1-cre. Our results showed that DNA methylation is crucial for the survival of cortical and hippocampal neurons during the first three weeks of postnatal life--a critical window for CNS neuronal maturation. How DNA hypomethylation selectively induces postnatal CNS neuronal degeneration is currently under investigation.

**Environmental exposures, DNA methylation and breast cancer.** *D. Rodenhiser, B. Sadikovic.* London Regional Cancer Centre and The University of Western Ontario, London, ON, Canada.

Compromised patterns of DNA methylation result in genomic instability, altered patterns of gene expression and tumour formation. Specifically, aberrant DNA hypermethylation in gene promoter regions leads to chromatin condensation and gene silencing, while global hypomethylation changes can result in chromosomal instability and oncogene activation. Potential links exist between environmental agents and DNA methylation, but the destabilizing effects of environmental exposures on the DNA methylation machinery are not understood in the context of breast cancer etiology. We have assessed genome wide changes in methylation patterns and have identified gene sequences with altered methylation profiles in response to the common pollutant benzopyrene. A unique methylation profiling technique called amplification of inter-methylated sites (AIMS) has been used to generate easily readable fingerprints representing the cells DNA methylation profile. This novel protocol is based on the differential cleavage of DNA with isoschizomeric restriction enzymes having distinct methylation sensitivity. We have validated this approach by demonstrating both unique and reoccurring sites of genomic hypomethylation in four separate human breast carcinoma cell lines treated with the cytosine analog 5-azacytidine. Comparison of treated versus control samples reveals individual bands displaying methylation changes, and these bands can be excised, cloned, sequenced and the precise genomic location individually identified. In most cases, these regions of hypomethylation coincide with susceptible target regions previously associated with chromosome breakage, rearrangement or gene amplication. Similarly, we have observed that acute benzopyrene exposure is associated with altered methylation patterns in these same cell lines. These results reinforce a link between environmental exposures, DNA methylation and breast cancer and support a role for AIMS as a rapid, affordable screening method to identify environmentally induced DNA methylation changes that could initiate tumourigenesis. (Supported by the Canadian Breast Cancer Research Initiative.).

**Progressive epigenetic inactivation of RASSF1A in human mammary epithelial cells.** *M. Strunnikova<sup>1</sup>, G.P. Pfeifer<sup>2</sup>, R. Dammann<sup>1</sup>*. 1) AG Tumorgentik, Medizin. Fak., Martin-Luther-Universität, 06097 Halle/S., Germany; 2) Department of Biology, Beckman Research Institute, City of Hope Cancer Center, Duarte, California 91010, USA.

Epigenetic inactivation of the RASSF1A tumor suppressor gene by promoter hypermethylation was frequently detected in breast carcinoma. In this study, we investigated the mechanism of RASSF1A inactivation in normal human mammary epithelial cells (HMECs), which were grown for consecutive cell passages. In proceeding passages, the transcription of RASSF1A was highly reduced in the pre-senescent cells and a spreading of methylation into the RASSF1A CpG island from the flanking regions was observed. In parallel, the transcripts of the downstream RASSF1C and upstream BLU gene were significantly up-regulated. Furthermore, the p16INK4a tumor suppressor gene was epigenetically silenced in the post-senescent HMECs. In the post-senescent cells, the expression pattern of RASSF1A, RASSF1C, BLU and p16 was similar to the transcription levels observed in breast cancer cell lines. In conclusion, we observed drastic silencing of the RASSF1A tumor suppressor in proliferating HMECs and this inactivation was associated with progressive CpG island methylation, which may be triggered by promoter occlusion.

**CancerEpigenomics identifies a candidate tumor-associated gene.** *L.T. Smith<sup>1,2</sup>, C. Plass<sup>1,2</sup>*. 1) Department of Molecular Virology, Immunology, and Medical Genetics, The Ohio State University, Columbus, OH; 2) Division of Human Cancer Genetics, The Ohio State University, Columbus, OH.

Genetic changes resulting in DNA abnormalities including deletions, mutations and chromosomal anomalies are accepted determinants of cancer. In addition, epigenetic mechanisms, including DNA methylation, silence genes without altering their genomic sequence. Studies from our lab have demonstrated the utility of Restriction Landmark Genomic Scanning for identifying novel targets of DNA methylation on a genome-wide level. In the past, mainly genetic approaches guided searches for tumor suppressor genes. We hypothesize that by combining genetics with epigenetics (CancerEpigenomics) we can identify genes from regions of LOH by RLGS. BAC contigs were assembled spanning the chromosomal region, 6q23-6q24, for which LOH has been described in head and neck cancer squamous cell carcinomas (HNSCC) and non-small cell lung cancer (NSCLC). From this region, we identified 5 NotI and 5 AscI sites on the RLGS profiles. Detailed analysis of 18 tumor profiles demonstrated widespread aberrant methylation in this region, with a maximum peak at an AscI site located in the TCF21 gene. Upon RLGS analysis, TCF21 was identified as becoming aberrantly methylated in the majority of HNSCC, lung tumors, as well as lung cancer cell lines. To further assess the extent of TCF21 methylation, COBRA was performed, demonstrating that normal adjacent tissues are largely unmethylated, while tumor samples are aberrantly hypermethylated. Analysis in methylated patient samples and cell lines demonstrates reduced expression of TCF21. 5-aza-deoxycytidine treatment of cell lines resulted in reexpression, supporting gene silencing by DNA methylation. TCF21 functions in the transition from mesenchymal to epithelial cells in several developing organs. TCF21 knock-out mice die immediately following birth due to poor lung differentiation. However, the role of TCF21 inactivation in neoplastic disease has yet to be described. In summary, by combining common regions of LOH with RLGS, we have successfully identified a candidate gene that becomes altered in tumors by multiple mechanisms: genetically and epigenetically.

**Large fragile X premutation alleles may often contain two AGG interruptions.** *S.L. Nolin, G.E. Houck, A. Glicksman, A.D. Gargano, W.T. Brown.* Human Genetics Dept, Inst Basic Research, Staten Island, NY.

In the general population, the FMR1 CGG repeat is interrupted by AGGs, most commonly at positions 10 and 20. Males with premutation alleles are thought to contain one or no AGG interruptions within the repeat region. We have sequenced the region in 40 premutation males with >90 repeats and found that 25% have 2 AGG interruptions, 27.5% have 1 AGG and 47.5% have no AGG interruptions. Among 10 males with 2 AGGs, interruptions were observed at positions 10 and 20 from the 5' end. However, among 11 males with 1 AGG, 6 had an AGG at position 10, while 4 had an AGG at position 11. One additional male carried an AGG at position 12. The number of pure repeats inferred for 21 mothers of the males averaged 63, 69, and 72 CGGs for those with 2, 1 or no AGGs, respectively. The presence of 2 AGGs in the mothers appeared to offer some protection from expansion to full mutation in the offspring. For premutation transmissions from fathers, 8 (38%) daughters inherited a larger repeat, 10 (48%) inherited a smaller repeat and 3 (14%) inherited the same repeat size as their fathers. No apparent relationship to AGG patterns was evident. These studies suggest the role of AGG interruptions may have a greater importance in female than male transmissions and that there may be more than one path for repeat expansion.

**X inactivation skewing patterns change as women age.** *C.L. Anderson, C. Hatakeyama, C.L. Beever, M. Hayden, B. Casey, C.J. Brown, W.P. Robinson.* Dept Medical Genetics, University of BC, Vancouver, Canada.

While X chromosome inactivation (XCI) is generally thought to be a random process, most females exhibit some bias in terms of the frequency with which one or the other X is inactivated. Extremely skewed XCI (90% inactivation of one X) has been associated with various genetic diseases, recurrent pregnancy loss and trisomy risk, and has also been reported to increase as women age. This age-related increase has been suggested to be due to either selective differences between cells that have inactivated one X or the other, or to depletion of the stem cell pool with time. To further evaluate how XCI patterns change with age, we analyzed XCI status using a methylation assay at the AR locus in 332 women aged 0 to 88 with no known genetic disorders or abnormal pregnancy history. The incidence of extreme skewing increased with age, being observed in 8% of women under 20 years (N=75), and 24% of women over 60 years (N=89). Using a linear model, the average level of skewing increased from 66% at birth to 78% by age 80 ( $r^2 = 0.066$ ,  $p < 0.001$ ). A slightly better fit was observed with a quadratic model, with skewing increasing more rapidly later in life ( $r^2 = 0.068$ ,  $p < 0.001$ ), favouring a decrease in stem cell precursors as the explanation for increased skewed XCI with age. A surprisingly low concordance between the analysis of XCI using methylation assays at the AR and FMR1 loci was observed ( $r^2 = 0.287$ ,  $p < 0.001$ ). We hypothesize that this discordance reflects alteration of methylation, and are determining whether increases in skewed XCI are due to allele-specific methylation changes with age.

**A Coat Color Tagged Green Mouse with EGFP Expressed from the RNA Polymerase II Promoter.** *Y.C. Hsiao<sup>1</sup>, S.F. Lin<sup>1</sup>, C.Y. Tsai<sup>1,3</sup>, L.S. Horng<sup>1</sup>, H.H. Chang<sup>1</sup>, T.F. Tsai<sup>2,3,4,5</sup>*. 1) Dept of R&D, Level Biotechnology Inc., Taipei, Taiwan, Taiwan; 2) Department of Life Science, National Yang-Ming University, Taipei, Taiwan; 3) Institute of Genetics, National Yang-Ming University, Taipei, Taiwan; 4) Genome Research Center, National Yang-Ming University, Taipei, Taiwan; 5) Department of Medical Research and Education, Veterans General Hospital-Taipei, Taiwan.

To achieve visual genotyping for transgenic identification on the FVB/N albino background, we have successfully applied the tyrosinase cDNA to generate coat color tagged transgenic mice with high EGFP expression from the promoter of RNA polymerase II large subunit gene. The EGFP was expressed in more than 90% of the transgenic founders with the introduction of two copies of insulators. The green fluorescence was detected as early as the 1-cell fertilized egg stage and last for the whole embryo development. The EGFP was also expressed in all of the adult tissues examined with especially robust signal detected in the testis. Over-expression of EGFP may have toxicity to the testis leading to male sterile or decreased fertility. The coat color tagged green mice offer the opportunity for visual genotyping of newborns by dark eye pigmentation. The genotypes can be reconfirmed on postnatal day 7 by the light tan coat color that was clearly distinct from the albino coat.

**Genome-wide Analysis of Alternative Splicing in Human Tissues and Tumors.** *K. Mitsouras*<sup>1</sup>, *K. Lee*<sup>2</sup>, *Q. Xu*<sup>2</sup>, *C. Lee*<sup>2</sup>, *S. Nelson*<sup>1</sup>. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Chemistry and Biochemistry, UCLA, Los Angeles, CA.

The goal of our studies is to investigate the pattern of alternative splicing in a subset of normal human tissues and, second, in a variety of brain tumor samples. We are developing a microarray platform that can specifically and sensitively detect tissue- and tumor-specific isoforms of human genes. We have used datasets of predicted alternatively spliced forms of human genes generated by computational methods to select candidates for printing on high-density oligonucleotide microarrays manufactured by Agilent Technologies. These arrays are designed to detect tissue- and tumor-specific isoforms of 142 human genes, and also contain probes for 30 yeast alternatively spliced isoforms from previously characterized yeast spliceosome mutants. Proof-of-principle experiments with yeast samples indicate that this technology can reliably pick up relative differences in the abundance of specific exons and splice junctions ranging from 3 to 20 fold. These experiments also suggest that an optimal probe length of 35-40mers is required to sensitively distinguish between splice isoforms. Preliminary experiments designed to compare the alternative splicing patterns between three normal human tissues (brain, spleen and liver) and a glioblastoma (GBM) sample revealed good correlation with the predicted alternative splicing events, especially in the brain vs GBM group. Many of these isoforms are in transcriptional regulators, or regulators of cell growth, thus implying that alternative splicing may play a role in tumorigenesis.

**Negative regulation of FOXC1 activity by the p44/p42 MAP kinase pathway.** *F. Mirzayans, F.B. Berry, R.A. Saleem, M.A. Walter.* Ophthalmology & Medical Gen, Univ Alberta, Edmonton, AB, Canada.

FOXC1 a member of the forkhead box transcription factor family of genes, plays an important role in ocular development. Mutations in FOXC1 result in Axenfeld-Rieger malformations, accompanied by secondary glaucoma in about 50% of cases. FOXC1 contains N- and C-terminal transcriptional activation domains. In addition, FOXC1 contains a 152 amino acid transcriptional inhibitory domain that when deleted results in a hyperactive FOXC1 protein and a decrease in its phosphorylation, suggesting an inverse relationship between FOXC1 phosphorylation and transactivation. There are 3 predicted p44/p42 MAP kinase sites in FOXC1. Therefore the effects of activation and inhibition of the MAP kinase pathway on FOXC1 ability to activate transcription were examined. Activation of this pathway in HeLa cells by PMA reduced FOXC1 transactivation by 5 fold, while inhibition with the MEK 1 and 2 inhibitor PD98059 stimulated FOXC1 transcriptional regulatory activity by 3 fold. Therefore stimulation of p44/p42 MAP kinase pathway results in inhibition of FOXC1 activity. However PMA treatment did not hamper the DNA binding ability of FOXC1, suggesting that the PMA induced FOXC1 defect was the result of impairment in the ability of FOXC1 to recruit transcriptional machinery. Interestingly, stimulation of the MAP kinase pathway has a stabilizing effect on FOXC1 protein levels. This stabilizing effect was not observed when cells were pre-treated with the inhibitor PD98059. The effect of mutating the 3 predicted MAP kinase phosphorylation sites on FOXC1 is being investigated. Together these data indicate that FOXC1 transcriptional activity is negatively regulated by p44/p42 MAP kinase activity. Such complex modulation of FOXC1 activity may be necessary for the proper execution of growth and differentiation programs.

**The role of *EYA1* and *EYA4* in deafness.** *Y. Zhang*<sup>1</sup>, *R.A. Friedman*<sup>2</sup>, *G. Van Camp*<sup>3</sup>, *R.J.H. Smith*<sup>1</sup>. 1) Department of Otolaryngology and Interdepartmental PhD Program in Genetics, University of Iowa, Iowa City, IA 52242, USA; 2) Department of Cell and Molecular Biology, House Ear Institute, 2100 West Third Street, Los Angeles, CA 90057, USA; 3) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

The vertebrate *Eya* gene family is comprised of 4 transcriptional activators that interact with other proteins in a conserved regulatory hierarchy to ensure normal embryologic development. The structure of these proteins as deduced from their cDNA sequences includes a highly conserved 271 aa C-terminus called the *eya*-homologous region (*eyaHR*) and a more divergent transactivation domain at the N-terminus (*eya* variable region, *eyaVR*). Allele variants of *EYA1* and *EYA4* underlie two types of inherited human deafness, BOR syndrome and DFNA10, respectively. To clarify how mutations in these two genes impact the normal biology of hearing, we completed a number of functional studies. Using the yeast 2-hybrid system, we verified that *Eya1* and *Eya4* interact with *Six1*; we found no interaction with *Dach1*. As measured by -galactosidase activity, we found *Eya1-Six1* interaction to be stronger than *Eya4-Six1*. We next subcloned c-myc-tagged *Eya1HR* or *Eya4HR*, and HA-tagged *Six1*, and by immunofluorescence staining showed *Eya4* localization to the cytoplasm. After co-expression of *Six1*, *Eya4* was translocated to the nucleus. Results with *Eya1* were similar. Translation of mutant constructs (*Eya4*<sub>DFNA10</sub> and *Eya1*<sub>BOR</sub>) could not be demonstrated in transfected HEK 293 cells. We generated other truncated constructs of *Eya4* and also found that none localized to the cytoplasm. We were unable to demonstrate a translation product of mutant constructs by western blotting. Using a dual *Eya* construct (containing one wild type and a second one mutant or wild type allele), we confirmed no translation of the mutant allele, even if the mutation was non-truncating. These data suggest that haplo-insufficiency is the major cause of BOR and DFNA10. This research was supported by R01-DC03544 (RJHS).

**Expression of Degenerin BNaC/ASIC Isoforms in Hair Cells of the Mammalian Cochlea.** *H. Ostrer*<sup>1</sup>, *B. Fritsch*<sup>2</sup>, *T. Giudice*<sup>2</sup>, *R. Bing*<sup>1</sup>, *D. Hillman*<sup>1</sup>, *K. Beisel*<sup>2</sup>. 1) New York Univ Sch Medicine, New York, NY; 2) Creighton University School of Medicine, Omaha, NE.

The degenerins are a superfamily of genes that encode cation channels. The first degenerin cation channels to be identified were *mec4* and *mec10* in *C. elegans*, where mutations in the genes result in neurodegeneration. These subunits form complexes that are postulated to anchor to both sides of the membrane, producing mechanical tension that gates the cation channels. In mammals, two classes of degenerin ion channels have been identified, the epithelial sodium channels (ENaCs) that are expressed in kidney, colon and lung and the brain sodium channels (BNaCs), also known as the acid-sensitive ion channels (ASICs) that are expressed in different regions of the human and rat brain and spinal cord. Members of both the ENaC and the ASIC families are expressed in sensory neurons, suggesting that they could play a role in mechanically-gated ion touch receptors, including those that play a role in the mechanical transduction of sound waves in the cochlea. A role for ENaC was excluded because mice homozygous for a knockout mutation in this gene had normal hair cell function. By *in situ* hybridization, we have shown that members of the BNaC/ASIC family, ASIC and ASIC2, including their and splice isoforms, are expressed in inner and outer hair cells of the cochlea. By Western blot analysis, we have shown that these RNAs have been translated into proteins. By immunocytochemistry, we have shown that ASIC2 is expressed at tip links in hair cells of the cochlea. Despite their widespread expression in sensory neurons, members of the BNaC/ASIC family of degenerins may play a role in signal transduction in the cochlea.

**Generation and characterization of a DFNA5 knockout mouse.** *L. Van Laer<sup>1</sup>, M. Pfister<sup>2</sup>, S. Thys<sup>1</sup>, M. Mueller<sup>2</sup>, K. Vrijens<sup>1</sup>, L. Umans<sup>3</sup>, L. Serneels<sup>3</sup>, F. Kooy<sup>1</sup>, J.P. Timmermans<sup>4</sup>, F. Van Leuven<sup>3</sup>, G. Van Camp<sup>1</sup>.* 1) Department of Medical Genetics, University of Antwerp (Campus Drie Eiken), Antwerp, Belgium; 2) Hals-Nasen-Ohrenklinik, Universität Tübingen, Tübingen, Germany; 3) Experimental Genetics Group, K.U.Leuven, Leuven, Belgium; 4) Laboratory of Cell Biology and Histology, University of Antwerp (Campus Middelheim), Antwerp, Belgium.

A complex intronic insertion/deletion in DFNA5 is responsible for an autosomal dominant type of hearing impairment that segregates in an extended Dutch family. The hearing impairment starts in the high frequencies between 5 and 15 years of age and progressively affects all frequencies. On the mRNA level, the mutation results in exon 8 skipping. Despite extensive computational analysis, no putative function for DFNA5 could be deduced. In order to study its function *in vivo*, DFNA5 partial and complete knockout mice were generated by deleting exon 8 by targeted recombination in 129 ES cell lines to mimic the human mutation. An additional P-lox site was inserted before exon 7 to ensure the generation of a complete knockout mouse in case the deletion of exon 8 was insufficient. Because the 129 mouse strain exhibits early-onset hearing impairment, this genetic background was replaced by backcrossing for 6 generations into the C57Bl strain, which displays late-onset hearing loss, and into the CBA/Ca strain, which is a good-hearing reference strain. In homozygous DFNA5<sup>-/-</sup> mice, the presence of aberrant mRNA was demonstrated by RT-PCR. However, no protein could be detected using Western blotting, demonstrating that the DFNA5 gene was effectively silenced. To test the hearing impairment, frequency-specific ABR (Auditory Brainstem Response) was performed at different ages in the two genetic backgrounds. Morphological studies using scanning electron microscopy, complemented with organ of Corti explant studies, demonstrated significant differences in the number of fourth-row outer hair cells between DFNA5 knockout mice and their wild-type littermates. A complete histopathological analysis of 57 other organs revealed no additional abnormalities in the DFNA5 knockout mice.

**Missense CLDN14 proteins with defects in subcellular localization and inability to form tight junctions result in deafness.** *M. Wattenhofer*<sup>1</sup>, *A. Reymond*<sup>1</sup>, *A. Charollais*<sup>2</sup>, *D. Caille*<sup>2</sup>, *V. Falciola*<sup>1</sup>, *C. Borel*<sup>1</sup>, *A. Pampanos*<sup>3</sup>, *R. Rabionet*<sup>4</sup>, *M.B. Petersen*<sup>3</sup>, *X. Estivill*<sup>4</sup>, *P. Meda*<sup>2</sup>, *S.E. Antonarakis*<sup>1</sup>. 1) Division of Medical Genetics, University of Geneva Medical School; 2) Department of Morphology, University of Geneva Medical School; 3) Aghia Sophia Children Hospital, Athens; 4) Centre de Regulacio Genomica, Barcelona.

In developed countries, about 2/3 of the cases of isolated deafness have a genetic origin and about 50% of recessive cases are due to mutations in the GJB2 gene. Mutations in CLDN14 cause the DFNB29 deafness. This gene encodes a member of the claudin family, major components of tight junctions (TJ). To determine which CLDN14 function(s) was (were) altered in DFNB29, we studied the functional consequences of 2 missense substitutions associated with deafness. The first is the V85D substitution reported in a Pakistani family. The second is a G101R variant identified in a screen of CLDN14 ORFs in 183 non-syndromic deaf patients from Spain and Greece, negative for GJB2 mutations. A single chromosome was shown to harbor the 301G>A transition leading to G101R, which affects a conserved residue. At this position, part of the second transmembrane domain, all claudins examined have either a Gly (18/20 human CLDNs) or small hydrophobic residues (Ala or Val) but no arginine or other charged amino acid. R101 has been transmitted by the hearing father and cannot therefore be considered a highly penetrant dominant mutation. We screened the UTRs, for a potential maternally inherited mutation, in particular 3 newly-identified 5 exons and found no mutation. We ruled out large deletion through analysis of SNPs and microsatellites. This study indicates that mutations in CLDN14 do not substantially contribute to non-syndromic deafness in the Mediterranean population. The CLDN14 V85D protein shows a diffused cytoplasmic localization. In contrast, the CLDN14 G101R and WT proteins localize at the plasma membrane. However, LM cells transduced with the CLDN14 G101R show no formation of TJ unlike CLDN14 WT-transduced cells. These results suggest that the DFNB29 pathogenesis is due to, either subcellular mislocalization of the CLDN14 protein, or inability to form TJ.

**Development of a biochemical assay for the transporter function of ABCR.** *W. Wiszniewski<sup>1</sup>, J.R. Lupski<sup>1</sup>, T.G. Wensel<sup>2</sup>.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Biochemistry, Baylor College of Medicine, Houston, TX.

Mutations of the ABCR gene are associated with many retinal phenotypes including Stargardt disease, Fundus Flavimaculatus, combined cone-rod dystrophy or retinitis pigmentosa. Some heterozygous mutations are associated with multifactorial disorder Age-related Macular Degeneration. The ABCR gene is expressed in the retina and encodes an ATP binding cassette transporter. This 220kD protein is exclusively found in discs of photoreceptors outer segments. The biochemical studies of ABCR and observations of mice lacking ABCR suggest that ABCR functions as a cytoplasm- directed flipase for N-retinylidene-PE (APE) that is a product of condensation of all-trans-retinal and phosphatidylethanolamine. The abnormally high concentration of APE in outer segments discs is considered to be the first step in pathogenesis of the ABCR associated retinal diseases. The aim of this study is to confirm directly the flipase function of ABCR and develop a biochemical assay for validation of the functional consequences of ABCR mutations. Our approach consists of the comparison of the transport rate of retinal initially conjugated to PE across the membrane of lipid vesicles containing wild type or mutated forms of ABCR using spectrophotometric analysis. The preliminary results showed that retinal in the form of APE localized in the internal layer of vesicles is transported slowly (many minutes) to the outer layer, likely as a result of slow Schiff's base hydrolysis rather than even slower spontaneous lipid flipping, so the acceleration of this process could have important significance in vivo. To test this hypothesis the vesicles containing ABCR proteins were formed and now are under investigations. The development of direct assay is crucial for a complete understanding of the role of ABCR in retinoid cycles and reliable validation of functional consequences of disease associated mutations found in patients with retinal diseases.

**Bridging structural biology and genetics by computational methods: An investigation into how the R774C mutation in the androgen receptor gene can result in complete androgen insensitivity syndrome.** *B. Gottlieb*<sup>1,2,3</sup>, *J.H. Wu*<sup>1,2,3</sup>, *G. Batist*<sup>1,2,3</sup>, *T. Sulea*<sup>4</sup>, *E.O. Purisima*<sup>4</sup>, *L.K. Beitel*<sup>1</sup>, *M. Trifiro*<sup>1,2,3</sup>. 1) Dept Cell Genetics, Lady Davis Institute for Medical Research, Sir Mortimer B. Davis-Jewish General Hospital, 3755 Cote-Ste-Catherine Rd, Montreal, Quebec, Canada, H3T 1E2; 2) Departments of Oncology and Medicine, McGill University, Montreal, Quebec, Canada; 3) Montreal Centre for Experimental Therapeutics in Cancer; 4) Biotechnology Research Institute, National Research Council of Canada, 6100 Royalmount Ave, Montreal, Quebec, Canada, H4P 2R2.

Recent structural studies of the ligand-binding domain (LBD) of the androgen receptor (AR) have raised more questions than answers, as most of the known pathogenic mutations of the AR gene causing androgen insensitivity syndrome (AIS) are not in the putative ligand-binding pocket. In this study, we have investigated one such pathogenic mutation, by examining details of its altered atomic structure using a computational technique of molecular dynamics (MD) simulations extended over 4ns, effectively creating a 4D structural model. The mutation R774C which is in the LBD of the AR gene, causes complete AIS (CAIS) producing ARs that have a unique thermolabile profile, being thermostable at 22°C but thermolabile at 37°C. We have therefore investigated this mutation by MD simulations at 310 K (37 °C), 300 K (27 °C) and 293 K (20 °C). The MD simulations indicate that: i) the mutation causes local structural distortions, which result in changes in the shape of the ligand-binding pocket; ii) the mutation alters the dynamic nature of the protein and results in a more diverse conformational distribution of the ligand-binding pocket; and iii) the effect of the mutation on AR structure could be largely reversed by lowering the temperature at which the MD simulations were conducted. These results therefore strongly support the biochemical data, e.g., the mutants inability to form AR-ligand complexes at 37 °C and its characteristic reversible thermolability, clearly indicating the value of such computational methods.

**Identification of Similar Domains in Orthopoxvirus and Human Complement Regulators.** *J. Krushkal*<sup>1</sup>, *A. Emery*<sup>2</sup>, *E. Ciulla*<sup>2</sup>, *D. Konz*<sup>2</sup>, *R. Adkins*<sup>1</sup>, *I. Gigli*<sup>3</sup>. 1) University of Tennessee-Memphis, Memphis, TN; 2) Worcester Polytechnic Institute, Worcester, MA; 3) University of Texas-Houston, Houston, TX.

Genus Orthopoxviridae includes variola major virus that causes human smallpox. Many other orthopoxviruses are also important for public health, e.g. vaccinia, cowpox, monkeypox, camelpox viruses, and others. Genomes of orthopoxviruses encode for proteins with sequences similar to human regulators of complement activation (RCA), which allows these viruses to evade the host defense by downregulating the human complement.

We employed phylogenetic analysis to evaluate the structural relationships among SCRs of two types of orthopoxvirus RCA-like proteins and those of the human complement regulators, C4 binding protein chain (C4bp), membrane cofactor protein (MCP), decay accelerating factor (DAF), complement receptor type 1 (CR1), and factor H (FH). All complement regulators analyzed contain tandem short consensus repeats (SCRs). The first group of viral proteins analyzed included key regulators of complement activation in variola major virus (smallpox inhibitor of complement enzymes, or SPICE), vaccinia virus (vaccinia virus complement control protein, or VCP), and cowpox virus (inflammation modulatory protein, or IMP). These proteins were similar to N-terminal SCRs of MCP, DAF, CR1, and FH, and a number of additional SCRs. We provide a detailed list of similarity relationships between poxviral and human complement regulators. Sequence analysis suggested that orthopoxvirus complement regulators VCP, SPICE, and IMP arose from a single ancestral sequence that shared similarity with all human complement regulators.

The second group of poxviral proteins analyzed included plaque size-host range proteins B7R in variola virus, B5R in vaccinia virus, B4R in cowpoxvirus, and C1R in ectromelia virus. These proteins have function other than regulation of human complement. We found that these proteins have the order of their short consensus repeats different from that in functional complement regulators, and one of their SCRs, SCR 2, is very divergent from the functional regulators of complement activation.

**Cat eye syndrome critical region: Two overlapping mammalian genes within the *CECR6* mRNA? *I.M.D.***

*Mousseau, H.E. McDermid.* Biological Sciences, University of Alberta, Edmonton, Alberta, Canada.

Cat eye syndrome (CES) is a rare genetic disorder caused by supernumerary (trisomic or tetrasomic) copies of the short arm and part of the long arm of chromosome 22. Symptoms for this rare condition are caused by the overexpression of one or more dosage-sensitive genes in the duplicated region and can include coloboma of the iris causing a "cat-like" pupil, heart defects, anal atresia, and renal and skeletal abnormalities. Mild mental retardation is also associated with this condition.

Analysis of the CES critical region (CESCR) by the McDermid laboratory led to the identification of 14 transcripts. Based on expression during development and the analysis of sequence motifs, we are presently concentrating on the functional analysis of three of these genes: *CECR1*, *CECR2* and *CECR6*. *CECR6* (Cat Eye syndrome, Critical Region, candidate 6) has several unusual features. The mRNA has the potential to code for two completely different novel proteins, which overlap in different reading frames. The smaller open reading frame (ORF, 627bp) starts two thirds into the larger ORF (1734bp) and their stop codons are less than 100bp apart. The predicted protein structure of the larger ORF is highly unusual, with numerous amino acid repeats such as poly-proline, poly-histidine, poly-glycine and poly-cysteine stretches. We are characterizing the structure and function of *CECR6*. Phylogenetic studies show that the larger ORF (578 amino acids) is conserved in mouse, rat, baboon and human, although no non-mammalian homologues have been found. The smaller ORF (209 amino acids) is only conserved in baboon and human (89% similarity) as the first methionine codon is not present in mouse or rat. We are conducting further phylogenetic studies in primates and other mammals to characterize the evolution of the small ORF sequence.

**Phylogenetic Footprinting of the *NF1* 5 Upstream Region (5UR).** *T.K. Lee, J.M. Friedman.* Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

The 5UR of the human neurofibromatosis 1 gene was defined as the 59756 bp region between the *NF1* translation start site and the end of the first upstream GenScan prediction (NT\_010799.114). The 5URs of mouse and rat were defined as 59756 bp upstream of the translation start site of the *NF1* homologs in these species. The 5UR in *Fugu* was defined as the 1488 bp segment between the known 5 flanking gene (FN5) and the *NF1* translation start site. Sequence alignments were established by mVista, and windows of identity greater than that of the coding regions and extending 50 bp or more in length among all 3 mammalian species were identified with Frameslider, a Perl program written for this research. These highly homologous regions (HHRs) were compared to the *Fugu* 5UR using Pairwise BLAST and analyzed for potential transcription factor binding sites and other promoter-associated sequences with MATCH, MatInspector, Eukaryotic Promoter Database and TRRD.

Three HHRs were discovered in the *NF1* 5UR. HHR1, located 42626-42696 bp upstream of translation start site, contains an AP-1 site shared by all four species. HHR2, located 640-689 bp upstream of translation start site, has no promising predictions for recognized transcription factor binding sites. HHR3, located 233-519 bp upstream of the *NF1* translation start site, contains a previously-described CREB site that is shared by all three mammalian species.

HHR3 also includes a 24 bp sequence 310-333 bp upstream of the translation start that is identical in human, mouse and rat and differs by only 1 bp in *Fugu*. Bioinformatic analysis and correlation with previously-published in vitro transcription studies indicate that this sequence, which we call NF1 Highly Conserved Sequence (NF1HCS), is likely to be involved in transcriptional regulation. NF1HCS lies 151bp downstream from the *NF1* major transcriptional start site but appears to be a strong candidate for the *NF1* core promoter element despite its position further downstream than any previously-described eukaryotic downstream core promoter element.

Program Nr: 998 from 2003 ASHG Annual Meeting

**From ABC to ZNF, gene nomenclature and functional annotation.** *V.K. Khodiyar<sup>1</sup>, E.A. Bruford<sup>1</sup>, R.C. Lovering<sup>1</sup>, C.C. Talbot Jr<sup>2</sup>, M.W. Wright<sup>1</sup>, M.J. Lush<sup>1</sup>, S. Povey<sup>1</sup>, H.M. Wain<sup>1</sup>, HUGO Gene Nomenclature Committee (HGNC).* 1) The Galton Laboratory, Department of Biology, University College London, Wolfson House, 4, Stephenson Way, London, NW1 2HE, UK; 2) The Johns Hopkins School of Medicine, Institute of Genetic Medicine, The Johns Hopkins University, Baltimore, MD, 21287, USA.

Genome annotation is now the highest priority in the field of genomics and the HUGO Gene Nomenclature Committee (HGNC) is in an ideal position to assist in its provision. Our aim is to increase the ability of scientists to find and discuss information about genes by providing a unique, approved name and short-form symbol for every human gene. Assignment of approved nomenclature involves data analysis, reading the literature and corresponding with authors; information gathering which can be used for further annotation. Gene names can describe many characteristics including phenotype, domain structure, location, function and inter-species homology. However, the approved name can include only part of the wealth of data that may be known for a gene. It is the unique gene symbol (derived from the name) that is crucial in ensuring the association of related information e.g. functional Gene Ontology terms, with the correct gene record in both databases and the literature. We have named over 100 gene families and groupings from ABC to ZNF, and will present examples that demonstrate conservation of homology or function. Our close collaboration with the Mouse Genomic Nomenclature Committee has enabled synchronisation of the naming of human/mouse orthologous genes, and the sequencing of other genomes has provided increasing (and exciting!) help in annotation. The work of the HGNC is supported by NIH contract N01-LM-9-3533 (60%) and by the UK Medical Research Council (40%). Please come and see us at the HUGO Booth.

**Assessment of accuracy of protein function prediction from gene expressions and protein-protein interactions.** Z. Tu, M. Deng, T. Chen, F. Sun. Molecular and Computational Biology, University of Southern California, Los Angeles, CA.

Several methods have been used to predict protein functions based on gene expression data and protein-protein interactions using the guilt-by-association principle. However, for gene expression data, not all the biological regulations can be observed at the transcript level. For some functional categories related to protein metabolism (rRNA processing, amine biosynthesis, amino acid metabolism and protein biosynthesis as defined in Gene Ontology (GO)), proteins within the same functional category have highly correlated gene expressions and these functions can be more accurately predicted using highly correlated gene pairs (HCGP). While functions of other categories cannot be accurately predicted since gene expressions are not significantly correlated. Protein-protein interactions including physical and genetic interactions have also been used to predict protein functions. Not all protein functional categories can be predicted with the same accuracy using different interaction datasets.

We develop a new statistical method to assess the accuracy of protein function predictions using gene expressions, protein physical and genetic interactions based on GO functional categories. We analyze three different microarray gene expression datasets (Rosetta compendium, yeast cell cycle and stress response) and MIPS physical and genetic interaction data. For all the three gene expression datasets, function categories related to protein metabolism can be more accurately predicted. A detailed analysis of the yeast stress response data shows that the set of functional categories with high prediction accuracy depends on experiment conditions. For example, when yeast are treated with H<sub>2</sub>O<sub>2</sub>, proteins having the ubiquitin-dependent protein catabolism function show significant levels of co-regulation, as opposed to untreated cells. We also apply this new method to study the prediction accuracy based on physical and genetic interactions. All the functional categories can be predicted with comparatively high accuracy for both interaction datasets with genetic interactions having the highest prediction accuracy.

Program Nr: 1000 from 2003 ASHG Annual Meeting

**Genome-wide search for 3'UTR motifs associated with mRNA turnover in Human T lymphocytes.** *L. Wang, X. Xu.* Program for Population Genetics, Harvard School of Public Health, Boston, MA.

The 3' untranslated regions of eukaryotic mRNAs are known to play an important role in post-transcriptional regulation of gene expression. Although several studies have determined mRNA turnover rate at genome scale with high-density DNA microarrays, few systematic studies on sequence motifs related to mRNA turnover have been reported. Raghavan et al. previously reported the turnover rate of approximately 6000 mRNAs in human T lymphocytes. Using this data set, we selected 215 fast-decay and 194 slow-decay mRNAs to conduct a systematic search for the sequence motifs in the 3' UTR that are associated with mRNA turnover. We compared the count frequencies in fast and slow decay mRNAs of all possible 7-nt motifs, repetitive sequences, as well as end sequences of 82 known human microRNAs. Furthermore, we searched for conservative motifs in both the fast and the slow decay mRNAs using a hidden Markov model implemented in the software BioProspector. The AT-rich repetitive sequences, which may contain the well-known AU-rich elements (AREs), were significantly more abundant in the fast decay mRNAs. No other repetitive sequences were found associated with the turnover rate. In addition, we found several novel elements that were associated with mRNA turnover. Specifically, we found GCCCNNG was associated with slow decay and WWUGUWW associated with fast decay. The latter was consistently detected by both the frequency counting and the HMM methods. We also found the occurrence of the reverse complement of the 5' end of human microRNA mir-106, ACUUUU, was significantly higher in fast decay mRNAs.

**Novel structure and functional peculiarities of human gene MOB.** *I.P. Vladychenskaya, L.V. Dergunova, V.G. Dmitrieva, S.A. Limborska.* Dept Human Genetics, Inst Molecular Genetics, Moscow, Russia.

Here we report new data on structure and functional peculiarities of novel human gene MOB. Transcript of 3734 nucleotides in length was predicted in silico for this gene. The 5-end of the coding region lies within the exon VII and the 3-end within the exon XI. 5-untranslated region of this transcript is represented by exons I-VI and partly exon VII. Exon I is rich in G and C and seems to be highly structured; three short ORFs are localized within the exons I, V and VI. This transcript was detected by means of RT-PCR as the major MOB gene transcript in human cerebellum tissue. Also less abundant alternative transcripts of MOB gene were revealed in the same tissue. We have determined the primary structure for the major transcript and for the smallest of the alternative transcripts. Nucleotide sequence of the major transcript was identical to that predicted in silico, the alternative transcript under study did not harbour the largest MOB gene coding exon (exon VII). MOB gene reported previously as brain-specific was shown to be expressed also in non-brain human tissues by means of semi-quantitative RT-PCR. The highest expression level of MOB gene was detected in human cortex, hippocampus and cerebellum. The comparable expression level was detected in kidney. The lowest expression level was demonstrated in spleen and lymphatic nodes.

**Regulated alternative splicing of an exon in the 3' end of a type V collagen gene, *COL5A1*.** A.L. Mitchell, U. Schwarze, P.H. Byers. Univ Washington, Seattle, WA.

Type V collagen is a heterotrimer of 2 pro1(V) chains (*COL5A1*), and 1 pro2(V) chain (*COL5A2*) or a pro1(V) homotrimer. Mutations in *COL5A1* result in classical Ehlers Danlos syndrome (EDS). While screening cDNA from individuals with EDS, we found that the sequence of exon 64 was heterogeneous as a result of alternative use of 2 exons, 64A and 64B. They differ at 35/69 basepairs and the proteins differ at 12/23 residues. The 2 exons are separated by an intron (IVS64A) of 63bps in humans and 61bp in the mouse and rat. IVS64A is too small to allow inclusion of both exons so only 1 version is included in each transcript. Upstream mutations that destabilize mRNA from one allele still result in production of both transcripts, indicating that alternative splicing is transcript specific and not allele-dependent. None of the known or our new mutations (W165X; G1489R; C1835S; IVS19+1GA; IVS27-1GA; IVS35+1GA; IVS35-2 AC; ins3680+T; del4916-4931) in *COL5A1* affect either exon. To determine if these exons are differentially used and a source of tissue variation, we analyzed RNA from adult mouse tissues. Although all tissues expressed both transcripts, the proportions differed dramatically. In many, the 2 isoforms were expressed in approximately equal amounts. However, testis, brain, and lung expressed predominately the A isoform. Computational folding of 380nt of precursor RNA identified several different structures that could present splice donor sites, a factor that could contribute to the preferential identification of 64A or 64B by the spliceosome. Exon 64 is just upstream of the region that encodes a domain involved in chain selection for fibrillar pro chains. We have cloned and expressed the cDNA coding sequences of the C-terminal domains (3' end of the mRNA) from the 3 type V collagen genes (*COL5A1*-the 64A and 64B isoforms separately, *COL5A2*, *COL5A3*). Co-expression studies to determine the interaction partners are underway and should identify the important domains for chain association. Tissue specific differences in expression are likely related to functional differences in the molecules, so mutations in these domains could have different phenotypes.

**A new ENU-induced allele of the mouse quaking gene causes severe central nervous system dysmyelination.** *J.D. Dapper*<sup>1</sup>, *J.K. Noveroske*<sup>1,2</sup>, *R.J. Hardy*<sup>3</sup>, *H. Vogel*<sup>4</sup>, *N. Box*<sup>1</sup>, *M.J. Justice*<sup>1</sup>. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) The Jackson Laboratory, Bar Harbor, ME; 3) Division of Neuroscience, Imperial College School of Medicine, London, UK; 4) Department of Pathology, Stanford University, Stanford, CA.

The mutant allele series of the mouse *quaking* gene consists of the spontaneous  $qk^v$  allele that is homozygous viable with a dysmyelination phenotype, and four ENU-induced alleles ( $qk^{kt1}$ ,  $qk^{k2}$ ,  $qk^{kt3/4}$ , and  $qk^{l-1}$ ) that are homozygous embryonic lethal. Here we report the isolation of  $qk^{e5}$ , the first ENU-induced, viable allele of *quaking*. Unlike  $qk^v/qk^v$ ,  $qk^{e5}/qk^{e5}$  animals have early onset seizures, severe ataxia and a drastically reduced life span. Ultrastructural analysis of  $qk^{e5}/qk^{e5}$  brains reveals a severe lack of myelin when compared to both wild-type and  $qk^v/qk^v$  brains. In addition, detection of calbindin in the cerebellum of young adult  $qk^{e5}/qk^{e5}$  mice reveals Purkinje cell axonal swellings that are not reported in young adult  $qk^v/qk^v$  mice, indicative of neurodegeneration. Although the molecular defect in the  $qk^{e5}$  allele is not evident by sequencing or Northern analysis of quaking transcripts, protein expression studies show that two of the quaking protein isoforms, QKI-6 and QKI-7, are absent and QKI-5 is reduced in  $qk^{e5}/qk^{e5}$  postnatal oligodendrocytes. The oligodendrocyte developmental markers PDGFaR, NG2, O4, CNP and MBP are present in the  $qk^{e5}/qk^{e5}$  postnatal brain, with the later markers showing reduced levels suggesting an oligodendrocyte maturation defect may also be occurring.

**LERN1, a novel leucine-rich repeat protein with specific expression in the limbic system.** *L. Carim-Todd*<sup>1</sup>, *X. Estivill*<sup>2</sup>, *L. Sumoy*<sup>1</sup>. 1) Programme of Bioinformatics and Genomics, Centre de Regulació Genòmica (CRG), Barcelona, Catalunya, Spain; 2) Programme of Genes and Disease, Centre de Regulació Genòmica (CRG), Barcelona, Catalunya, Spain.

Using an *in silico* approach we have analyzed the gene content of human chromosome 15q24-q26. Among the several genes identified we focused on the molecular characterization of a novel leucine-rich repeat encoding gene, LRRN6A (Leucine-Rich Repeat Neuronal 6 A). We have confirmed the mapping of LRRN6A to 15q24, at the centromeric end of a highly complex region of susceptibility to panic and anxiety disorders. LRRN6A encodes a transmembrane leucine-rich repeat protein, LERN1 (Leucine-Rich Repeat Neuronal protein 1), with similarity to proteins involved in axonal guidance and migration, development of the nervous system and axonal regeneration processes. The identification of homologous genes to LRRN6A on human chromosomes 9 and 19 and of orthologous genes in the mouse genome and other organisms suggests that LERN proteins constitute a novel subfamily of LRR (Leucine-Rich Repeat) containing proteins. *In situ* hybridization with a mouse *Lrrn6A* probe reveals a specific central nervous system pattern of expression, highly and broadly expressed in the nervous system during somitogenesis stages (E10-E17) and gradually restricted to forebrain structures as development proceeds (E17 onwards). Overall levels of expression in adulthood are lower but remain constant and significantly enriched in structures belonging to the limbic system. Taken together, LRRN6A's inclusion in the 15q24-q26 region of susceptibility to anxiety disorders, its transcript distribution within the brain, its predicted protein structure and the homology of the LERN1 protein to other neural LRR proteins, suggest that LRRN6A is a potential candidate gene to contribute to the molecular and cellular pathogenesis of mental disorders.

**Loss of *Cecr2* causes neural tube defects.** *T.M. Ames, M.D. Kardel, H.E. McDermid, G.S. Banting.* Biological Sciences, University of Alberta, Edmonton, Alberta, Canada.

Neural tube defects (NTDs), the second most common birth defect in humans, are caused by the failure of the neural tube to close during early development. NTDs are considered multifactorial in humans, however in mice the loss of many single genes have been shown to cause NTDs. We show here that loss of putative transcriptional coactivator *Cecr2* also causes NTDs in mice. We have created a knockout mouse using ES cells containing a genetrapp insertion within intron 7 of *Cecr2*. Mice homozygous for the genetrapp exhibit the NTD exencephaly, equivalent to anencephaly in humans, with a penetrance of 67% on a mixed 129P2:BALB/c genetic background. Nonpenetrant individuals are normal and fertile. LacZ reporter gene expression from the gene trap vector in heterozygous mouse embryos show *Cecr2* expression in the brain, spinal cord, spinal ganglia, nasal cavities, eyes and the digits of the limbs. Northern blot analysis of *CECR2* shows expression in most human adult tissues as well as human fetal brain, lung, and kidney.

*Cecr2* is a complex gene with the potential for multiple alternatively spliced transcripts. The protein sequence contains a bromodomain, nuclear localization signal, and AT hook, as well as several LXXLL-like binding motifs. The presence of these motifs suggests that *Cecr2* is a transcriptional coactivator, and therefore likely to be involved in chromatin remodeling and controlling the expression of other genes.

This mouse model will be useful for studying NTDs since exencephaly is the only phenotype shown to be caused by the loss of *Cecr2*. As *Cecr2* is likely a transcriptional coactivator, it may interact with other proteins already shown to cause exencephaly, thereby elucidating connections between such genes. Further characterization of *Cecr2* will shed new light on the mechanisms of neural tube closure.

***WHSC4* - a novel ncRNA gene in the Wolf-Hirschhorn syndrome critical region 1.** *S. Endele*<sup>1</sup>, *S. Schlickum*<sup>1</sup>, *N. Pfarr*<sup>2</sup>, *A. Winterpacht*<sup>1</sup>. 1) Institute of Human Genetics, Univ Erlangen-Nuremberg, Erlangen, Germany; 2) Childrens Hospital, University of Mainz, Mainz, Germany.

The Wolf-Hirschhorn syndrome (WHS) is a complex and variable malformation syndrome associated with the deletion of the terminal short arm of one chromosome 4. The WHS critical region has been confined to 165 kb in chromosomal subband 4p16.3. Recently, Zollino et al. (2003) suggested a second critical region (WHSCR2) immediately distal to WHSCR1. Clinical and cytogenetic data indicate that WHS is a contiguous gene syndrome, which means that haploinsufficiency of more than one gene in the affected chromosome region contribute to the phenotype. In order to elucidate the etiology and pathogenesis of this syndrome our studies aimed at identifying all genes and regulatory regions (in WHSCR1) contributing to the phenotype by comparative sequencing, computer assisted analysis, as well as functional studies. Two known and three novel genes (*WHSC1*, *WHSC2*, *LETM1*, *WHSC3*, *WHSC5*) were identified in the WHSCR1. In addition, we detected several EST matches as well as predicted exon sequences that did not correspond to any of these transcription units. By extensive RT-PCR analysis and rapid amplification of cDNA ends (RACE) as well as Northern blot analysis we could demonstrate that most of these sequences correspond to a single novel gene (*WHSC4*) which is expressed in a complex pattern in several tissues. *WHSC4* contains repetitive sequences, does not display any significant open reading frame and undergoes complex alternative splicing, leading to at least 4 different transcript classes (A-D). RACE experiments suggested at least 3 different transcriptional start sites and at least 3 different 3exons. The 5-end of one of these transcripts (A) overlaps with exon 1 of *WHSC3* on the opposite strand indicating that it might function as an antisense transcript. Other transcripts (B-D) span the entire *WHSC3* gene and/or overlap with parts of *WHSC2* in sense direction. All verified exons of *WHSC4* together span about 60 kb of the WHSCR1. The lack of significant open reading frames as well as its possible antisense function suggests a putative regulatory function of *WHSC4*.

**CAT 53: a protein phosphatase 1 nuclear targeting subunit encoded in the MHC Class 1 region may take part in memory and learning.** *J. Gruen*<sup>1</sup>, *R. Raha-Chowdhury*<sup>2</sup>. 1) Dept Pediatrics, Yale Univ Sch Medicine, New Haven, CT; 2) Centre for Brain Repair, University of Cambridge, Cambridge, UK.

CAT 53 is a phosphatase 1 nuclear targeting subunit (PNUTS), and a potent inhibitor of nuclear serine/threonine protein phosphatase 1 (PP1). It was identified by cDNA hybridization selection as an expressed sequence tag (EST) located in the vicinity of HLA-C and designated as CAT for HLA-C associated transcript number 53. It is a 99kDa protein expressed in several tissues including brain, muscle and liver. Fluorescence analysis with anti-CAT 53 antibody shows a punctate nucleoplasmic staining with accumulation in the nucleolus. In-situ hybridization studies of mouse brain show high expression in the olfactory cortex, piriform cortex and hippocampus, where CAT 53 is expressed in CA1, CA3, and mainly in the dentate gyrus. The hippocampus is important in development and plasticity, plays a fundamental role in learning and episodic memory, and has been implicated in a number of neurological and psychiatric disorders including Alzheimers disease, epilepsy, and schizophrenia. We present the genomic organisation of CAT 53, characterise the unique expression pattern in human brain, localize specific sites of mRNA transcription in thin sections of mouse brain by in-situ hybridization, and perform a structural analysis of the peptide domains.

**Characterization of Genes for the Calcitonin Gene Related Peptide (CGRP), its Receptor Component Protein (RCP) and the Generation of RCP Mouse Embryonic Stem Cells.** *L. Mnayer, I. Dickerson.* Physiology and Biophysics and The Dr. John T. Macdonald Foundation Center for Medical Genetics University of Miami School of Medicine, Miami, FL.

CGRP is a potent vasodilator neuropeptide secreted by central and peripheral nerves. Its receptor, the calcitonin receptor-like receptor (CRLR) signals through Gs and generates cyclic AMP. A receptor component protein (RCP) is necessary, but not sufficient for the formation of a stable receptor complex. We demonstrated that RCP was required for CGRP receptor signaling using antisense RNA to RCP expression in NIH3T3 cells. The reduction in RCP expression correlated with diminished CGRP-mediated signal transduction. Using co-immunoprecipitation we identified a complex of CRLR, RCP and a third accessory protein, receptor activity modifying receptor (RAMP-1) in NIH3T3 cells, guinea pig cerebellum and mouse embryonic stem cells (ES). Transcription start sites of the RCP promoter were identified using reverse transcriptase, ribonuclease protection assays and primer extension. The promoter is TATA-less, GC-rich and has four transcription start sites within a 50 bp region. We constructed an RCP target vector with 55% of the RCP gene replaced by green fluorescent protein, and neomycin phosphotransferase. RCP heterozygous ES cells were selected and confirmed by PCR, Southern blot analysis. A 50% reduction in RCP protein was observed in the heterozygotic cells. In conclusion we demonstrate the use of cell culture to determine the *in vitro* role of RCP in CGRP-mediated signal transduction. The generation of heterozygous knockout (RCP) ES cells should enable *in vivo* ascertainment of its functions.

**Fine mapping of duplication endpoints in Pelizaeus-Merzbacher disease.** *G. Hobson*<sup>1</sup>, *M. Cundall*<sup>2</sup>, *K. Sperle*<sup>1</sup>, *J. Kamholz*<sup>3</sup>, *J. Garbern*<sup>3</sup>, *H. Heng*<sup>3</sup>, *E. Sistermans*<sup>4</sup>, *S. Malcolm*<sup>2</sup>, *K. Woodward*<sup>2</sup>. 1) Dept Research, A I duPont Hosp Children, Wilmington, DE; 2) Inst Child Health, London, UK; 3) Wayne State Univ, Detroit, MI; 4) Univ Med Ctr Nijmegen, Netherlands.

Duplication of a portion of the long arm of the X-chromosome which includes the proteolipid protein 1 gene (*PLP1*) encoding the major central nervous system (CNS) myelin protein is the most common cause of the leukodystrophy Pelizaeus-Merzbacher disease (PMD). Animal studies have shown that overexpression of PLP1, a result of increased dosage of *PLP1*, can account for the disease pathogenesis, and that the severity of the disease is related to the amount of PLP1 overexpression. A study by Inoue and colleagues on 13 patients suggested that clinical severity of PMD is also related to the size of the duplicated segment. In this work we have investigated the size and location of the endpoints of the X-chromosome duplication in a cohort of 54 patients with PMD and a chromosomal duplication using a combination of interphase fluorescence in-situ hybridization (FISH), fiber FISH, quantitative PCR, and long range PCR. Although we find variability in the size of the duplicated region, from 100kb to 4.6Mb, we have not found a correlation between size of the duplicated region and clinical severity of the patients as assessed by a functional disability score developed for this purpose. Analysis of DNA sequence in the vicinity of duplication breakpoints does not demonstrate the presence of flanking low copy number repeats, suggesting that the chromosomal rearrangements are not mediated by non-allelic homologous recombination as commonly found in other genomic disorders. Recombination at the duplication breakpoints is likely caused by non-homologous end joining as proposed by Inoue and co-workers for deletions affecting this same chromosomal region. The molecular and genetic mechanisms underlying differences in disease severity, however, are not known, but are currently under investigation.

**Mutant ataxin-2 disrupts the Golgi complex and causes cell death.** *S.M. Pulst, D.P. Huynh, H. Ng, D. Nguyen, H.T. Yang.* Division of Neurology, Cedars-Sinai Medical Center-UCLA School of Medicine, Los Angeles, CA.

Spinocerebellar ataxia type 2 (SCA2) belongs to a class of neurodegenerative diseases caused by the expansion of the polyglutamine (polyQ) repeat. In contrast to other polyQ diseases, intranuclear inclusions of the SCA2 gene product ataxin-2 are not prominent in SCA2. In this report, we investigated the mechanisms underlying SCA2 pathogenesis using cellular models. COS1 cells and PC12 neurons were transiently transfected with plasmid constructs that express either GFP- or HA-tagged ataxin-2 proteins containing polyQ repeats of 22, 58, or 104 glutamines. Transfected cells were examined by confocal laser microscopy for morphological alteration, and cell death was determined by trypan blue exclusion assay, TUNEL staining, and caspase 3 enzymatic assays. In COS1 cell, both the endogenous and exogenous ataxin-2 proteins were localized in the Golgi apparatus. Ataxin-2 has an ER-exit signal and a trans-Golgi signal, and deletion of these motifs resulted in an altered subcellular ataxin-2 distribution. Expression of a full-length ataxin-2 with an expanded polyQ repeat disrupted the normal morphology of the Golgi complex and colocalization with Golgi markers was lost. Intranuclear inclusions were only seen when the polyQ repeat was expanded to 104 glutamines, and even then, were only observed in a minority of cells. Expression of ataxin-2 with expanded polyQ repeats in PC12 and COS1 cells increased cell death compared with normal ataxin-2, and elevated the levels of activated caspase-3 and TUNEL-positive cells. Cell death was completely inhibited by caspase-3 inhibitors. In conclusions, these results suggest a link between cell death mediated by mutant ataxin-2 and the stability of the Golgi complex. The formation of intranuclear aggregates is not necessary for cell death caused by expression of full-length mutant ataxin-2 in cultured cells.

**Investigation of the subcellular localisation of wildtype and mutant isoforms of spartin, mutated in a complicated form of HSP.** *H. Patel*<sup>1</sup>, *K. Whiting*<sup>2</sup>, *M.A. Patton*<sup>1</sup>, *A.H. Crosby*<sup>1</sup>. 1) Medical Genetics Unit, St. George's Hospital Medical School, London, UK; 2) King-George Laboratory, St. Georges Hospital Medical School, Cranmer Terrace, Tooting, London, UK.

The hereditary spastic paraplegias (HSPs) are a clinically diverse group of disorders in which progressive lower limb spasticity and weakness are primary features. We have shown that mutations in spartin underlie an autosomal recessive variant of HSP (Troyer syndrome, SPG20) present at high frequency amongst the Old Order Amish. Comparative sequence alignment revealed that spartin contains three protein domains (a MIT domain and two plant-related domains), one of which is also present in spastin, commonly mutated in autosomal dominant forms of HSP (SPG4). We have made a number of GFP-tagged constructs, both wildtype and three mutants including; (i) C-terminal portion deleted construct retaining only the N-terminal MIT domain, (ii) MIT domain deleted retaining only the plant-related regions, and (iii) a construct containing the 1110delA mutation identified in the Amish population, to evaluate the subcellular localisation of the spartin variants in the mouse neuronal cell line NSC34.

***WHSC5* - A novel candidate gene for neurological features of Wolf-Hirschhorn syndrome.** A. Winterpacht<sup>1</sup>, N. Pfarr<sup>1,2</sup>, S. Schlickum<sup>1</sup>, S. Richter<sup>1</sup>, B. Zabel<sup>2</sup>, S. Endele<sup>1</sup>. 1) Institute of Human Genetics, Univ Erlangen-Nuremberg, Erlangen, Germany; 2) Childrens Hospital, University of Mainz, Mainz, Germany.

The Wolf-Hirschhorn syndrome (WHS, MIM 194190) is caused by deletions in chromosome region 4p16.3 and is thought to be a true contiguous gene syndrome with a yet unknown number of genes contributing to the phenotype. Recently, several candidate genes have been described (*WHSC1*, *WHSC2*, *WHSC3*, *LETM1*) which are located in or immediately adjacent to the previously defined 165 kb WHS critical region 1 (WHSCR1). We have now focused our attention on the identification and functional characterization of genes which are involved in the neurological features (e.g. seizures, learning and motor deficiencies, ADHD) of the syndrome. Besides *LETM1*, which has become a strong candidate for seizures, we identified two further candidate genes by comparative sequencing and intensive database analysis (*WHSC3*, *WHSC5*). Here we describe the further functional characterization of *WHSC5*. *WHSC5* encodes a protein of approximately 300 aa in human and mouse. The protein most probably belongs to the superfamily of GCN5 related N-acetyltransferases (GNAT), showing the highest homology to members of the camello family of acetyltransferases. A member of this not very well characterized family has recently been implicated in early developmental processes. Northern Blot analysis revealed two main transcripts of approximately 3 and 6 kb in human and murine brain and testis. Whole mount and RNA in situ hybridization in early developmental stages of mouse development as well as in adult mouse brain showed that the expression is restricted to the neopallial cortex and the roof of the midbrain. Analysis of the *WHSC5* promotor has been performed and revealed putative target sites for transcription factors involved in development. The strong expression of the gene in fetal and adult brain tissues suggests an implication in brain development and/or function. Together with the predicted function in cell signaling and/or early developmental processes, *WHSC5* represents an excellent candidate gene for neurological features of Wolf-Hirschhorn syndrome.

**Characterization of an N-terminally Truncated WT1 Protein with Distinct Function Derived from an Alternative Promoter.** *A. Hossain, M. Nixon, C. Li, G.F. Saunders.* Department of Biochemistry and Molecular Biology, UT M. D. Anderson Cancer Center, Houston, TX 77030.

The Wilms tumor suppressor gene 1 (WT1) was originally identified as its association with Wilms tumor, a childhood nephroblastoma. In addition to causing Wilms tumor, mutations in WT1 often cause two distinct but overlapping urogenital defects in men Denys-Drash and Frasier syndromes. Alternative splicing of the WT1 transcript generated four major isoforms with different functional properties. We report here a previously unrecognized transcript originating from a second promoter that lies in intron 1 of the WT1 gene. This 2.5 kb WT11 transcript encodes a protein of about 35-37 kD depending on the alternatively spliced exon 5 and insertion/deletion of KTS amino acids in between the 3rd and 4th zinc-fingers. The N-terminal region of WT1 is known to contain the repressor domain and an RNA recognition motif encoded by exon 1. WT11 retains the intact DNA-binding and transactivation domain, but lacks the N-terminal 147 amino acids responsible for transcriptional repression. WT11 activates the Cyclin E promoter that is normally repressed by WT1. The expression pattern of WT11 is different from WT1 in different tissues. WT11 is highly expressed in adult testis, although low level expression can be detected in kidney, lung, spleen, and ovary. WT11 transcript is over expressed in almost all types of Leukemia, whereas full-length WT1 transcript is expressed in few cases. WT11 overexpression causes mesenchymal to epithelial conversions of SaOS-2 cells. Whereas, overexpression of full length WT1 causes cell death of SaOS-2 cells.

Program Nr: 1014 from 2003 ASHG Annual Meeting

**The role of transcription factor BTEB3 in the regulation of smooth muscle-specific gene expression in vivo.** *M. Keramatipour, P.D. Ellis, A.A. Grace, J.C. Metcalfe, P.R. Kemp.* Cardiovascular Biology Section, Department of Biochemistry, University of Cambridge, Cambridge CB2 1QW, United Kingdom.

Control of gene expression in vascular smooth muscle cells (VSMCs) is important in development and disease. During normal development smooth muscle  $\alpha$ -actin (SM  $\alpha$ -actin) is expressed prior to SM22a with smooth muscle myosin heavy chain (SM-MHC) expressed last. Dedifferentiation of these cells is a major pathological change seen in a number of conditions including atherosclerosis and restenosis after angioplasty. Recent evidence has implicated the Krppel like family of transcription factors (KLF family) in the control of SM-specific gene expression. BTEB3, a KLF identified in our laboratory, is widely expressed in both adult and embryonic mouse tissues. Our studies have implicated BTEB3 as a selective regulator of the smooth muscle-specific gene, SM22a, in VSMCs but not of either SM-MHC or SM  $\alpha$ -actin. To investigate the role of BTEB3 further we use two different methods to modify its expression in mice, standard knock out and siRNA transgenic mice. To make siRNA transgenic mice first two siRNA vectors were developed and showed that they knock down > 85% of BTEB3 expression in vitro. The siRNA construct was used to make transgenic mice and phenotype was analysed at different embryonic stages. Preliminary data showed that BTEB3 siRNA transgenic mice are not viable from ED 12 although the phenotype does not show full penetration. The effect of knock down of BTEB3 will be compared with the effect of knock out of BTEB3.

**Modulation of 5-hydroxytryptamine 4 (5HT4) receptor isoform expression predisposes to atrial fibrillation after coronary artery bypass surgery.** *S. Yusuf<sup>1</sup>, C. Fenske<sup>2</sup>, C. Dalageorgou<sup>2</sup>, N. Carter<sup>2</sup>, N. Al Saady<sup>1</sup>, N. Maarouf<sup>1</sup>, A.J. Camm<sup>1</sup>.* 1) Cardiovascular Medicine, St George's Hospital Medical School, London, UK; 2) Clinical Developmental Sciences, St George's Hospital Medical School, London UK.

5HT is a novel hormonal trigger to atrial fibrillation (AF), the commonest and most challenging of all the cardiac arrhythmias. 5HT is produced by serotonergic neurones in the central / enteric nervous systems and is stored / released by platelets when activated. It acts upon 5HT4 receptors on human atrial myocytes, which in turn are positively coupled to adenylyl cyclase, increasing heart rate. There are at least three different 5HT4 receptor isoforms resulting from alternate splicing and their exact role in atrial arrhythmias is not understood. We postulated that 5HT4(a) and (b) receptor isoform levels would be higher in patients susceptible to post coronary artery bypass grafting (CABG) AF and in those with the established arrhythmia (present pre and post operatively), the expression of both receptor isoforms would be down regulated due to electrical remodelling. Right atrial appendage samples were harvested from 52 patients undergoing bypass surgery. All patients had their pre operative underlying heart rhythm assessed and were followed up after the operation until discharge. 23 patients maintained sinus rhythm (SR) throughout; 14 patients developed AF post operatively and 15 patients had established AF. mRNA was extracted, purified and cDNA was synthesized using reverse transcriptase (Sensiscript Qiagen). Real time relative quantification PCR was carried out (Light Cycler Roche). Results showed ubiquitous 5HT4(a) and variable 5HT4(b) expression. A statistically significant reduction in 5HT4(a) expression levels in patients with established AF was shown (Student T-test  $p=0.001$ ). 5HT4(b) expression was higher in SR patients who developed post operative AF; this effect was even greater in patients with established arrhythmia compared to those who maintained SR throughout. Our study shows that expression of the 5HT4(b) receptor isoform predisposes to AF post CABG and also helps maintain AF.

Program Nr: 1016 from 2003 ASHG Annual Meeting

**CLN6 encodes linclin, a novel 28kD transmembrane protein.** *H. Gao, J. Espinola, ME. MacDonald.* Molecular Neurogenetics Unit, Massachusetts General Hospital, Harvard University, Charlestown, MA 02129.

The neuronal ceroid lipofuscinoses (NCLs) are recessive neurodegenerative disorders with lysosomal accumulation of autofluorescent membranous deposits. Mitochondrial ATP synthase subunit c is a major component of the deposits in the juvenile, late infantile and variant late infantile forms of the disease, suggesting that these are disorders of mitochondrial degradation. We have recently cloned CLN6, associated with Costa Rican vLINCL and have shown that disease stems from recessive mutations that alter the activity of linclin, a novel 311 amino acid transmembrane protein. To set the stage for studying linclin function in mitochondrial turnover, we are characterizing linclin. In vitro transcription and translation of CLN6. cDNA gives rise to a a 28kD polypeptide, that is not processed when microsomal membrane is added. We have used a lentiviral vector system to generate stable human brain cell lines that express linclin-V5 fusion protein. Immunoblot confirms an ~28 kD fusion protein, without evidence of stable processed isoforms. Confocal analyses with V5 monoclonal antibody reveals linclin in association with endoplasmic reticulum (ER), suggesting that linclin may be involved in steps of mitochondrial autophagy that require ER function. Our stable linclin neuronal cell lines, with others that express mutant linclin associated with vLINCL, will be valuable reagents for deciphering the activity of linclin in mitochondrial autophagy.

**Detection and characterization of beta-globin cluster rearrangements using Quantitative Multiplex PCR of Short fluorescent Fragments.** *S. Pissard*<sup>1,2</sup>, *J.P. Tabut*<sup>1</sup>, *Hao. Le Thi*<sup>4</sup>, *M. Goossens*<sup>1, 2</sup>, *T. Frebourg*<sup>3</sup>, *M. Tosi*<sup>3</sup>. 1)

Biochemistry and genetics, AP-HP, hop Henri Mondor, creteil, france; 2) INSERM U468 Hop Henri Mondor Creteil France; 3) INSERM EMI 9906, facut de Medecine et de Pharmacie, Universit de Rouen, Rouen, France; 4) departement of Human genetics, University of medicine and pharmacy, Ho Chi Minh city, Vietnam.

The beta-globin cluster contains approximately 50 percent of repeat sequences of various type, as revealed by Repeat Masker analysis and is therefore prone to deletion and recombination events. A great number of large deletions removing entirely or partially the globin gene and other globin locus genes have been described, which cause severe beta thalassemia disease. Since PCR is the common step of nearly all methods used for the molecular characterization of thalassemia, deletions are frequently not diagnosed and the real prevalence of such molecular defects is under evaluated. To make the detection of such events as easy as that of point mutations, we have designed a QMPSF (quantitative multiplex PCR of short fluorescent fragments) assay with a high density of test fragments around the b globin gene. We targeted 8 positions on the b globin locus : the LCR HS2, the gene, the A gene, the gene, the gene, the gene, two intergenic regions (inter and 3 of b gene) and a control gene not located on chromosome 11. We tested the method using samples displaying several known deletions (Chinese del: a thal, Sicilian del: thal, del -619) and recombination events generating hybrid genes like Hb lepore ( gene) and antilepore type ( gene). Our results were consistent with the expected deletion. However, using the antilepore sample, we found a pattern that does not correspond to the expected lepore counter-type recombination. This result would be in agreement with a gene conversion rather than a recombination event for the antilepore chain. This adaptation of QMPSF to the globin locus, provides a simple and reliable tool not only for detection but also for detailed characterization of the deletions or amplifications within the locus and should help to determine the real prevalence of these events and their molecular mechanisms.

**Norrie Disease Gene Mutations in Retinopathy of Prematurity.** *P. Paluru*<sup>1</sup>, *K. Hutchenson*<sup>2</sup>, *J. Koh*<sup>1</sup>, *E. Rappaport*<sup>1</sup>, *T. Young*<sup>1</sup>. 1) Ophthalmology, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Children's National Medical Center, Washington DC.

**PURPOSE:** Norrie disease is an X-linked recessive disorder characterized by bilateral retinal detachments, and variable hearing loss and developmental delay. Norrie disease gene (NDP) screenings primarily limited to exon 3 have been associated with heritable retinal vascular disorders, and in a small subset of patients with severe retinopathy of prematurity (ROP). We sought to correlate severity of ROP disease to NDP mutations in a large cohort of premature infants performing a mutation screen of the entire 3-exon gene. Parental carrier status was also evaluated.

**METHODS:** A total of 118 individuals of different ethnic backgrounds were consented and screened- 87 were pre-term infants and were 31 parents. Of the 87 infants, 52 had severe ROP (Stages 3-5). The median gestational age was 28.5 weeks (range 23-34), and the median birth weight was 1062.5 grams (range 367-1758). Seven amplicons spanning NDP were optimized for DHPLC and direct sequencing analysis. Three amplicons covered the coding region, and the remaining 4 spanned the 3UTR region.

**RESULTS:** Two sequence alterations were found, both in the 3UTR region of exon 3. A GA polymorphism at mRNA position 824 was found in an African American female and male with pre-threshold and threshold ROP, respectively. An AG polymorphism at mRNA position 1103 was found in an African American male and his normal mother.

**CONCLUSIONS:** Two novel nucleotide changes were found in the 3UTR region of exon 3 in our cohort. This is the first identification of NDP polymorphisms shown in African American infants who generally are less likely to develop severe levels of ROP. The results suggest that no association exists between NDP sequence alterations and severity of ROP in a large cohort of infants.

**Analysis of GJB2 heterozygotes for mutations affecting connexin 26 expression.** *R. Taggart*<sup>1</sup>, *E. Cohn*<sup>2</sup>, *P. Kelley*<sup>2</sup>, *W. Kimberling*<sup>2</sup>, *W. Sanger*<sup>3</sup>, *D. DiMaio*<sup>3</sup>, *M. Nelson*<sup>3</sup>, *J. Kenyon*<sup>3</sup>, *S. Smith*<sup>3</sup>. 1) Ctr Hearing & Deafness, SUNY Buffalo, Buffalo, NY; 2) Boys Town Natl Res Hosp, Omaha, NE; 3) University of Nebraska Med Ctr, Omaha, NE.

GJB2 (connexin 26) mutations are found in 20-30% of subjects with congenital nonsyndromic deafness, however as many as 30% have a single GJB2 mutation. The interpretation of a GJB2 heterozygote is difficult; hearing loss could be due to an undetected GJB2 mutation, an interaction with another gene mutation, or to an unrelated cause. One recently identified mutation is a 342 kb deletion (GJB6-D13S1830) that includes a portion of the coding exon of GJB6 (connexin 30), located 30 kb proximal to GJB2. The deletion includes the entire 5' upstream region of GJB6 and highly conserved noncoding regions that may coordinate expression of Cx26 & Cx30 within the inner ear. Hearing loss in subjects doubly heterozygous for the GJB6-D13S1830 deletion and a GJB2 mutation may be digenic inheritance, as a result of reduced expression of both Cx26 & Cx30. Alternatively, the GJB6-D13S1830 deletion may cause Cx26 related deafness by alteration of tissue specific Cx26 expression combined with loss of Cx30. We screened GJB2 heterozygotes with polymorphic markers in the region, FISH of metaphase chromosomes, quantitative PCR for gene copy differences and examined skin and retinoic acid treated fibroblasts for connexin 26, 30 and 43 expression. 101 deaf subjects with 2, 1 or no GJB2 mutations were examined with 11 polymorphic markers. Significantly increased levels of homozygosity ( $p < 0.0001$ ) were observed in subjects with 2 or 1 GJB2 mutations compared to subjects with no GJB2 mutations and controls. A GJB6 associated deletion was found in 2 of 21 GJB2 heterozygotes. No Cx26 expression was detected in skin from GJB2 35delG homozygotes, however reduced Cx26 expression was observed in retinoic acid induced fibroblast cultures from a subject heterozygous for the GJB6-D13S1830 deletion and the GJB2 35delG mutation. This suggests the GJB6-D13S1830 deletion removes regions that coordinate the expression of Cx 26 and 30. Screening for Cx26 expression in skin could prove invaluable to identify previously undetected mutations.

**Regulation of the nuclear translocation of the Carbohydrate Response Element binding protein, the Williams Beuren Syndrome Protein 14.** *G. Merla<sup>1</sup>, A.K. Stoeckman<sup>2</sup>, C. Howald<sup>1</sup>, S.E. Antonarakis<sup>1</sup>, H.C. Towle<sup>2</sup>, A. Raymond<sup>1</sup>.* 1) Division of Medical Genetics, Univ Geneva Med School, Geneva, Switzerland ; 2) Department of Biochemistry, Molecular Biology and Biophysics, University of Minnesota.

The Williams-Beuren syndrome (WBS) is a contiguous gene syndrome caused by chromosomal rearrangements at chromosome band 7q11.23. While our understanding of the etiology of WBS has improved greatly, the molecular basis of all except the cardiovascular phenotype remain unknown. Several endocrine phenotypes have been described for this clinically complex disorder, in particular impaired glucose tolerance (IGT) and silent diabetes.<sup>23</sup> Single copy loci map to the 1.5 Mb haploinsufficient region, while its flanking low copy repeat support multiple copies of 9 transcription units. Here, we study the potential involvement of one of the WBS genes, WBSCR14 in this pathology. The WBSCR14 gene encodes a member of the basic-Helix-Loop-Helix Leucine Zipper family of transcription factors, that dimerizes with the Max-like protein, Mlx, to bind E-box motifs in the promoter region of target genes. The rat ortholog of WBSCR14 is expressed under high glucose diet and inhibited under high fat diet in INS-1 pancreatic beta-cells. Its overexpression in primary cultured hepatocytes results in increased transcription of the LPK gene through direct binding of the Carbohydrate Response Element (ChoRE) of the LPK promoter. High glucose level activates also the nuclear translocation and the DNA-binding activity of rat WBSCR14. To identify new proteins that interact with WBSCR14, and potentially regulate its nuclear translocation, we performed a yeast two-hybrid selection and isolated four 14-3-3 isotypes and NIF3L1, that form a single polypeptide complex with WBSCR14 in mammalian cells. The active nuclear export of WBSCR14 is dependent upon the ability to bind 14-3-3, while its cytoplasmic retention is controlled by the NIF3L1 protein. Through these processes these interactors affect directly WBSCR14 transcription activation of lipogenic genes, as increasing amounts of NIF3L1 repress WBSCR14:Mlx ChoRE-driven transcription. We suggest a correlation between the WBSCR14 haploinsufficiency and the IGT observed in WBS patients.

**Complex Chromosome Rearrangement (CCR), 46,XY,t(5;6;20)(p13;p23;q13) in a male with oligospermia reproductive failure.** *D.S. Krishnamurthy, N. Al-Torki, S.A. Al-Awadi.* Cytogenetics Laboratory, Medical Genetics Ctr, Maternity Hospital, Kuwait.

Numerical and structural chromosomal abnormalities of autosomes and sex chromosomes are not uncommon in male infertility cases. Majority of structural rearrangements observed in constitutional cases originate from one or two break points (simple translocations, inversions, ring chromosome...). Complex chromosome rearrangement (CCR) occurring in phenotypically normal persons is rare. The rearrangement is considered to be balanced in phenotypically normal persons. CCR arise as familial or de novo mutation. A normal healthy couple (husband 29 yrs and wife 25 yrs) were investigated for secondary infertility and history of one spontaneous abortion (1st trimester). The husband's semen analysis confirmed oligospermia. The family history was unremarkable. Husband's seven brothers and 2 sisters are all phenotypically normal. Chromosome analysis of the wife confirmed normal 46,XX karyotype. Karyotype of the husband showed a balanced complex chromosome rearrangement (CCR), involving translocation of chromosomes 5;6;20 at break points, p13, p23 and q13 respectively. [46,XY, t(6;5)(p23;p13), t(5;20)(p13;q13)]. Heterozygote female carriers of CCR may be fertile and have pregnancies that produce phenotypically normal/balanced/affected children. However, male heterozygotes of CCR are often sterile or subfertile, because of spermatogenic arrest. The significance of CCR in male infertility will be discussed.

**Analysis of human-mouse conserved genomic sequences (Conserved Sequence Tags, CST) potentially involved in genetic diseases.** *S. Banfi*<sup>1</sup>, *D. di Bernardo*<sup>1</sup>, *A. Boccia*<sup>3</sup>, *A. Guffanti*<sup>5</sup>, *M. Petrillo*<sup>3</sup>, *S. Confalonieri*<sup>5</sup>, *F. Mignone*<sup>4</sup>, *G. Pesole*<sup>4</sup>, *C. Missero*<sup>1</sup>, *G. Ballabio*<sup>1, 6</sup>. 1) TIGEM, Naples, Italy; 2) Department of Natural Sciences, University of Molise, Campobasso, Italy; 3) Biogem, Naples, Italy; 4) Department of Biochemistry, University of Milan, Milan, Italy; 5) FIRC Institute of Molecular Oncology, Milan, Italy; 6) Department of Pathology, Second University of Naples, Naples, Italy.

Comparative sequence analysis among genomes of different species represents an effective tool to identify conserved sequence elements that play a functional role in fundamental biological processes. The identification of conserved genomic regions surrounding disease-related genes is of crucial importance to better understand the cause of the disease and to gain important insights into mechanisms of gene regulation. We carried out a systematic genomic sequence comparison between 1000 human genes involved in the pathogenesis of genetic disorders and their murine counterparts. This analysis revealed the presence of over 60,000 sequence elements showing an identity greater than 75% between human and mouse over a region of at least of 100 base pairs. Approximately 65% of these sequences which we termed CSTs (Conserved Sequence Tags)- did not correspond to previously known exon sequences. We undertook a detailed bioinformatics analysis in order to gain insight into the possible role of these conserved sequences. In particular, we classified CSTs into the following subgroups: 1) transcribed CSTs (either belonging to coding or to non-coding transcripts); 2) non-transcribed CSTs with a high probability of representing functional elements, such as expression control elements; and 3) non-transcribed CSTs with a lower probability of having a functional role. These information, which will be entered into a publicly available CST database, should lead to a better comprehension of the biological role of CSTs and to a further elucidation of the mechanisms leading to human inherited diseases.

**Interleukin 31 is a novel four-helical-bundle cytokine that signals through a heterodimeric receptor complex expressed in epithelial cells of lung and skin.** *J.E. Parrish-Novak, C. Sprecher, A. Hammond, S. Presnell, J. Kuijper, F. Grant, Z. Gao, H. Haugen, S. Dillon, T. Whitmore, M. Franklin, M. Dasovich, M. Maurer, B. Harder, K. Waggle, T. Bukowski, D. Dong, P. Shea, D. Foster, J. Gross.* ZymoGenetics, Inc., Seattle, WA.

Four-helical-bundle cytokines have divergent primary sequences despite conserved secondary and tertiary protein structures. Cytokine receptors, however, share conserved primary sequence motifs readily recognized in sequence databases. Queries designed to detect these motifs identified a novel gp130-like receptor, *IL31RA*, in human genomic sequence. *IL31RA* is expressed in activated monocytes and T cells, and in epithelial cells in lung, skin, and prostate. *IL31RA* was expressed in a factor-dependent cell line along with other receptors in the gp130 class. Cells bearing *IL31RA* and OSM receptor responded to conditioned media from activated T cells. Functional cloning identified a novel cytokine, interleukin 31 (IL31). The intron phasing and exonic placement of structural elements in the *IL31* gene are conserved with those found in the genes encoding LIF, OSM, CT-1, and CLC; these related cytokines all activate gp130-class receptor complexes. In vitro assays using purified IL31 protein show activation of the Jak/STAT pathway in cells expressing both receptor subunits; expression of *IL31RA* alone is sufficient for binding but not for signal transduction. *IL31* is expressed in activated T and NK cells, with higher levels of transcript in Th2 than in Th1 cells. The genomic localization of the *IL31* gene to 12q24.3 is interesting in light of its characterization as a Th2 cytokine; this region includes a susceptibility locus for asthma, which is clearly Th2-driven. Overexpression of IL31 in transgenic mice resulted in a phenotype resembling human atopic dermatitis, also thought to be Th2-mediated. The transgenic phenotype is recapitulated with chronic delivery of pure IL31 to adult mice, demonstrating that it is not due to a defect in development. These data support a role for IL31 in Th2-mediated immune responses, and suggest that it may be a key cytokine in the pathogenesis of Th2-driven atopic diseases such as atopic dermatitis.

**Mouse PC7/LPC deficient embryonic fibroblast cell can process HIV gp160 protein.** *M. Ebihara*<sup>1,3,4,5</sup>, *D. Akanuma*<sup>2,4</sup>, *B.D. Young*<sup>3</sup>, *J. Meerabux*<sup>3,4</sup>, *Y. Sato*<sup>5</sup>, *T. Amagasa*<sup>2</sup>. 1) HMRO, The University of Kyoto, Kyoto, Kyoto, Japan; 2) Maxillofacial Surgery, Graduate School, Tokyo Medical and Dental University, Tokyo, 113-8549, Japan; 3) Medical Oncology Laboratory, Cancer Research UK, London, EC1M 6BQ, United Kingdom; 4) Laboratory for Molecular Psychiatry, RIKEN Brain Science Institute, Saitama 351-0198, Japan; 5) Department of Pathology IMCJ RESEARCH INSTITUTE, Tokyo, 162-0052, Japan.

Proprotein convertases (PCs) cleave proproteins to produce the mature form of regulatory proteins such as neuropeptides, growth factors, peptide hormones, enzymes and viral glycoproteins. There are now 7 known members of this family which includes furin, PC1/PC3, PC2, PC4, PC5/PC6, PACE4, and LPC/PC7/PC8/SPC7. Human immunodeficiency virus (HIV) glycoprotein (gp160) is processed by host cell proteases to produce gp120 and gp41. Recent study revealed that furin and/or PC7/LPC may involve in the processing of gp160. To investigate the role of PC7/LPC in the processing of gp160, we have produced knockout mice for the PC7/LPC gene, followed by establishing PC7/LPC (-/-) embryonic fibroblast cell line. Processing of gp160 was observed when the gp160 gene was transfected into PC7/LPC (-/-) cells, suggesting two possibilities, that is, (1) both the furin and PC7/LPC act as a processing enzyme for gp160 protein, (2) third enzyme exists as a major processing enzyme for gp160 protein.

**Promoter analysis of single-minded 2 (SIM2) and DSCR4 genes located on human chromosome 21q22.2. Y.**

*Shimizu<sup>1</sup>, A. Yamaki<sup>1</sup>, M. Uno<sup>1</sup>, S. Asai<sup>1</sup>, J. Kudoh<sup>2</sup>, S. Minoshima<sup>2</sup>, N. Shimizu<sup>2</sup>.* 1) Dept Medical Genetics, Kyorin Univ Sch Health Sci, Tokyo, Japan; 2) Dept Molecular Biology, Keio Univ Sch Medicine, Tokyo, Japan.

Human SIM2 gene is a homolog of *Drosophila* single-minded gene which plays a key role in the midline cell lineage of a central nervous system. To understand the molecular mechanism of SIM2 gene expression, we have analyzed the promoter region by transient transfection using a series of deletion constructs and point mutants fused with luciferase reporter gene and by gel retardation assay. We found that the c-myb like transcription factor cis-element located between nt-1351 and 1334 and the CAAT cis-element located between nt-1015 and -1004 appears to be important for SIM2 gene expression in T98G glioblastoma cells. Furthermore, we performed chromatin immunoprecipitation assay and found anti-C/EBPbeta but not anti-c-myb antibodies precipitated specifically the SIM2 promoter region between nt-1351 and 1004. We are in progress of identifying the protein which binds to c-myb like cis-element using the oligonucleotide beads. DSCR4 is expressed only in human placenta but its function is not known although the estimated protein has a low homology to TNF ligand family. We found DSCR4 is expressed in human placental choriocarcinoma cells BeWo. Using this cell line we determined the transcription starting site and analyzed the promoter region (about 2kb containing upstream of nt-94). We found OLF-1 cis-element between nt-790 and 760 has strong stimulative activity for DSCR4 expression and detected three specific bands consisting of OLF-1 cis-element and certain proteins in the gel retardation assay.

**Identification and analysis of the new, Vps13-like gene (V13LG) family that includes *CHAC*, the gene altered in chorea-acanthocytosis.** A. Velayos, A. Vettori, C. Dobson-Stone, A.P. Monaco. Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Oxford, OX3 7BN, UK.

*CHAC* (9q21) was recently identified as the gene altered in Chorea-acanthocytosis, a rare autosomal recessive neurological disorder, whose characteristic features include hyperkinetic movements and abnormal red blood cell morphology. It encodes chorein, a large (3174aa) protein that shares significant homology with the yeast protein Vps13p, implicated in sorting of proteins like Kex2p. Comparison of chorein with the databases resulted in the identification of a number of human protein fragments not encoded by *CHAC*. We decided to analyse the genes encoding these proteins, as their study could lead to a better understanding of the function carried out by chorein. This analysis was performed as follows: i) deduction of the gene structures in silico, ii) verification of this structure by RT-PCR and sequencing, iii) analysis of the expression by northern blot and PCR in different tissues, iv) sequence comparison of the deduced proteins with each other and with homologous proteins in other organisms.

Three new *Vps13*-Like Genes (*V13LG2*, 3, 4), similar to *CHAC* (*V13LG1*) were identified, mapping on chromosome 15q21, 8q22 and 1p36, respectively. The main transcripts code for 3710, 4021 and 4362 aa proteins, respectively. *V13LG2* is highly similar to *CHAC*, suggesting a recent gene duplication; it also contains an internal duplication that explains the difference in size of both genes. Similarity of *V13LG3* protein with chorein is reduced to the N- and C-termini; this gene has been recently reported as *COH1*, involved in Cohen syndrome. *V13LG4* shows an intermediate similarity with *CHAC*. The four genes are widely expressed in human tissues, though several alternative splicing forms show difference in tissue distribution. Amino-acid sequence comparison shows the presence of two conserved regions at the N-terminus and the C-terminus of these proteins. These proteins could be involved in transport of different proteins, such as the proprotein convertases, homologous to the yeast Kex2p, which also constitute a gene family in higher species.

**Motoneuron Trophic Factor (MNTF) enhances peripheral nerve regeneration.** *D.L. Ash, D. Nussbaum, E.W. Jabs, T. Brushart.* Johns Hopkins Univ., Balto., MD.

MNTF is a 33 amino acid peptide identified from three wk old rat muscle extract electrophoresed on a 20% native PAGE gel. Thirty-four bands were resolved and excised (Chau et al 1992). Gel slices able to support survival of motor neuron colonies were selected for the production of polyclonal antibodies. These antibodies were used to screen a human retinoblastoma cDNA library. One plaque produced a novel transcript of 927bp that was localized to human chromosome 16q22 by use of a CHO/human hybrid chromosomal panel. Nucleotide BLAST of the transcript against the human EST database showed a 150 bp match, from normal adult human nerve tissue, which included the 99 bases that code for the MNTF human protein. We have found the human gene to be expressed in several tissues, including: human fetal thymus, liver, kidney; adult pituitary, 8-9 wk placenta, and weakly in the fetal skeletal muscle. To test function rat sciatic nerves were cut and the nerve endings sutured into the ends of a tube, leaving an 8mm gap between the ends. The enclosed gap was then filled with a solution of either 90% collagen and the MNTF protein, or collagen alone. Different concentrations of MNTF were tested by labeling the distal stump with the tracer Fluorogold, and counting the number of axons that managed to cross the gap within four wks. The results for each experimental group were: saline control, 540 axons;  $10^{-7}$ M MNTF, 687;  $10^{-6}$ M, 765;  $10^{-5}$ M, 873;  $10^{-4}$ M, 1111;  $10^{-3}$ M, 1130. We assessed whether MNTF had a specific effect on regeneration of motor versus sensory branches. End-to-end repairs of the rat femoral nerve were bathed in MNTF at the optimal concentration of  $10^{-4}$ M or in saline solution for three wks. Regeneration was evaluated by double-labeling the femoral muscle and cutaneous branches. With saline alone, a mean of 100 motor neurons projected correctly to muscle and a mean of 87 projected incorrectly to skin; a mean of 51 were double-labeled. After MNTF treatment, the mean number of motor neurons projecting correctly to muscle increased to 173 ( $p=0.0008$ ), with means of 59 projecting to skin and 47 double-labeled. Thus MNTF is present during development and has a specific effect on motor neuron regeneration with little impact on sensory projections.

**Cloning of the Human TSARG1 gene and the Mouse Mtsarg1 gene and the Expression Analysis in different development stages.** *J.J. Fu, L.Y. Li, X.W. Xing, S.F. Liu, G. Liu, G.X. Lu.* Human Reproduction & Stem Cell Institute, Central South University Xiangya Medical College, People's Republic of China.

Abstract: Applying the bioinformatics and experiment technique, we have cloned human and mouse novel gene cDNA sequences-human testis and spermatogenesis cell apoptosis related gene 1 (TSARG1) and mouse testis and spermatogenesis cell apoptosis related gene 1(Mtsarg1) from human and mouse testis cDNA library respectively, using a cDNA fragment (GenBank accession number: BE644538) as an electronic probe, which was significantly changed in expression in cryptorchidism in mouse by SSH technique. The GeneBank accession numbers of Mtsarg1 and TSARG1 are AF399971 and AY032925 (NM\_139073), respectively. The Mtsarg1 has a 55% identity and 61% similarity with TSARG1 at the amino acid level, which did not share significant homology with any other known protein in databases. The full-length cDNA of TSARG1 gene is 973 base pairs(bp)including 549 bp open read frame(ORF) and coding 183 amino acids, whereas the full-length cDNA of Mtsarg1 gene is 1103 bpincluding 576 bp ORF and coding 192 amino acids. The predicted molecule weight of TSARG1 is 19948.61 Daltonand the deduced iso-electric point is 10.24, whereas the Mtsarg1 is 20875.93 and is 9.83, being alkaline proteins. RT-PCR analysis showed that Mtsarg1 was expressed significantly in testis and faintly in epididymis in the ten tissues of testis, ovary, spleen, kidney, lung, heart, brain, epididymis, liver and skeletal muscle in mouse, while it wasn't expressed in the other eight tissues. Multiple tissues Northern blotting showed that Mtsarg1 expressed a 1.1kb fragment only in testis. To study the developmental regulations of the Mtsarg1 gene, RNAs were isolated from the testis of mice in the time of birth before, day 21, 35, 49, 280 and cryptorchid testis of day 14, and transported to the Nylon membrane. Northern blotting has been performed. Results showed that the Mtsarg1 transcript was detected lower signals in the time of day of 35 and higher in the time of day 49, 280 and cryptorchid testis of day 14, didn't detect any signals in the time of birth before, day 21 in testis in different development stages. Sex mature in mouse is about day 42 and indicated Mtsarg1 gene close related with the mouse spermatogenesis. Therefore, our results suggested that Mtsarg1 and TSARG1 would be pay important roles in the regulation of spermatogenesis cell apoptosis or spermatogenesis.

**Molecular identification of novel genes, especially transcription factors, from a human fetal growth plate cartilage library.** *S. Schlaubitz*<sup>1, 2</sup>, *C. Stelzer*<sup>1</sup>, *P. Hermanns*<sup>2</sup>, *A. Winterpacht*<sup>3</sup>, *T. Hankeln*<sup>4</sup>, *E.R. Schmidt*<sup>4</sup>, *F. Jakob*<sup>5</sup>, *B. Lee*<sup>2</sup>, *B.U. Zabel*<sup>1</sup>. 1) Children's Hospital, Mainz / Germany; 2) Dept. of Molecular and Human Genetics and Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX; 3) Institute of Human Genetics, Erlangen-Nuremberg / Germany; 4) GENTERprise GmbH, Mainz / Germany; 5) Orthopedic Clinic, University of Wuerzburg / Germany.

We initiated a project aimed at the systematic identification and characterization of novel genes and the dissection of regulatory pathways involved in the complex processes of cartilage formation, growth, differentiation and homeostasis. The goal is to generate a number of candidate genes for inherited monogenic (skeletal dysplasias) as well as complex disorders (osteoarthritis / osteoarthrosis and osteoporosis) by sequence analysis of a fetal human cartilage cDNA library. So far, 5000 ESTs have been generated and analysed using the NCBI databases as well as the Ensembl Genome Browser (EMBL-EBI and Sanger) and the EST identification task ESTsweep provided by the HUSAR bioinformatics group at the DKFZ in Heidelberg/ Germany. By using the protein domain identification tool SMART we found potential transcription factors that are poorly characterized and performed electronic northern analyses. We selected those that show a specific expression in cartilage and / or bone, and have orthologous mouse and rat genes. At the moment, several ESTs are being characterized by RACE / RT-PCR analysis and expression studies using in-situ hybridization and Northern blotting. By construction of full-length cDNA libraries from different RNA samples (e.g. human fetal cartilage and human chondrocytes and osteocytes that were differentiated from mesenchymal stem cell culture) we will determine the complete cDNA sequence. These experiments will help us understand the influence of potential candidate genes in processes like pattern formation, ossification, postnatal growth and development of the skeleton.

**Characterization of cis elements and transcriptional determinants that confer tissue-specific expression of type X collagen gene during chondrogenesis in vivo.** Q. Zheng<sup>1</sup>, G. Zhou<sup>1</sup>, R. Morello<sup>1</sup>, D. Napierala<sup>1, 2</sup>, Y. Chen<sup>1</sup>, B. Keller<sup>1</sup>, X. Garcia-Rojas<sup>1</sup>, B. Lee<sup>1,2</sup>. 1) Molecular & Human Genetics,; 2) Howard Hughes Medical Institute, Baylor College of Med., Houston, TX.

Type X collagen (*Col10a1*) is the only known hypertrophic chondrocyte-specific molecular marker. Its deficiency causes Schmid metaphyseal chondrodysplasia (MCDS). Until now, cis elements directing its hypertrophic chondrocyte-specific expression in vivo have not been described. Our studies show that a 4-kb murine *Col10a1* promoter can drive -galactosidase expression in lower hypertrophic chondrocytes in transgenic mice, and *Runx2*, a Runt domain transcription factor, contributes to the transactivation of this promoter via conserved *Runx2* binding sites. *Col10a1* expression was decreased in *Runx2*<sup>+/-</sup> and was barely detectable in *Runx2*<sup>-/-</sup> mice limbs by real-time RT-PCR analysis. Moreover, *Runx2* showed two-fold up-regulation in hypertrophic MCT cells in which *Col10a1* was concurrently upregulated. Thus, *Runx2* directly regulates the activation of the type X collagen gene during chondrocyte maturation *in vivo*. However, this 4 kb *Col10a1* promoter containing RUNX2 elements can only drive weak reporter gene expression in the lower hypertrophic zone of transgenic mice. To identify additional cis-regulatory regions, we generated transgenic reporter mice for further promoter analysis. An 8 kb *Col10a1* regulatory region encompassing the same 4 kb proximal promoter and second intron can direct reporter gene expression throughout the zone of hypertrophy. In another transgenic mouse line containing a 10 kb regulatory element that adds an additional 2 kb 5' region to the 8 kb construct, the tissue-specific expression of transgene is even stronger than those of the 8 kb *Col10a1* sequence that directs expression throughout the hypertrophic zone. These in vivo data suggest the presence of strong enhancer elements in both *Col10a1* distal 5' promoter and intron 2 that cooperate with the Runx2 binding elements in the proximal promoter to specify high level expression throughout the hypertrophic zone of long bones. It will be important to determine if mutations in corresponding *COL10A1* regions can also causes MCDS.

**Expression of the PAX7 protein isoforms is regulated by alternative termination of transcription.** *E. Vorobyov, D. Horst, B. Dworniczak, J. Horst.* Institut fuer Humangenetik, Universitaetsklinikum, Muenster, Germany.

Expression of the PAX7 gene is known to be associated with determination of myogenic cell lineage in development of vertebrates. Recent data obtained in the Pax7 K/O-mice revealed its exclusive function in specification of muscle satellite cells during post-natal period (Seale et al., Cell 102, 2000). The fact that PAX7 is expressed in fast proliferating embrional myoblasts and in quiescent satellite cells of adults raised the question whether different PAX7 protein isoforms may have distinct roles in these myogenic precursors. In our previous study we have identified a PAX7 isoform expressed in human tumor of striated muscle, rhabdomyosarcoma (Vorobyov et al., Genomics 45, 1997). The C-end of this protein encoded by the last portion of exon 8 does not show any homology to the PAX7 orthologous genes of mouse, chicken, zebrafish and lamprey. In order to verify that this isoform of PAX7 is not an artificial product we extended the study of 3-ends of the Pax7 mRNAs in human and mouse. As a result, two main transcripts of Pax7 were identified in both organisms. The long Pax7 cDNA represents the complete protein ended with the conservative C-peptide, encoded by exon 9. The short cDNA results from premature termination of transcription caused by the presence of weak affinity termination signals in intron 8 of this gene. This truncated cDNA encodes a different C-end of the PAX7 protein. The existence of both protein isoforms was shown by immunoblotting with the PAX7-specific monoclonal antibody. We speculate that regulation of the Pax7 alternative termination of transcription may be dependent on the changes in concentration of termination-specific factors (e.g. the cleavage stimulating factors, CstF) that varies in different cell states. Finally we established stable cell lines with ectopic expression of these two Pax7 isoforms and performed a comparative analysis of the gene expression profiles in the corresponding cells by means of the Affymetrix gene chip system. Certain differences in expression of the cell cycle and extracellular matrix genes were identified that can be considered as candidates for future analyses of the PAX7 downstream regulatory pathways.

Program Nr: 1032 from 2003 ASHG Annual Meeting

**Overview of the signalling cascades of PTPN11, mutated in Noonan syndrome.** *G. Sivapalan, A. Crosby, S. Jeffery, K. Kalidas, A. Shaw, M. Patton.* Medical Genetics Research, St George's Hospital Medical School, London, UK.

Noonan syndrome is an autosomal dominant disorder characterized by dysmorphic facial features, short stature and a congenital heart defect, predominantly pulmonary stenosis. We have previously mapped the gene for Noonan syndrome to chromosome 12q24.3. As part of a collaborative group we recently identified mutations in the PTPN11 gene, which encodes a non-receptor protein tyrosine phosphatase (SHP2), in patients with Noonan syndrome. SHP2 is a ubiquitously expressed molecule which appears to play a role in a number of cell signalling and developmental pathways including the Ras-Raf-MAPK and JAK/STAT cascades. We have subsequently shown that Noonan syndrome is heterogenous and that mutations within PTPN11 account for ~40% of cases. In the absence of a single large pedigree unlinked to PTPN11 for linkage analysis, a candidate gene approach offers a possible strategy for the identification of a second causative gene. Consequently we have produced a comprehensive evaluation of the SHP2 signalling cascades and evaluated a number of genes in these pathways for disease associated mutations.

**Cloning and characterization of human zinc transporter 1 (*ZNT1*).** V.A. Coronado<sup>1</sup>, M.S. Nanji<sup>1</sup>, R.D. Palmiter<sup>2</sup>, D.W. Cox<sup>1</sup>. 1) Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada; 2) Dept Biochemistry, Univ Washington, Seattle, WA, USA.

Zinc is an essential metal, required for the proper function of several enzymes. However, when present in excess, zinc can become toxic to cells. Many of the pathways involved in zinc homeostasis have been studied in yeast, which use at least three different mechanisms to maintain zinc homeostasis. First, zinc-uptake transporters, Zrt1 and Zrt2, are under transcriptional regulation, being induced in zinc-limiting conditions. Secondly, these same transporters are then inactivated post-translationally by high zinc concentrations. The third mechanism of zinc homeostasis, in which Zrc1, Cot1, and Zrt3 have been implicated, is the sequestration of zinc in the vacuole, a suggested site for storage and detoxification under steady states of excess zinc. In mammals, zinc homeostasis is maintained by the SLC30 family of transporters, which has nine members, Znt1-9. Zinc is the only metal known to be transported by these proteins and counterparts of the SLC30 family are found in all organisms. We have cloned the human zinc transporter 1 (*ZNT1*) cDNA and show that the predicted protein has 85% amino acid identity to mouse and rat ZnT1. Northern blot analysis shows that *ZNT1* is expressed as a transcript of 2.4 kb and 7.5 kb in multiple tissues with highest expression in the kidney and liver. The gene spans a region of approximately 4 kb and consists of two exons separated by a 1.7 kb intron. The 5-prime region of the gene has a 73% GC content and two potential metal response elements for regulation. *ZNT1* was mapped to human chromosome region 1q32-41, using a human/hamster radiation hybrid panel. The *ZNT1* clone was unable to complement a *ZRC1* knockout in yeast, but did confer resistance to a zinc-sensitive BHK cell line lacking functional ZnT1. Mutation analysis of *ZNT1* in two patients with liver cholestasis associated with high hepatic zinc concentrations showed no mutations in the coding region or splice junctions.

Program Nr: 1034 from 2003 ASHG Annual Meeting

**Characterization of mammalian cell mutants with altered PCNA.** *N.C. Mishra, K. Taylor.* Biological Sciences, The University of South Carolina, Columbia, SC.

Mutants of Chinese hamster cells resistant to aphidicolin, DNA polymerase-inhibitors, were selected to gain insight into mechanism of DNA replication. Such mutants earlier were found to possess changes in alpha-family DNA polymerases. PCNA genes were cloned and encoded proteins were further characterized. The mutant PCNA showed substitution of nucleotides at three different positions in the sequence of the gene and in the (inferred) amino acid sequence of the protein encoded by the cloned gene. The mutant PCNA was further found to be unable to interact with CDK2 in a pull down assay, CDK2 is an important protein of the cell cycle. The mutant PCNA was also found to show its altered activity and binding to FEN1, an important protein involved in the removal of Okazaki fragments during eukaryotic DNA replication. The significance of these results will be discussed.

Program Nr: 1035 from 2003 ASHG Annual Meeting

**A novel alternative splicing isoform of the human FGD1 gene.** *T. Kaname, K. Yanagi, K. Naritomi.* Dept Medical Genetics, Univ Ryukyus, Nishihara, Japan.

*FGD1* gene is a responsible gene for facio-genital dysplasia (Aarskog-Scott syndrome, MIM No.305400.) The gene encodes a guanine nucleotide exchange factor (GEF), which activates the Cdc42, and the products affect cell morphology *in vitro*.

We have found a new splice-variant of the human *FGD1* gene, which is generated by alternative splicing of parts from intron 8 as a novel exon 8B. The new exon 8B consists of 59 nucleotides which causes frame shift of the authentic transcript. The predicted product from the alternative form has only Proline-rich domain and GEF domain, but lacks pleckstrin homology domains and a FYVE-finger domain. This truncated product will inhibit filopodia formation, in contrast to the wild type of product has such activity *in vitro*. The alternative form is expressed in the lung and kidney and also in transformed B cells.

**Cloning and characterization of a murine orthologue of NYX responsible for complete congenital stationary night blindness (cCSNB).** *M.A. Sarna, N.T. Bech-Hansen.* Medical Genetics, University of Calgary, Calgary, Alberta, Canada.

The complete form of X-linked CSNB (cCSNB) manifests in patients with clinical symptoms of impaired night vision, reduced visual acuity and in some cases myopia, nystagmus, and strabismus. The gene responsible for cCSNB has been identified as *NYX* and positioned to the X chromosome (Xp11.4). Greater than 80% of *NYX* mutations in patients with cCSNB are missense mutations. The *NYX* gene encodes nyctalopin, a GPI-anchored, leucine-rich protein of 481 amino acids. In this study, the mouse *Nyx* gene was identified and sequenced by using mouse BAC clones which had been obtained by screening with a human *NYX* probe. Subsequently, the mouse BAC clones were used in co-positioning *Nyx* and *Cask*, *CASK* is positioned to Xp11.4, on the mouse X chromosome. The mouse nyctalopin protein is predicted to be 476 amino acids in length and shares 84.2% identity with human nyctalopin. Similarly, the rat *NYX* gene has been located on the rat X chromosome. Using genome sequence (Accession: NW 044417.2) as well as EST clones, rat *NYX* was found to encode a protein of 476 amino acids, which shares 96% and 83.8% identity with the mouse and human nyctalopin proteins, respectively. In all three species, the *NYX* gene appears to be organized into three exons with exons 2 and 3 contributing to the open reading frame. These two exons are separated by a 25.5, 18.8 and 17.8 Kb intron in human, rat and mouse genes, respectively. The rodent nyctalopin proteins have a leucine-rich domain and a signal peptide sequence similar to that seen in the human protein but neither the mouse nor the rat nyctalopins are predicted to be GPI anchored, based on predictions using the available GPI-anchoring programs. Analysis of mRNA expression in mouse tissue, using the RNase protection assay, showed distinct *Nyx* expression in the eye and very low levels of expression in the brain, heart and lung. In contrast to the human *NYX* gene, which was shown to be expressed robustly in kidney, in addition to the retina, no expression was seen in mouse kidney tissue. On-going studies are aimed to elucidate the roles that nyctalopin plays in the neural circuitry of the visual system.

**Complementary genetic and functional analyses of SNPs in the extracellular domain of the human leptin receptor gene (LEPR).** *D.W Meechan*<sup>1,2</sup>, *N.D. Quinton*<sup>3</sup>, *R. Eastell*<sup>4</sup>, *A.I.F. Blakemore*<sup>2</sup>. 1) Biomedical Research Centre, Sheffield Hallam University, Sheffield, United Kingdom; 2) Department of Medical and Community Genetics, Imperial College London, St.Marks hospital, Watford road, Harrow, HA1 3UJ, United Kingdom; 3) School of Biomedical Sciences, University of Leeds, St.James Hospital, Leeds, United Kingdom; 4) Division of Biomedical Sciences, University of Sheffield, Northern General Hospital, Sheffield, S5 7AU, United Kingdom.

Previous studies have demonstrated an association between the GLN223ARG SNP of the human leptin receptor gene (LEPR) and indicators of adiposity in a cohort of postmenopausal Caucasian women. Subjects homozygous or heterozygous for the A allele (which codes for the GLN amino acid) have significantly higher BMI than those not carrying the A allele ( $p=0.007$ ). Further studies involving the same group indicated an association with the LYS109ARG SNP in the same gene. Individuals that are homozygous or heterozygous for the A allele, which codes for the LYS amino acid, have significantly higher BMI than those not carrying the A allele ( $p=0.017$ ). Linkage disequilibrium was observed between the two SNPs ( $D = 0.64$ ). To determine the functional significance and relative effects of the two SNPs, a series of LEPR extracellular domain cDNA constructs which code for the different amino acid combinations have been generated, and the protein variants expressed in COS-7 cells. Following antibody affinity purification, SDS-PAGE gel analysis revealed a single protein band of approximately 130KDa, which shifted to approximately 95KDa following N-deglycosylation. The variants were analysed by their ability to bind leptin via a radioactive ligand binding assay. Preliminary results establish that the protein variants are able to bind leptin, enabling future kinetic studies to determine potential differences between SNPs.

**Distinct cellular and biochemical effects of specific mutations in ABCA1 predicts the phenotype in TD and FHA.**

*R. Singaraja, H. Visscher, E. James, M. Hayden.* Dept Medical Genetics/CMMT, Univ British Columbia, Vancouver, BC, Canada.

We generated in vitro 15 missense mutations described in the ABCA1 gene, and characterized changes in HDL-C levels in patients harboring these variants. In order to elucidate the mechanism underlying the varying phenotypic effects caused by these mutations, specific functional assays were established exploring different stages of pathways of activation of ABCA1, including subcellular localization by immunofluorescence, glycosylation status and cell surface localization by biotinylation, ApoA-I binding and both phosphocholine and cholesterol efflux assays. These assays reveal a distinct correlation between the biochemical defects of the variants and disease severity in the patients with mutations and provide insights into the structure function relationships of ABCA1. Based on patient HDL-C levels, we hypothesized that in those homozygous for ABCA1 mutations, the patients with both alleles of ABCA1 showing no activity would have almost 0% HDL-C, whereas those with both alleles showing partial activity would have >10% HDL-C levels when compared to controls. Of the heterozygotes, those with the mutant allele retaining partial activity would be expected to show >50% HDL-C levels, those in whom the mutant allele lacks activity would be expected to show ~50% HDL-C levels, and those in whom the mutant allele acts in a dominant-negative manner would be expected to show <50% HDL-C levels. Indeed, when the HDL-C levels of all patients harboring specific mutations were compared to LRC age and sex matched controls, the patients could be thus classified. Importantly, there was a correlation between the different phenotypic groups and the in vitro biochemical activity of ABCA1. Taken together, our results show that discrete functional effects caused by changes in ABCA1 underlie the observed variation in disease severity and phenotype observed in TD and FHA patients.

**Fabry disease: Characterization of the D313Y plasma -galactosidase A pseudodeficiency allele.** *M. Yasuda*<sup>1,2</sup>, *J. Shabbeer*<sup>1</sup>, *S.D. Benson*<sup>3</sup>, *I. Maire*<sup>4</sup>, *R.M. Burnett*<sup>3</sup>, *R.J. Desnick*<sup>1</sup>. 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) Dept Pediatrics, Tokyo Women's Medical University, Tokyo, Japan; 3) The Wistar Institute, Philadelphia, PA; 4) Laboratoire de Biochimie Pédiatrique, Hôpital Debrousse, Lyon, France.

Fabry disease, an X-linked inborn error of glycosphingolipid catabolism, results from mutations in the gene encoding the lysosomal exoglycohydrolase, -galactosidase A (-Gal A). In two unrelated classically affected males, two -Gal A missense mutations were identified: R112C + D313Y and C172G + D313Y. The D313Y lesion was previously identified in classically affected males as the single mutation [Eng et al., 1993] or in cis with another missense mutation, D313Y + G411D [Guffon et al., 1998]. To determine whether the D313Y mutation was a deleterious mutation, or a coding region sequence variant, the frequency of D313Y in normal X-chromosomes, as well as its enzymatic activity and subcellular localization in COS-7 cells were determined. D313Y occurred in 0.45% of 883 normal X-chromosomes, while the R112C, C172G, and G411D missense mutations were not detected in over 500 normal X-chromosomes. Expression of D313Y in COS-7 cells resulted in ~60% of wild-type enzymatic activity and showed lysosomal localization, while R112C, C172G, G411D, and the double-mutated constructs had markedly reduced or no detectable activity and were all retained in the endoplasmic reticulum. The expressed D313Y enzyme was stable at lysosomal pH (pH 4.6), while at neutral pH (pH 7.4), it had decreased activity. A molecular homology model of human -Gal A, based on the X-ray crystal structure of chicken -galactosidase B (-Gal B; -N-acetylgalactosaminidase) [Garman et al., 2002] was generated, which provided evidence that D313Y did not markedly disrupt the -Gal A enzyme structure. Thus, D313Y is a rare exonic variant with about 60% of wild-type activity in vitro and markedly reduced activity at neutral pH, resulting in low plasma -Gal A activity.

**Towards comprehensive characterization of the human retinal transcriptome.** *H.L. Schulz, H. Stöhr, J. Stojic, B.H.F. Weber.* Institute of Human Genetics, University of Wuerzburg, Germany.

The human retina is a complex tissue specialized in the conversion of light into neuronal signals which are then transmitted to the brain. An as yet unknown number of active genes are required to perform these versatile functions and to establish and maintain the structure of the individual retinal cell types. As a consequence, this highly evolved system is susceptible to a great number of genetic defects, thus leading to a wide range of retinal disease phenotypes. To date, more than 130 distinct genes have been linked to monogenic retinal dystrophies. Fewer advances have been made in dissecting the molecular basis of the multifactorial age-related macular degeneration, the most frequent cause of legal blindness in the developed world.

Our research, part of the German Human Genome Project, targets the identification and characterization of genes exclusively or preferentially expressed in the retina. To achieve this, two complementary approaches were used, namely the assessment of retinal expressed sequence tag (EST) clusters indexed in the UniGene database and the large scale generation of single-pass ESTs derived from a human retina suppression subtracted cDNA library. A total of 6616 EST clusters from both sources were evaluated and from these 879 were subjected to detailed in silico analysis. The expression profiling of 337 selected EST clusters was achieved by RT-PCR, conventional and virtual Northern blot, and real-time PCR. These methods led to the identification of 67 transcripts expressed abundantly or exclusively in retina and 48 genes expressed in retina and other areas of the neuronal system. To date, the full-length coding sequence of 47 genes has been established and the possible involvement of five genes in retinal diseases has been examined. In order to assess the completeness of the retinal transcriptome, the data assembled and analyzed in this project was compared with the reports of other retina-gene identification projects. The results indicate that there are still numerous retina-specific genes waiting to be discovered.

**Evaluation of Stat5b target genes in non-obese diabetic (NOD) mice by northern blot analysis and DNA microarray.** A. Davoodi-Semiromi<sup>1</sup>, S. Litterland<sup>1</sup>, M. Atkinson<sup>1</sup>, J-X. She<sup>2</sup>, M. Clare-Salzler<sup>1</sup>. 1) Dept of Pathology, Immunology and laboratory Medicine, PO Box 100275, Univ Florida, Gainesville, FL; 2) Center for Biotechnology and Genomic Medicine, Medical College of Georgia, 1120 15th Street, PV6B108, Augusta, GA 30912.

In human and in mice it has been generally accepted that type 1 diabetes is a multifactorial autoimmune disease in which susceptibility is determined by genetic and environmental factors. We have recently reported a natural novel point mutation in DNA binding domain of Stat5b in the NOD mice using mutation and functional assays. In mice, this gene is located on chromosome 11 where one of candidate interval for type 1 diabetes, *idd4*, has been mapped to this region but the gene yet to be identified. In this study, we assessed expression of putative Stat5b target genes, genes bear stat5b consensus sequence in their promoter region, by Northern blot analysis. The NOD mice (10 weeks) and normal strain (B6) were induced by GM-CSF (intraperitoneally injection) for 20 min and 2 hours and then total RNA were extracted from spleen and subjected to northern blot and microarrays for cytokines and their receptor and inflammatory genes. The northern blot data shown that the expression level of some of these genes has been changed in NOD mice when compared to normal strain. Using gene specific microarrays for cytokines and their receptors and inflammatory genes we not only confirmed the northern blot data, but also identified several genes in which their expression has been changed in the NOD mice. All of these genes bear the stat5b consensus sequence in their promoter region suggesting that their expression might be under the control of the Stat5b gene. Interestingly, two of these gene are just one and 2 cM away from the *Idd4* (chromosome 11) and *Idd13* (chromosome 4) loci, respectively. This study candidate two genes for the *Idd4* and *Idd13* in mice and more investigation is underway in order to rule in and/or rule out the candidacy of these genes in the pathogenesis of type one diabetes in mice. This study supported by an advance postdoctoral fellow ship (JDF10-2001-589) awarded to the ADS.

**Phosphorylation of the fragile X mental retardation protein regulates translation of its mRNA ligands.** *W.T. O'Donnell, S. Ceman, S.T. Warren.* Human Genetics, Emory Univ Sch Med, Atlanta, GA.

Fragile X mental retardation protein, FMRP, is absent in patients with fragile X syndrome, the most common inherited form of mental retardation. FMRP is an RNA binding protein that shuttles into and out of the nucleus and is found associated with polyribosomes. In neurons FMRP is found beneath dendritic spines and is thought to play a role in synapse maturation. FMRP is a translational repressor in cell free in vitro systems and may regulate the translation of its specific mRNA ligands in vivo. Using mass spectrometry we identify a fragment of FMRP that is phosphorylated in both murine brain and in cultured cells. By site-directed mutagenesis we show primary phosphorylation occurs on the highly conserved serine 499 residue. This first event then triggers hierarchical phosphorylation of at least one nearby serine. In contrast to the *Drosophila* ortholog dFxr, the phosphorylation status of mammalian FMRP neither affects its ability to dimerize nor influences its association with specific mRNAs in vivo. However, we show that a serine to alanine point mutant of FMRP mimicking dephosphorylation associates with actively translating polyribosomes while a serine to aspartate mutant mimicking phosphorylated FMRP associates with stalled polyribosomes. We analyze the specific messages associated with these translating or stalled polyribosomes by microarray and compare those sets of messages with the in vivo FMRP mRNA ligands. Of the 65 transcripts that co-immunoprecipitate with FMRP, 61 (94%) are found enriched greater than 4-fold in the heavy fractions of a linear sucrose gradient of azide treated cells containing Asp-FMRP compared to those from an azide treated Ala line. Our data suggest the phosphorylation status of mammalian FMRP regulates the translation of FMRP-associated mRNAs and dephosphorylation may be a trigger for translation during synapse formation.

**Variation of histone acetylation/methylation in the FMR1 gene of the fragile X syndrome following pharmacological reactivation.** *E. Tabolacci, R. Pietrobono, P. Chiurazzi, G. Neri.* Institute of Medical Genetics, Catholic University, Rome, Rome, Italy.

Fragile X syndrome is caused in most cases by a >200 CGG repeat expansion and methylation of the FMR1 gene, which, as a consequence, becomes inactive. We demonstrated that treatment of fragile X lymphoblasts with 5-azadeoxycytidine (5-azadC) reactivates the FMR1 gene (Hum Mol Genet 7:109-113, 1998), by demethylating the CpG residues of the promoter region (Nucl Acids Res 30: 3278-3285, 2002), and that histone hyperacetylating drugs synergistically potentiate the FMR1 gene reactivation induced by 5-azadC (Hum Mol Genet 8:2317-2323, 1999). We went on to investigate the histone acetylation and methylation status using ChIP assay with antiacetylated-H4/ -H3 antibodies and with anti-H3 dimethylated-K4/ -K9 antibodies (Upstate Biotechnology). To quantify the IP-DNA, fluorescent PCR (ABI 7700) was performed with three different TaqMan probes for the FMR1 and HPRT (internal control) genes, respectively. Here we provide evidence that 5-azadC treatment induces an increase of H3 and H4 acetylation and of K4-H3 methylation but a decrease of K9-H3 methylation, on three fragile X cell lines. Then we have explored the potential acetylating action of acetyl-L-carnitine (ALC), an FDA-approved drug, which reduces fragile sites expression in vitro (Am J Med Genet 51: 447-450, 1994). After ALC treatment, H3 and H4 acetylation levels undergo a change similar to that induced by 5-azadC; K9-H3 methylation decreases, while K4 methylation is only slightly increased. Finally, we have studied these histone modifications in an unmethylated full mutation cell line (5106): surprisingly, H3 and H4 acetylation and K9 methylation patterns are similar to those of a methylated full mutation, while K4 methylation resembles that of a wild type cell line, in accordance with its normal transcriptional activity. Supported by grants from FRAXA Foundation, Conquer Fragile X, Sigma-Tau, MIUR, Fondazione Cariplo and Associazione Anni Verdi, Italy.

**Evaluation of *Caenorhabditis elegans* model for lysosomal diseases caused by deficits of glycosidases. M.**

*Hrebicek, J. Sikora, J. Hujova, D. Holanova, H. Poupetova, B. Asfaw, J. Ledvinova, M. Kostrouchova.* 1st Faculty Med, Char, Institute of IEM, Praha 2, Czech Republic.

We have studied the relevance of *C.elegans* as a model for the study of molecular pathology of Pompe disease (-glucosidase - GAA), Fabry disease (-galactosidase, -GAL), and Schindler disease (-N-Acetyl-galactosaminidase, -NAGA). GAA, -GAL and -NAGA measurements in *C.elegans* mixed culture shown significant activities in the range of tens to hundreds of nmol/mg protein/hour for all three enzymes. BlastP searches for potential GAA, -GAL and -NAGA orthologs in the *C.elegans* genomic database, revealed four predicted genes with high GAA family homology (Ce GAA 1- 4) and a single predicted gene (Ce GAL/NAGA) both for -GAL and -NAGA. Phylogenetic analysis of evolutionary relevant sequences further supported common ancestral origin of mammalian -GAL and -NAGA. Full length cDNAs for Ce GAL/NAGA and Ce GAA 1 were amplified and sequenced including 5 and 3 UTR to confirm the in-silico prediction. Sequencing revealed SL1 trans-splicing RNA pattern for Ce GAL/NAGA and SL2 trans-splicing for Ce GAA 1. C-terminal GFP tagging was used to evaluate the expression pattern of the studied genes and to define their functional promoter. 5kb extrachromosomal GFP expressing promoter Ce GAA 1 construct showed broad tissue expression pattern including intestine, pharyngeal and vulval muscle, coelomocytes and head and tail neurones during all developmental stages of *C.elegans*. RNA interference (RNAi) method employing previously sequenced cDNA clones and genomic DNA as templates for dsRNA synthesis was performed to evaluate phenotypic presentation of Ce GAA 1 RNAi induced deficiency. Strong egg-laying phenotype was observed in at least 20% of the progeny of either N2 or rrf-3 injected worms. Translational C-terminal GFP construct of Ce GAL/NAGA showed coelomocyte vesicular compartment positivity after lysosomal alkalinisation with ammonium chloride or concanamycin.

**Molecular and biophysical characterization of Voltage-Dependent Anion Channel homologs in *Drosophila melanogaster*.** B.H. Graham<sup>1</sup>, A. Komarov<sup>2</sup>, M. Colombini<sup>2</sup>, W.J. Craigen<sup>1</sup>. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Biology, University of Maryland, College Park, MD, 20742.

Voltage-dependent anion channels (VDACs) are a family of small pore-forming proteins of the mitochondrial outer membrane found in all eukaryotes. VDACs play an important role in the regulated flux of metabolites between the cytosolic and mitochondrial compartments and three distinct mammalian isoforms have been identified. The specific physiologic and potential pathophysiologic roles of the various isoforms are not understood. Recent annotation of the *Drosophila melanogaster* genome has revealed three putative VDAC isoforms (*CG17137*, *CG17139*, *CG17140*) closely linked to the previously reported *Drosophila* VDAC (*porin*). Molecular characterizations of these genes reveal a male-specific expression pattern for all three genes as well as potential dicistronic expression for *CG17139* and *CG17140*. When expressed in yeast deficient for VDAC, *porin* and *CG17137* rescue a conditional-lethal phenotype, demonstrating complementation. Electrophysiological characterizations of these proteins in reconstituted systems demonstrate a differential ability to permeabilize lipid bilayers and liposomes, with *CG17137* displaying the most prototypic VDAC behaviour. These studies indicate that *Drosophila* VDAC homologs have retained aspects of VDAC structure and function, warranting further studies to utilize this genetic model system in delineating fundamental conserved roles of VDACs in eukaryotic cell function.

**C5545T: a novel functionally dominant mitochondrial DNA mutation.** *M. Davidson, S. Sacconi, L. Salviati, E. Hernandez, Y. Nishigaki, R. Pons, D. DeVivo, S. Shanske, E.A. Schon, E. Bonilla, S. DiMauro.* Columbia University, New York, NY.

Several pathogenic mitochondrial tRNA mutations have been described in patients with mitochondrial diseases. The wild type and mutant molecules coexist (heteroplasmy) within a cell. Generally, clinical symptoms of the disease are manifested only when the percentage of mutant molecules exceeds 70-90% indicating that these mutations are functionally recessive. We studied a 11-year old patient who presented with brain, heart and muscle involvement. Muscle histochemistry revealed a generalized reduction in COX histochemistry and no ragged-red fibers, unlike other tRNA mutations. Analysis of respiratory chain enzymes showed 88% reduction in complex IV and 25-50% reduction in other complex I and III. Sequence analysis of the tRNA genes revealed a C->T transition at nt5545 in tRNA<sup>Try</sup> gene, which alters the anticodon sequence (UGA) to a stop codon (UAA). The mutation was present at unusually low level in patients muscle (around 25%) and at even lower levels in patients blood and fibroblasts (13-17%), while it was absent in the mothers tissues. Contrary to other pathogenic tRNA mutations, where COX-negative fibers harbor more than 90% mutated mtDNA, single fiber analysis of the patients muscle biopsy revealed a 31% mutation load in COX-negative fibers, while the mutation was virtually absent in COX-positive fibers. We have ruled out the presence of a secondary mtDNA mutation in the other tRNA genes and COX subunits by sequencing. Screening for SCO1, SCO2 and SURF1 nuclear genes were negative.

This is the first mtDNA mutation to affect the central base of the anticodon in a tRNA gene. The pathological threshold in muscle was around 30% or less. Despite the low mutation load, the patient showed a severe biochemical and clinical phenotype. The functional dominance of this mutation is the exception to the general rule and therefore, the pathogenic mechanism may be different from other mutations studied. There may be other dominant mtDNA mutations that may have been overlooked because of the limit of detection by conventional methods.

**Ablation of Mitochondrial Intermediate Peptidase gene leads to embryonic lethality during mouse gastrulation.**

*R.T. Mantcheva*<sup>1</sup>, *A. Chew*<sup>2</sup>, *A.R. Thornhill*<sup>3</sup>, *J.M. van Deursen*<sup>1</sup>, *G. Isaya*<sup>1</sup>. 1) Dept. of Pediatric & Adolescent Medicine and Biochemistry & Molecular Biology, Mayo Clinic, Rochester, MN; 2) Genaisance Pharmaceuticals, Inc., Five Science Park, New Haven, CT; 3) Dept. of Obstetrics & Gynecology, Mayo Clinic, Rochester, MN.

Most mitochondrial precursor proteins are processed to the mature form in one step by mitochondrial processing peptidase (MPP), while a subset of precursors destined for the matrix or the inner membrane are cleaved sequentially by MPP and mitochondrial intermediate peptidase (MIP). MIP cleavage sites are found in respiratory components, including subunits of the electron transport chain, tricarboxylic acid cycle enzymes, iron-sulfur cluster-containing proteins and ferrochelatase, as well as components of the mitochondrial genetic machinery, including ribosomal proteins, translation factors, and proteins required for mitochondrial DNA metabolism. MIP catalyzes the maturation of ferrochelatase. We showed previously that yeast MIP (YMIP) is required for mitochondrial function in *Saccharomyces cerevisiae*. To further define the role played by two-step processing in mitochondrial biogenesis, we have generated a mouse model by deletion of exons 12 and 13. The deletion encompasses the peptidase active site and is predicted to result in the inactivation of the MIP gene product. We show that homozygosity for this deletion causes embryonic lethality a few days after implantation, demonstrating an important role for MIP during early development. Consistent with the fact that some of the MIP substrates are essential for the maintenance of oxidative phosphorylation (OXPHOS), these results suggest that high energy demands during early development are not met in the absence of MIP due to impaired proteolytic processing.

Program Nr: 1048 from 2003 ASHG Annual Meeting

**The Induced Mutant Resource: Mouse mutants with applications to human disease.** *S.F. Rockwood, D.B. Lane, L.E. Mobraaten, M.T. Davisson.* Induced Mutant Resource, Jackson Laboratory, Bar Harbor, ME.

Advances in transgenic and gene targeting technologies have yielded a wide variety of mouse models that have proven to be extremely useful in addressing questions that explore the mechanisms of human disease. To ensure the greatest possible access to these tools, the Induced Mutant Resource (IMR) at The Jackson Laboratory was created in 1992 to serve as a centralized facility to collect, cryopreserve and distribute induced mutant mice to the scientific community. Since its inception, the IMR has accepted over 950 different induced mutant mouse strains, distributing over 130,000 mice annually to the scientific community. Current growth in the IMR collection is approximately 60-70 new strains each year.

A wide variety of new mutants have recently been accepted into the IMR. A targeted mutant of the *Aire* (autoimmune regulator) gene, useful for studies related autoimmune disease is currently under development. Also new, are models for fragile X mental retardation syndrome and Huntington's disease. Floxed alleles of the *Pten* (phosphatase and tensin homolog) and *Bdnf* (brain derived neurotrophic factor) genes have been added to the growing list of loxP-flanked alleles. One of the more creative additions to the IMR is a diphtheria toxin-inducible transgenic mutant that allows scientists to transiently deplete dendritic cells.

An on-line resource is available allowing researchers to retrieve information related to the mutant strains maintained in the IMR. Mutant strain records retrieved from the IMR database include brief phenotype descriptions, strain construction and husbandry information and a listing of related references. Researchers wishing to have mutant strains considered for inclusion in the IMR collection may submit their strains using the form available at the IMR web site: <http://www.jax.org/imr/index.html>.

The Induced Mutant Resource is supported by the National Center for Research Resources (RR09781/RR11081), National Institute for Allergy and Infectious Disease and The Howard Hughes Medical Institute.

**Identification and characterization of a DNase hypersensitive region of the human tyrosinase gene.** *W.S. Oetting<sup>1,2</sup>, J.P. Fryer<sup>1</sup>, R.A. King<sup>1,2</sup>*. 1) Dept. Medicine; 2) Institute of Human Genetics, Univ Minnesota, Minneapolis, MN.

A significant number of individuals with oculocutaneous albinism (OCA) have been found to have only one heterozygous mutation of the tyrosinase gene, when the analysis includes the entire coding region, flanking intron/exon boundaries, and 500 bp of the proximal promoter. Based on the allele frequency of mutant tyrosinase alleles, we assume that these individuals have OCA1, rather than a type of OCA resulting from mutations of another locus while also being carriers of a tyrosinase mutation. Our inability to detect the second tyrosinase mutation suggests that these cryptic mutations in the homologous allele could reside in regulatory regions that are removed from the direct proximity of the coding sequence, and this would account for their having OCA1. It has been previously reported that the mouse tyrosinase gene has a distal enhancer that provides position-independent stimulation of tyrosinase gene expression. A sequence homology search between the mouse and human tyrosinase promoter has identified a region of the human tyrosinase promoter that is similar to this mouse distal enhancer. We report a region of the human tyrosinase promoter, 9 kb upstream of the transcriptional start site, which exhibits DNase I hypersensitivity in a cell lineage-specific manner. This region also has significant enhancer function when reporter vectors constructs containing this region are transfected into either human or mouse melanocyte cell lines. Furthermore, elimination of core sequences extinguishes the enhancer function. We believe that this region contains sequences critical in the regulation of the human tyrosinase gene and is a candidate for the location of cryptic mutations in OCA1.

**The Effect of Sarcoglycan Mutations on the Assembly of the Sarcoglycan Complex.** *Y. Chan, W. Shi.* The Henry Hood Research Program, Sigfried and Janet Weis Center for Research, The Geisinger Clinic, Danville, PA 17822.

Sarcoglycans are a group of novel single-pass transmembrane proteins predominantly expressed in skeletal and cardiac muscle. They form a specific multi-meric complex on the muscle membrane. Mutations in sarcoglycans have been reported to cause the autosomal recessive Limb-girdle muscular dystrophy (LGMD) type 2C-F as well as dilated cardiomyopathy (DCM). Using a heterologous expression system, our previous study has demonstrated that the assembly of the sarcoglycan complex occurs at a discrete step-wise process and involves the formation of a  $\alpha$ -sarcoglycan core structure. In this report, we use the same system to examine the effect of sarcoglycan mutations on the sarcoglycan complex. Our data have shown that different mutations perturb specific stages in the assembly process of the sarcoglycan complex.  $\alpha$ -sarcoglycan mutants defective in glycosylation result in aggregation and disrupt its interaction with  $\beta$ -sarcoglycan. Disease-causing point mutations near the N-linked glycosylation sites of sarcoglycans have an adverse effect on glycosylation. A common mutation in  $\beta$ -SG (C283Y) is shown to affect its association with the  $\alpha$ -sarcoglycan core structure. Interestingly, a mutation in the intracellular domain of  $\beta$ -sarcoglycan (Q11E) has no effect on sarcoglycan complex formation. This raises the possibility that some mutations in sarcoglycans might affect a function unrelated to the assembly process. Understanding the molecular mechanism on how a particular sarcoglycan mutation causes LGMD or DCM will likely provide specific strategy for disease treatment in the future. This information might also benefit clinicians in disease management by better addressing the phenotypic variation in LGMD.

**EFFECT OF FILAMINC DEFICIENCY IN MUSCLE.** *I. Dalkilic<sup>1</sup>, L.M. Kunkel<sup>1,2</sup>*. 1) Dept Genetics, Children's Hospital, Boston, MA; 2) Howard Hughes Medical Institute.

Filamins (A, B, and C), are a family of actin binding proteins. FilaminC (FLNC) is muscle specific, expressed in heart and skeletal. FLNC previously has been shown to interact with d- and g- sarcoglycans, which when mutated give rise to LGMD2F and 2C. FLNC is localized to the Z-disc and at very low levels to the sarcolemma (~3%). Interestingly in DMD and LGMD2C where the sarcoglycan complex is lost from the membrane the amount of FLNC at the membrane increases (~24%). Apart from the sarcoglycans, FLNC has been shown to interact with other proteins involved in muscular dystrophies, such as myotilin and calpain-3. All of this evidence indicates an important role for FLNC in muscle and muscular dystrophy pathogenesis, although to date no disease has been found to have mutations in the FLNC gene. To study the effects of FLNC loss in the skeletal muscle we have taken two different approaches. First we have created a partial knockout model that deletes the portion of FLNC shown to interact with the sarcoglycans and calpain-3. This knockout is embryonic lethal. We are currently investigating these knockouts further to deduce the reason for embryonic lethality. The second approach is the use of siRNAs (small interfering RNAs) to knockdown the expression of FLNC in mouse myoblast cell lines (C2C12). siRNAs are 19-23 nt long double stranded RNAs, which through their homology target the endogenous mRNA for degradation, hence knocking down the expression. We have applied this system to knockdown the expression of FLNC in C2C12 cell line and achieved 80% decrease in FLNC expression with various siRNAs. We are currently investigating the phenotype of cells with FLNC deficiency.

**Retinal dystrophin isoform Dp260 promoter includes a GRE (glucocorticoid response element) and transcription is upregulated *in vitro* by steroids.** *D.M. Pillers*<sup>1,2</sup>, *J.T. den Dunnen*<sup>3</sup>, *J. Pang*<sup>1</sup>. 1) Dept Pediatrics, Oregon Health & Science Univ, Portland; 2) Dept Molecular and Medical Genetics, Oregon Health & Science Univ, Portland; 3) Human and Clinical Genetics, LUMC, Leiden, Nederland.

Introduction: Dystrophin is the product of the Duchenne muscular dystrophy gene (DMD). In addition to full length dystrophin (Dp427), the DMD gene encodes several shorter isoforms that vary in their tissue distribution. The redundancy in the composition of the isoforms offers the potential to substitute for Dp427 to ameliorate the Duchenne muscular dystrophy phenotype. We have investigated the potential of pharmacogenetic manipulation as a means of upregulating the expression of specific isoforms. Methods: A human genomic fragment from a cosmid clone containing the first exon of Dp260 was characterized, and a fragment was subcloned in a pGL2 luciferase reporter vector that was transfected into cell lines Y79 (retinoblastoma), HeLa, COS-7, and C2 (myoblast) for assays of transcription and pharmacologic intervention. Results: Sequence analysis using the TESS (Transcription Element Search System) identified a glucocorticoid response element (GRE). Exposure of transfected cell lines to methylprednisolone resulted in upregulation of activity as demonstrated by relative luciferase activity: Y79 (2 fold), HeLa (6 fold) and C2 (6 fold). COS-7 transfectants showed no effect after steroid exposure, as expected for this GR defective cell line. Conclusions: The retinal dystrophin Dp260 promoter includes a GRE which when exposed to steroids *in vitro* leads to upregulation of Dp260 transcription in a variety of cell lines, including muscle-derived (C2). In clinical studies, steroidal agents have been associated with improvement in muscle disease in some individuals. Our results indicate that pharmacogenomic approaches to DMD gene product expression may be useful as potential therapies for muscular dystrophy.

**Mutation and single nucleotide polymorphisms in *RUNX2* and *CBFb* genes in patients with cleidocranial dysplasia (CCD).** *D. Napierala*<sup>1</sup>, *X. Garcia-Rojas*<sup>1</sup>, *R. Mendoza*<sup>2</sup>, *Q. Zheng*<sup>2</sup>, *G. Zhou*<sup>2</sup>, *E. Munivez*<sup>1</sup>, *Y. Chen*<sup>2</sup>, *B. Lee*<sup>1,2</sup>. 1) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX; 2) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston TX.

Cleidocranial dysplasia (CCD) is a dominantly inherited condition characterized by hypoplastic clavicles, large fontanel, dental abnormalities and delayed skeletal development. It is caused by mutations in *RUNX2*, a transcription factor essential for osteoblasts differentiation. The majority of mutations are missense and abolish *RUNX2* binding to a target OSE2 sequence. These and additional nonsense, splicing and frame shift mutations are detectable in approximately 60% of CCD patients. It has been recently described that mice carrying a *CBFb* hypomorphic allele have a skeletal phenotype similar to CCD. *Cbfb* acts as a transcriptional coactivator with runt domain proteins. The objective of the current study was to describe additional mutations leading to CCD phenotypic spectrum. We performed PCR amplification of genomic DNA for *RUNX2* gene and sequenced all of its 8 exons for 14 unrelated patients. For 27 CCD patients with no mutation identified in *RUNX2* coding region, we performed sequencing analysis of a 1.3 kb fragment of *RUNX2* promoter and all of the 6 exons of the *CBFb* gene. A total of 3 new mutations in *RUNX2* coding region, 4 variants in the *RUNX2* promoter and 3 variants in *CBFb* gene were detected. We analyzed the frequency of all detected SNPs in general population. DHPLC analysis in 180 control chromosomes showed two common polymorphisms in *RUNX2* promoter with allele frequencies of 10% and 15%. Two other sequence variants were not found in the control group. Both rare sequence variants occur within zinc finger transcription factors binding sites. Electrophoretic mobility shift assay (EMSA) using nuclear extracts from ROS17, 10T1/2 cell lines showed a specific protein-DNA complex corresponding to both cis elements. These data suggest that mutations in *CBFb* do not contribute to the CCD spectrum. Additionally, analysis of the CCD cohort has identified SNPs in the *RUNX2* promoter that may be relevant cis-elements for transcriptional regulation of *RUNX2* and the pathogenesis of CCD.

Program Nr: 1054 from 2003 ASHG Annual Meeting

**The human PRKCQ gene is positively associated with rheumatoid arthritis.** *S. Hall, C. Stack, K. Magnuson, A. Seymour.* Pfizer, Groton, CT.

Rheumatoid arthritis (RA) is one of the most common autoimmune diseases. It is a chronic disease characterized by prolonged inflammation, swelling and pain of multiple joints. Activated T-cells are thought to play a role in initiating the disease as well as driving the chronic inflammatory process. PKC theta demonstrates restricted expression in T lymphocytes and skeletal muscle and has been shown to be required for T cell activation. In this study, we have investigated whether genetic polymorphisms with the PRKCQ gene are associated with an increased susceptibility to RA.

A case control genetic association study design was used to test the hypothesis that polymorphisms within the PRKCQ gene contribute to disease susceptibility. 120 RA subjects and 120 age, ethnic, and CRP/RF control subjects were genotyped for 11 polymorphisms evenly spaced across the 87 kb PRKCQ gene. Logistic regression models were used to compare the relationship between PRKCQ genotype and RA phenotype. Several polymorphisms were found to be highly significant with p-values ranging from 0.02-0.05. We identified a haplotype that is associated (p-value = 0.005) and represents an odds ratio of 1.7, assuming a dominant model of inheritance. We conclude that polymorphisms in the PRKCQ gene are associated with an increased susceptibility to RA.

**Abnormal connective tissue remodeling in mice deficient for relaxin receptor (LGR7).** A.A. Kamat, S. Feng, N. Bogatcheva, A.I. Agoulnik. Obstetrics & Gynecology, Baylor College of Medicine, Houston, TX.

Relaxins are peptide hormones produced primarily in reproductive organs. In the mouse, there are two relaxin genes, Rln1 and Rln3 that encode related peptides with an overlapping pattern of expression. Deletion of relaxin-1 in mice causes remodeling of connective tissues in several organs. Recently, biochemical studies have identified two closely related G protein-coupled receptors (LGR7 and LGR8/GREAT) as putative receptors for relaxins. Additionally, insulin-like factor 3 has been identified as a cognate ligand for Lgr8, but not for Lgr7. Using real time polymerase chain reaction, we have shown that the Lgr7 receptor is expressed in a variety of murine organs including reproductive organs, brain, heart, aorta, etc. Using insertional gene targeting approach, we targeted the lacZ gene into the mouse Lgr7 locus.

Lgr7 deficient mice have abnormal mammary development with smaller, poorly developed nipples. Mutant females are unable to deliver milk to their pups. The uterine size appears to be smaller in mutant mice without any alteration in morphology. These females also have significantly prolonged length of parturition compared to littermates. Examination of sections of the lung in Lgr7 deficient mice reveals pulmonary fibrosis that is seen as early as one month of age compared to 6 months in relaxin-1 knockout mice. Additionally, there is excessive deposition of connective tissue around pulmonary veins, which is not seen in controls. Examination of collagen content using trichrome staining of histological sections reveals increased collagen deposition around pulmonary veins in mutant mice. Thus, analysis of the Lgr7 deficient mice reveals a more severe phenotype than the one in relaxin-1 deficient mice, indicating ligand redundancy for Lgr7 in vivo.

We have also produced mice with a deficiency of both Lgr7 and Lgr8 receptors, as well as Lgr7 deficient mice with an additional transgenic copy of Insl3. Analysis of their phenotype did not reveal additional phenotypic abnormalities, indicating a non-overlapping nature of the relaxin and Insl3 signaling in vivo.

**Polymorphisms and functional analysis in the promoter of the interleukin-4 receptor alpha chain gene.** *N.*

*Hosomi<sup>1</sup>, K. Fukai<sup>1</sup>, N. Oiso<sup>1</sup>, A. Kato<sup>1</sup>, T. Murakami<sup>1</sup>, M. Ishii<sup>1</sup>, H. Kunimoto<sup>2</sup>, K. Nakajima<sup>2</sup>.* 1) Department of Dermatology, Osaka City University Graduate School of Medicine, Osaka, Japan; 2) Department of Immunology, Osaka City University Graduate School of Medicine, Osaka, Japan.

The gene encoding the interleukin-4 receptor alpha chain (IL4RA) is a candidate gene for atopic diseases. Previously, we reported four polymorphisms in the IL4RA transcriptional promoter: -327A/C, -326C/A, -186A/G, -184A/G. These polymorphisms were mainly classified into two haplotypes: alpha (.ac..a.a..) and beta (.ca..g.a..), and alpha haplotype is more frequent in atopic dermatitis, and beta haplotype is more frequent in psoriasis as compared with healthy controls.

In this study, we further investigated -482 to -3249 of the 5-flanking region of the IL4RA and identified two novel polymorphisms: -1803T/C, -3112C/T and we carried out association study of these polymorphisms. In atopic dermatitis patients, at -1803T/C and -3112C/T, C allele and T allele are significantly higher (P=0.0034 and P=0.0075) than normal controls. Linkage disequilibrium between alleles at the SNP loci in the promoter and coding region of IL4RA was calculated. There was strong linkage disequilibrium between four SNPs, -327A/C, -1803T/C, -3112C/T and I50V.

We also investigated the functional analysis of the IL4RA transcriptional promoter in Jurkat and HaCaT cells. However, luciferase reporter assay revealed no statistical difference of the promoter activity between alpha haplotype and beta haplotype, and allele C and T at both -1803 and -3112. Although the computer-aided transcription search predicted that GATA-3, the Th2 type transcription factor, should bind only to -3112T allele of the promoter, co-transfection of GATA-3 expression vector did not up-regulate the promoter activity of our luciferase reporter system.

Despite the association of the six promoter polymorphisms with atopic dermatitis and psoriasis, *in vitro* transient expression analysis did not show evidence that these are functionally significant.

**Multi-species comparative sequence analysis of the *WS4/CMT1/Sox10* locus.** A. Antonellis<sup>1,4</sup>, S.Q. Lee-Lin<sup>1</sup>, L.L. Baxter<sup>2</sup>, T.G. Wolfsberg<sup>1</sup>, N.C.S. Program<sup>3</sup>, W.J. Pavan<sup>2</sup>, E.D. Green<sup>1,3</sup>. 1) Genome Technology Branch, NHGRI, NIH, Bethesda, MD; 2) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD; 3) NIH Intramural Sequencing Center, NHGRI, NIH, Gaithersburg, MD; 4) Genetics Program, George Washington University, Washington, DC.

Mutations in the gene for the high-mobility group transcription factor *Sox10* have been implicated in Waardenburg-Shah syndrome (WS4) and a Charcot-Marie-Tooth disease type 1 (CMT1) phenotype. While the role of this gene is well documented in both neural crest cell development and myelin-specific gene regulation, the factors that regulate *Sox10* expression remain unclear. Indeed, there is currently no defined functional promoter at this locus. To understand the transcriptional regulation of *Sox10*, we have performed multi-species comparative sequence analysis, a powerful approach for identifying cis-acting transcriptional regulatory elements. For this analysis, nearly 150 kb of genomic DNA spanning the *Sox10* coding sequence plus upstream and downstream regions were sequenced in cow, pig, cat, dog, and rat, and added to the data already available for human and mouse. In addition, we have developed a highly stringent method for identifying short exact matches between orthologous sequences. By applying this method to the genomic sequence of these seven species and incorporating data from promoter and transcription factor binding site predictions, we have identified a number of putative biologically interesting regulatory elements and a potential gene promoter. We believe these results will facilitate two specific areas of research at the *Sox10* locus: (1) the identification of functional cis-acting regulatory elements, and (2) additional screening for disease-associated mutations in conserved non-coding sequences.

**The role of Steroidogenic Factor 1 (SF1) in transcriptional regulation of human *CYP17*.** A.S. Barbosa, C.J. Lin.  
Div. Endocrinol, Dep. Int. Med, University of Sao Paulo, Sao Paulo, Sao Paulo, Brazil.

The *CYP17* gene encodes cytochrome P450c17, a key enzyme for the production of corticosteroids and sex steroids. *CYP17* gene expression is regulated in a tissue-specific and species-specific fashion by trophic hormones. Human adrenals and gonads also exhibit basal transcription of *CYP17*. The promoter of human *CYP17* harbors four recognition sites for SF1, two NF-1 sites, one Sp1/Sp3 site, and a GATA site. To investigate the contribution of SF1 and GATA to basal *CYP17* transcription, mutant constructs containing isolated or combined inactivation of the SF1 and GATA sites were cloned into luciferase reporter vector and expressed in human adrenal NCI-H295A cells, which express SF1 endogenously, and COS-7 cells. Promoter activity was tested in the context of endogenous and overexpressed SF1. In SF1-overexpressing NCI cells, isolated inactivation of the SF1 sites decreased promoter activity by 75% (SF1-1mut), 50% (SF1-2mut), 37.5% (SF1-3mut), and 12.5% (SF1-4mut). The impact of these mutations is less prominent in the absence of SF-1 expression vector (respectively, 62, 31, 34 and 8,5%). In NCI cells, mutation of GATA site increased transcription in 12.5% when SF1 was overexpressed. Combined inactivation of SF1-1 and GATA sites, of the four SF1 sites, and of three SF1 sites (SF1-2/3/4mut) reduced activity by 70-87.5% when SF1 was overexpressed, but had little impact in the context of endogenously expressed SF1. In COS-7, isolated inactivation of any SF1 site decreased promoter activity by 50%, irrespective to its distance to the *TATA box*. GATA site inactivation increased activity by 50%, and combined inactivation of multiple SF1 sites reduced transcription by 75%. Our data indicate that: i) all four SF1 sites contribute to *CYP17* transcription, and, in adrenocortical cells, the influence of a SF1 site decreases as its distance to *TATA box* increases; ii) the GATA sequence might be part of an inhibitory recognition site; iii) the impact of overexpression of SF-1 in the activities of promoter/reporter constructs in NCI cells suggests that co-transfection of SF-1 expression vector may not recapitulate the physiological environment of adrenocortical cells.

Program Nr: 1059 from 2003 ASHG Annual Meeting

**Regulation of ADAM33 and Airway Remodeling.** *R. Del Mastro, H. Giese, R. Little, P. Van Eerdewegh.* Human Genetics, Genome Therapeutics Corp, Waltham, MA.

We previously identified ADAM33 as an asthma susceptibility gene using a positional cloning approach. Statistical analysis revealed disease-associated SNPs within the coding and noncoding regions of the gene. We hypothesize that the associated SNPs are within regions of the gene that affect the efficiency of sequence elements to recruit proteins necessary for transcriptional regulation and/or splicing modulation. We have performed a comprehensive search within ADAM33 using multiple computational analyses to identify regions that contain potential transcriptional regulatory and splicing elements (TRASE). We identified conserved non-coding sequences using the human and mouse ADAM33 genes within introns AB, BC and ST. The latter two introns contained conserved non-coding sequences that were within the vicinity of the most significant disease-associated SNPs. Exonic splicing enhancer elements (ESEs) were also identified within the gene and several of these cis-acting elements spanned significant disease-associated SNPs. The predicted TRASE and SNP data were integrated onto the ADAM33 gene structure. Using this map, we have generated a comprehensive set of mini-gene constructs to examine the effects of nine of the most significant SNP pair combinations (p-value below 0.0005) on transcription and splicing. Preliminary data suggest that these SNPs may have an effect on splicing modulation. Based on expression patterns, we have previously suggested that ADAM33 may play a role in airway remodeling. To gain an insight into ADAM33s function, we have designed a cell-based airway remodeling assay and coupled the RNAi technology to knockdown the gene. Using primary lung fibroblasts and bronchial smooth muscle cells, ADAM33 expression was reduced to 6% and 20% respectively. We were able to maintain these low levels of expression over 7 days post siRNA transfection. We have measured the effects of the ADAM33 knockdown in these primary cells by monitoring the expression of genes known to be involved in airway remodeling. The results from the use of this targeted cell-based assay and the evaluation of the mechanistic role of the SNPs on ADAM33 regulation will provide a greater understanding of the genetic factors that affect susceptibility to asthma.

**Functional characterisation of transcription factors deleted in Williams-Beuren Syndrome.** *P.D. Cunliffe, N. Hart-Holden, T. Hinsley, A.P. Read, M. Tassabehji.* Medical Genetics, University of Manchester, St Mary's Hospital, Manchester, UK.

Williams-Beuren syndrome (WBS) is a developmental disorder caused by deletion of approximately 1.5Mb on human chromosome 7q11.23 which occurs in approximately 1/20000 live births. Phenotypic features of the disease include the heart defect, supra-valvular aortic stenosis (SVAS), along with a distinctive cognitive profile combining mild mental retardation with an outgoing personality. Other phenotypic features include a dysmorphic face, growth retardation and hypercalcaemia. The only aspect of the WBS disease phenotype unambiguously associated with deletion of a particular gene is the SVAS, caused by deletion of the elastin gene. Detailed mapping of the WBS critical region has identified genes encoding a family of transcription factors as strong candidates for other aspects of the disease phenotype. The members of the family show a high degree of similarity to one another and contain varying numbers of a repeated motif known as an I repeat. Here we present functional data showing the effects of three of these genes (*GTF2I*, *GTF2IRD1* and *GTF2IRD2*) on downstream target genes. *In vitro* DNA binding studies show that *GTF2IRD1* binds a consensus DNA sequence present in several distinct enhancer elements via the fourth of its five I repeats. Luciferase assays show that both *GTF2IRD2* and some, but not all, isoforms of *GTF2IRD1* act as repressors of transcription from the *c-fos* promoter whereas *GTF2I* acts as an activator of this gene. Aberrant levels of protein from members of this family of genes are likely to influence expression of a number of downstream target genes that could result in some of the developmental abnormalities manifest in WBS.

Program Nr: 1061 from 2003 ASHG Annual Meeting

**Functional analysis of the transcriptional regulation of the human bile salt export pump gene.** *J. Byrne, S. Strautnieks, G. Mieli-Vergani, R. Thompson.* Institute of Liver Studies, King's College Hospital, Guy's, King's and St Thomas' School of Medicine, Bessemer Road, London, UK.

The bile salt export pump, BSEP, encoded by *ABCB11*, is the major bile salt transporter of human liver. *ABCB11* is mutated in a form of low <g>-GT progressive familial intrahepatic cholestasis (PFIC), known as BSEP deficiency. It has been documented that transcription of *ABCB11* is positively regulated by bile salts. However, little is known about which other transcription factors are involved in controlling the expression of the human gene, as well as the effect of exogenous compounds on its transcription. This study was designed to investigate these questions. Three *ABCB11* transcription start sites were identified using 5' Rapid Amplification of cDNA Ends (RACE) experiments, two of which are novel. These transcription start sites were found to be utilised both in normal liver and in the liver from patients with various cholestatic syndromes. 3' RACE experiments identified the previously unknown transcription termination site for the *ABCB11* mRNA. 2 kb of the promoter region of the human gene was subsequently amplified by polymerase chain reaction and cloned into the luciferase expression vector, pGL3-basic. 0.2 kb 5' deletion constructs were subsequently generated and cloned. All constructs were transfected into HepG2 cells and left for 48 hours before harvest. Analysis of the luciferase activity given for each deletion construct has identified areas of transcriptional importance in the human promoter, including a putative silencer motif. Current work is focusing on defining the exact role of these regions through the use of electrophoretic mobility shift assays. Furthermore, the ability of drugs and hormones to repress *ABCB11* transcription is being assessed. In conclusion, this work is providing an insight into the transcriptional regulation of *ABCB11* under normal and cholestatic conditions. Furthermore, it provides an experimental system to assess the effect of *ABCB11* promoter sequence variants found in cholestatic patients.

Program Nr: 1062 from 2003 ASHG Annual Meeting

**The Role of TFII-I and HDAC3 in  $\gamma$ -globin gene expression.** *V.J. Crusselle, K.F. Vieira, J. Bungert.* Biochemistry and Molecular Biology, University of Florida, Gainesville, FL.

High level and developmental stage-specific erythroid  $\gamma$ -globin gene expression is controlled by proximal and distal elements. It is well known that  $\gamma$ -globin gene expression is regulated by multiple transcription factors. We previously found that TFII-I, a helix-loop-helix protein, binds to the promoter region of the  $\gamma$ -globin gene in human embryonic erythroid cells in which the gene is repressed. Studies have shown that histone deacetylase 3 (HDAC3) is known to functionally and physically interact with TFII-I in COS7 cells. By deacetylating histones, HDAC3 preserves their basic nature and impedes DNA accessibility. We therefore hypothesized that TFII-I recruits HDAC3 to the promoter region of the  $\gamma$ -globin gene, thus inhibiting the expression of the  $\gamma$ -globin gene. ChIP and co-immunoprecipitation experiments showed that TFII-I and HDAC3 interact at the inactive  $\gamma$ -globin promoter in human embryonic erythroid cells. We then used RNA interference to knock down the expression of these proteins in murine adult erythroid cells and human embryonic erythroid cells and determined the effect on  $\gamma$ -globin gene expression. Our results suggest that TFII-I plays a role in the regulation of the  $\gamma$ -globin locus.

**Down-regulation of p21 gene expression by the transcription factor NF1.** *S. Ouellet<sup>1</sup>, S. Leclerc<sup>2</sup>, R. Drouin<sup>1</sup>, S. Guérin<sup>2</sup>.* 1) Division of Pathology, Departement of Medical Biology, Faculty of Medicine, Laval University and Unité de recherche en génétique humaine et moléculaire, Research Centre, Hôpital St-François d'Assise, Centre Hospitalier Universitaire de Québec, Canada; 2) Oncology and Molecular Endocrinology Research Center, CHUL Research Center (Québec), Canada.

P21waf1cip1 is known to mediate cell-cycle arrest, apoptosis, senescence and differentiation via specific protein-protein interactions with the cyclins, cyclin-dependent kinase (Cdk), PCNA, Topoisomerase II, etc. The regulation of p21waf1cip1 gene expression occurs mainly at the transcription level. Many DNA damaging agents strongly activate transcription of the p21waf1cip1 gene via a p53-dependent or independent mode, leading to cell-cycle arrest or apoptosis. P21waf1cip1 was also up-regulated in the apparent absence of genotoxic stress, following growth factors exposition, hormones or serum stimulation and for terminally differentiated cells. However, the cell proliferative influence of p21waf1cip1 appears to rely on the nuclear level of p21. Through the use of the Ligation Mediated PCR (LMPCR), we identified several DNA target sites on the proximal promoter of the human p21 gene for nuclear transcription factors expressed in primary cultured human fibroblasts. One of these sites contain a perfect consensus binding sequence for E2F1 whereas another bears a perfect consensus sequence for the members of the nuclear factor-1 (NF1) family of transcription factors. The role of the E2F transcription factor family in the transcriptional regulation of the p21 gene has already been reported previously but so far, nothing was known about the regulatory influence exerted by NF1 on the p21waf1cip1 transcriptional regulation. Using both EMSA and supershift analyses, NF1 was recognized as the major protein interacting with the most proximal footprinted region from the p21waf1cip1 promoter. Through transient transfections of recombinant constructs bearing the CAT reporter gene under the control of either the wild type p21 proximal promoter or a derivative in which the NF1 site was deleted, we demonstrated that NF1 can act as a repressor in primary cultured fibroblasts, human HeLa and rat pituitary GH4C1 cells. Our results therefore suggest a role for NF1 in the cell-cycle dependent expression of p21 both in vivo and in vitro.

**HNF4 is Essential for Expression of the Human Hepatic Lipase Gene (*LIPC*) in vivo: HNF4 and ARP-1 Bind to DR1 and DR4 Elements of the Promoter and Fine-Tune its Activity in vitro.** *B. Kurdi-Haidar*<sup>1</sup>, *S.A. Duncan*<sup>2</sup>, *M.A. Battle*<sup>2</sup>, *S.S. Deeb*<sup>1</sup>. 1) Departments of Medicine and Genome Sciences, University of Washington, Seattle, WA; 2) Department of Cell Biology, Neurobiology and Anatomy, Medical College of Wisconsin, Milwaukee, WI.

The *LIPC* promoter contains two conserved direct repeats of the core motif RGG/TTCA with one- and four-base spacing (DR1 and DR4). HNF4a and ARP-1 together activate the *LIPC* promoter via the DR1 element, and excess ARP-1 suppresses this activation via the DR4 element. RARa/RXRa heterodimers, in the presence of 9-cis retinoic acid, attenuate HNF4a/ARP-1-mediated activation. We analyzed direct interactions of HNF4a, ARP-1, RARa and RXRa with wild type and mutant DR1 and DR4 elements using electrophoretic mobility shift assays (EMSA) with nuclear extracts from human hepatoma HuH7 cells and recombinant HNF4a and ARP-1 overexpressed in COS7 cells. EMSA and supershift of bands with specific antibodies showed that homodimers of HNF4a bind the 5 and 3 half-sites of DR1, while ARP-1 monomers bind exclusively to its 5 half-site, with dissociation constants (Kd) of 14 nM and 1.5 nM, respectively. These results suggested that HNF4a/ARP-1 heterodimers bind to DR1 and activate the *LIPC* promoter, with ARP-1 occupying the 5 and HNF4a the 3 half-site. RARa/RXRa heterodimers also bind to the DR1 element with equal affinity as HNF4a and ARP-1. HNF4a and ARP-1 bind independently to the 5 half-site of DR4 with Kd of 14 and 3 nM, respectively, suggesting that excess ARP-1 binds to the 5 half-site of DR4 and suppresses HNF4a/ARP-1-DR1-mediated co-activation. We confirmed an essential role for HNF4a in *LIPC* expression in vivo by showing that liver-specific targeted disruption of HNF4a gene in mice prevents liver expression of HL mRNA. We conclude that HNF4a is necessary but not sufficient for activation of *LIPC* expression in hepatocytes, and that the intracellular balance between HNF4a, ARP-1, RARa and RXRa controls its expression by interacting with the DR1 and DR4 promoter motifs.

**In vivo analysis of protein-DNA interactions in the  $\gamma$ -globin gene locus.** *K.F. Vieira, J. Bungert.* Biochemistry and Molecular Biology University of Florida, Gainesville, FL.

The human  $\gamma$ -globin genes are expressed at high-levels in erythroid cells. This high-level expression is dependent on the presence of the locus control region (LCR), which is 8-20 kb upstream of the  $\gamma$ -globin genes. Recent data support the hypothesis that transcription complexes are recruited to the LCR and to the genes. It has been suggested that the LCR is the primary attachment site for transcription complexes, which are subsequently transferred to individual globin genes. To investigate the order of recruitment of RNA polymerase II and other factors to the active gene promoters and to the LCR, erythroid cells were synchronized at the border of G1 and S phase of the cell cycle using the double thymidine block method. These cells were then released from the block and used for ChIP analysis. The data show that before release from the block, members of the transcription machinery were present both at the active gene promoter and within the LCR. Within early S phase no factors were present at the active gene promoter, while they could still be detected at the LCR. Later in S phase there is faint detection of the factors at the active gene promoter, and less at the LCR. By late S phase, the factors have returned to both locations. Also, it seems that NF-E2 returns first, followed by the transcription machinery. DNA analysis using multiplex PCR suggests that replication of the active globin gene is likely to have occurred between 45 minutes and 2 hours into S phase. Taken together, our data supports a model by which the transcription machinery is first recruited to the LCR and subsequently transferred to the active gene promoters.

***In vivo* protein-DNA interactions analysis using dimethylsulfate, UVC and DNaseI at the murine survival motor neuron gene promoter.** F. Vigneault<sup>1</sup>, R. Rouget<sup>2</sup>, C. Rochette<sup>2</sup>, S. Morissette<sup>2</sup>, C. Codio<sup>2</sup>, I. Paradis<sup>1</sup>, L.R. Simard<sup>2</sup>, R. Drouin<sup>1</sup>. 1) Research Center, Hospital Saint-Francois d'Assise, CHUQ, Laval University, Quebec, QC, Canada, G1L 3L5; 2) Research Center, Hospital Sainte-Justine, University of Montreal, Montreal, QC, Canada.

In humans, loss or mutation of the Survival Motor Neuron (SMN) gene is responsible for proximal spinal muscular atrophy, the second most common autosomal recessive disease of childhood after cystic fibrosis. Previous studies suggest that in mouse, the *Smn* gene is subject to temporal and spatial regulation both at the level of transcription and post-translational modification. In order to define the regulatory elements that account for the control of *Smn* gene expression, we have conducted *in vivo* footprinting analysis of the *Smn* gene promoter region in the P19 embryonal carcinoma cells, as they can be induced to differentiate into neuronal-like cells by retinoic acid. To do so, we have used DMS, UVC and DNaseI as probing agents to characterize the *Smn* promoter using ligation-mediated polymerase chain reaction. Systematic comparison of the footprints obtained from differentiated and undifferentiated P19 EC cells does not explain the down-regulation of the promoter activity for the sequence studied. Footprints were observed at putative sites of sequence-specific DNA binding proteins like Sp1, AP-2, H4TF2, ADR1, GABP, Elk-1, NFIL-6 RE, GAGA PEA-3, Ets-1, GABP, PU.1, MEF-2, E1A-F. *In vitro* studies by transient transfection experiments with a reporter gene and EMSA experiments have confirmed that Sp1-like (AP-2), NFIL6-RE and Ets (PEA-3/Ets-1) cis-elements are essential for the core *Smn* promoter activity in undifferentiated P19 cells; whereas only the NFIL6-RE and Ets sites were required in differentiated P19 cells. *In vivo* footprinting analysis results confirmed most of those interactions but abrogate some like the AP-2 interaction. Furthermore, some other footprints were detected on sequences that do not correspond to any known transcription factor binding sites. These results demonstrate the importance of *in vivo* studies as *in vitro* studies do not exactly reflect DNA-protein interactions implicated in gene regulation.

**A frameshifting mutation causes skipping of a preceding exon and modifies the effects of nonsense-mediated mRNA decay (NMD).** *K. Ohno, M. Milone, J.M. Brengman, X.-M. Shen, A.G. Engel.* Dept Neurology, Mayo Clinic, Rochester, MN.

Nonsense-mediated altered splicing affects splice site selection of a mutation-bearing exon, but not of a remote exon. We here report that a frameshifting 7-bp deletion (553del7) in exon 7 of *CHRNE* encoding the acetylcholine receptor subunit, observed in seven congenital myasthenic syndrome patients, unexpectedly causes skipping of the preceding 101-bp exon 6 in muscle. Skipping of exon 6 restores the open reading frame after 553del7. To understand how the preceding exon is skipped in *CHRNE*, we cloned the entire *CHRNE* spanning 12 exons and 11 introns, engineered a series of *CHRNE* mutants, transfected wild-type and mutant constructs into COS cells, and analyzed pre-mRNA splicing by RT-PCR and by the ribonuclease protection assay.

Transfected COS cells showed the same aberrant splicing that was detected in the patient muscles. When NMD was inhibited by anisomycin, even wild-type *CHRNE* produced an exon 6-skipped transcript, but optimization of splicing signals for exon 6 prevented skipping of exon 6. This indicates that inherently weak splicing signals at the boundaries of exon 6 results in skipping of exon 6 even in wild-type *CHRNE*, but the transcript is degraded by NMD. Therefore, the consequences of the weak splicing signals for exon 6 are corrected by NMD, which removes the abnormal transcript arising from wild-type *CHRNE*. In contrast, an exon 6-skipped transcript harboring 553del7 has no premature stop codon, and is immune to NMD, whereas the normally spliced transcript harboring 553del7 is degraded by NMD. Therefore, in the presence of 553del7, NMD works only on the normally spliced transcript, and the exon 6-skipped transcript remains intact. A similar mechanism likely causes skipping of remote exons in other genes.

Presence of weak splicing signals for *CHRNE* exon 6 also prompted us to search for mutations in exon 6 that disrupt an exonic splicing enhancer. Indeed, we found that EF157V and E154X in exon 6, observed in two other patients, cause aberrant splicing of exon 6.

**Activation of exon incorporation into mRNA by SAP 145 or Tat-SF1 in *in vitro* mini-dystrophin splicing.** A. Surono, Y. Takeshima, M. Matsuo. Dept Pediatrics, Kobe Univ Grad Sch Medicine, Kobe, Hyogo, Japan.

Exonic splicing enhancers (ESEs) are RNA sequences required for accurate splicing that removes intron sequence from pre-mRNA. ESEs are believed to exert its function through its association with nuclear protein. In the previous study, we characterized the 5' part of deleted sequence of the dystrophin Kobe as ESE and named as ESE-19. We have isolated the nuclear proteins bound to ESE-19 by using two-step chromatography. Amino acid analysis revealed two known proteins of spliceosome-associated protein 145 (SAP145) and Tat-SF1, the essential splicing factor assembled on the branch point site and general transcription elongation factor, respectively. The binding characters were examined using recombinant SAP145 (rSAP145) and Tat-SF1 (rTat-SF1). The interacting rSAP145 with ESE-19 was enhanced by rTat-SF1 in a dose dependent manner. In addition, the binding ability of ESE-19 to nuclear proteins was strongly enhanced by addition of individual rSAP145 and rTat-SF1. The rSAP145 and ESE-19 interaction was abrogated completely by using mutant ESE-19 and antisense RNA complementary to ESE-19. We also revealed that 8 nucleotides at the 5' end of ESE-19 is a novel binding site of SAP145. In order to see the function of rSAP145 and rTat-SF1, *in vitro* mini-dystrophin splicing system was used. Surprisingly, either rSAP145 or rTat-SF1 could activate incorporation of exon of mutant dystrophin minigenes into mRNA in a dose dependent manner, indicating a direct involvement of both proteins on splicing activation. Our results show a nuclear proteins binds to ESE-19 and these proteins enhance exon incorporation.

These provide important new insight into how SAP145 interacts with ESE in addition to be present in spliceosome assembly on the branch point site and its association with Tat-SF1 on splicing regulation of dystrophin mRNA.

**Novel alternatively spliced forms found for seven genes in transcriptional profiling of asthma candidate genes in**

**11 asthma related cell lines and lung tissue.** A. Polvi<sup>1</sup>, S. Ruosaari<sup>2</sup>, J. Vendelin<sup>1,3</sup>, A. West<sup>4</sup>, I. Saarikko<sup>4</sup>, A. Reinikainen<sup>4</sup>, J. Hollmn<sup>2</sup>, T. Laitinen<sup>1,3</sup>, H. Mannila<sup>2</sup>, R. Lahesmaa<sup>4</sup>, J. Kere<sup>1,3,5</sup>. 1) Department of Medical Genetics, Biomedicum Helsinki, University of Helsinki, Finland; 2) Laboratory of Computer and Information Science, Helsinki University of Technology, Finland; 3) Geneos oy, Helsinki, Finland; 4) Turku Centre for Biotechnology, University of Turku and Åbo Akademi University, Turku, Finland; 5) Karolinska Institute, Department of Biosciences at Novum, Clinical Research Center, Sweden.

To study expression of a large group of asthma susceptibility genes simultaneously in cell types relevant to asthma pathogenesis we used a microarray with 2225 asthma/immunology related genes and a representative panel of 11 cell lines and lung tissue. Cells included Jurkat, Ramos, U-937, HMC-1, clone 15 HL-60 (15 HL-60), A549/NCI-H358, IMR-90/CCD-25Lu, BE(2)-C and RD to represent T-lymphocytes, B-lymphocytes, monocytes, mast cells, eosinophils, epithelial cells, fibroblasts, nerve cells and muscle cells, respectively. We determined cell line- and cell type-specific genes using bootstrap analysis, database analysis and RT-PCR. Previously undetected expression of several genes was found in many cell lines. Also, novel alternatively spliced forms were found for seven of 34 genes studied by RT-PCR (21%), for CDS1, MX2, CDC7L1, TNFSF10/TRAIL, AQP1, FOXF1/FREAC1 and CCL4/SCYA4/ACT-2. Alternatively spliced forms were generally expressed in same cell lines, but weaker than full length forms. Only AQP1 splice variants had different tissue distribution. According to sequence, alternative splicing excluded exon 11 from CDC7L transcript, but did not change the reading frame. In transcripts of five genes, reading frame and the coded amino acid sequence of the rest of the protein also changed in the alternative spliced site. Surprisingly high percentage of novel alternatively spliced forms for genes were found in a usual RT-PCR amplification experiment. In general, alternatively spliced forms and their importance should be more carefully studied.

**Purification and Characterization of Vaccinia Expressed FLAG-ATM Protein.** *H.H. Chun<sup>1</sup>, R.A. Cary<sup>2</sup>, D.J. Rawlings<sup>3</sup>, R.A. Gatti<sup>1</sup>.* 1) Department of Pathology, The David Geffen School of Medicine at UCLA, Los Angeles, CA 90095; 2) Biosciences Division, Los Alamos National Laboratory, Los Alamos, NM 87545; 3) Department of Pediatrics, University of Washington School of Medicine, Seattle, WA 98195.

The ATM gene product plays an important role in responding to double strand DNA breaks produced during cellular metabolism or by environmental agents. Some biochemical studies of ATM function have been hampered by the lack of efficient expression systems and purified ATM protein. We report the construction of a vaccinia virus expressing ATM, vWR-ATM, which is used to produce large amounts of functional FLAG-tagged ATM protein (FLAG-ATM) in HeLa cells. *In vivo* assays show expression of FLAG-ATM protein in an ATM-deficient cell line infected by vWR-ATM, and functional activity, as measured by p53 Ser15 phosphorylation. Purification of FLAG-ATM, from  $8 \times 10^6$  HeLa cells infected with vWR-ATM, was achieved through binding to a FLAG affinity resin and elution by peptide competition. We recovered about 40 mg of FLAG-ATM, where the majority of purified protein was ATM. Kinase assays using purified FLAG-ATM showed that GST-p53 serine 15 phosphorylation increased in the presence of DNA double strand breaks when compared to reactions without DNA or those with DNA containing no breaks. FLAG-ATM kinase activity was dependent on manganese and independent of magnesium. Atomic force microscopy (AFM) of FLAG-ATM with linear DNA showed FLAG-ATM binding to DNA with a preference for DNA ends. Immunoblotting after purification showed that FLAG-ATM was phosphorylated at Ser1981, which was removed after phosphatase treatment. Purification of FLAG-ATM from vWR-ATM infected cells has produced the highest yield of purified protein reported to date.

**Splice site mutations in the *Jagged1* Gene.** A.O. Laney, J.J.D. Morrissette, J. Abed, J. Wound, N.B. Spinner. Children's Hospital of Philadelphia & University of Pennsylvania School of Medicine, Philadelphia, PA.

Mutations in *Jagged 1* cause the autosomal dominant disorder Alagille syndrome, and some forms of isolated cardiac disease. The majority of mutations are protein truncating, with a smaller percentage being missense (10%), splicing (10%) or total gene deletions (5-7%). Mutations in the invariant nucleotides of the splicing consensus sequence always lead to abnormal RNA production, however, there mutations near these sequences, and even some mutations in exons have been shown to lead to abnormal splicing. We have studied potential splicing mutations (in invariant and consensus sequence nucleotides) to determine their impact. Determination of the impact of mutations on splicing requires analysis of cDNA, as outcome cannot always be predicted.

Eleven patients were studied by preparing cDNA from RNA after treatment with cycloheximide to stabilize the RNA. Selected regions of the *Jagged1* gene were then sequenced. Five patients had mutations in the invariant splicing consensus sequences (GT or AG at intron exon boundaries) and 7 patients had mutations further from the invariant positions, but within the general splicing consensus region. All 5 patients with mutations in the invariant nucleotides demonstrated abnormal splicing. These included abnormal splicing of exons 3, 6, 11 and 21.

Of the seven patients with potential mutations in the consensus sequence, 1349-12T>G was found to cause abnormal splicing of exon 11, and 2458+5G>A caused abnormal splicing of exon 20. Three other variants did not result in abnormal products, 1721-21G>A, 1121-25A>G and 1349-11T>G. It is noteworthy that two mutations (1349-12T>G and 1349-11T>G) were only a single base apart, both resulted in loss of a T from the splice acceptor region, yet only 1349-11T>G caused abnormalities, while the change in the minus 12 position resulted in a normal product.

**Abnormal subcellular localization and apoptotic cell death of mutant ELOVL4, the gene for Stargardt-like macular dystrophy (STGD3).** *G. Karan, N. Faulkner, M. Payne, M. Machan, S. Thirumalaichary, S. Sims, L. Jiang, Z. Yang, K. Zhang.* Department of Ophthalmology and Visual Science, Programme in Human Molecular Biology and Genetics, University of Utah Health Science Center, Salt Lake City, UT 84112.

**Purpose :** *ELOVL4* belongs to fatty acid elongase (*ELO*) family of genes. Members of the *ELOVL4* family share common structural features, including multiple putative membrane-spanning domains, a single histidine cluster motif and putative dilysine motifs thought to signal ER retention. A 5 bp deletion of human *ELOVL4* causes autosomal dominant stargardt like macular dystrophy (STGD3). This deletion results in a frame-shift and loss of C-terminal 51 amino acids that include the dilysine ER targeting signal. The goals of this study are to determine the subcellular localization of wild type and mutant *ELOVL4* proteins in the transfected cells. **Methods :** Both wild type and mutant *ELOVL4* cDNAs were cloned in a pEGFPC1 expression vector. The resultant recombinant constructs express EGFP-*ELOVL4* fusion proteins. Each plasmid construct was used to transfect NIH 3T3, HEK293, COS7 and primary retina cells. To determine the subcellular localization of EGFP-*ELOVL4* fusion proteins, a series of markers for ER, mitochondria and peroxisomes were used. The transfected cells were viewed using confocal and episcopic-fluorescence microscopy. Western blotting was performed to analyze the expression of fusion proteins using anti-GFP antibody. **Results :** We expressed EGFP-*ELOVL4* proteins in NIH 3T3, HEK293, COS7 and primary retina cells. Wild type EGFP-*ELOVL4* protein was localized in the ER compartment. The mutant EGFP-*ELOVL4* did not distribute uniformly in ER, but appeared to localize into spots or pools throughout transfected cells. Cells expressing mutant EGFP-*ELOVL4* underwent apoptotic cell death. **Conclusions :** Wild type EGFP-*ELOVL4* is localized to ER, as predicted from its primary sequence. Mutant EGFP-*ELOVL4* protein has a different localization and causes apoptotic death. The above results could be an explanation of the photoreceptor cell degeneration in patients with STGD3.

**Cloning and characterization of a human gene (*rwd*) encoding a RING finger and WD-40 repeats containing protein.** W. Huang, J.K. Kane, M.D. Li. Dept. of Psychiatry, Univ. of Texas, HSC, San Antonio, TX 78229.

Recently we identified a novel human gene (*rwd*), which encodes a RING finger and WD-40 repeats containing protein, from a human brain cDNA library. Sequence analysis indicated that the complete mRNA is approximately 4.5 kb. Northern blotting analysis showed that the gene is expressed in several human tissues, most abundantly in brain and testis. Additionally, a transcript of approximately 7.5 kb was detected in human brain only. Radiation hybrid mapping analysis demonstrated the gene is located on chromosome 3q26, which was further confirmed by BLAST searching of human genome sequence. The genomic structure of *rwd* gene was characterized to span over 200 kb region with 19 exons. The transcription initial site of *rwd* gene was determined by primer extension. And its promoter features a typical housekeeping gene, with several putative GC box motifs for the binding of SP1 transcription factor family, but lacking a classical TATA box motif. The predicted protein RWD consists of 1,008 amino acid residues with RING finger, B-box, coiled-coil domains in N terminus and WD-40 repeats domain in C terminus. Western blotting analysis indicated an expected protein of approximately 110 kD was detected in the human brain extract and several human cell lines. Cellular localization studies with expressed protein tagged in the N terminus with HA or enhanced green fluorescent protein demonstrated the protein is localized in the cytoplasm of human HEK293 cell line. Functional studies are under way to further elucidate its biological role and its potential involvement in the etiology of human disease(s). (supported by DA-12844 and DA-13783).

**TBX5, a gene mutated in Holt-Oram Syndrome, is regulated through a GC box and T-box binding elements.** *G. Sun<sup>1</sup>, L. Scott<sup>1</sup>, X. Huang<sup>1</sup>, Q. Nguyen<sup>1</sup>, C. Price<sup>1</sup>, T. Huang<sup>1,2</sup>*. 1) Department of Pediatrics, University of California, Irvine, Irvine, CA; 2) Developmental and Cell Biology, University of California, Irvine, CA.

TBX5 is a member of the T-box gene family and encodes a transcription factor that regulates the expression of other gene(s) in the developing heart and limbs. Mutations of TBX5 cause Holt-Oram syndrome (HOS), an autosomal dominant condition characterized by congenital heart defects and limb anomalies. How TBX5 gene expression is regulated is still largely unknown. In order to identify transcription factors regulating TBX5 expression, we examined the 5'-flanking region of the human TBX5 gene. We determined that up to 300 of the 5'-flanking region of the TBX5 gene was necessary for promoter activity in ECL2 cells. One GC box, three potential T-box binding sites (TBX5-A, TBX5-B, and TBX5-C), and one NKX2.5 binding site were identified. Site-directed mutagenesis of the potential binding sites revealed that the GC box, TBX5-B, TBX5-C, and NKX2.5 are functionally positive for the expression of TBX5. DNA footprint analysis showed that these binding regions are resistant to DNase I digestion. Electrophoretic Mobility Shift Assays further demonstrated the protein-DNA interactions at the GC box and the potential TBX5-B, TBX5-C and NKX2.5 sites in a sequence-specific manner. The ability of TBX5 to regulate its own promoter was further demonstrated by the ability of ectopically expressed human TBX5 to increase reporter expression. We conclude that the GC box, T-box binding sites and NKX2.5 binding sites play important roles in the regulation of TBX5 expression, and that TBX5 is likely to be autoregulated as part of the mechanism of its transcription.

**Mutation Studies and Ocular Localization of Optineurin Protein in Primary Open Angle Glaucoma (POAG).** *T. Rezaie*<sup>1</sup>, *A. Child*<sup>2</sup>, *R. Ritch*<sup>3</sup>, *T. Krupin*<sup>4</sup>, *J. Liebmann*<sup>3</sup>, *E. Ilitchev*<sup>3</sup>, *M. Sarfarazi*<sup>1</sup>. 1) Molecular Ophthalmic Genetics, Univ Connecticut Health Ctr, Farmington, CT; 2) St. Georges Hospital, London, UK; 3) New York Eye and Ear Infirmary, NY; 4) University Eye Specialists, Chicago, IL.

We have previously reported mutations in Optineurin (*OPTN*) in a group of families with adult-onset POAG (*Science* 2002; 295:1077). Subsequently, we sequenced a total of 76 familial (including 22 high-pressure glaucoma, HPG) and 206 sporadic LPG (low-pressure glaucoma) patients for the entire of *OPTN* gene. Altogether, we identified 6 mutations, 1 susceptibility allele and several other SNP variants. Extensive genotyping of 7 families with E50K mutation over a region of 2.65 Mb confirmed that E50K is a recurrent mutation. Overall, we identified mutations in 13% of familial and 3% of LPG sporadic cases. One risk-associated factor (M98K) was observed in 12% of familial, 16% of sporadic LPG and 2% of normal controls. Therefore, mutations in the *OPTN* gene are more frequently observed in familial and LPG patients than, sporadic and HPG cases, respectively. This is also in a general agreement with previously reported mutations in *CYP1B1* and *MYOC* in patients with Primary Congenital Glaucoma and JOAG/POAG, respectively. By Western blotting, we detected *OPTN* protein in aqueous humor samples from human and 7 other species. By immunohistochemistry, we further studied ocular localization of *OPTN* protein in human, Rhesus monkey and mouse eyes. In anterior segments, positive staining was observed with non-pigmented ciliary epithelium, ciliary muscle, lens epithelium, iris constrictor muscle, endothelial cells of blood vessels and Schlemm's canals. In retina, intense positive labeling detected in nerve fiber layers, ganglion cells, inner and outer plexiform layers and pigmented epithelium. In monkey and mouse, axons of optic nerve ganglion cells, glial cells and endothelial cells of optic nerve blood vessels were also stained. Immunocytochemistry showed positive labeling in human optic nerve head astrocytes obtained from normal and glaucomatous eyes. In conclusion, Optineurin protein expressed in various ocular tissues and *OPTN* mutations mainly observed in patients with LPG. Supported By: EY-09947.

**TRPM5 is a transient calcium-activated cation channel.** *D. Prawitt<sup>1</sup>, L. Brixel<sup>1</sup>, M.K. Monteilh-Zoller<sup>2</sup>, C. Spangenberg<sup>1</sup>, A. Fleig<sup>2</sup>, B.U. Zabel<sup>1</sup>, R. Penner<sup>2</sup>.* 1) Molecular Genetics Laboratory, Children's Hospital/ University of Mainz, 55131 Mainz, Germany; 2) Laboratory of Cell and Molecular Signaling, Center for Biomedical Research at The Queens Medical Center and John A. Burns School of Medicine University of Hawaii, Honolulu, HI 96813, U.S.A.

Transient receptor potential (TRP) proteins are a diverse family of proteins with structural features typical of ion channels. They are grouped into three subfamilies, named after their founding members TRPC (canonical TRPs), TRPV (Vanilloid receptor like) and TRPM (Melastatin like). To date the human TRPM subfamily consists of eight members with partly unknown physiological function but possible involvement in human disease. We cloned and initially described *TRPM5*, a member of the TRPM subfamily, which plays an important role in taste receptors (Perez et al., 2002 and Zhang et al., 2003), although its activation mechanism remains controversial and its function in signal transduction is unknown. We demonstrate that *TRPM5* is expressed as a 4.5 kb transcript not solely in the gustatory cells, but in a variety of fetal and adult tissues. To further elucidate the biological function of *TRPM5* we studied the exact activation mechanism of this protein by establishing stable transgenic HEK293 cell lines with the human *TRPM5* and *TRPM5*-EGFP fusion constructs. The latter enabled us to localize the protein to the cell membrane, suggesting a role as a functional channel. We then characterized the electrophysiological properties of the *TRPM5* channel by using whole cell recordings and excised membrane patch-clamp analysis. *TRPM5* displays characteristics of a CAN (Calcium-activated-nonselective) cation channel. It is directly activated by  $[Ca^{2+}]_i$ , but seems not to conduct  $Ca^{2+}$  ions. Instead it carries monovalent ions ( $Na^+$ ,  $K^+$ ) after receptor mediated cytosolic  $Ca^{2+}$  increase, thereby modulating the membrane potential (depolarisation) with effects in cells with non-excitabile and excitabile membranes. We could also show the specific electrophysiological properties of the channel in cells with endogenous *TRPM5*, supporting the proposed functional involvement in the conversion of a chemical stimulus into an electrical signal.

**Characterization of a novel brain specific transcript on human chromosome 20q13.** *S. Worch, I. Hansmann, D. Schlote.* Institute of Human Genetics, Halle, Germany.

Based on human EST-markers we have identified a novel human gene on HSA20q13.32 whose expression appears to be restricted to the brain as Northern analysis of 8 human tissues revealed expression of a 3.2 kb and a 3.0 kb transcript in brain only. One corresponding cDNA (AJ311122) contains a 1680 bp ORF distributed on 13 exons, a second one as part of the EMBL sequence database has a different initial exon resulting in a 1671 bp ORF. Both ORFs show a homology of the endmost 1557 bp beginning in exon 2. Multiple tissue Northern analysis of the corresponding mouse transcripts has revealed 3 major signals of 3.3 kb, 2.9 kb and 2.5 kb visible in brain only emphasizing the tissue specificity of the human expression pattern. Analysis of the 5'-end of the transcribed RNA by RACE-PCR yielded four initial exons suggesting, as in man, alternative splicing. These four different mRNAs of the gene, mapping to mouse chromosome 2H4, could be verified by RT-PCR. During detailed expression analysis using 8 different mouse brain specific tissues a complex tissue specific pattern has been detected concerning the quantity of individual transcripts. A developmental specific expression pattern has been found during embryogenesis displaying weak signals from day 10 pc and strong signals from day 15 pc onwards to adult mice suggesting a function from late development. Further on, this complex expression pattern is not restricted to the 5'-end as we could demonstrate alternative polyadenylation in hybridization experiments. The transcripts vary in ORF size but all show the 1557 bp homology as found in man. Searching the databases a striking homology of approximately 120 aa at the C-terminal end of the predicted protein was found shared with 3 other human proteins with so far unknown function, suggesting a putative domain which seems to be highly conserved down to *D. melanogaster* and *C. elegans*. Therefore further experiments should lead to characterization of the gene product, possibly relevant in brain development or function.

**Fanconi Anemia and oxidative stress: The FANCG protein interacts with Peroxiredoxin 3.** *S.E. Plon<sup>1,2</sup>, K. Leung<sup>1</sup>, S.S. Mukhopadhyay<sup>1</sup>, H. Youssoufian<sup>2,3</sup>*. 1) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 2) Dept Molecular and Human Genetics, Baylor Col Medicine, Houston, TX; 3) Bristol-Myers Squibb CO, Princeton, NJ.

Fanconi anemia (FA) is an autosomal recessive disorder that results in bone marrow failure and increased susceptibility to cancer. Currently, mutations in eight distinct genes, labeled complementation groups A-G can result in FA. FANCA, C, F, and G proteins have been shown to interact together by two-hybrid and biochemical methods, forming a nuclear protein complex needed to activate FANCD2 in response to DNA damage. Several reports have also linked FANCC and FANCG to proteins in the cytochrome P-450 pathway, indicating their potential roles in oxidative stress. In order to further identify binding partners of the FA proteins we performed a yeast two-hybrid screen utilizing a bait construct containing the carboxy terminus of the FANCG protein (amino acids 300-622) and a human B-lymphocyte cDNA prey library. One of the positive interacting clones contained a cDNA encoding peroxiredoxin 3 (PRDX3), a member of the peroxiredoxin family of proteins possessing peroxide reductase activity which protects against oxidant injury. PRDX3 is regulated by c-myc and has been observed to be overexpressed in breast cancer and hepatocarcinoma cells. The positive interaction in yeast was shown to be dependent on the presence of both the PRDX3 and the FANCG encoding plasmids. Two different rabbit polyclonal antibodies to PRDX3 were raised. Co-immunoprecipitation assays utilizing protein extracts from undamaged COS-1 cells reveal that the endogenous PRDX3 protein can interact with an exogenously expressed HA-epitope tagged FANCG protein. These results provide additional evidence that Fanconi Anemia proteins interact with cellular proteins that regulate the response to oxidative damage.

**Microarray analysis of mouse forebrain gene expression after TCDD exposure.** *H. Fujita*<sup>1</sup>, *T. Mitsuhashi*<sup>1</sup>, *J. Yonemoto*<sup>2</sup>, *T. Takahashi*<sup>1</sup>, *K. Kosaki*<sup>1</sup>. 1) Dept Pediatrics, Keio Univ Sch Med, Tokyo, Japan; 2) Environmental Health Sciences Division, National Institute for Environmental Studies, Tsukuba, Japan.

Dioxins have been shown to possess developmental toxicity on mammals. The effects of dioxins are mediated via the aryl hydrocarbon receptor. The dioxin-aryl hydrocarbon receptor complex binds to the cognate xenobiotic responsive elements in the promoter regions of the target genes. Most downstream target genes of the dioxin receptor are unknown. Recently, we demonstrated that *in utero* exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) delays neocortical neurogenesis in mice. Using the Affymetrix cDNA microarray, we evaluated overall change of expression profile in the fetal forebrain following dioxin exposure to identify potential downstream target genes of the aryl hydrocarbon receptor. A single oral dose of TCDD (20 mcg /kg body weight) was administered to pregnant C57BL/6 mice on gestation day (GD) 7. Three pups were sacrificed and their forebrains were collected on GD12. DNA was prepared from the forebrains of dioxin-exposed mice and non-exposed mice, and was hybridized on the Murine genome U74Av2 array (Affymetrix) which carries more than 10,000 genes. In comparison with the control, seven genes were expressed more than two fold in the forebrain of the exposed pups. Among the 7 genes were *Cyp1a1* and *Cyp1b1*, which are already known to be induced by dioxins, *BSCv*, and LIM homeobox protein *Lhx8*. *BSCv* is a gene homologous to plant strictosidine synthase, a member of the metabolic pathway of indole alkaloids. Prenatal exposure to dioxins leads to cleft palate. It is interesting to note that loss-of-function mutations in *Lhx8* also lead to the same malformation. Teratogenic action of dioxin on palate formation might be mediated by abnormal expression of *Lhx8*.

Program Nr: 1080 from 2003 ASHG Annual Meeting

**A computational survey of young Alu subfamilies within non-human primate genomes.** *M. Carroll.* Department of Chemistry, Xavier University, New Orleans, Louisiana.

We have employed computational genomics to survey non-human primate genomic DNA sequence databases to determine a unique subfamily sequence diversity among recently integrated Alu Y elements and to measure Alu polymorphism among unrelated non-human primates. Alu elements are the most abundant Short INterspersed Elements (SINEs) at over one million copies in the human genome. Alu repeats compose greater than 10% of the mass of the human genome. *Pan troglodyte*, the common chimpanzee, is believed one of the closest living ancestors to humans. Its genome is 95-99% identical to the human genome and is a likely place to find clues to the dynamics of Alu insertion and evidence of the influence of Alu retroposition in genome structure and gene distribution. The youngest subfamilies of Alu elements, Ya8, Ya5, Yb8, appeared in the human genome between 2.5 to 7 million years ago after the divergence of the human and non-human primate genomes. These young subfamilies are absent from non-human primates. We assert that a similar appearance and pattern of mobile element subfamily structure and distribution exists in non-human primates. The purpose of this study is two-fold: to identify and describe using the available non-human primate genome a young Alu subfamily structure by describing diagnostic nucleotide patterns among Alu Y elements; and to amplify these sequences for a preliminary assessment of Alu polymorphisms among a small population of non-human primates. This is accomplished using the InfoMax VectorNTI Advance software suite and PCR. We are encouraged by the efforts to sequence non-human primate genomes because enormous benefit to understanding human genome structure and gene distribution will result.

**AUG-independent translation of human LINE-1 ORF2.** *R.S. Alisch, J.L. Garcia-Perez, J.V. Moran.* Dept Human Gen & Internal Med, Univ Michigan, Ann Arbor, MI.

Retrotransposition-competent L1s contain two open reading frames (ORF1 and ORF2), which are separated by a 66 nucleotide inter-ORF sequence that includes two in-frame stop codons. Previous studies demonstrated that both proteins are required for efficient retrotransposition (RTSN) in cultured human cells. Here, we have conducted a genetic study to determine how ORF2 is translated. Deletion analysis shows that neither the inter-ORF sequence nor the carboxyl-terminus of ORF1p is required for RTSN. Similarly, we showed that the putative ORF2 AUG could be mutated to any other amino acid without drastically affecting RTSN (i.e., the resultant constructs retrotransposed at 10-70% wild type levels). In contrast, changing the AUG to a stop codon (M1X) reduced RTSN to <2% wild type levels. Since there are no other initiation codons near the amino terminus of L1 ORF2p, our data suggest that ORF2 can be translated in an AUG-independent manner. To further explore how ORF2 is translated, we placed in-frame stop codons (i.e., TG23XX) or a frame-shift induced stop codon (i.e., T2X) at the same putative amino acid position of ORF2p. Paradoxically, the in-frame stop codons nearly eliminated L1 RTSN, whereas the frame-shift induced stop codon only reduced RTSN by ~2-fold. Interestingly, while the frame-shift induced stop codon interrupts the ORF2 reading frame in the 5'-3' direction, it still allows for a continuous ORF if we scan backwards (i.e., in the 3'-5' direction) from a conserved Asn residue (N14) required for L1 EN function. Thus, we proposed that L1 mRNA contains a downstream landing pad that positions incoming ribosomes at position one of ORF2. To test this hypothesis, we inserted a single guanosine nucleotide immediately downstream of each of the M1X stop codon mutations described above. Consistent with our hypothesis, each of the resultant constructs retrotransposed at efficiencies ~10-fold higher than the original M1X mutants. Thus, our data suggest that L1 ORF2 translation either occurs by an unusual mechanism such as ribosome shunting or is facilitated by an unconventional internal ribosome entry sequence. Indeed, our data demonstrate a novel form of gene regulation in human cells.

**Direct visualization of L1 ORF2 protein in human cells.** *J.L. Goodier<sup>1</sup>, K.A. Engleka<sup>1,2</sup>, E.M. Ostertag<sup>1</sup>, M.C. Seleme<sup>1</sup>, H.H. Kazazian<sup>1</sup>.* 1) Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, PAC; 2) Division of Cardiology, University of Pennsylvania School of Medicine, Philadelphia, PAO.

The human L1 retrotransposon contains two open reading frames separated by a short intergenic spacer. ORF1 encodes a 40 kDa protein which binds L1 RNA to form cytoplasmic RNPs. The 150 kDa ORF2 protein has endonuclease and reverse transcriptase activities and is expressed at very low levels in comparison to ORF1. Functional analyses have been hampered by difficulties detecting ORF2 protein. We report detection of both ORF1 and ORF2 proteins in cultured human cells following their overexpression using a vaccinia virus/T7 RNA polymerase hybrid expression system. Epitope-tagged forms of overexpressed ORF1 and ORF2 were detected by immunoblotting using antibodies against the epitope, and co-migrated with the respective ORF proteins produced in a baculovirus system. Furthermore, antibodies raised against an ORF2 amino-terminus peptide revealed several bands, including full length protein. However, antibodies against an ORF2 carboxy-terminal peptide detected only full length protein. This is consistent with the generation of truncated ORF2p forms lacking a carboxy-terminus. ORF2 overexpression appeared toxic to cells, and ORF2p containing mutations in the endonuclease and/or reverse transcriptase domains was detected in significantly greater amounts than wild-type protein. We used the vaccinia virus/T7 RNA polymerase hybrid system to track subcellular localization of L1 proteins, both as fusions with green fluorescent protein (GFP) and by immunocytochemistry. ORF1p localizes in the cytoplasm with a speckled pattern. ORF2p is also cytoplasmic but without speckled patterning, even when coexpressed with ORF1p from a bicistronic construct. Furthermore, ORF2p is detected in nucleoli in a significant percentage of cells. Data suggest that C-terminally-deleted but not full length ORF2 protein is directed to nucleoli. Putative nucleolar localization signals were identified. This work represents the first direct visualization of ORF2p within mammalian cells.

**Nonsense surveillance regulates diverse classes of physiologic transcripts and mutes a noisy genome. *J.T.***

*Mendell*<sup>1,2</sup>, *N.A. Sharifi*<sup>1</sup>, *H.C. Dietz*<sup>1,2</sup>. 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) HHMI.

Transcripts containing premature termination codons (PTCs) are rapidly degraded in eukaryotic cells through nonsense-mediated mRNA decay (NMD). In mammals, PTCs can also induce nonsense-mediated altered splicing (NAS), a complementary pathway through which nonsense codons influence pre-mRNA processing. Although these pathways have the ability to modulate the phenotype arising from nonsense or frameshift mutations, remarkably little is known regarding the physiologic role of NMD and NAS. To address this issue, we used RNA interference in mammalian cells to silence expression of *rent1/hUpf1*, a factor essential for both NMD and NAS, and performed expression profiling using Affymetrix microarrays. Of the approximately 5000 assayed transcripts, 4% were upregulated at least 2-fold and 4% were down-regulated at least 2-fold. Transcripts that were upregulated in response to NMD inhibition could be stratified into broad classes: transcripts with introns in the 3' untranslated region, alternative PTC-encoding exons, or upstream open reading frames; transcripts that encode selenocysteine-containing proteins; and transcripts derived from pseudogenes, ancient transposon families, or endogenous retroviruses. These physiologic substrates are unified by the presence of a spliced intron downstream of a termination codon, a context known to be sufficient to initiate NMD. In order to confirm that these transcripts are primary substrates for the NMD pathway, mRNA decay rates were determined for selected examples. The vast majority of transcripts examined were significantly stabilized in the absence of *rent1/hUpf1*, demonstrating that they are directly regulated by the nonsense surveillance machinery. These data provide the first systematic analysis of endogenous mammalian transcripts regulated by nonsense surveillance and dramatically expand the known repertoire of genes regulated by NMD. Our results document that nonsense surveillance constitutes a critical post-transcriptional regulatory mechanism that influences the expression of thousands of mammalian transcripts and the proteins they encode.

**Human L1 Transcription and Retrotransposition are Regulated by Transcription Factor RUNX3.** *N. Yang<sup>1</sup>, L. Zhang<sup>2</sup>, Y. Zhang<sup>1</sup>, H.H. Kazazian Jr.<sup>1</sup>.* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Center for Research on Reproduction and Women's Health, University of Pennsylvania, Philadelphia, PA.

LINE-1s are abundant non-LTR retrotransposons that comprise 17% of the human genome. The 5' untranslated region (5'UTR) of human L1 (L1Hs) houses a poorly understood internal promoter. Here we report that mutations at a putative RUNX site (+83 to +101) in the 5'UTR decrease L1Hs transcription and retrotransposition up to 90% in cell culture-based assays. Exogenous expression of RUNX3, but not the other two RUNX family members, RUNX1 and RUNX2, increases L1Hs transcription (by 2-fold) and retrotransposition (by 70%), which are otherwise decreased by siRNAs targeting RUNX3 (up to 70%) and a dominant negative RUNX (up to 87%). Furthermore, the specific interaction between RUNX3 and its binding site is demonstrated by an electrophoretic mobility shift assay (EMSA) using an anti-RUNX3 antibody. Previously an antisense promoter has been shown in the L1Hs 5'UTR in the +400 to +600 region. However, no specific transcription factor or nucleotide sequence has been implicated. Here we show by site-directed mutagenesis and exogenous expression of RUNX factors that RUNX3 can regulate the antisense promoter activity of L1Hs 5'UTR via another putative RUNX site (+526 to +508). Our results indicate an important role for RUNX3 in L1Hs retrotransposition as well as transcription from its 5'UTR in both sense and antisense directions. They will contribute to our understanding of the mechanism underlying L1Hs retrotransposition and its impact on the expression of adjacent cellular genes.

**Expression of mutant TBP and huntingtin in cultured cells.** *M. Friedman*<sup>1,2</sup>, *SH. Li*<sup>2</sup>, *XJ. Li*<sup>2</sup>. 1) Graduate Program in Gen/Molec Biol, Whitehead, Emory Univ, Atlanta, GA; 2) Dept Human Genetics, Whitehead, Emory Univ, Atlanta, GA.

Considerable phenotypic similarity is observed among the nine known polyglutamine (polyQ) diseases with regard to clinical manifestation, pathology, and molecular changes. Transcriptional dysregulation, which can be induced by aberrant interactions between polyQ proteins and transcription factors, has been proposed as a potential basis for the pathogenesis of polyQ diseases. Previous studies suggest that the TATA-binding protein (TBP) is recruited into polyglutamine aggregates formed by mutant huntingtin (htt), a protein of unknown function that causes Huntingtons disease (HD). Expansion of a polyglutamine repeat (>44 repeats) in TBP causes neurological symptoms and neuropathology in spinocerebellar ataxia 17 (SCA17) with marked similarities to what is observed in HD. Thus, it is interesting to study whether mutant TBP forms inclusions that can recruit normal huntingtin. We have generated TBP cDNA constructs containing 15, 38, 60, and 98 CAGs. Expression of these cDNAs in HEK 293 cells indicated that only pathogenic repeats (60 and 98 CAGs) cause TBP to form small aggregates in the nucleus. When co-transfected with normal huntingtin, mutant TBP was still concentrated in the nucleus. No obvious co-localization of mutant TBP and huntingtin was observed. However, similar to mutant huntingtin transfected cells, HEK 293 cells expressing mutant TBP had reduced viability as compared with those expressing normal TBP. Expression of mutant exon1 huntingtin resulted in aggregates that were primarily localized in the cytoplasm. When normal TBP and mutant huntingtin were co-transfected into HEK 293 cells, the latter induced the formation of predominantly cytoplasmic aggregates while the former was detected almost exclusively in the nucleus. Although it remains possible that soluble mutant htt may interact with TBP, the different subcellular localization of mutant TBP and huntingtin suggests that they may mediate cytotoxicity in transfected cells via different mechanisms.

**Role of a Tetranucleotide Repeat Polymorphism in the First Intron of the Tyrosine Hydroxylase Gene in Expression and Behavioral Phenotypes.** *X. Hu*<sup>1</sup>, *C. Mazzanti*<sup>2</sup>, *R.H. Lipsky*<sup>1</sup>, *D. Goldman*<sup>1</sup>. 1) Laboratory of Neurogenetics, NIAAA, NIH, Rockville, MD; 2) NCI, NIH, Bethesda, MD.

Tyrosine hydroxylase (TH) is the rate-limiting enzyme in the biosynthesis of catecholamines that include dopamine, noradrenaline, and adrenaline. These catecholamines are important neurotransmitters and hormones that regulate visceral functions, motor coordination, and arousal and are highly expressed in certain neurons of the ventral tegmental area or the locus ceruleus. The TH gene is located on the short arm of chromosome 11 (11p15.5). A variable number tandem repeat (VNTR) composed of TCAT repeat units with seven alleles from 5-11 repeat units is located within intron 1. The TH10 allele is composed of perfect repeats (TH10p) and a variant (TH10i) that has a 1-bp deletion creating an incomplete repeat unit. An association of the 10p allele with schizophrenia was found in one population, supporting a possible link with dysregulated dopamine synthesis and the disease. The TH VNTR polymorphism influences transcriptional activity. When linked to a CMV promoter, we determined that allelic variations of HUMTH01 commonly found in humans had a quantitative silencing effect on TH gene expression. To determine if the allelic variants affected activation of the TH gene, we initiated a more detailed expression study using the native TH promoter as part of a "mini-gene" construct composed of exon1, intron1, and exon 2 fused to a DsRed reporter gene. Six constructs containing different alleles of the repeat were selected for expression studies in different cell lines under the control of the cAMP-responsive element within the TH promoter. Each of the six alleles allow for forskolin-dependent activation of the DsRed reporter. We are currently quantifying the response to determine the contribution of each allele to TH expression.

**Cloning and expression studies of zebrafish *pitx3* gene.** *D. Bosenko*<sup>1</sup>, *N. Zinkevich*<sup>1</sup>, *B. Link*<sup>2</sup>, *E.V. Semina*<sup>1</sup>. 1) Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) Cell Biology, Neurobiology and Anatomy, Medical College of Wisconsin, Milwaukee, WI.

*PITX3* is a homeodomain transcription factor involved in anterior segment dysgenesis, cataracts and glaucoma in humans and *aphakia* in mice. We have now identified zebrafish *pitx3* gene and studied its expression and sequence. We used PCR primers designed from human and frog *pitx3* sequences to amplify different regions of the gene. The combined sequence of the zebrafish *pitx3* was found to be highly homologous to the human gene with overall 67% identity at the nucleotide and 62% at the protein level. The HD region showed 100%, the C-terminal region 70% and the N-terminus 65% identity. Zebrafish *pitx3* and *pitx2* proteins were found to be 67% identical to each other with most identity seen in the HD (100%), then C-terminal (78%) and divergent N-terminal regions (10%). Expression of zebrafish *pitx3* was studied by *in situ* hybridization with dig-labeled antisense riboprobe in 18-20, 24 and 48-hour embryos. The first expression was detected in the forebrain and midbrain regions in 18-h embryos continuing at least till 48-h stage. The first ocular expression of *pitx3* was evident in 19-20-h embryos at the stage of lens placode. The *pitx3* transcripts are abundant in the eye region in 24-h embryos at the lens vesicle stage. In the 48-h embryos, the expression was detected in the equatorial and posterior regions of the lens and in the periocular mesenchyme. The expression pattern of zebrafish *pitx3* gene is highly conserved with other species and therefore zebrafish represents a good model to study regulation of *pitx3* and its molecular pathways, aberrations of *pitx3* may result in lens phenotypes. Therefore we are studying *pitx3* sequence for mutations in a69 zebrafish mutant. The phenotype of the a69 mutant is characterized by arrest of lens development. Further studies of *pitx3* expression in the a69 mutant and wt fish are ongoing. We have also identified partial genomic sequence of the zebrafish *pitx3* gene and located several regions of conservation outside of *pitx3* coding sequence. These regions are likely to play role in regulation of *PITX3* expression and are being investigated further.

**Identification and characterization of regions involved in regulation of Pitx2 expression.** N. Zinkevich<sup>1</sup>, D. Bosenko<sup>1</sup>, K. Frees<sup>2</sup>, M. Shi<sup>2</sup>, Y. Trembath<sup>2</sup>, J.C. Murray<sup>2</sup>, B. Link<sup>3</sup>, E.V. Semina<sup>1</sup>. 1) Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) Pediatrics, University of Iowa, Iowa City, IA; 3) Cell Biology, Neurobiology and Anatomy, Medical College of Wisconsin, Milwaukee, WI.

*PITX2* is a homeodomain transcription factor associated with Axenfeld-Rieger syndrome in humans and multiple animal phenotypes identified by misexpression and knockout studies. Therefore, precise level, site and timing of *PITX2* expression are important for normal development. In order to reveal elements involved in regulation of *PITX2* we first searched for regions of sequence conservation outside of *PITX2* coding region using human, mouse, rat, fugu and zebrafish *Pitx2* genomic sequences identified by a combination of database searches and our own sequencing efforts. *PITX2* gene was found to span ~ 20 kb in human, mouse and rat genomes, ~ 9kb in fugu and ~ 15 kb in zebrafish genomic sequence. Human *PITX2* sequence including 100-kb of 5' and 20-kb of 3' sequence was compared to other sequences and ten highly conserved regions have been identified. Five elements are located 5' of *PITX2*, four are internal regions but located upstream of *PITX2c* isoform and one internal element. The average length of the conserved sequence is ~ 150 nt and average identity ~ 76%. We hypothesized that these regions are enhancers involved in regulation of *PITX2*. We plan to use zebrafish transgenic to identify specific sites and timing of expression controlled by these elements. Down this path, we first analyzed expression of zebrafish *pitx2*. The first expression was detected at 90% epiboly stage (9 hrs) as reported by others. In 48-h embryos, a strong signal was seen in discrete regions in the brain, periocular mesenchyme, brachial arches and heart with expression in these regions continuing at least till 72-h stage. This expression pattern is conserved with other species and therefore zebrafish represents a useful model for identification of elements involved in regulation of *PITX2*. The conserved regions have been cloned into GFP-reporter plasmids and are now being tested for expression in zebrafish transient transgenics.

**Mig12, a novel Opitz syndrome gene product partner, co-operates with Mid1 to stabilize microtubules.** *B. Fontanella, C. Berti, R. Ferrentino, A. Ballabio, G. Meroni.* TIGEM, Napoli, Italy.

Opitz G/BBB syndrome (OS) is a genetic disorder characterized by developmental midline abnormalities, such as hypertelorism, cleft of lip and palate, and hypospadias. The gene responsible for the X-linked form of this disease, MID1, encodes a TRIM/RBCC protein that is anchored to the microtubules. The association of Mid1 to the cytoskeleton is regulated by dynamic phosphorylation, through the interaction with the 4 subunit of phosphatase 2A (PP2A). This interaction with 4 also involves Mid1, acting as an ubiquitin E3 ligase, in the control of PP2A degradation.

In spite of these data, the biological role exerted by the OS gene product is still to be elucidated and the presence of other potential interacting moieties in Mid1 structure prompted us to search for additional cellular partners through a yeast two-hybrid screening. We identified a novel gene, MIG12, whose protein product interacts with Mid1. Transiently expressed Mig12 is diffused in both nucleus and cytoplasm, although enriched in the microtubule-organizing center (MTOC) region. When co-expressed with Mid1, Mig12 is massively recruited to filamentous structures composed of tubulin. These bundles are resistant to high dose of microtubule depolymerizing agents and are composed of acetylated tubulin, thus representing stabilized microtubule arrays. Microtubule stabilization is crucial in processes such as cell division and migration. Mig12 high expression in the embryonic neuroepithelial midline and urogenital apparatus suggests that Mid1-Mig12 complexes might be implicated in such cellular processes during the development of some of the midline systems that are affected in OS patients.

**Dystrophin Dp71 isoforms expressed in PC12 cells. Interaction between Dp71f and DGC.** *C. Montanez<sup>1</sup>, J. Romo-Yanez<sup>1</sup>, F. Depardon<sup>1</sup>, V. Ceja<sup>1</sup>, A. Rendon<sup>2</sup>, D. Mornet<sup>3</sup>, F. Velazquez<sup>1</sup>*. 1) Dept Genetics & Molec Biol, CINVESTAV IPN, Mexico, Mexico; 2) Laboratoire de Physiopathologie Cellulaire et Moleculaire de la Retine, Hospital Saint-Antoine, Paris, France; 3) Institute National de la Sante et de la Recherche Medicale, U 128 IFR, Montpellier, France.

Duchenne Muscular Dystrophy (DMD) is a lethal X chromosome-linked recessive disease. This disorder is caused by mutations in the DMD gene that encodes dystrophin. A 71kDa C-terminal dystrophin isoform (Dp71) has been identified as the major product in brain. It has been suggested that Dp71 is involved in the anchorage and/or organization of specific membrane components. It is also known that Dp71mRNA goes through alternative splicing. Our group is interested in studying Dp71 function in nervous system, for this reason, we have examined the expression of Dp71 isoforms in PC12 cell line and we have shown that the expression and localization of two Dp71 isoforms is differentially regulated during PC12 cells NGF-induced differentiation. To gain insight into the function of each Dp71 isoform, we isolated, three cDNA clones corresponding to Dp71 isoforms expressed in PC12 cells. One cDNA clone corresponds to the isoform lacking exon 71, the second cDNA clone corresponds to the transcript lacking exons 71 and 78. Interestingly, a third cDNA clone encodes a novel and low abundant Dp71 isoform lacking exons 71 to 74. Sequence analysis shows that these cDNAs are highly homologous to human Dp71 isoforms. With the aim of identify proteins of the DGC that interact with Dp71 isoforms, we first analyzed DGC proteins expression in PC12 cells by Western blot. The results show that PC12 cells express -dystroglycan, 1-syntrophin, 1-dystrobrevin and -dystrobrevin proteins. We have established by co-immunoprecipitation assays that Dp71f forms a complex with -dystroglycan, 1-syntrophin, and -dystrobrevin in PC12 cells which strongly supports the existence of a DGC-Dp71f structural and/or functional complex in PC12 cells. We will use Xpress and/or Myc-tagged versions of each Dp71 isoform to farther identify interacting proteins. This work was supported by Conacyt 37515.

**Developing an Illustrated Context-Sensitive Medical Genetics Glossary.** *R. Pagon<sup>1</sup>, C. Abair<sup>1</sup>, L. Ribas<sup>1</sup>, J. Edwards<sup>1,2</sup>, A. Amemiya<sup>2</sup>, G. Feldman<sup>3</sup>, M. Espeseth<sup>1</sup>, N. Stevens<sup>1</sup>, J. Breuner<sup>4</sup>, L. Pinsky<sup>1</sup>, K. Marymee<sup>1</sup>, C. Dolan<sup>1,2</sup>, P. Baskin<sup>1</sup>, P. Tarczy-Hornoch<sup>1</sup>.* 1) U of WA, Seattle; 2) Children's Hosp and Reg Medical Ctr, Seattle; 3) Wayne State U, Detroit; 4) Swedish Hosp, Seattle.

**SIGNIFICANCE:** The GeneTests (www.genetests.org) Laboratory Directory information on medical genetics testing and the GeneReviews descriptions of test use need to be useful to both genetic and non-genetic healthcare professionals.

**BACKGROUND:** GeneTests uses a specialized vocabulary, yet the majority of its 20,000 searches/day are by non-geneticists. Most genetics resources for clinicians do not explain molecular genetic test methods used by clinical labs.

**METHODS:** The GeneTests staff and three primary care physicians developed an illustrated context-sensitive glossary. Over 220 terms on the GeneTests Web site most relevant to genetic testing and genetic counseling were defined using textbooks and other glossaries as references. Over 100 terms were illustrated with a Learn More page, a section on Some Clinical Implications, and either a Case Example vignette or a Disease Example discussion. Context-sensitive links to glossary definitions appear in the Methodology section of the Laboratory Directory and in all sections of each GeneReview, where the reader can simultaneously view the relevant definition and text.

**RESULTS:** 1) Primary care physicians requested that a) the glossary, which defines genetic counseling and testing terms, be accompanied by educational materials that elaborate on the same concepts, b) glossary terms be categorized and case examples created for teaching purposes. 2) In April 2003, glossary entries were viewed ~200 times/day and the full glossary ~150 times/day. About 25% of users chose to leave the GeneReviews glossary links enabled.

**CONCLUSIONS:** 1) Both clinical geneticists and non-genetic healthcare professionals need an accessible glossary that includes definitions of molecular genetic test methods. 2) For effective communication among geneticists and between geneticists and non-geneticists, shared meaning of terms is necessary.

**Transmission of Full Mutation Alleles from Premutation Males to Daughters.** *W.T. Brown<sup>1</sup>, S.L. Nolin<sup>1</sup>, C. Dobkin<sup>1</sup>, L. Gane<sup>2</sup>, X.D. Ding<sup>1</sup>, G.E. Houck<sup>1</sup>, A.D. Gargano<sup>1</sup>, A. Glicksman<sup>1</sup>, S.Y. Li<sup>1</sup>.* 1) Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY; 2) UC Davis M.I.N.D. Institute, Sacramento, CA.

In Fragile X, the dramatic CGG expansion to >200 repeats in a full mutation occurs nearly exclusively from premutation females to their offspring. Males with premutations or full mutations have premutation-size repeats in sperm and transmit premutations to their daughters. We observed two unrelated transmissions of full mutations from premutation males to their daughters. In the first family, the CGG repeat was examined by PCR in the mother, father and three daughters. The mother was found not to be a carrier. The father had 105 repeats and two of the daughters had 100 and 95 repeats. The third daughter had predominantly 145 repeats and a series of bands extending into the full mutation range. Southern analysis revealed a series of unmethylated fragments extending from premutation to full mutation, and the normal allele. In the second family, PCR and Southern analysis of one daughter of a premutation male revealed repeats from 135 to >200. The unusual molecular patterns of these two females were notable for the exclusively unmethylated fragments; a pattern not associated with females carrying maternally transmitted full mutation alleles. Two similar cases have been reported (Bridge, *Gen Med*, 23A, 1999; Ventura, *AJHG*, A471, 1999). We suggest a paternally transmitted allele may expand to a full mutation with a distinctive molecular pattern. While this expansion leads to somatic instability typical of maternally transmitted full mutations, the size of the expansion is limited and does not lead to aberrant methylation. We suggest paternal transmission of full mutations involves unique mechanisms.

**Assessment of patient response to genetic counseling for hereditary pancreas cancer.** *J.E. Axilbund, K.A. Brune, M.I. Canto, B.C. Brehon, L.D. Wroblewski, C.A. Griffin.* The Johns Hopkins University, Baltimore, MD.

**Introduction:** Genetic counseling is currently offered for a variety of cancers, including breast, ovarian and colorectal cancers. Genes have been discovered that cause a significant percentage of these cancers, and genetic testing is available. Although pancreas cancer is associated with several known hereditary syndromes, a major causative gene for this cancer remains undiscovered. It is unknown if genetic counseling in the absence of a known gene is beneficial to patients. **Methods:** At-risk patients with three or more family members with pancreas cancer received genetic counseling while participating in an endoscopic ultrasound screening study. Participants were mailed a questionnaire after the visit regarding their views about the genetic counseling session. Responses were based on a 5-point Likert scale, ranging from "strongly agree" to "strongly disagree". **Results:** Thirty-two participants responded, having an average of 3.75 relatives with pancreas cancer. 69% completed college or graduate school, and 69% had read information about hereditary pancreas cancer. 84% agreed that the genetic counseling session was helpful, and 88% would recommend genetic counseling for pancreas cancer to a friend or relative with a family history of the disease. 94% "agreed" that genetic counseling for pancreas cancer is helpful despite the lack of an identified major causative gene, and 88% "disagreed" that genetic counseling should not be offered until such a gene is identified. 84% would want to be tested if a major causative gene were found, and 91% would be interested in another genetic counseling session when more information is learned. Respondents were ambivalent about the ability of currently available genetic testing to help them, as well as their desires to pursue such testing. However, 66% felt that the pancreas cancer in their family was caused by a gene mutation, and 44% thought that they had inherited the mutation. **Conclusions:** Despite the lack of an identified major causative gene for pancreas cancer, the majority of patients at increased risk find genetic counseling for this disorder to be helpful. Supported by NCI grant CA78148-05.

**Effect of Genetic Counseling for Hereditary Breast and Ovarian Cancer (BOC) on Health Behaviors and Perceived Personal Control (PPC).** *S. Hensley-Alford*<sup>1</sup>, *R.R. Lebel*<sup>1, 2</sup>, *R. Pollack*<sup>1</sup>, *J.R. Roberson*<sup>1</sup>, *D.L. Van Dyke*<sup>1</sup>. 1) Henry Ford Hospital, Detroit, MI; 2) Hinsdale Hospital, Hinsdale, IL.

PPC and health behavior change have been studied in the context of genetic counseling for BOC risk. We examined self-reported changes in a population-based retrospective cohort of 218 women counselled for BOC between 1/1/00 and 2/28/03. We sent questionnaires twice, 2-4 weeks apart; second mailing was followed by a phone call within 4 weeks. Mean age of respondents 50; 88% white, 88% married or living with a partner, 85% with children, 43% with BOC, 85% had some college, 66% had household income of \$80,000 or more. We requested reports on general health behaviors (diet, exercise, check-ups, vitamin use, prescription drug use, smoking) and breast health behaviors (mammography, clinical and self- breast exam, chemoprevention, prophylactic surgery) before and after genetic counseling. Using a Wilcoxon Signed Rank test, we evaluated reported behavior changes. 47% of women reported change in at least 1 general health behavior, with significant changes for diet ( $p=0.035$ ), exercise ( $p=0.002$ ), multivitamin use ( $p<0.001$ ). 41% of women reported change in at least 1 breast health behavior. There was marginal evidence in for chemoprevention ( $p=0.065$ ) and prophylactic surgery ( $p=0.070$ ). We asked a standard set of questions for PPC. 68% of women reported change in at least 1; the importance of family history ( $p=0.005$ ), effect of cancer inheritance ( $p<0.001$ ), BOC risk ( $p<0.001$ ), evaluating risk management options ( $p<0.001$ ), making decisions about familys future regarding breast cancer ( $p=0.003$ ), easing the situation regarding breast cancer ( $p<0.001$ ), deciding next steps regarding BOC risk ( $p<0.001$ ). Our data suggest that genetic counseling for BOC may impact health behaviors, with effects stronger for general health than breast health. The women participating in this study are not representative of the general population, suggesting that either the effects are limited to a subgroup receiving counseling or that other women may not elect genetic counseling or genetic counseling research. We find that the participants were representative of the population who are seeing us for counseling.

**Phenotypic heterogeneity in patients with Gaucher disease and the N370S (1226G) / V394L (1297T) genotype.** A. Zimran<sup>1</sup>, C.R. Scott<sup>3</sup>, M. Zeigler<sup>2</sup>, A. Abrahamov<sup>1</sup>, D. Elstein<sup>2</sup>. 1) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Genetics Laboratory, Hadassah Medical Center, Jerusalem, Israel; 3) Molecular Diagnostic Laboratory, Childrens Hospital & Regional Medical Center, Seattle WA; USA.

Correlation between genotype and phenotype in Gaucher disease is limited. It is known that the most common mutation N370S (1226G) is protective of or at least mitigates neurological involvement, but for the V394L (1297T) mutation, described as the fifth most common among Ashkenazi Jews, in whom there is a predilection for Gaucher disease, little data is available. Too, the V394L mutation is included in standard kits for large-scale screening. This study reports all known patients with Gaucher disease who are documented to have the N370S/V394L genotype from a large referral clinic in Israel and from the International Collaborative Gaucher Group (ICGG) registry. Of 476 patients in the Jerusalem Gaucher Clinic, seven patients (2.0%) had the N370S/V394L genotype; of 2836 patients in the registry there were 14 patients (0.8%) with this genotype. There was an overlap of three patients making a total of 18 patients, reflecting the rarity of this genotype among the studied cohorts. Most of these patients had mild disease: while eight of these patients required specific enzyme therapy, none was splenectomized and only three patients had skeletal involvement, but other baseline parameters were very diverse. Although genotype-phenotype correlation in this case may be difficult because of the low numbers, since the V394L mutation when seen in a compound heterozygote with a null allele results in neuronopathic disease, one cannot conclude that this mutation is protective of neuronopathic disease in a manner similar to the N370S mutation, and hence may have continued importance for large-scale screening of at risk populations.

**Posttraumatic stress disorder of women after stillbirth with fetal anomalies.** *S. Sohda*<sup>1, 2</sup>, *H. Tsukamoto*<sup>2</sup>, *Y. Fujiki*<sup>2</sup>. 1) Dept OB/GYN, Mito Saiseikai General Hospita, Mito, Japan; 2) Dept OB/GYN, University of Tsukuba, Tsukuba, Japan.

At least 15 percent of clinically recognized pregnancies result in miscarriage during the first trimester. Stillbirth with fetal anomalies occurs suddenly in the second and third trimester. Posttraumatic stress disorder (PTSD) has been found after pregnancy loss in the first trimester and some pregnancy complications. However PTSD has not been assessed in women who have had stillbirth with fetal anomalies. We studied about the mental health of women who have had stillbirth due to congenital fetal anomalies included in the cases with prenatal diagnosis. To assess PTSD, we used the Impact of Event Scale-Revise (IES-R). The IES-R can be a useful self-rating diagnostic instrument particularly for survivors with PTSD symptoms as a clinical concern by using a 24/25 cutoff in total score. Of the 11 women who had a stillbirth, the score of the IES-R is 26.713.3(averageSD). Over 50% of women who had a stillbirth were PTSD, 5 (46%) women were over 30 with score of IES-R. Our result suggests we have to make same psychosocial care system and educational system for women who had stillbirth. It is need that further debate and research in the area.

**Who should be tested? Genetic counselors' opinions of carrier testing.** *C.L. Cina, S. Metzenberg, A. Metzenberg, M. D'Addario.* California State University, Northridge, Northridge, CA.

During a prenatal genetic counseling session, many clients are now routinely given the option of carrier testing, even without an indication or a family history. Due to the growing number of carrier tests available, genetic counselors are often devoting more of their time to discuss testing options. The purpose of this study was to investigate what types of carrier testing are routinely offered to prenatal clients, and to assess the opinions of genetic counselors towards carrier testing by determining what factors they feel are important when offering testing. The hypothesis was that the severity of a disorder, its frequency in an ethnic group, and the sensitivity of a test are the primary factors that counselors consider before offering carrier testing.

This study was conducted through an anonymous survey distributed at the National Society of Genetic Counselors Annual Education Conference and posted through a link from the NSGC website. A three-part questionnaire was designed to assess counselor demographics, opinions of carrier testing, and thoughts when presented with hypothetical and actual scenarios. A total of 371 responses was obtained.

The main findings were (1) genetic counselors are divided on what factors to consider before offering testing, (2) based on hypothetical and actual scenarios, a significant number of counselors favors broad testing, and (3) many counselors do not agree with their center policy regarding who should be tested. Comments provided by many respondents indicated that carrier testing is an individualized process that should be considered on a client-by-client basis. Based on the finding that counselors are divided on what to consider before offering testing, the service that clients receive may depend on counselors opinions. In addition, since a significant number of counselors favors routine testing, the implications of their beliefs on the health care system may need to be examined in light of the expected increase in availability of carrier testing.

Program Nr: 1098 from 2003 ASHG Annual Meeting

**A Comparison of Teaching Methods in Conveying Genetic Information.** *C.T. Dvorak, K.E. Jackson, H.C. Andersson, J.G. Thoene.* Hayward Genetics Center, Tulane University Medical School, New Orleans, LA.

Access to sources of reliable information about rare diseases is difficult in many parts of the country, particularly in rural areas. We assessed learning about lysosomal storage diseases in health care providers (nurses, physicians) and families of affected patients after a scripted teaching session, or after exposure to a video which covered the same material. The subjects took the same examination (10 questions, multiple choice) before and after the intervention. There were 21 subjects in each group. The base-line level of knowledge of lysosomal storage disorders was similar in both groups: 5.12.0 (video exposure) versus 4.71.6, (instructor exposure)  $p>0.4$ . After intervention a substantial improvement in knowledge was found in each group. The group exposed to the video scored 8.51.4 post exposure, compared to 5.12.0 pre-exposure ( $p=.005$ ) The group that experienced live instruction scored 8.11.2 post teaching, versus 4.71.6 pre-teaching ( $p=.075$ ). There was no significant difference between the post intervention scores (8.51.4 versus 8.11.2,  $p=0.4$ ). We conclude that, for general information unrelated to specific patient family circumstances, the use of educational videos can be an effective way to inform health professionals and families who do not have ready access to genetic professionals.

**Too much, too soon? Genetic testing offered at the same time as a breast cancer diagnosis in women under forty years of age.** *A. Ardern-Jones<sup>1</sup>, R. Kenen<sup>2</sup>, R. Eeles<sup>3</sup>.* 1) Dept Cancer Genetics, Royal Marsden NHS Trust, Sutton Surrey, United Kingdom; 2) The College of New Jersey, Ewing NJ, 08628 US; 3) Institute of Cancer Research and The Royal Marsden NHS Trust. Downs Road. Sutton. Surrey. SM2 5PT. UK.

Recent research suggests that women who develop breast cancer between the ages of 30-34 and have specific tumour characteristics e.g. high grade, oestrogen receptor negative type tumours have between a 10%-27% chance of being a BRCA1 gene carrier. Furthermore, recent research indicates that prophylactic mastectomy and/or oophorectomy offer a significant risk reduction in the development of breast/ovarian cancer. In the near future, patients may be offered the choice of a genetic test close to the time of diagnosis. This timing not only provides additional dimensions to treatment decisions, but has psycho-social familial implications as well. This small exploratory study investigates 1) whether or not women diagnosed with breast cancer under the age of 40 would want to be offered information about genetic testing close to the time of their diagnosis 2) whether the health professionals treating them support the idea 3) reasons for patients' and professionals' perspectives and concerns. We held focus groups of 13 women who had their only, or first, breast cancer under the age of 40 and who were known carriers of a BRCA gene how they felt about the timing. We also interviewed 14 health care professionals involved in various aspects of breast cancer care and cancer genetics. The large majority of former breast cancer patients and professionals believed that there was already emotional overload in coping with the cancer diagnosis and that adding genetic testing discussions would be too much. Some members of both groups, however, thought that offering genetic testing close to the time of breast cancer diagnosis might make sense because the results could alter treatment decisions.

Program Nr: 1100 from 2003 ASHG Annual Meeting

**Generalized Bayesian risk calculations for autosomal recessive disease when only one mutation is detected, incorporating test sensitivity and each parent's ethnicity information: what if a fetus has echogenic bowel and one detectable CFTR mutation?** *W. Grody*<sup>1</sup>, *S. Ogino*<sup>2, 3, 4</sup>. 1) Med Genetics/Molec Pathology, UCLA Sch Medicine, Los Angeles, CA; 2) Dept. of Pathology, Brigham and Women's Hospital, Boston, MA; 3) Dept. of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 4) Harvard Medical School, Boston, MA.

Bayesian analysis plays a central role in risk calculations for genetic counseling. It is occasionally less than straightforward to calculate the risk for an autosomal recessive (AR) disease, especially when a fetus has one detectable mutation, and the frequencies of the disease allele and each mutation vary among various populations. A typical example is a fetus with echogenic bowel and one detectable CFTR mutation. We have developed novel generalized Bayesian methods to calculate the AR disease risk of a fetus when only one mutation is detected and another independent risk factor is present. Our methods incorporate such information as genetic test results on either or both of the parents, each parents ethnicity, and test sensitivity for the particular ethnicity. Excel spreadsheets to facilitate risk calculations are available upon request. We also meta-analyzed and estimated the conditional probabilities of echogenic bowel if the fetus has CF or not, as 0.55 or 0.0069, respectively. Using our methods, for example, if a fetus with echogenic bowel has one detectable CFTR mutation, and both parents (one northern and one southern Europeans without a family history of CF) have not been tested, the posterior disease risk of the fetus is ~0.22. In conclusion, our generalized Bayesian methods are versatile, and allow the AR disease probability to be calculated accurately, taking into account all relevant information.

**A Pilot Study of First-Degree Relatives of Patients with Colorectal Cancer Who Have Received Hereditary Cancer Education: Applying Family Hardiness and Health Belief Variables to Predict the Uptake of**

**Colonoscopy.** *P. Gambol<sup>1</sup>, V. Lagos<sup>1</sup>, G. Uman<sup>2</sup>, L. Jacobs<sup>3</sup>, M. Grant<sup>1</sup>, D. MacDonald<sup>1</sup>, J. Weitzel<sup>1</sup>.* 1) Clinical Cancer Genetics, City of Hope, Duarte, CA; 2) Vital Research, LLC, Los Angeles, CA; 3) University of Pennsylvania Cancer Ctr, Ardmore, PA.

The risk for colorectal cancer (CRC) ranges from 5% to 80% depending on age, family history, and genotype. An individual with 2 affected first-degree relatives (FDRs) has a 17% risk for developing CRC; mortality rates are directly proportional to cancer stage at diagnosis. Decreased mortality is achieved by early detection. Our first objective was to measure Family Hardiness and Health Beliefs to predict the uptake of colonoscopy in FDRs of persons with CRC. Our second was to determine if hereditary cancer education given to persons with CRC increases the uptake of colonoscopy in their FDRs. Methods: A case-control study of 2 distinct cohorts was conducted. Cases: Persons with CRC that have received hereditary cancer education and their FDRs. Historical Controls: Persons with CRC that have not received hereditary cancer education and their FDRs. Persons with CRC (N=30) were recruited, 14 males and 16 females with a mean age at diagnosis of 41. Fifty percent completed surveys that measured communication and Family Hardiness. Fourteen FDRs, 4 males and 10 females with a mean age of 46 completed a demographic and a Health Belief survey. Results: FDRs of cases were White (57%), Hispanic (36%) and African American (7%) with no prior cancer diagnosis. Fifty seven percent had a college degree and 21% had less than a high school education. Eleven (79%) were told by their family member that they were at an increased risk for CRC. Colon screening was undertaken by 71% (57% had a colonoscopy and 14% had a sigmoidoscopy) compared to 41% in the historical controls. Logistic regression analysis revealed that two Health Belief Model variables (benefits and barriers) were predictive of FDRs participation in lower GI endoscopy. Conclusion: FDRs of cases had a higher uptake of lower GI endoscopy (20% higher) than controls. In addition FDRs of cases with less than a high school education had a high uptake of colonoscopy (100%).

**Cancer Surveillance and Preventative Surgery in Members of BRCA1/2 Positive Families.** *S. Nanda<sup>1</sup>, G. Sheridan<sup>1</sup>, N. Scanlan<sup>2</sup>, A. Horler<sup>1</sup>, J.H. Jung<sup>1,2</sup>, P.J. Ainsworth<sup>1,2</sup>.* 1) London Health Sciences Centre, Ontario, Canada; 2) London Regional Cancer Centre, Ontario, Canada.

Individuals with germline BRCA1/2 mutations are known to be at increased lifetime risk of developing breast, ovarian and prostate cancer. Clinical genetic testing for BRCA1/2 is available however, little information is available on the impact of genetic testing on an individual's life. This study aims to assess the impact of genetic testing on screening for breast/ovarian cancer and uptake of preventative surgery in members of families with a known BRCA1 or BRCA2 mutation. A questionnaire assessing participation in cancer screening and uptake of preventative surgery was sent to 203 individuals from known BRCA1/2 families in Southwestern Ontario. All individuals had received their results at least 6 months prior to receiving the questionnaire. Of the participants, 84.3% were female, 54.9% were mutation carriers and 45.1% were non-carriers. Twenty-eight percent were diagnosed with breast cancer and 5.9% were diagnosed with ovarian cancer. Of carriers (male and female), 51.8% had not made changes to their cancer surveillance practices since receiving their test results. Of the female carriers, 41.3% proceeded with prophylactic mastectomy (PM) and 58.7% proceeded with prophylactic oophorectomy (PO) after receiving their test results. Of the non-carriers (male and female), 69.6% had not made changes to their cancer surveillance practices since receiving their test results. None of the female non-carriers proceeded with prophylactic surgery after receiving their test results, however 27.3% were still considering PM and 40% were still considering PO. Although not statistically significant, women under the age of 50 and participants with a high school education or higher were more likely to consider prophylactic surgery. Overall, a majority of participants did not alter their screening practices based on their test results though a substantial proportion of carriers did opt for prophylactic surgery. Interestingly, many non-carriers were still considering prophylactic surgery.

Program Nr: 1103 from 2003 ASHG Annual Meeting

**Use of video for patient education: A survey of cancer genetic counselors.** *L.A. Hamby, J.E. Axilbund, D.B. Thompson, S.J. Olsen, C.A. Griffin.* Mid-Atlantic Cancer Genetics Network, The Johns Hopkins University, Baltimore, MD.

Cancer genetic counselors use a variety of teaching modalities for patient education. The prevalence of video use in cancer genetic counseling is unclear, and little is known about genetic counselors' preferences regarding its use. Fifty cancer genetic counselors responded to a survey assessing their use of educational videos and their recommendations for content of future videos. Thirty percent (n=15) of respondents currently use videos for patient education. The most commonly cited benefits included reinforcement of information (n=9), ability to share information with other family members (n=7), and increased counselor efficiency (n=6). Of the 70% (n=35) who do not use videos, predominant barriers included the perceived lack of an appropriate or unbiased video (n=14), lack of space and/or AV equipment (n=11), and concern that videos are impersonal (n=10). If an appropriate video were developed, 69% of respondents would be "likely" or "somewhat likely" to use it before the genetic counseling visit, while 83% gave a similar response for after the visit. Additional suggestions included use with referring physicians and for professional education. Regarding content, respondents desired a video that is inclusive and representative of the genetic counseling session, but emphasized the importance of using broadly based information. All respondents ranked the following content areas as "critical" or "somewhat important": the pros and cons of genetic testing, psychosocial implications, and genetic discrimination. The next most desired content areas included a description of inheritance, the basis of DNA and chromosomes, and cancer development. Ranked by the majority of respondents as "not at all important" was information about the human genome project. This exploratory study provides data relevant for development of an educational video to be used in association with a personalized genetic counseling session. Supported by NCI grant CA78148-05.

**SUCCESSSES AND CHALLENGES IN GENETICS EDUCATION OF HEALTH PROFESSIONALS: THE HUMAN GENOME EDUCATION MODEL II (HuGEM II) PROJECT EXPERIENCE.** *C. Kozma<sup>1</sup>, EV.*

*Lapham<sup>1</sup>, C. Dunne<sup>1</sup>, JO. Weiss<sup>2</sup>, MA. Wilson<sup>2</sup>, J. Benkendorf<sup>1</sup>.* 1) Department of Pediatrics , Georgetown University Hospital, Washington, DC; 2) The Genetic Alliance, Washington, DC.

After completing four years of educating health professionals across the country as part of the HuGEM II Project, analysis of the education methods provides important information. The HuGEM II Project, a collaborative effort between Georgetown University and the Genetic Alliance (1997-2001, NIH funding) used a three-pronged approach to the genetics education of the members of seven national health professional organizations. The faculty was multidisciplinary and composed of health professionals as well as consumers. The focus of the education included the Human Genome Project, its related Ethical, Legal, and Social issues, and the impact of genetics progress on the perspective discipline. Three distinct groups within each organization, Administrators, Leader Educators and Practitioners, were targeted for genetics education, each with a unique educational approach. 1) Orientation sessions averaging 1 hour were held with 130 national staff and board members of the associations. 2) A week-long core course in genetics was attended by 60 health professional Leaders Educators. 3) Training workshops averaging 3 hours, were held at 48 national and regional conferences of the associations for over 1550 health professional practitioners. Results of the evaluation data for each approach will be presented. The HuGEM II Project provides a replicable model for working with health professionals organizations in a collaborative genetics education mode.

**Genetic counseling of medullary breast cancer patients.** *C. Kroupis*<sup>1</sup>, *N. Goutas*<sup>2</sup>, *S. Vasilaros*<sup>3</sup>, *D. Yannoukakos*<sup>4</sup>, *E. Lianidou*<sup>1</sup>, *M.B. Petersen*<sup>5</sup>. 1) Laboratory of Analytical Chemistry, Dept. of Chemistry, University of Athens, Athens, GREECE; 2) Pathology Lab, Evgenidion Hospital, Athens, GREECE; 3) Prolipsis Breast Cancer Center, Athens, GREECE; 4) Molecular Diagnostics lab, Demokritos Research Center, Athens, GREECE; 5) Dept. of Genetics, Institute of Child Health, Athens, GREECE.

Medullary carcinoma of the breast is very rare (<3% of cases in most populations). An overrepresentation of these carcinomas among patients with mutations in the BRCA1 gene has recently been reported and it has been proposed that all breast medullary cancer patients should be referred for BRCA1 mutation analysis. The goal of our study was to examine the validity of such a proposal in 17 patients with this rare carcinoma in Greece. **METHODS.** Patients were asked about their family history in counseling sessions. After informed consent, mutation analysis was performed on genomic DNA isolated from blood leukocytes employing a combination of the Protein Truncation Test (PTT) for the large exon 11 of the BRCA1 gene and DNA sequencing of the other small exons. Various techniques were performed in order to assess phenotypic characteristics in the corresponding tumor specimens: immunohistochemistry (IHC) for the presence of hormone receptors, Ki-67 proliferation marker, accumulation of p53 protein and overexpression of c-erbB-2 and cytometry for DNA ploidy and S-phase estimation. **RESULTS.** Only five patients had a positive family history. Seven out of the 17 tumor specimens were showing the phenotype of a BRCA1 carcinoma: negative for hormone receptors, overexpression of c-erbB-2, and also highly proliferative as seen by the intense Ki-67 immunostaining, high S-phase fraction. Mutations were detected in 2 patients: the recurrent in the Greek population 5382insC mutation in exon 20 and the rare R1203X in exon 11 in patients whose tumors fulfilled the phenotypic criteria of a BRCA1 carcinoma, but only one of the patients had a family history. **CONCLUSION.** Breast medullary carcinoma patients should be referred for the expensive BRCA1 mutation analysis only when they possess either family history or the appropriate phenotypic characteristics in their tumors.

**Accurate carrier risk calculations for autosomal recessive disorders.** *R. Wilson*<sup>1</sup>, *S. Ogino*<sup>2, 3, 4</sup>. 1) Pathology/ Lab Med, Rm 509A, Univ Pennsylvania, Philadelphia, PA; 2) Pathology, Brigham and Women's Hospital, Boston, MA; 3) Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 4) Harvard Medical School, Boston, MA.

**Introduction:** Risk assessment is an essential component of genetic counseling and testing. Carrier risks for autosomal recessive disorders can be calculated using Bayesian analysis, taking into account family history and/or genetic test results. However, it is often less than straightforward to calculate the carrier risks of relatives distant from the index case of an autosomal recessive disorder with a known carrier frequency. Non-negligible de novo mutation rates further complicate the calculation of carrier risks in such scenarios. **Methods:** We developed novel systematic Bayesian methods to calculate carrier risks for autosomal recessive disorders when the disease allele frequency or de novo mutation rate is non-negligible. Excel spreadsheets that can be used independently or sequentially to calculate carrier risks in various typical settings are available upon request. **Results:** The effect of the disease allele frequency on the carrier risk is larger when the relationship to the affected is more distant. Using our methods, e.g., the carrier risk of a second cousin of a patient with cystic fibrosis is calculated as ~0.0900 (rather than 0.0625), taking into account the relatively high disease allele frequency for cystic fibrosis. The number of unaffected siblings has little effect on risk calculations. The risk that the fetus of a consanguineous couple is affected depends not only on the carrier risks of the parents, but also on whether the mother's carrier probability is independent of the father's. The probabilities that the fetus is affected with two mutations that are identical-by-descent, or identical-by-state, need to be considered. **Conclusion:** Our generalized Bayesian methods are versatile and allow accurate carrier risk assessments for autosomal recessive disorders, taking into account all relevant information.

**Genetic Counselling and Testing Process in BRCA1/2 Families- Are Patients Satisfied?** *N. Scanlan<sup>1</sup>, G. Sheridan<sup>2</sup>, S. Nanda<sup>2</sup>, A. Horler<sup>2</sup>, J.H. Jung<sup>1,2</sup>, P.J. Ainsworth<sup>1,2</sup>*. 1) Cancer Genetics, London Regional Cancer Centre, London,ON,Canada; 2) Cancer Genetics, London Health Sciences Centre, London,ON,Canada.

The discovery of the BRCA genes has provided an increased demand for genetic counselling and testing in families with histories of breast/ovarian cancer. Limited information is available regarding the impact of genetic testing on an individual's life. The purpose of this study was to assess individuals' satisfaction with the genetic counselling and testing process. A questionnaire was sent to 203 individuals from known BRCA1/2 families in Southwestern Ontario asking them to rate the genetic counselling and testing process. All individuals had received their results at least 6 months prior to receiving the questionnaire. Of the respondents, 54.9% were carriers and 45.1% were non-carriers. Eighty-four percent were female and 15% were male with a median age of 48.7 years. Ninety-five percent were extremely satisfied with the genetic counselling they received, 95% would still proceed with testing regardless of current knowledge, and 96% indicated that they would recommend testing to a non-family member. On average the waiting time for test results was 6-9 months (mean 5.8). Sixty-nine percent of respondents were satisfied with this waiting time though 6.9% were extremely dissatisfied. The majority (88.8%) were pleased to receive results in person. Some participants indicated that they would prefer to receive their results by telephone (4.9%), mail (7.8%) and through their family physician (2.9%). Overall, the majority of participants were extremely satisfied with both the genetic counselling and testing process.

**The Psychosocial Impact of Genetic Testing on Members of BRCA1/2 Positive Families.** *G. Sheridan<sup>1</sup>, N. Scanlan<sup>2</sup>, A. Horler<sup>1</sup>, S. Nanda<sup>1</sup>, J.H. Jung<sup>1,2</sup>, P.J. Ainsworth<sup>1,2</sup>.* 1) London Regional Cancer Centre, London, Ontario, Canada; 2) London Health Sciences Centre, London, Ontario, Canada.

With the discovery of the breast cancer susceptibility genes, BRCA 1/2, there is a greater demand for genetic counselling and testing of individuals at risk. Very little information is available regarding the psychosocial impact of BRCA testing on an individual's life. The purpose of this study was to determine how genetic testing has affected the lives of individuals belonging to a BRCA mutation positive family. Psychosocial questionnaires were mailed to 203 individuals in Southwestern Ontario at least 6 months after they received their test results. There were 102 respondents belonging to 44 different BRCA positive families. Fifty-five percent were carriers and 45% were non-carriers. Carriers reported that they were angry (17.9%), anxious (35.7%), worried (50%) and depressed (16.1%) after they received their results. At the time of the questionnaire, carriers reported that they felt worried (41.1%) and relieved (25.0%). Non-carriers reported that they were relieved (84.8%) after they received their results. At the time of the questionnaire, 69.9% reported that they were still relieved. Four percent reported that they experienced feelings of guilt. The majority of participants (88.2%) shared their result with one or more immediate family members. Seventy-two percent also shared their result with one or more members of their extended family. Thirty-seven percent shared their result with a family member under the age of 18. Individuals reported that family members' reactions to the results varied. Carriers reported that their family members experienced feelings of guilt, anger, anxiousness and fear. Non-carriers reported that their family members experienced feelings of relief, non-concern and guilt. Overall the results of this survey appear to be consistent with other studies that have been reported. The survey was based on a small population size and was limited to one geographic location in Ontario. It may be beneficial to have a similar multicentre survey to include the entire province of Ontario.

**Parental coping with Proteus syndrome: A chronic progressive disorder.** *J.T. Turner<sup>1</sup>, B.B. Biesecker<sup>1</sup>, J.R. Leib<sup>2</sup>, L.G. Biesecker<sup>1</sup>, K.F. Peters<sup>3</sup>.* 1) National Human Genome Research Institute/National Institutes of Health, Bethesda, MD; 2) National Institute of Neurological Diseases and Stroke/National Institutes of Health, Bethesda, MD; 3) Department of Biobehavioral Health, Pennsylvania State University, University Park, PA.

Little is known about how parents cope with raising a child with Proteus syndrome, a progressive disfiguring overgrowth condition. The psychosocial consequences of this condition are likely analogous to other progressive genetic conditions. Genetic counseling seeks to enhance clients ability to adjust to their child's condition by assisting clients in identifying and utilizing their coping resources. The purpose of this qualitative study was to learn how parents perceive Proteus syndrome and how health professionals can help to facilitate their coping process. Qualitative interviews with 31 parents, average age 35.6 years, were conducted using a semi-structured guide developed using Goffman and Jones stigma delineations. Codes used for analysis were derived from recurring themes that emerged from the data. Coping strategies depicted in Carver, Weinstraub, and Scheiers COPE inventory tool and answers to targeted questions were assessed. Three independent coders validated the coding scheme and there was high inter-coder reliability. Parents were found to utilize a combination of coping mechanisms including problem and emotional focused strategies. The majority was adaptive and 76% reported to have come to accept their child's condition. The most common coping mechanisms described include seeking emotional support (68%), positive reappraisal and growth (67%), active coping strategies (66%), downward comparison (58%), turning to religion (52%), seeking instrumental support (57%), and restraint coping (48%). Less than 3% reported using maladaptive coping mechanisms such as alcohol or other substance abuse. While 25% described mental disengagement, <10% reported behavioral disengagement. These findings provide insight into the avenues genetic counselors may explore with their clients to facilitate coping and overall adjustment among parents of children with progressive disfiguring conditions like Proteus syndrome.

**Feasibility and utility of the Colored Eco-Genetic Relational Map(CEGRM) in women at risk for hereditary breast cancer.** *J.A. Peters<sup>1</sup>, R. Kenen<sup>2</sup>, R. Giusti<sup>1</sup>, J. Loud<sup>1</sup>, N. Weissman<sup>1</sup>, M.H. Greene<sup>1</sup>.* 1) Div Cancer Epid & Genetics, NCI/NIH/DHHS, Rockville, MD; 2) Sociology Dept.The College of New Jersey, Ewing, NJ.

Genetic counseling involves not only the provision of genetic information, but also helps at-risk individuals integrate new genetic information, adjust to it emotionally and socially, and make informed decisions. To address these latter goals, we conducted a pilot test of the CEGRM (Colored Eco-Genetic Relational Map), a novel, recently-developed psychosocial assessment tool, which combines features of the genetic pedigree, family systems genogram, and ecomap (Kenen & Peters, JGC, 2001). The CEGRM presents a simple, concise, visual representation of the social interaction domains of information, services, and emotion exchanges through the application of color-coded symbols to the genetic pedigree. The process of completing the CEGRM was designed to facilitate contemporary genetic counseling goals of: (a) understanding the client in the context of her/his social milieu; (b) bolstering client self-awareness and insight; (c) fostering active client participation and mutuality in the counseling interaction; (d) eliciting illuminating family history social narratives; and (e) addressing outstanding emotional issues. Twenty participants in a breast imaging study of women from families with BRCA1/2 mutations completed and evaluated various aspects of the CEGRM. We found that the efficient construction of the CEGRM was feasible, and that compliance was excellent. Participants developed insights into themselves and their social milieu through the pattern of relationships revealed by the CEGRM's visual display. The process of co-constructing the CEGRM fostered the participant's active involvement in the genetic counseling session, which was noteworthy for mutuality of interaction between participant and researcher. In this context, the participants felt free to share poignant social narratives about their friends and families. Further studies are planned to refine the CEGRM, and to examine its utility in clinical cancer genetics research.

**Cumulative Clinical and Molecular Diagnostic Experience of 361 Patients in the Genetics of Hearing Loss Clinic.**

*D. Yaeger<sup>1</sup>, K. Lewis<sup>2</sup>, L. Soslow<sup>2</sup>, U. Shah<sup>3</sup>, J. McCallum<sup>1</sup>, L. Sellen<sup>1</sup>, C. Stolle<sup>4</sup>, I. Krantz<sup>1</sup>.* 1) Division of Human Genetics and Molecular Biology; 2) Audiology; 3) Otolaryngology; 4) Clinical Laboratories, The Children's Hospital of Philadelphia, PA.

Hearing loss (HL) occurs in approximately 2 out of every 1000 births and is genetic in origin in approximately 50% of cases. This high incidence, coupled with the recent discovery of genes involved in hearing loss and the trend toward universal newborn screening, has led to the establishment of the Genetics of Hearing Loss Clinic at The Children's Hospital of Philadelphia. We present our experience in this clinic over the past four years. To date 361 individuals have been evaluated, most having been referred by an Otolaryngologist and/or Audiologist. Of these 361 patients, 279 (77.3%) had bilateral HL and 82 (22.7%) had unilateral HL. To determine the cause of their hearing loss and screen for syndromic forms of hearing loss, individuals were offered a panel of tests. Depending on the type and severity of the hearing loss, recommendations included GJB2 (Connexin 26) mutation analysis, renal and thyroid function studies, a CT scan of the temporal bones, an ophthalmology evaluation, and an EKG. Of the 361 patients evaluated 59 (16.3%) had a syndromic etiology for their hearing loss assessed either through physical exam, medical history, or abnormal test results. Forty-two (71.2%) of these had bilateral HL and 17 (28.8%) had unilateral HL. Twenty-five different syndromic etiologies were identified, the most common of which included Waardenburg syndrome, Usher syndrome, Mire's disease, Pendred syndrome, Stickler syndrome, and 18q- syndrome. Genetic testing of the GJB2 gene was completed for 219 (78.5%) patients with bilateral sensorineural HL, 26 (11.8%) of which were found to carry two mutations in the GJB2 genes and an additional 26 (11.8%) were found to be heterozygous for a mutation in the GJB2 gene. Seventeen different variants were identified in the GJB2 gene, the most common being 35delG, M34T, V37I and 167delT. Proper clinical evaluation in the context of a hearing loss clinic combined with molecular testing leads to more appropriate patient care and medical management.

**Development of two decision aids for genetic testing for hereditary cancer.** *C. Wakefield<sup>1, 2</sup>, B. Meiser<sup>2</sup>, J. Homewood<sup>1</sup>, E. Lobb<sup>2</sup>, J. Kirk<sup>3</sup>, K. Tucker<sup>2</sup>.* 1) Department of Psychology, Macquarie University, NSW, Australia; 2) Department of Medical Oncology, Prince of Wales Hospital, Randwick, NSW, Australia; 3) Familial Cancer Service, Department of Medicine, Westmead Hospital, Westmead, NSW, Australia.

Background: The demand for genetic counseling and genetic testing for individuals with a family history of cancer is considerable and increasing. Current best practice in genetic counseling may not allow a full deliberation of the consequences of decisions about genetic testing for cancer susceptibility. Literature on risk perception in high-risk breast cancer families reveals persistent over-estimation of risk, even after counseling. In this study, two decision aids were designed to assist people to participate actively with practitioners in deciding about genetic testing for cancer susceptibility. Methods: Stage 1. We present the development of two decision aids for individuals considering genetic testing for breast/ovarian cancer and hereditary non-polyposis colorectal cancer (HNPCC) susceptibility. The aids were developed by a team of experts guided by expectancy-value decision theories and the literature on risk communication and the psychological impact of genetic testing. Results: Stage 1. Two 20 page full-colour decision aids were developed using varying formats of words, numbers, graphs, pie-charts and illustrations. They address a) the population risk of breast or bowel cancer b) inherited breast cancer or HNPCC c) the cumulative risk for patients with high risk genetic mutations d) the individual's suitability for genetic testing e) the differences between mutation search and predictive testing f) the potential benefits and risks of genetic testing and g) screening and management options. Fold-out charts ask individuals to rate the importance of each potential risk and benefit as a leaning towards or against having the genetic test. Stage 2: (yet to be undertaken) involves two concurrent randomised controlled trials of the decision aids, each with 120 patients, assessed by questionnaire at two time points after genetic counseling. The decision aids and data supporting its development will be presented.

Program Nr: 1113 from 2003 ASHG Annual Meeting

**The Living Genome: Reading the Book of Life.** *R. Alford<sup>1</sup>, C. Sumners<sup>3</sup>, S. Wright<sup>3</sup>, K. Henderson<sup>3</sup>, C. Maxwell<sup>3</sup>, D. Gassmann<sup>3</sup>, K. Ghonima<sup>3</sup>, K. Bradley<sup>3</sup>, H. Valdes<sup>3</sup>, D. Brooks<sup>3</sup>, N. Greig<sup>3</sup>, J. Wise<sup>3</sup>, D. Van Tuerenhout<sup>3</sup>, D. Temple<sup>3</sup>, K. Morris<sup>2</sup>, M. Rives<sup>2</sup>, S. Scherer<sup>2</sup>, G. Weinstock<sup>2</sup>, R. Gibbs<sup>2</sup>, R. McDonald<sup>3</sup>.* 1) Otorhinol & Communicative Sci, Baylor Col Medicine, Houston, TX; 2) Human Genome Sequencing Center, Dept Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 3) Houston Museum of Natural Science, Houston, TX.

**The Living Genome: Reading the Book of Life** is a 3,000 sq ft genetics/genomics exhibit at the Houston Museum of Natural Science (HMNS). The exhibit is a partnership between the HMNS and the Baylor College of Medicine Human Genome Sequencing Center. The exhibit is divided into nine content areas including the history of genetics/genomics, the structure and function of DNA, inheritance, the Human Genome Project, comparative genomics, genetically modified organisms, medical genetics, biotechnology, and genetics in natural science. The exhibit invites visitors to learn the science of genetics/genomics; explore the ethical, legal and social challenges presented by recent discoveries; and, consider the impact of new knowledge and technologies. The exhibit incorporates six video displays, one theater, four interactive computer kiosks, and six hands-on activities. At the exhibit's exit, 30 questions are posed through three polling stations. Preliminary data predict surprising findings: 44% said the patenting of genes should not be allowed; 45% would be concerned if their employer learned of presymptomatic genetic test results; 46% believe their insurance company should not know if they carry a gene that places them at risk for future disease; 29% stated genetic information is never different from other personal health information; 45% stated that it is acceptable to use gene therapy to treat disease, modify physical traits, increase intelligence, or confer special abilities; 55% stated human cloning would never be acceptable; 66% would not clone a pet; 51% support human stem cell research while 19% said that they would only support such research if stem cells come from adults; and, 42% believe newborn screening programs should report any disease discovered, regardless of whether it is treatable. Data collection will continue through December 2003.

**Multi-Institutional Survey to Assess the Need for Genetic Counseling in Pediatric Cardiology Settings. D.**

*Gruber<sup>1</sup>, R.S. Cooper<sup>2,5</sup>, J.D. Menasha<sup>3</sup>, M. Rutkowski<sup>4</sup>, D.T. Hsu<sup>5</sup>, J.G. Davis<sup>6</sup>, J.G. Pappas<sup>7</sup>.* 1) Biological Sciences, Columbia University, New York, NY; 2) Department of Pediatrics, Division of Pediatric Cardiology, Weill Cornell Medical Center of New York Presbyterian Hospital, New York, NY; 3) Department of Human Genetics and Pediatrics, Mount Sinai School of Medicine, New York, NY; 4) Department of Pediatrics, Division of Pediatric Cardiology, New York University School of Medicine, New York, NY; 5) Department of Pediatrics, Division of Pediatric Cardiology, Columbia Presbyterian Medical Center, New York, NY; 6) Department of Human Genetics, Weill Cornell Medical Center of New York Presbyterian Hospital, New York, NY; 7) Department of Pediatrics, Human Genetic Program, New York University Hospital Center, New York, NY.

The continuous advancements in human genetics have changed the delivery of care in many fields of medicine, including Cardiology. Among the many roles of the Genetic Counselor, gathering pertinent medical information, explaining genetic concepts, and helping patients and families deal with the psychosocial implications of these diseases are of utmost importance. In most institutions, the Cardiologists themselves perform these functions. This study sought to assess the level of training in and the knowledge base of genetics among Pediatric Cardiologists, as well as to assess their attitudes towards genetic testing and genetic counseling. The probability sample of pediatric cardiologists (N=610) was randomly selected from 30 geographically representative states. 81 (14.4%) completed surveys were analyzed. This project also includes an ongoing survey that seeks to evaluate the genetic counseling needs in pediatric cardiology patients and their families. The study revealed a deficiency in knowledge, among the Cardiologists study group, of genetics and genetic counseling and significant differences in their responses to patients psychological concerns. Additionally, Pediatric Cardiologists frequently did not recognize the importance of certain issues considered essential in a genetic counseling setting, such as anxiety, reproductive options, implications of the results on other family members, support networks and test methodology.

**Genetics and Education in the Public Arena - an Ethical Perspective.** *F. Cunningham*<sup>1,2</sup>, *M. Aitken*<sup>1,2</sup>, *S. Metcalfe*<sup>1,2,3</sup>, *R. Dow*<sup>1,2</sup>, *R. Williamson*<sup>1,2</sup>. 1) Education Unit, Gene CRC, Melbourne, Australia; 2) Genetics Education Unit, Murdoch Childrens' Research Institute, Melbourne, Australia; 3) Dept of Paediatrics, The University of Melbourne, Australia.

Completion of the Human Genome Project is a monumental milestone in the search for genes associated with human disease. It has great implications for medicine, and raises ethical issues for our society as a whole. Despite media speculation, this significant achievement is really the first step in a long journey to unravel the genetic nature of being human. Likewise, we are only at the first step in dealing with the impact these discoveries will have in our society in medicine, law and everyday life.

The Gene CRC recognises the importance of involving the public in debates surrounding genetic technologies in medicine. We have developed an education program aimed to promote an awareness that genetics is an integral part of our society, and that informed debate is essential to make decisions about applications of genetic technologies that will be acceptable in the moral framework of an Australian community. Unique sets of resources and activities have been developed which aim to engage the public to learn more about human genetics through ethical issues. These resources target many audiences, including ethics committees, health professionals and primary and secondary schools; and utilise a diverse range of media. These include a website designed for public education, worksheet kits, a CD-ROM and a unique essay competition for secondary students and teachers, and a manual for ethics committees. The tangible products of this program are being adopted by other genetics education providers and researchers, and have succeeded in raising the level of informed debate on human genetics in the public arena.

**Standardized patient methodology is an effective way for medical students to gain experience in the clinical application of genetic concepts.** *A. Greb, A. Trepanier, M. Kavanagh, G.L. Feldman.* Wayne State University, Detroit, MI.

We previously reported that the standardized patient (SP) methodology is a valuable way for medical students to apply genetic concepts clinically. To continue to evaluate their effectiveness, we report the results of two years experience comparing SP methodology with student role-plays. During a small group session that is part of our medical genetics course, students were assigned one of two cases. In one case, SP's were trained to present the clinical scenario which involved a pregnant woman at risk for carrying a dystrophin mutation (DMD case). For the other case, students were given specific information and instructed to play the role of a 43-year-old woman with a family history of spina bifida (NTD case). In both cases, students were given referral information and told to work as a team. They were expected to ascertain the patients concerns, review lab results, collect targeted history information, perform a risk assessment, explain the genetics and natural history of the condition, offer genetic testing and disclose results. As one group worked through their case the other observed. Observing students documented if the genetic principles inherent in the case were correctly applied. All students were asked to complete an evaluation form assessing their perception of the usefulness of SP's compared to student role-playing (n=326). Seventy-three percent of the students stated that SP's enhanced their learning compared to student role-playing; 71% stated that the SP was a beneficial addition to the DMD case; and 61% stated they would recommend using SP's again. Student comfort level when talking with the patient was also assessed. During the first year of our experience, students who participated in the SP case were more likely to report that they felt uncomfortable when talking to the patient (22%) than students who participated in the other case (13%). During both years, students commented that they took the encounter more seriously when an SP was the patient. In conclusion, we found the learning experience is enhanced when using the SP methodology as a way for medical students to gain experience applying basic genetic principles clinically.

**Genetics Home Reference: a new federal government resource.** *J. Mitchell*<sup>1</sup>, *C. Fomous*<sup>2</sup>, *S. Morrison*<sup>2</sup>, *D. Mucci*<sup>2</sup>, *S. Davenport*<sup>3</sup>, *A. McCray*<sup>2</sup>. 1) University of Missouri, Columbia, MO; 2) National Library of Medicine, Bethesda, MD; 3) Sensory Genetics, Bloomington, MN.

The Human Genome Project generated a great deal of interest in the promise of genomic medicine but, at the same time, left the public (and many healthcare professionals) scrambling to understand how genetics applies to the prevention, diagnosis, and treatment of disorders and diseases. Although the sequencing data produced by the Human Genome Project are freely available, little of this information or its impact is understandable to the general public. To address this problem, the National Library of Medicine developed an online resource called the Genetics Home Reference (GHR), located at <http://ghr.nlm.nih.gov>.

Launched in April 2003, GHR provides a bridge between the clinical questions of the public and the rich technical data emerging from the Human Genome Project. GHRs integrated web-based approach provides brief, consumer-friendly summaries of genetic conditions and related genes. Understanding is enhanced by direct links to glossary definitions and a resource called Help Me Understand Genetics that explains the basics of genetics. Additional links to consumer information on MEDLINEplus, applicable clinical trials, and relevant patient support groups are provided. Each summary also includes links to advanced sources of information such as LocusLink, GeneReviews, OMIM, and PubMed.

The GHR target audience is the motivated lay public with some understanding of biology, but the website also serves as a tool for a wide spectrum of healthcare professionals. The summaries answer preliminary questions about genes and genetic disorders that might be of interest to patients and their family members, students, journalists, and the curious public. For healthcare professionals, the website provides a central source of information suitable for patients and also links to genetic databases for primary data or detailed discussions. Currently, GHR summarizes single-gene disorders, with long-range plans to include some chromosomal and multifactorial disorders and to address additional health implications of the Human Genome Project.

**Teaching genomic medicine to third year medical students: The Einstein experience.** *R. Marion*<sup>1,2</sup>, *C. Campbell*<sup>2</sup>.  
1) Dept Pediatrics, Montefiore Medical Ctr, Bronx, NY; 2) Sarah Lawrence College, Bronxville, NY.

Genomics will play an increasingly important role in medicine in the future. In the clinical years of medical school, however, little emphasis is placed on teaching molecular medicine, largely due to a paucity of trained personnel. To address this, we have developed a curriculum in which genetic counselors play an active role in teaching basic concepts in genomic medicine. The pilot study, a series of 7 weekly seminars that spans the pediatrics clerkship at the Albert Einstein College of Medicine, was taught by the co-authors. Seminar topics included: clinical and molecular cytogenetics, gene expression, single gene mutations, molecular therapy, triplet repeat disorders, and genetic approaches to common disease. Each session was case-based, often relating to a patient on the wards. In each session, the case was discussed in terms of general pediatric themes (clinical course, pathophysiology, and treatments). However, the specific diagnoses served as a basis for the exploration of concepts such as molecular classifications of disease, diagnostic tools, treatments, and ethical issues in genetic medicine. Prior to each session, students were provided with a summary of the case, as well as background reading material. The curriculum was implemented in July 2002. Verbal feedback indicated that: 1) students favored the didactic approach using inpatient cases; 2) integration of the clinical course and molecular basis of diseases made basic concepts and the practical applications of molecular medicine more comprehensible; and 3) participants appreciated the different perspectives that the pediatrician and genetic counselor brought to the discussion. On written evaluation, the series received extremely high marks from the students. We believe that by combining genetic counselors and clinicians in a team-teaching format, this modular, case-based curriculum can be successfully transported and used to teach genomics to medical students at other institutions and in other specialties. The development of this curriculum creates a new niche for genetic counselors as educators at the medical school level.

**Teaching about genetic disorders: A survey of Resident understanding of Inborn Errors of Metabolism.** *P.A. Levy, R.W. Marion.* Pediatrics - Genetics, Children's Hosp Montefiore, Bronx, NY.

As Genomic Medicine becomes more incorporated into the practice of medicine, how effective are we at conveying the necessary information to our trainees? Each year the residents have lectures about Inborn Errors of Metabolism (IEM). Consult services often ask for genetic testing. Residents are called on to understand which test might be appropriate, how it needs to be collected and to some degree, how to interpret the results. As part of their differential, they should also be expected to include IEM as warranted. We decided to survey Pediatric residents at our institution to assess their understanding of IEM. Questions were asked about newborn screening, genetic testing, and their experience and training with this type of genetic patient. Clinical scenarios were presented to assess recognition of IEM. Results: For newborn screening, the residents had a fair knowledge of which disorders are screened for in our state (NY). 60-70% of the residents could correctly identify one of three tests recently added to the NY newborn screen (MCAD, CAH, CF). With questions dealing with procedural issues related to IEM testing, about 50% correctly identified the type of tube needed for plasma amino acids and for ammonia, 50% knew that a random urine specimen was sufficient for urine organic acids, and 60% understood that using a tourniquet would raise lactic acid levels. The residents were unable to identify a patient presenting with MSUD, could not state that MSUD was an disorder of amino acid metabolism, and could not correctly order plasma amino acids to confirm the diagnosis. 50% knew that Galactosemia is associated with jaundice and E. coli sepsis. Only 4% of the residents recognized a typical presentation of Metachromatic Leukodystrophy. Most of the residents surveyed felt that their teaching and experience with patients with IEM had been deficient. Conclusion: More effort must be made to provide access to information about genetic testing to the residents, possibly over the hospitals intranet web site. Efforts must also be made to increase the residents knowledge about genetic disorders such as IEM so these disorders can be included in their differentials.

**Genetic knowledge and attitudes among individuals at risk for Alzheimer's disease.** *T. Moscarillo*<sup>1</sup>, *R. Go*<sup>2</sup>, *H. Holt*<sup>2</sup>, *S. Goldberg*<sup>1</sup>, *A. Chaglassian*<sup>1</sup>, *J. Stoler*<sup>3</sup>, *D. Blacker*<sup>1</sup>. 1) Psychiatry, Mass General Hosp, Charlestown, MA; 2) Epidemiology, U of Alabama, Birmingham, AL; 3) Genetics and Teratology, Mass General Hosp, Boston, MA.

For those at risk for Alzheimer's disease (AD), the growing complexity of genetic information is a particular concern. To examine baseline knowledge of AD genetics and attitudes toward genetic testing among at-risk individuals and to pilot educational materials for future clinical use, we recruited 247 unaffected relatives in the NIMH AD family sample (mean age 61, sd 9, range 40-90; 25% male; 97% white, 3% black; mean education 15 years, sd 4). Subjects were assessed at baseline, immediately after a randomized educational intervention (AD genetic educational video + pamphlet vs. the pamphlet alone vs. a placebo pamphlet), and 3-6 months later. At baseline, self-assessment of AD genetic knowledge was low (e.g., 58% reported little or no understanding), and answers to specific questions bore this out (e.g., 44% overestimated the increase in risk due to family history). Knowledge of general risk factors was somewhat better (e.g., 93% thought age increased risk and 63% thought vitamin E decreased risk). Subjects recognized the names of some AD genes, but few could correctly state their impact on risk or age of onset. As for genetic testing, 70% said they would be interested in a test offering certain results, but only 59% in a test for disease risk. The most commonly cited reasons for interest were the chance to institute preventive measures, the need to attend to personal affairs, and the desire to prepare loved ones for the future; for lack of interest, the most commonly cited reasons were fear of losing insurance and lack of effective preventive treatments. Qualitative review of follow-data on 44% of the subjects showed little gain in confidence, but real gains in knowledge, particularly in the video group, and somewhat decreased interest in genetic testing. Future results will include complete immediate and long-term follow-up data as well. Educational methods like these will be critical to any future treatment strategies entailing genetic testing for patient selection or treatment optimization.

**Interactive system of Clinical Genetic Semiology: a new pedagogic resource for medicine students.** *F. Suarez, J. Prieto, I. Zarante, C. Gutierrez.* Instituto de Genetica Humana, Univ Javeriana, Bogota, Colombia.

Clinical Genetics have begun to be part of clinical practices in most of the Central and South American hospitals showing the importance of implementing these area in medical education. Therefore new pedagogical tools are needed to include the genetic approach of the diseases in students training. We considered that medical semiology is fundamental in the correct clinical approach of the patient, especially semiology used in clinical genetics, but its teaching becomes difficult by the specialized terminology and the variety of signs that in most of the cases are of difficult definition. The importance of a proper use of semiology is proved in a suitable diagnosis that assures a good treatment. In order to satisfy the necessity of a high quality education in clinical genetics semiology, we presented an educational tool that combines an interactive CD-ROM, a Textbook and Web page, designed in the Instituto de Genetica Humana of Pontificia Universidad Javeriana. The interactive CD-ROM allows the user to compare the findings in his patient with photographies of clinical signs classified by anatomical area and characteristics like color, size, forms, appearance or fusion defects. If the user considers that is the same sign, the one see it in the CD-ROM than the one in the patient, he asks for the software in the CD-ROM, to give information about the sign, from its name, concept, genetic and molecular definition, until its relations with specific syndromes. It is important to stand out that the student arrives at the name and concept of the sign comparing images, which defers from the traditional search in dictionaries or atlas in which the user must know beforehand the name of the sign. The textbook follows the same principle in where the index, guide the user through systems and anatomical areas, that finally show the anomalies and by comparison the student identify the sign, therefore reading the text will known the name the sign and its concept. The Web page combines these characteristics with clinical cases, practical clinical exercises and theory of genetic semiology.

Program Nr: 1122 from 2003 ASHG Annual Meeting

**Web-based Module for Parametric Linkage Analysis.** *S. Slifer, W.K. Scott, M.C. Speer.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Lod score linkage analysis remains a key analytic technique for localization of trait-associated genes. We have developed an on-line interactive module for instruction in parametric (lod score) linkage analysis. Concepts included are genetic distance and recombination, the use of recombination to identify the location of a disease gene, scoring recombinants and non-recombinants, calculating lod scores, and identifying a minimum candidate interval through the use of multipoint linkage analysis, haplotype analysis, and visual inspection of pedigree data. The site can be accessed at: <http://wwwchg.duhs.duke.edu/Duke2/geneticAnalysis/>. We have also developed a companion module on introductory genetics (<http://wwwchg.duhs.duke.edu/Duke/geneticAnalysis>) which covers, among other topics, meiosis and crossing over, both of central importance to understanding linkage analysis. We gratefully acknowledge support from HG000026 for development of these two modules, and from HP10000 and HP19168 for additional support for the development of the introductory genetics module.

**Attitudes towards psychiatric genetic research and its implication.** *M. Rietschel*<sup>1, 2</sup>, *F. Illes*<sup>1</sup>. 1) Central Inst. Mental Health, Univ. Heidelberg, Mannheim, Germany; 2) Dept. Psychiatry, Univ. Bonn, Bonn, Germany.

### **Objective**

The soon-coming availability of genetic testing in psychiatric disorders raises new and complex ethical issues. Psychiatrists, psychologists, gynecologists, and human geneticists will be in the crucial position to transfer knowledge about psychiatric genetics to their mentally ill patients and families. Differences in attitudes between counselors and their patients could cause misunderstandings and problems.

### **Method**

In a population-based study 3077 persons of the general population were interviewed about their knowledge, attitudes and fears towards psychiatric genetics research and its possible application (e.g. predictive testing). Furthermore, 83 psychologists, 118 psychiatrists, 61 gynecologists, 56 human geneticists, and 316 patients with a DSM-IV diagnosis of a major affective disorder (n=196) or schizophrenia (n=120) were included in the study

### **Results and Conclusions**

The majority (80%) is in favor for psychiatric genetic research. Simultaneously however, more than 50% expressed moral doubts. Whereas the consultants showed a relative homogeneity in their attitudes, these differed significantly from those of their patients and the general population. While only 7% of the human geneticists and only a minority of medical consultants (22% of psychiatrists, 17% of psychologists, and 19% of gynecologists) favored predictive psychiatric genetic testing for themselves, 45% of the general populations and 81% of the patients did so. Testing minors on demand of their parents was favored by none (0%) of the human geneticists, less than 5% of psychiatrists, psychologists, and gynecologists, but by 36% of the general population and 42% of patients. To avoid problems in future consultations, experts have to learn about the specific hopes, fears and objections of their patients and the general population.

**Feasibility study to identify methods for enhancing African American (AA) recruitment to an NCI-funded Cancer Genetics Network (CGN).** *S.J. Olsen<sup>1</sup>, C. Hughes Halbert<sup>2</sup>, K.T. Malvern<sup>3</sup>, C. Smith<sup>2</sup>, C. Griffin<sup>4</sup>, Minority Recruitment Working Group, Cancer Genetics Network, [www.epi.grants.cancer.gov/CGN](http://www.epi.grants.cancer.gov/CGN). 1) Sch Nursing, Johns Hopkins Univ, Baltimore, MD; 2) Univ of Pennsylvania, Philadelphia, PA; 3) National Educational Foundation, Zeta Phi Beta Sorority, Inc (NEFZPhiB), Washington, DC; 4) Sch of Medicine, Johns Hopkins Univ, Baltimore, MD.*

Research documents the challenges of recruiting minority populations to participate in research; reduced participation is even more apparent in cancer genetics research. For example, while prevalence of BRCA1/2 mutations is 12-21% among AAs in high risk clinics, <5% of samples in 3 studies of BRCA1/2 genetic test acceptance were from AAs. Barriers to AA participation in cancer genetics research may include concerns about exploitation, greater levels of psychological distress, reduced knowledge about cancer genetics, and limited exposure to information about inherited cancer. Concerns about exploitation may be heightened in research such as the CGN for which there may be no direct benefit. This feasibility study consists of two sub studies each conducted in different CGN centers. The common outcome is to increase AA enrollment into the CGN. The Penn study is a randomized trial in which potential participants are offered CGN enrollment in the standard fashion vs. an invitation to participate plus participation in a risk assessment program. The Hopkins CGN entered into a collaborative agreement with the NEFZPhiB Sorority whose broad mission includes community education about the Human Genome Project. Standard recruitment is a direct mail campaign to members in 4 states. Enhanced recruitment entails a personalized CGN invitation during a cancer genetics education session at 4 state leadership conferences. Recruitment statistics, Jan-June 2003, include: source of contacts [physician referral (58%), Zetas (42%)] and contacts made [total (n=479); completed CGN enrollment (10%), no f/u (5%), declined (3%), ineligible (1%), pending (81%)]. Lessons learned: there are high levels of interest in cancer risk assessment among AA women; recruitment can build on existing genetics and/or health initiatives. Statistics will be updated.

**Informed Consent for a Population Based Genetic Database: A qualitative assessment of understanding.** *K. Ormond, A. Cirino, R. Chisholm, W. Wolf.* Northwestern University, Chicago, IL.

In November 2002, the NUGene project began recruiting subjects for a large, longitudinal genetic database. Concurrently, we solicited participants for interviews to address attitudes about NUGene participation. Interviews were conducted an average of 22 + 9 days after NUGene enrollment, and 107 transcribed interviews were analyzed (44.6% of NUGene enrollment). Subjects were 58% self-recruited, and mostly female (67%), Caucasian (83.5%), Christian (66.7%), married (48.1%), college educated (66.0%) and with household incomes > \$50,000 (66.3%). Several themes emerged from the data, focusing around reasons for participation, risks/benefits of the study, expectations regarding results and preferences for recontact if future studies or results become available. Most enrolled in NUGene in order to help mankind in some manner, to help find disease genes, treatments or cures, and/or to contribute to the overall scientific knowledge. Less common reasons for participation were a personal interest in science or genetics, or in research participation in general. Many (~30%) clearly expressed a hope for personal benefit, and named specific disorders or family members. Only 10% explicitly stated they had no expectation for personal benefit. Confidentiality protections were described as good by most (>50%), and almost half specifically described one or more of the study's privacy protections. While many were able to articulate the general privacy concerns, and a reasonable minority specifically cited concerns with employer (12%) or insurance discrimination (25%), most considered the risks to privacy low (25%) or none (~60%). When asked whether they expected to be contacted with study results, respondents were split between having no expectation of results (42/107), being hopeful/open to results (40/107) and stating clearly that they expected to be contacted with results (13/107); common explanations were if something I need to know or something serious was discovered. Over 75% of study participants felt that if a genetic test became available for their family they would wish to undertake it; few caveats were mentioned. Implications will be discussed.

**Genetic heterogeneity in a tuberous sclerosis family: implications for genetic counseling.** *A.T. Williams<sup>1</sup>, H. Northrup<sup>1</sup>, K.-S. Au<sup>1</sup>, B.B. Roa<sup>2</sup>*. 1) The University of Texas Medical School at Houston, Department of Pediatrics, Division of Medical Genetics, Houston, Texas; 2) Baylor College of Medicine, Baylor DNA Diagnostic Laboratory, Department of Human and Molecular Genetics, Houston, Texas.

Tuberous sclerosis complex (TSC) is an autosomal dominant neurocutaneous disorder characterized by the development of hamartias and hamartomas in multiple organ systems. The incidence of TSC is approximately 1 in 6000. Mutations occur in either the *TSC1* or *TSC2* genes. One-third of cases are due to inherited mutations and two-thirds are due to *de novo* mutations. We describe a family with distinct mutations identified in two affected members. Research based sequence analysis of the proband (Hou50-01) identified a 22 base pair deletion mutation in the *TSC2* gene (3762\_3783del). The mutation was confirmed at the Baylor DNA Diagnostic Laboratory, where subsequent analyses determined that the proband's mildly affected mother was mosaic for the *TSC2* deletion mutation, while the clinically unaffected maternal grandmother and maternal great-grandparents were negative. A maternal great aunt, clinically suspected to have TSC, underwent sequence analysis of the coding regions of both *TSC1* and *TSC2* at Athena Diagnostics, Inc. Her results were negative for the *TSC2* mutation identified in Hou50-01; a nonsense mutation in the *TSC1* gene (1498 C>T, R500X) was discovered. The *TSC1* mutation is not present in Hou50-01; further familial analyses for the *TSC1* mutation are pending. Our case is the second report of genetic heterogeneity influencing the interpretation of a TSC pedigree and potentially complicating the provision of genetic risk assessment and counseling. Given the frequency of *de novo* events in TSC, both locus and allelic heterogeneity should be considered in the evaluation of extended families with TSC. To ensure the provision of accurate genetic counseling, providers should consider utilizing complete sequencing of both TSC genes in lieu of targeted analyses on a case-by-case basis. This approach may be particularly relevant in pedigrees suggesting non-penetrance or when targeted mutation evaluations yield unexpectedly negative results.

**Impact of direct-to-consumer advertising for BRCA1 and BRCA2 testing on genetic services at a Managed Care Organization.** *J. Mouchawar*<sup>1</sup>, *S. Alford-Hensley*<sup>3</sup>, *S. Laurion*<sup>2</sup>, *D. Ritzwoller*<sup>1</sup>, *R. Meenan*<sup>4</sup>, *J. Ellis*<sup>1</sup>, *A. Kulchak-Rahm*<sup>1</sup>, *M. Finucane*<sup>4</sup>. 1) Clinical Research Unit, Kaiser Permanente Colorado, Denver, CO; 2) Boulder, CO; 3) Henry Ford Health System, Detroit, MI; 4) Centers for Health Research, Kaiser Permanente, Portland, OR.

In September, 2002, Myriad Genetic Laboratories, Inc. initiated an intensive five-month direct-to-consumer advertising campaign for genetic testing for the BRCA1 and BRCA2 genes (DTC) using television, radio, and print media, projected to reach more than 90% of metro Denver homes an average of 16.5 times each. This study describes the genetic counseling and testing impact of Myriads marketing campaign within two Managed Care Organizations, Kaiser Permanente Colorado (KPCO) in Denver, Colorado, where the ad campaign occurred, and Henry Ford Health System (HFHS) in Detroit, Michigan, where there were no advertisements. At KPCO, referrals increased 300% (p-value <0.001) during the advertising campaign, compared to the same time period a year earlier, and the proportion of high risk referrals dropped from 70% the previous year to 49% during the campaign (p-value <0.001). There was no significant change in mutation risk status of women who underwent testing between the 2 time periods. HFHS reported no significant change between the two time periods for numbers or risk status of referrals, or for risk status of women tested. Direct-to-consumer advertising of genetic testing for breast cancer risk resulted in a significant increase in counseling referrals, even for women who did not have a profound enough family history to be considered for testing, but no increase in low risk women actually being tested. Future DTC may create a challenge of how to identify high-risk members in the face of a potential large-scale counseling demand of lower-risk members driving costs and delaying access to higher-risk women.

**Oppenheims dystonia: The challenging genetic counseling associated with prenatal diagnosis.** *T.C. Falik-Zaccai<sup>1</sup>, L. Shachak<sup>2</sup>, M. Khayat<sup>1</sup>, M. Frydman<sup>3</sup>, Z. Borochowitz<sup>2</sup>, N. Giladi<sup>4</sup>.* 1) Med genet, Western Galilee Hosp, Nahariya, Israel; 2) Inst Human Genet, Bnai-Zion Med Cent, Haifa; 3) Inst of Human Genet, Shiba Med Cent, Tel Aviv; 4) Movement Disorders Unit, Sourasky Med Cent, Tel Aviv, Israel.

Oppenheims dystonia (OD) is an autosomal dominant (AD) movement disorder with a variable phenotype and penetrance of 30-40%. It is characterized by early onset, sustained, involuntary muscle contractions that cause significant morbidity. The identification of the causative GAG deletion in the DYT1 gene, enabled prenatal diagnosis (PND). We have ascertained 53 OD affected individuals within 28 families, confirmed molecularly. Five couples requested PND in which three men were non-manifesting carriers and two women affected with OD. Comprehensive genetic counseling was provided twice by a medical geneticist, genetic counselor and a movement disorder specialist before prenatal testing and when results were delivered. Seven PNDs were performed. Three fetuses of three couples were found not to carry the mutation. One of those requested not to be informed the result. Four fetuses of two couples were found to carry the GAG deletion. One couple decided to continue the pregnancy although the mother is a manifested carrier. The second couple, in which the father is a non-manifesting carrier, had three fetuses carrying the deletion and two affected children born previously. They decided to terminate the first two pregnancies but to continue the third. The two affected women practiced uncontrolled body movements during the PND procedure and report that the obstetricians were not aware and impatient to their difficulties. Marital problems arose in at least two couples. Genetic counseling in OD is challenging and presents intellectual, emotional, and moral dilemmas. The fact that only one parent is "responsible", that inheriting the mutation does not necessarily mean being affected, and the modern treatments that allow most patients a relatively good quality of life, contribute to its complexity. A multidisciplinary approach and possibly preimplantation diagnosis are suggested to best meet the needs of couples at risk.

**What's the story? Narrative styles of people living with intersex conditions.** *S. Metcalfe*<sup>1,2</sup>, *E. Hughes*<sup>1,2</sup>, *M. Sahhar*<sup>2,3</sup>, *Murdoch Childrens Research Institute Sex Study Group*. 1) Genetics Education Unit, MCRI, Parkville, Australia; 2) Dept Paediatrics, The University of Melbourne, Australia; 3) Genetic Health Services Victoria, Parkville, Australia.

Intersex is a group of biological conditions with various aetiologies, primarily genetic, where the affected person's sex does not easily fit into one of the two accepted categories of male and female. Current management often involves early surgery to 'fix' genital appearance, however, this is a subject of controversy among the intersex community. A study is being carried out to look at psychological outcomes of people with intersex and their attitudes towards issues in current management, to inform best practice. Part of this study involves interviewing participants to tell their story about living with their condition. It has been suggested by Frank\*, a sociologist, that people who experience an illness tell their story in one of several styles. We are investigating whether those illness narrative styles can be applied to people's stories of intersex conditions and whether they can be a useful listening tool for health professionals. Stories were collected through in-depth interviews with 5 people with intersex conditions, followed by written and telephone correspondence. The data were triangulated and enriched by commentary from treating doctors. The narratives were analysed using Frank's theory, enabling the style of each participant's story to be identified. It was found that each participant told a distinct style of story, even when superficially their experiences seemed similar. Thus, Frank's narrative styles can generally be applied here, with some modifications. Certain cultures and institutions focus on a particular narrative type, making it difficult to recognise other styles of the story. Certainly there are unspoken elements to a person's story not included in the narrative. But the way they tell the narrative reflects how they want their audience to perceive them and recognition of this should contribute to an empathic relationship of listening for the health professional.\*Frank, A. W. (1995). *The wounded storyteller: body, illness and ethics*. Chicago, University of Chicago Press.

**22q11 Deletion Syndrome: Exploration of Attitudes towards the Disclosure Process of the Increased Prevalence of Psychiatric Illness.** *N. Martin<sup>1</sup>, C. Cytrynbaum<sup>1</sup>, P. AbdelMalik<sup>2</sup>, R. Weksberg<sup>1</sup>, A. Bassett<sup>2</sup>.* 1) Hospital for Sick Children, Toronto, Canada; 2) Centre for Addiction and Mental Health, Toronto, Canada.

22q11 Deletion Syndrome (22qDS), also known as Velocardiofacial or DiGeorge syndromes, is the most common microdeletion syndrome. Several reports have documented a high prevalence of psychiatric illness, especially schizophrenia, in patients with 22qDS. The aim of our research was to explore parental attitudes and genetic counsellors' current practice and perspectives regarding disclosure of the common clinical manifestations of 22qDS, particularly the risk of developing a psychiatric illness. To do this we conducted semi-structured interviews with 4 parents of offspring with 22qDS and schizophrenia, and used standard qualitative methods to examine responses. To investigate genetic counsellors' current practice and perspectives we delivered a questionnaire via established list serves, 54 of which were completed and returned. The results showed that parents and the majority of counsellors felt that information regarding the increased risk to develop a psychiatric illness in patients with 22qDS is important to disclose. However, questionnaire results showed that psychiatric disorders were the least likely to be discussed in the initial counselling session after a diagnosis was made in infancy (41%) and prenatally (72%) compared to other features of 22qDS like hypocalcemia (93%; 89%) and learning difficulties (91%; 98%). Parents felt information should be given before psychiatric symptoms are likely to arise. Counsellors' responses were fairly evenly divided between disclosure in infancy (38%), childhood (31%) and adolescence (31%). Counsellors also revealed that they found the discussion of psychiatric issues with parents challenging due to the stigma associated with mental illness, and lack of knowledge about psychiatric illness and treatment. Studies show that early diagnosis and treatment for schizophrenia and related disorders are likely to lead to improved outcome. Counsellors should disclose information regarding prevalence and treatability of psychiatric illness in 22qDS prior to onset of symptoms, which may occur as early as childhood.

**Effects of guided imagery on women considering BRCA1/BRCA2 testing: A feasibility study.** *B.A. McGregor<sup>1</sup>, A. Fishbach<sup>1</sup>, D.J. Bowen<sup>1</sup>, D. Valley<sup>1</sup>, E. Ludman<sup>2</sup>, K.A. Leppig<sup>2</sup>, L. McAuliffe<sup>2</sup>.* 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Group Health Cooperative, Seattle, WA.

Women at high familial risk for breast cancer report short and long-term distress about their risk for cancer. This has been shown to interfere with comprehension of risk information and effect adherence to breast cancer screening guidelines. There is evidence from several studies in numerous medical and non-medical settings that guided imagery interventions are beneficial in reducing distress and increasing coping. In a feasibility study, we adapted guided imagery for women at high risk for breast/ovarian cancer in women considering genetic testing for BRCA1/2. Subjects were eight women from the genetic counseling clinic at Group Health Cooperative in the Seattle/Tacoma area. The intervention was introduced following a general genetic education session (which did not include individualized breast, ovarian cancer or BRCA1/2 risk estimates). Women were asked to listen to a guided imagery tape twice a week for the next 8 weeks. The intervention was delivered to all the women, who responded favorably to the intervention experience. We examined the short-term effects and acceptability of a guided imagery intervention among these women. We measured psychological variables at baseline and two months post-intervention. These women report elevated perceived risk for breast and ovarian cancer than expected. They also report elevated risk estimates for breast cancer in women in the general population. These women overestimate their risk to carry a BRCA1/2 mutation, compared with BRCApro risk estimates. They report higher than average cancer worry scores and elevated anxiety. We will also present results related to changes in distress, coping, optimism, social support, health related quality of life, genetics comprehension and knowledge level, intention to pursue genetic counseling and/or genetic testing, satisfaction with testing choice and breast and ovarian cancer screening intentions. These preliminary data provide support for further studies using guided imagery as an adjunct to standard genetic counseling.

**Knowledge of non-disease genetic traits and the effect on self-concept.** *H.A. Gordish-Dressman<sup>1</sup>, E.S. Gordon<sup>1</sup>, J.M. Devaney<sup>1</sup>, L.S. Pescatello<sup>3</sup>, B. Kelsey<sup>3</sup>, G. Gianetti<sup>3</sup>, P.M. Clarkson<sup>2</sup>, M.J. Hubal<sup>2</sup>, P.M. Gordon<sup>4</sup>, E.E. Pistilli<sup>4</sup>, E.P. Hoffman<sup>1</sup>.* 1) Center for Genetic Medicine, Children's Natl. Med. Center, Washington, DC; 2) University of Massachusetts Amherst, Amherst, MA; 3) University of Connecticut, Storrs, CT; 4) West Virginia University, Morgantown, WV.

With the recent media attention given to genetics and the Human Genome Project, more and more people are becoming aware of genes and their possible consequences. As information on non-disease genetic traits emerges, the social and psychological impact of this information on an increasingly aware public must be addressed. Here we present data from 135 healthy volunteers and the effect knowledge of non-disease genetic traits has on their self-concept. The subjects were part of an ongoing four-year study titled Functional SNPs Associated with Muscle Size and Strength (FAMuSS). This subset of subjects was given a series of standardized assessments of self-concept (the Tennessee Self-Concepts Scale and the Health Orientation Scale) at the time of enrollment. Each subject donated a blood sample for genotyping of four SNPs (ACE, CNTF, gamma sarcoglycan, and UCP-2) previously shown to be associated with human muscle size and/or strength. After completion of a 12-week supervised exercise regimen, subjects were given information on which SNPs they possessed and what muscle size/strength traits those SNPs were associated with. Assessments of self-concept were then repeated to determine what effect, if any, the non-disease genetic knowledge had. When changes in self-concept measures were compared between subjects who possessed only negatively/neutrally associated SNPs and subjects who possessed positively associated SNPs, several significant differences emerged. The two groups showed significantly different changes in physical self-concept ( $t=2.98$ ;  $p=0.015$ ) and in total self-concept ( $t=2.33$ ;  $p=0.021$ ). The groups also showed significantly different changes in health esteem and confidence ( $t=2.00$ ;  $p=0.046$ ). These results suggest that non-disease genetic information does have an effect on self-concept, making it an issue that will need further study as an increasing amount of non-disease genetic information becomes available.

**Knowledge of genetics relevant for daily practice among nearly graduated MDs.** *M.J.H. Baars<sup>1</sup>, A.J.J.A. Scherpbier<sup>2</sup>, L.W. Schuwirth<sup>3</sup>, L. Henneman<sup>1</sup>, A.M.J.J. Verweij<sup>4</sup>, M.C. Cornel<sup>1</sup>, L.P. ten Kate<sup>1</sup>.* 1) Department of Clinical and Human Genetics, VU University Medical Center, Amsterdam, The Netherlands; 2) Institute for Medical Education, University Maastricht, The Netherlands; 3) Department of Educational Development and Research, University Maastricht, The Netherlands; 4) Department of Medical Education, VU University Medical Center, Amsterdam, The Netherlands.

**Objective** To investigate the knowledge of genetics relevant for daily practice among nearly graduated medical doctors (MDs) in the Netherlands. **Methods** A genetic computer exam was designed by Clinical Geneticists (CGs) and Educational Specialists consisting of 215 questions divided over 194 case-histories and divided into three categories: a) essential for daily practice, b) desirable and c) specialized. By assigning one point for each correct answer a total exam score was calculated, expressed as the percentage of questions answered correctly. Three sub-scores were created for the above mentioned categories (a-c). After a validation study among 11 Non-Medical students, 11 nearly graduated MDs, and 10 CGs, showing ascending scores as expected from these groups, the exam was completed by a study sample of 291 nearly graduated MDs from 7 Medical Schools. **Results** The study sample of MDs scored 62% (SD 6.9; 95% CI 61-63%) correct on the total exam score. In the essential knowledge category (a), none of the MDs scored 90% or more correctly and only 15% of the MDs scored over 80% correctly. Not more than a quarter answered 60% of the desirable knowledge questions (b) correctly. Half of the students scored less than 44% correctly in the specialized genetic knowledge category (c). **Conclusions** The results suggest that nearly graduated MDs lack genetic knowledge necessary for daily practice. It is desirable that the genetic knowledge of MDs is upgraded in their postgraduate training and future MDs training programmes should focus more on this topic.

**Development of A Self-Assessment and Educational Tool Regarding Hereditary Breast Cancer Incorporating Views of at-Risk Women.** *W. Cohn<sup>1</sup>, S.M. Jones<sup>2</sup>, S. Miesfeldt<sup>3</sup>*. 1) Health Evaluation Sci, Univ Virginia, Charlottesville, VA; 2) Cancer Center, Univ Virginia, Charlottesville, VA; 3) Division of Hematology/Oncology, Department of Internal Medicine, Univ Virginia, Charlottesville, VA.

This 5-year study with 3 components examined the views of early-onset breast cancer (BC) survivors from Virginia regarding hereditary breast cancer (HBC) with the goal of developing self-assessment and educational materials for women and their clinicians. 1) 22 women with suspected HBC from varied racial and geographic backgrounds were interviewed to assess views concerning HBC. Addressed were: cancer treatment experiences; disease causation; risk perception for self/relatives; family issues; cancer prevention. We focused on 5 categories emerging from the interviews: causation; expectations of BC in self; expectations of BC in relatives; risk reduction and prevention; family communications. 2) 273 women with early-onset BC (<50 yrs), recruited from the Virginia Cancer Registry, responded to 2 mailed questionnaires. The 1st assessed whether participants had personal/family histories suggestive of HBC. The 2nd examined: health history and experience regarding BC; cancer early detection behaviors; knowledge of BC risk factors; knowledge of HBC; beliefs about BC causes; HBC information needs and use of such information; perception of childrens concerns about cancer risk; perceived information needs for children. 137 (~half) were deemed at risk for HBC. Survey results showed the following: cancer screening behaviors; knowledge about BC risk factors and HBC; concerns about childrens risk; HBC information needs and sources. 3) An instructional design process was used to develop and evaluate an educational brochure to assist un- and under-insured women to assess and understand their potential risk for hereditary breast and ovarian cancer (HBOC). The instructional goals of the brochure were to enable users to: identify and understand risk factors for HBOC; understand the importance of knowing if one is at risk; determine ones potential risk; know resources for women at risk. A companion brochure was developed to enable clinicians to assist women this assessment. NHGRI R29 HG01554.

**GenEd - Genetic education for non-genetic health professionals across Europe.** *C. Benjamin<sup>1</sup>, I. Nippert<sup>2</sup>, H. Harris<sup>1</sup>, K. Challen<sup>1</sup>, C. Julian-Reynier<sup>3</sup>, J. Schmidtke<sup>2</sup>, L.P. Ten Kate<sup>4</sup>, U. Kristofferson<sup>5</sup>, K. Henriksson<sup>5</sup>, E. Anionwu<sup>6</sup>, Y. Poortman<sup>7</sup>, A. Kent<sup>7</sup>, W. Holtzgreve<sup>8</sup>, C. Delozier<sup>9</sup>, R. Harris<sup>1</sup>.* 1) Manchester Uni,UK; 2) Inst fur Humangenetik, Universities of Muenster and Hannover, Germany; 3) INSERM 379, Marseille, France; 4) Free Uni Medical School, Amsterdam, Netherlands; 5) Uni Hospital, Lund, Sweden; 6) Mary Seacole Centre, London; 7) VSOP and GIG; 8) Universitaets-Frauenklinik, Basel, Switzerland; 9) ESHG.

GenEd is an innovative 3-year collaboration collecting data for a needs based assessment in education in genetics for primary health care providers in 11 countries. Information from medicine and midwifery was gathered by direct contact with professionals and available website documentation in 5 countries. Results show that countries have wide variation in content and duration of postgraduate genetic education and that France and Germany have a nationally agreed undergraduate medical curriculum but with minimal genetic education, mainly confined to basic science courses and often not immediately visible. In Sweden, the Netherlands and the UK to a large extent the content is at the discretion of individual universities. Evidence from UK and France show that genetic professionals are influencing the genetic content of curricula. Some specialties have adopted specific genetic educational requirements but many lacked any. We show that within each country many organisations may have nominal responsibility for setting, assessing and implementing education. The Phase II questionnaires surveying GPs, paediatricians, ob/gyns and midwives will be available at the meeting. They address the health professionals' knowledge, attitudes and skills in regard to using genetic information in their practice. Questions also ask about the amount and format of education needed. The creation has been initiated of a European Coalition of Health Professional Education in Genetics (ECHPEG) to facilitate collaboration between e.g. European Health Professional Organisations and Clinical Geneticists (EUMS), patient groups (EAGS), educationalists (ESHG Educational Affairs Committee), policy makers (The Wellcome Trust/ Department of Health UK Strategy) and international groups (NCHPEG).

Program Nr: 1136 from 2003 ASHG Annual Meeting

**Innovative Approach to Prenatal Education.** *T. Grant<sup>1</sup>, N. Callanan<sup>2</sup>, J. Griffith<sup>1</sup>, J.R. Sorenson<sup>1</sup>.* 1) U. of North Carolina Chapel Hill, NC; 2) U. of North Carolina Greensboro, NC.

Interactive Computer Assisted Instruction (ICAI) is an effective educational tool. We have developed an ICAI prenatal genetic education program providing education on multiple marker screening, advanced maternal age and carrier testing for sickle cell anemia, thalassemia, cystic fibrosis, Tay-Sachs and Canavan disease. The program uses text, audio, graphics, & animation. It operates by using a touch screen & allows women to identify topics they want to discuss with their provider. Education units were developed by: 1) review of professional practice guidelines & pamphlets from private & public health OB clinics in North Carolina; 3) Pilot work with the general population; 4) Cognitive Response Interviews (CRI); 5) Usability Tests (UT); & 6) provider interviews.

75 non-pregnant women answered pregnancy risk profile questions, questions regarding preference for medical information & knowledge of prenatal testing. Women were 18-49 yrs, 53% were White, 43% were African-American, & 83% reported having been pregnant previously. We used CRI to investigate content clarity of the educational units. Five women who were 20 weeks or less & at least 18, viewed two units each. From these interviews we learned: a) women understood the content, b) risk estimates should be stated as fractions & percents and c) more graphics & detailed explanation of some terms were needed. Five women who were 20 weeks or less, & at least 18, did UT. Each woman viewed one unit. From UT we learned that women liked the touch screen & audio features & that the program was easy to use. It was found, however, that women wanted to review instructions after they started certain parts of the program & that more detail on how to select topics that will be printed were needed. Thirteen providers reviewed 2 units each. They reported that our ICAI program is informative, easy to understand & use and they would recommend that ICAIs in general become a part of standard prenatal care. Together these data suggest that an ICAI program is an acceptable educational tool by both patients & providers.

**Microsatellite Instability Test Results: Perspective From Patients.** *S.K. Nigon<sup>1</sup>, N.L. Lindor<sup>1</sup>, R.D. Goldberg<sup>1</sup>, D.J. Bowen<sup>2</sup>, A. Roche<sup>2</sup>, G.L. Petersen<sup>1</sup>, S.N. Thibodeau<sup>1</sup>, L.J. Burgart<sup>1</sup>, B.W. Morlan<sup>1</sup>.* 1) Mayo Clinic, Rochester, MN; 2) FHCRC Seattle, WA.

**Purpose:** To determine which individuals with colorectal cancer were interested in knowing results of their tumor microsatellite instability (MSI) testing and immunohistochemistry (IHC) testing for DNA mismatch repair genes; also reasons patients had for choosing to learn results and the impact of results on self-assessed quality of life. Secondary endpoints looked at the effect of the supplemental educational material on the decision and the quality of life. This study was prompted by concern that the complex and ambiguous nature of MSI/IHC testing results might be problematic to convey and stressful to receive.

**Patients and Methods:** Colorectal cancers from 414 individuals from families of variable level of cancer risks, were assayed from MSI and IHC for three DNA mismatch repair gene products. Individuals were invited by mail to learn of their MSI/IHC test results. In the invitation, they randomly received either brief or extended educational materials about the testing and a pre-test survey.

**Results:** Of the 414 individuals, 307 (74%) chose to learn their results. There was no significant difference in interest in knowing test results according to: gender (men 72% vs women 77%), age (participants under 50 [74%] vs over 50 [74%]), educational level (1 year post high school [70%] vs over 1 year [77%]), or family history of colon cancer (participants with no family history [75%] vs participants with family history [72%]). Whether or not individuals received the brief or extended educational piece did not influence the decision. Self-assessed quality of life was not altered by receiving MSI/IHC results.

**Conclusion:** Individuals with colorectal cancer had a high level of interest in learning their individual MSI/IHC test results, and did not seem deterred by the inherent complexity or ambiguity of this information. Regardless of test outcome, results did not adversely affect quality of life. These conclusions held true for all subsets of patients that could be analyzed.

**Lay understanding of familial risk of common chronic diseases: a systematic review and synthesis of qualitative research.** *F.M. Walter<sup>1</sup>, J.D. Emery<sup>1</sup>, D. Braithwaite<sup>1</sup>, T.M. Marteau<sup>2</sup>*. 1) Dept of Public Health & Primary Care, University of Cambridge, UK; 2) Psychology & Genetics Research Group, King's College London, UK.

**Aims:** To systematically review and synthesise the qualitative literature to explore understanding about familial risk held by people with a family history (FH) of cancer, heart disease and diabetes mellitus. To develop a conceptual framework that explains the processes by which such individuals develop and deal with their personal perception of disease risk. **Methods:** 22 qualitative papers were identified by a comprehensive literature search. Standard proformas were used for the appraisal of papers and extraction of key concepts, giving 11 papers for inclusion. A meta-ethnographic approach was used to translate the studies across each other, synthesise the translation, and express the synthesis. **Findings:** 5 interconnected constructs ('diseases running in my family', experiencing the relative's illness, personal mental models of disease, personalising risk and control of familial risk) were synthesised to create a conceptual framework of 3rd order constructs centering on developing a personal sense of vulnerability to a disease. This dynamic process is influenced by the salience of the FH, such as numbers of affected relatives, personal experiences of disease, premature death, perceived patterns of illness relating to gender or age at death, and comparisons between themselves and the affected relative. The developing vulnerability is interpreted using personal mental models of disease causation, inheritance and fatalism. People's sense of vulnerability affects how they cope with, and attempt to control, their perceived familial risk. **Clinical Implications:** Individuals with a FH of a common chronic disease develop a personal sense of vulnerability, and features of the FH which give meaning to familial risk may be perceived differently by patients and professionals. Key areas are identified for health professionals to explore with patients that may influence the effectiveness of both risk communication and disease management strategies. A risk communication consultation model is being developed.

Program Nr: 1139 from 2003 ASHG Annual Meeting

**Contribution of X inactivation studies to genetic counseling in X-linked mental retardation.** *M.L. Jacquemont, V. Raclin, D. Genevieve, S. Lyonnet, V. Cormier-Daire, JP. Bonnefont, A. Munnich.* Departement de genetique, Hopital Necker-Enfants Malades, Paris, France.

X-linked mental retardation (XLMR) is frequently considered in mentally retarded males. Because accurate diagnosis is particularly difficult, studying chromosome X inactivation status in mothers is occasionally helpful. We have reviewed the X-inactivation status of thirty-five mothers of mentally retarded boys. Eight cases were sporadic and twenty-seven were familial. We used a PCR-digestion test at the Androgen Receptor (AR) locus and we compared it to the non digested PCR product to determine the status of the mothers. The significant threshold for non-random inactivation was set to 80 %. Twenty-five women (71 %) had random X inactivation (five familial cases), one (3 %) was non-informative at the AR locus and nine (26 %) had a skewed X inactivation (nine familial cases). However, we observed a discrepant chromosome X inactivation in obligate carriers. Indeed, family history suggested that three mothers were obligate carriers but their X inactivation studies revealed that one of these mothers had skewed inactivation while in the others inactivation was random. These results suggest that genetic counseling based on X inactivation studies should be particularly cautious in XLMR.

**Population-based assessment of risk of other cancers in relatives of prostate cancer cases.** *L. Cannon-Albright.*  
Prof, Medical Informatics, Univ Utah Sch Medicine, Salt Lake City, UT.

We performed a relative risk assessment for cancer of other sites in the first-degree relatives of prostate cancer cases. We analyzed the Utah Population Database (UPDB), a genealogy of Utah pioneers and their descendants record linked to a Utah Cancer Registry (1973-2003). We present estimates of relative risks for 34 cancer sites in relatives of prostate cancer cases. The observed cancers occurring in the relatives of 15,535 prostate cases were compared to internal, cohort and site-specific rates of cancer from the UPDB. 14,096 cases of cancer of all sites were observed in the 135, 947 first-degree relatives, with 9,178 expected; OR = 1.54. Over a 2-fold risk of prostate cancer was observed in first-degree relatives (OR 2.18, CI[ 2.10,2.27]. Those cancer sites with the highest significant OR were testicular (1.71) and brain (1.64). Other cancer sites in significant excess with OR > 1.50 included Hodgkins lymphoma, and cancers of the liver, gallbladder, and thyroid. When only relatives of the 1293 early prostate cancer cases (< 61 years) were considered, over a 3-fold risk of prostate cancer was observed (OR 3.24). Relatives of these early prostate cancer cases were at significant increased risk of stomach cancer (1.77), Non-Hodgkin's Lymphoma (1.47), Leukemia (1.63), kidney cancer (1.80), colon cancer (1.38), and breast cancer (1.27). The 3672 first degree relatives of the 385 "familial" early prostate cases (> 1 1st degree relative affected) were at significant increased risk for rectal cancer (2.57) and soft tissue/connective tissue cancers (3.65). Relatives of the early "non-familial" prostate cases were at significantly increased risk for breast cancer (1.52), colon cancer (1.84), and pancreatic cancer (2.12). A survey of the Utah population suggests that first-degree relatives of prostate cancer cases are at increased risk of developing cancer of other sites. Different patterns are observed when familial prostate cancer cases are considered. Analysis of this unique data resource suggests that consideration of other cancer predisposition genes may be warranted, especially for familial prostate cancer cases.

**Familial Myopia Study.** *G.P. Ibay<sup>1</sup>, B. Doan<sup>1</sup>, L. Reider<sup>2</sup>, D. Dana<sup>2</sup>, M. Schlifka<sup>2</sup>, H. Hu<sup>2</sup>, T. Holmes<sup>2</sup>, J. O'Neill<sup>1</sup>, J.E. Bailey-Wilson<sup>1</sup>, D. Stambolian<sup>2</sup>.* 1) Interited Disease Research Br, NHGRI/NIH, Baltimore, MD; 2) University of Pennsylvania.

**Purpose.** To identify regions of the human genome containing genes responsible for nonsyndromic myopia using pedigrees from four ethnic groups of the Myopia Family Study-- Ashkenazi Jewish, Amish, African- and Chinese-American families.

**Methods.** Cycloplegic and manifest refraction were performed on 39 Jewish and 52 Amish families. Individuals with  $-1.00$  D in each meridian of both eyes were classified as myopic. Genomic DNA was genotyped by PCR with 12 markers on chromosome 12q21-23 and 18p11.3. Parametric and nonparametric linkage analyses were conducted to determine whether these loci are important in families with less severe, clinical forms of myopia. A combined nonparametric analysis was performed by calculating the sum of NPL scores for each family divided by the square root of the total number of analyzed families ( $N=78$ ) across both populations.

**Results.** The overall results of these preliminary studies do not indicate any strong evidence of linkage of myopia in these families to the candidate regions on chromosomes 12 or 18. One Amish family showed nominal evidence of linkage ( $LOD>1.0$ ) to the region previously reported on chromosome 12q; another 3 Amish families each gave  $LOD >1.0$  to 2 markers on chromosome 18p; and 3 Jewish families each gave  $LOD >1.0$  to 5 markers on chromosome 12q. Although these families show marginal evidence of linkage to one of these regions, the results are not particularly strong and could be due to chance. A genome wide scan (GWS) is required to determine whether these families are most likely linked to this region, or whether the mild evidence of linkage observed is just a chance result. A GWS will also allow us to determine if other loci may play a role in myopia susceptibility in these families. Such a GWS is currently underway. Data collection is underway in both African-American and Chinese-American families.

**Evidence for a Free Fatty Acid-related Diabetes Susceptibility Locus on Chromosome 22 in Finnish Subjects.**

*A.U. Jackson<sup>1</sup>, R.W. Watanabe<sup>2</sup>, L.J. Scott<sup>1</sup>, K.L. Mohlke<sup>3</sup>, K. Silander<sup>3</sup>, T.T. Valle<sup>4</sup>, K. Doheny<sup>5</sup>, E. Pugh<sup>5</sup>, J. Tuomilehto<sup>4</sup>, R.N. Bergman<sup>2</sup>, F.S. Collins<sup>3</sup>, M. Boehnke<sup>1</sup>.* 1) Univ Michigan, Ann Arbor, MI; 2) University of Southern California, Los Angeles, CA; 3) National Human Genome Research Institute, Bethesda, MD; 4) National Public Health Institute, Helsinki, Finland; 5) Center for Inherited Disease Research, Baltimore, MD.

Dyslipidemia is a hallmark of metabolic syndrome and a common characteristic of type 2 diabetes mellitus (T2DM). Free-fatty acids (FFA) are thought to be a key component in the regulation of hepatic glucose output. As such, understanding the genes underlying the regulation of FFAs and other lipids may provide unique insights into the genetic predisposition for T2DM and related complex diseases. In the Finland-United States Investigation of NIDDM Genetics (FUSION) study, we analyzed fasting and 2-hour FFA levels from the oral glucose tolerance test and fasting lipids in the 491 non-diabetic offspring (age: 34.97.3, BMI: 25.94.3 (meanSD)) of a cohort of 201 families ascertained for T2DM affected sibling pairs. Mean fasting glucose and insulin were 5.00.5 mM and 65.732.8 pM, respectively. Mean fasting and 2-hr FFA levels were 0.45.14 mM and 0.17.05 mM. We estimated trait heritabilities ( $h^2$ ) and performed quantitative trait locus (QTL) linkage analysis by variance components.  $h^2$  for fasting FFA and 2-hr FFA were 0.13 and 0.30, respectively.  $h^2$  estimates for total, HDL, and LDL cholesterol, and triglycerides were 0.64, 0.34, 0.57, and 0.39, respectively.  $h^2$  estimates were not significantly altered when traits were adjusted for age, sex, and BMI. QTL linkage analysis for 2-hr FFA, adjusted for age, sex, and BMI, in a genome scan based on 392 microsatellite markers, yielded a LOD score of 1.94 on chromosome 22 near marker D22S428. The 2-hr FFA linkage signal overlaps with a previously identified region of strong FUSION T2DM association at and around D22S423 ( $p=.00002$ ) at 0.6 cM from D22S428. We currently are measuring 2-hr FFA levels in additional family members in an effort to identify the variant(s) responsible for T2DM risk and FFA variability in this region.

**A Utah Pseudo-Isolate: Proof of Concept using Longevity.** *N.J. Camp, J.M. Farnham, A. Thomas, L.A. Cannon-Albright.* Genetic Epidemiology, University of Utah School of Medicine, UT.

Utah was founded by Mormon pioneers in the mid 1800s. A Utah Population Database (UPDB) was developed based on genealogical records from descendants of these pioneers. Today the database contains genealogy data on ~2.8 million individuals linked to the Utah Cancer registry and Utah death certificates dating to 1904. For studies of complex disease a genetically homogeneous population is desirable. We investigated the potential of a Utah pseudo-isolate from which high-risk pedigrees for common traits could be ascertained for gene mapping. To create a Utah pseudo-isolate, we selected a set of founders and included all individuals descended only from these founders. To ensure enough chromosomes to allow for complex disease we chose a reasonably large number of founders (~38,000), which reduced the chromosomal diversity to ~12% of that for the full UPDB. This Utah pseudo-isolate contains approximately 280,000 individuals. To investigate whether this resource was useful for pedigree ascertainment, we investigated evidence for familiarity, clustering, and high-risk pedigrees in the pseudo-isolate for the example trait of longevity. We considered an age threshold of >100 yrs, as confirmed on a death certificate, to define longevity, and found 155 such individuals (compared to 359 in the full UPDB). Extremely significant excess familiarity was observed. Estimates of measures of familiarity were more extreme in the isolate than in the full UPDB. In the pseudo-isolate first degree relative risks of 5.9 (95% CI: 3.4, 9.6) and 3.2 (95% CI: 1.6, 5.7) were found for 1st and 2nd degree relatives, and 8.4 (95% CI: 3.3, 17.8) for parent-offspring. We identified 20 pedigrees containing at least 2 individuals older than 100 years. A definition of >95 yrs also yielded significant familiarity and 599 pedigrees. We chose a pedigree with 13 individuals >95 yrs and computed the expected number of individuals >95 yrs (2.65), which indicated a significant excess of longevity in the pedigree. Our preliminary findings confirm that a Utah pseudo-isolate has potential for ascertaining pedigrees with reduced genetic heterogeneity and excess risk to map genes involved in complex t.

Program Nr: 1144 from 2003 ASHG Annual Meeting

**Haploblocks, a software tool for visualization and analysis of haplotype blocks in the human genome.** *M. Zucchelli, J. Kere.* Department of Biosciences, Karolinska Institute, Huddinge, Sweden.

HaploBlocks is a software package for the visualization and the analysis of haplotype block structure in the human genome. Supported by a user friendly graphical interface, HaploBlocks computes different measures of linkage disequilibrium and visualizes them into 1D and 2D plots to graphically display the underlying block structure. A set of features has been developed to apply thresholds over allelic frequencies, smooth or shade linkage disequilibrium maps, zoom into particular regions and dynamically remove/insert markers. A dynamic programming algorithm is built in to decompose the DNA data into a set of continuous blocks and to extract the tagging SNPs and the haplotype patterns. In case/control studies Haploblocks computes both allelic and haplotype disease association in terms of odds ratios and their associated p-values by Fisher exact test. As an extra feature, Haploblocks can compare block structure as well as allelic and haplotype frequencies in different populations. Haploblocks accepts as input data both haplotypes and genotypes in standard linkage format. When genotypes are used, haplotype phase is reconstructed by using SnpHap. Haploblocks is programmed in C++ for platform compatibility and direct connection to NCBI database is under development. Applications to case/control studies with asthma and psoriasis data are shown as examples of the use of the tool.

Program Nr: 1145 from 2003 ASHG Annual Meeting

**Candidate Pathway Approach to Genetic Studies of Complex Traits.** *X. Zhou, JY. Zhao, FC. Arnett, MM. Xiong.*  
Inner Medicine, University of Texas, TX.

Traditional methods for genetic studies of complex traits is to investigate one or few genes at a time. However, Complex biology systems are not just the sum of their individual parts. The function of complex biological systems is carried out not only by genes, but also through various networks such as metabolic networks, genetic networks and protein networks, and their different level of organization. A comprehensive understanding of complex traits requires a novel conceptual framework for describing genetics of complex traits. As alternative method to candidate gene approach to mapping complex trait loci, candidate pathway approach to studying complex traits will be proposed. The test statistic for candidate pathway approach will be developed and the power for detecting candidate pathway which influencing complex traits will be investigated. The proposed methods will be applied to systemic sclerosis disease in native Americans.

**Widespread Purifying Selection at Polymorphic Sites in Human Protein-Coding Loci.** *M. Yeager*<sup>1</sup>, *B. Packer*<sup>1</sup>, *R. Welch*<sup>1</sup>, *A.W. Bergen*<sup>1</sup>, *S.J. Chanock*<sup>1,2</sup>, *A.L. Hughes*<sup>3</sup>. 1) Core Genotyping Facility, NCI/NIH, Gaithersburg, MD; 2) Section on Genomic Variation, Pediatric Oncology Branch, NCI/NIH, Bethesda, MD; 3) Department of Biological Sciences, University of South Carolina, Columbia SC.

Estimation of gene diversity (heterozygosity) can be informative in the investigation of molecular evolution. Analysis of 1442 single nucleotide polymorphism (SNP) loci mapped to 234 genes in an ethnically diverse sample of humans (N=102) revealed consistently reduced gene diversities at SNPs causing amino acid changes, particularly those causing amino acid changes predicted to be disruptive to protein structure. The statistically significant reduction of gene diversity at these SNPs, in comparison to SNPs in the same genes not affecting protein structure, is evidence that negative natural selection (purifying selection) has reduced the population frequencies of deleterious SNP alleles. This in turn suggests that slightly deleterious mutations are widespread in the human population and that estimation of gene diversity even in a sample of modest size can help guide the search for disease-associated genes.

**Associations of osseous dysplasias in Neurofibromatosis 1 (NF1).** *S.A. Alwan<sup>1</sup>, L. Armstrong<sup>2</sup>, P.H. Birch<sup>1</sup>, J.M. Friedman<sup>1</sup>.* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Eastern Ontario Genetics Program, The Childrens Hospital of Eastern Ontario, Ottawa, CANADA.

The most common sites of NF1-associated osseous dysplasia are the long bones (usually the tibia), vertebrae and sphenoid wing. Such lesions may cause profound clinical consequences, and available treatments are often unsatisfactory. The pathogenesis of osseous dysplasia and its relationship to short stature, a common feature in NF1 patients, are unknown. We examined associations between the occurrence of osseous lesions in 595 NF1 probands from the National NF Foundation International Database using logistic regression. After adjusting for age and gender, we found significant associations between the presence of long bone dysplasia and of dysplastic vertebrae (odds ratio [OR] = 1.9, 95% confidence interval [CI] = 1.0-3.6,  $p = 0.04$ ), the presence of long bone dysplasia and of sphenoid wing dysplasia (OR = 3.0, 95% CI = 1.5-6.2,  $p = 0.003$ ), and the presence of vertebral dysplasia and of sphenoid wing dysplasia (OR = 16.5, 95% CI = 5.6-48.6,  $p < 0.0001$ ). No significant association was found between the height of NF1 patients and the presence of either vertebral or long bone dysplasia. We conclude that some NF1 patients are more likely to develop osseous dysplasia than others and speculate that long bone dysplasia, vertebral dysplasia and sphenoid wing dysplasia in NF1 patients share a pathogenetic mechanism that differs from that responsible for NF1-associated short stature.

**Bone-related genetic markers and risk of osteoporotic hip fracture in Utah men and women.** *M. Willing<sup>1</sup>, R. Munger<sup>2</sup>, T. Beaty<sup>3</sup>, H. Wengreen<sup>2</sup>, N. West<sup>2</sup>, R. Cutler<sup>2</sup>, C. Corcoran<sup>2</sup>.* 1) Dept Ped, Div Medical Genetics, Univ Iowa, Iowa City, IA; 2) Dept Nutrition and Food Sciences, Utah State Univ, Logan, UT; 3) Dept Epidemiology, Johns Hopkins Univ, Baltimore, MD.

We examined associations between bone-related markers in candidate genes and risk of osteoporotic hip fracture in a population-based case-control study in Utah. Patients with hip fracture (cases) were ascertained via surveillance of Utah hospitals and were age-matched to controls. Genotypes for polymorphisms in the vitamin D receptor (VDR), estrogen receptor (ER), androgen receptor (AR), type I collagen genes (COL1A1 and COL1A2), osteonectin, osteopontin, and osteocalcin genes were obtained for 325 male and 789 female cases plus 443 male and 852 female controls. The VDR BsmI bb genotype was associated with a reduced risk of hip fracture in women (odds ratio (OR) = 0.77; 95 percent confidence interval (CI) = 0.63-0.94) but not in men. Three polymorphisms (PvuII, Xba I, and a TA repeat at the 5' end of the gene) in the ER gene were each significantly associated with fracture risk in women, but not in men. The polymorphic (AGC)<sub>n</sub> site in the AR gene showed no association with hip fracture risk in men or women. The SP1 polymorphism for COL1A1 (-/-) was associated with an increased risk of hip fracture in both men and women (OR = 1.61, 95% CI = 1.12-2.32); the COL1A1 RsaI, COL1A2 RsaI, and COL1A2 intron 12 VNTR polymorphisms showed no association with hip fracture risk in either men or women. The osteocalcin C/T promoter polymorphism (-/-) was associated with an increased risk in women (OR = 1.28, 95% CI = 1.05-1.57) but not in men. No associations were observed in either men or women for the tightly-linked osteocalcin marker, D1S3737, or the intragenic CA repeats in the osteopontin and the osteonectin genes. These findings provide evidence that polymorphisms in the VDR, ER, and osteocalcin genes are associated with risk of hip fracture in women and that the variation in the COL1A1 Sp1 gene is associated with greater risk of hip fracture in both men and women.

**Gender-mix and genetics: do they modify birth weight - IQ association?** *C. Derom<sup>1</sup>, E. Thiery<sup>2</sup>, R. Derom<sup>2</sup>, S. Van Gestel<sup>1</sup>, N. Jacobs<sup>1</sup>, R. Vlietinck<sup>1</sup>, J.P. Fryns<sup>1</sup>*. 1) Center for Human Genetics, Katholieke Universiteit Leuven, Leuven, Belgium; 2) Association for Scientific Research in Multiple Births, Belgium.

It is widely known that there is an association between birth weight and childhood IQ. The impact of genetic factors on this association can be determined through the investigation of birth weight and IQ in twins. Differences within dizygotic (DZ) pairs are a function of both genetic and non-genetic factors; differences within monozygotic (MZ) twin pairs are almost completely caused by non-genetic factors.

With the Wechsler Intelligence Scale for Children-Revised (WISC-R), IQ was measured in 596 twin pairs with different intra-pair birth weight. The twins (173 DZ same sex, 169 unlike sex, 254 MZ, aged 8-14 yrs) were selected at random from the East Flanders Prospective Twins Survey. Birth weight was obtained from the obstetrical record.

Comparison in MZ and same-sexed DZ twin pairs between co-twins with lowest and highest birth weight showed no significant association between birth weight and IQ. In male DZ pairs the association was suggestive but not significant. In contrast, the same comparison in opposite-sexed twin pairs resulted in a significant association ( $p=0.02$ ). The effect is more pronounced when the female co-twin is heavier than her twin brother: her mean IQ (105,1) is significantly higher than that of female co-twins with lowest birth weight (IQ 99,6) and significantly higher than the mean IQ of same-sexed female DZ co-twins, whether of highest (IQ 99.2) or lowest (IQ 100.1) birth weight.

These results are very suggestive for a gender-mix effect mediating the association between birth weight and IQ. As co-twins are the same age and share influences such as prenatal factors, parental age and smoking, socio-economic status, parity and gestational age, the influence of these possible confounders is negligible.

**Association of the DRD2 141 Indel Polymorphism with Anorexia Nervosa.** *A.W. Bergen<sup>1,2</sup>, M. Yeager<sup>1,2</sup>, R. Welch<sup>1,2</sup>, K. Haque<sup>1,2</sup>, J.K. Ganjei<sup>1</sup>, C. Mazzanti<sup>3,4</sup>, I. Nardi<sup>3</sup>, M.B.M. van den Bree<sup>1,5</sup>, M. Fichter<sup>6</sup>, K. Halmi<sup>6</sup>, A. Kaplan<sup>6</sup>, M. Strober<sup>6</sup>, J. Treasure<sup>6</sup>, B. Woodside<sup>6</sup>, C.M. Bulik<sup>6</sup>, S.-A. Bacanu<sup>7</sup>, B. Devlin<sup>7</sup>, W. Berrettini<sup>6,8</sup>, D. Goldman<sup>9</sup>, W.H. Kaye<sup>6,7</sup>.* 1) Biognosis U.S., Inc., Gaithersburg, MD (Dissolved); 2) Currently at: Core Genotyping Facility, NCI, Gaithersburg, MD; 3) University of Pisa, Pisa, Italy; 4) Currently at: Surgery Branch, CCR, NCI, Gaithersburg, MD; 5) Currently at: Division of Psychological Medicine, University of Wales, Cardiff, UK; 6) Price Foundation Collaborative Group ([www.anbn.org](http://www.anbn.org)); 7) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA; 8) Center for Neurobiology and Behavior, University of Pennsylvania, Philadelphia, PA; 9) Laboratory of Neurogenetics, NIAAA, Rockville, MD.

To investigate whether the dopaminergic system plays a role in the etiology of anorexia nervosa (AN) via the dopamine D2 receptor, we investigated association and transmission disequilibrium at seven single nucleotide polymorphisms (SNPs) spanning about 75kb of the gene DRD2. We studied 183 probands with a DSM-IV diagnosis of AN, 457 parents and affected relatives with a DSM-IV eating disorder diagnosis, and 92 unrelated, female, normal weight controls. The -141 C/- insertion/deletion (-141 Indel) polymorphism, previously shown to affect DRD2 transcription efficiency, exhibited statistically significant association with diagnosis in a wide array of analyses: both genotype and allele distributions differed significantly between AN probands and normal weight control individuals; the insertion C allele, which appears to increase expression of D2, is transmitted from parents to their affected offspring at rates significantly greater than that expected by chance; and haplotypes containing the insertion C allele and other SNP variants show even greater transmission distortion. Linkage disequilibrium between the -141 Indel and two exon 7 SNPs was observed over a distance of >50kbp in the AN probands but not in the controls. Genetically transmitted variation in D2 dopamine receptor expression appears to play a role in vulnerability to AN.

This abstract does not represent the opinion of the NIH or the Federal Government.

**Variability in white matter hyperintensity volume in men associated with a polymorphism in the NOTCH3 gene: The Framingham Heart Study.** *A.L. DeStefano*<sup>1,2</sup>, *P.A. Wolf*<sup>2</sup>, *S. Karamohamed*<sup>2</sup>, *A. Beiser*<sup>1</sup>, *L.A. Atwood*<sup>1,2</sup>, *J.M. Massaro*<sup>3</sup>, *R.B. D'Agostino*<sup>3</sup>, *C. DeCarli*<sup>4</sup>, *A. Herbert*<sup>2</sup>. 1) Dept Biostatistics, Boston Univ Sch Public Health, Boston, MA; 2) Dept Neurology, Boston Univ Sch Public Health, Boston, MA; 3) Dept Mathematics and Statistics, Boston Univ, Boston, MA; 4) Dept Neurology and Center for Neuroscience, Univ California at Davis, Sacramento, CA.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a hereditary syndrome characterized by stroke, dementia and diffuse white matter hyperintensity (WMH) present on brain magnetic resonance imaging scans. Mutations in the NOTCH3 gene, a membrane bound ligand in the WNT signaling pathway cause CADASIL. Most CADASIL mutations map to the extracellular domain of the protein. Other NOTCH3 polymorphisms may exist and their role cerebrovascular disease is unknown. We tested 10 single nucleotide polymorphisms (SNPs) in the NOTCH3 gene for association with WMH volume relative to total cranial volume in 952 unrelated stroke-free, dementia-free individuals from the NHLBI Framingham Heart Study. Multiple linear regression was used to evaluate genotypic effects, after adjusting for covariates, including age at MRI, age at MRI squared, and sex. In the total sample including both men and women no association was detected between any of the SNPs considered and WMH relative to total cranial volume, after adjustment for multiple comparisons. Analysis of men revealed significant association with SNP rs1548555 (nominal  $p = .01$ ; adjusted for multiple comparisons  $p = .043$ ). Assuming a dominant model, men with at least one A allele had a significantly higher percent WMH relative to total cranial volume (.0530 %) compared to men with the GG genotype (.0425 %) ( $p = .025$ ). No significant associations were detected in women. SNP rs1548555 in the NOTCH3 gene or a polymorphism in disequilibrium with this SNP is associated with increased WMH in men. Additional variants in this gene are being explored.

**Charcot Marie Tooth (CMT) disease: A founder effect of the R298G mutation in LMNA gene in Algeria and Morocco.** *G. Durosier<sup>1</sup>, H. Azzedine<sup>1</sup>, M. Tazir<sup>2</sup>, N. Birouk<sup>3</sup>, E. Genin<sup>4</sup>, D. Ente<sup>1</sup>, A. Bouhouche<sup>3</sup>, G. Stevanin<sup>1</sup>, D. Grid<sup>5</sup>, A. Brice<sup>1</sup>, E. Le guern<sup>1</sup>.* 1) INSERM U289-NEB, Neurogenetics, Hopital de la Salpetriere, Paris, France; 2) Service de Neurologie, Hopital Mustapha, Algiers, Algeria; 3) Service de Neurologie, Hopital des specialites, Rabat, Morocco; 4) INSERM U535, Hopital du Kremlin Bicetre, Paris, France; 5) BTR-AFM-Genethon, Paris, France.

Charcot Marie Tooth (CMT) disease is a pathological and genetic heterogeneous group of hereditary motor and sensory neuropathies. Two major types have been distinguished: demyelinating and axonal CMT. Only 3 loci account for axonal Autosomal Recessive (AR) CMT on chromosomes 1q21 (CMT2B1/1A), 8q13 (CMT4A) and 19q13 (CMT2B). Recently, the R298G mutation in the LMNA gene was reported on patients with CMT2B1 disease. We selected 60 consanguineous families with axonal ARCMT and perform a GeneScan on 15 microsatellites markers covering the 1q21 locus. Sequencing of the LMNA gene was performed in all the families with putative linkage to 1q21. In these families, the R298G mutation was predominant (74 %), highly suggesting a founder effect in North Africa. Indeed, a common haplotype with flanking markers segregated in these families. The R298G mutation found in the LMNA, is probably the result of a founder effect in North Africans. A computational analysis using the appropriate software's will be used to date the mutation. In the other hand, given the high frequency of R298G mutation in this population, it is therefore worth searching this mutation in families with positive linkage to the corresponding region. The Finalized results will be presented durind the meeting.

**Parkin mutations found in Louisiana Parkinson disease patients but not in those of Acadian ancestry. G.**

*Gaikwad<sup>1</sup>, J. Rao<sup>2</sup>, B.J. Keats<sup>1</sup>*. 1) Department of Genetics, Louisiana State University, New Orleans, LA; 2) Department of Neurology, Louisiana State University, New Orleans, LA.

Parkinson disease is a neurodegenerative disorder in which the motor function deficits are due to lesions in the basal ganglia, especially the substantia nigra. Both environmental and genetic factors contribute to the phenotype. In particular, various deletions and point mutations in the parkin gene on chromosome 6q have been reported in patients with onset of Parkinson disease before 50 years of age. Through the Parkinson disease clinic at LSUHSC we have ascertained 22 patients of Acadian ancestry and 87 non-Acadians. Of the 22 Acadian patients, 9 have affected relatives. The goal of this study is to identify susceptibility loci in Acadian families. We have sequenced exons 1-12 of the parkin gene to identify any deletions or point mutations that may be present in the 109 patients. No deletions or point mutations were detected in the 22 Acadian patients. These results indicate that mutations in the parkin gene are not associated with Parkinson disease in the Acadian population, and we are undertaking a genome screen to localize susceptibility genes in this population. However, point mutations were found in two of the non-Acadian patients. A novel missense mutation (Pro37Leu) in exon 2 was found in one patient. This mutation has not been found in any controls and we are checking affected and unaffected family members for the presence of this mutation. A previously reported mutation (Pro437Leu) in exon 12 was found in a patient with Parkinson disease and essential tremors. This patient has relatives with Parkinson disease and essential tremors, which had not previously been reported in patients with this mutation. We are examining other family members to determine if this mutation is associated with both phenotypes. Our results suggest that the Pro437Leu mutation may predispose individuals to both Parkinson disease and essential tremors, and may shed light on the earlier controversy concerning association between these two common movement disorders.

**Hospital-based survey for family history in multiple system atrophy.** *Y. Momose<sup>1</sup>, J. Goto<sup>2</sup>, M. Murata<sup>2</sup>, S. Tsuji<sup>2</sup>.*  
1) Dept Clinical Bioinformatics, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 2) Dept Neurology, Grad Sch Med, Univ Tokyo, Tokyo, Japan.

Multiple system atrophy (MSA) is an adult-onset, progressive neurodegenerative disorder characterized clinically by various combinations of autonomic failure, cerebellar symptoms, parkinsonism and pyramidal signs. MSA has been regarded to be a sporadic disease because familial occurrence has not been detected. Recent studies, however, suggest families in which multiple members were affected with pathologically-proven MSA. These studies raise the possibility that genetic factors are involved in the pathogenesis of MSA. To evaluate genetic components in MSA, we conducted a hospital-based survey on clinical genetics of MSA. Through the survey of consecutive medical records of patients who were admitted to University of Tokyo Hospital (1981 May 2003), we identified 87 patients with the clinical diagnosis of MSA (5 definite, 63 probable, and 19 possible cases) who satisfied the diagnostic criteria (except for the item of family history) for MSA formulated by the Consensus Committee of American Autonomic Society and the American Academy of Neurology. We identified a pedigree of familial MSA. There is no consanguinity. The proband was referred to our hospital because of progressive autonomic, cerebellar, pyramidal and extrapyramidal symptoms and his sister has also suffered from autonomic symptoms and parkinsonism refractory to l-dopa with MRI findings compatible with MSA. Although MSA has been regarded as a sporadic neurodegenerative disease, the present studies suggest involvement of genetic components in MSA. Identification of additional familial cases of MSA should provide important clues as to the pathogenetic mechanisms of MSA.

**Comprehensive analysis of candidate modifier genes for multiple sclerosis (MS) on chromosome 19q13.** *J.L. Haines<sup>1</sup>, S. Schmidt<sup>2</sup>, S. Sawcer<sup>3</sup>, L.F. Barcellos<sup>4</sup>, S.G. Gregory<sup>2</sup>, J. Sims<sup>2</sup>, M. Booze<sup>2</sup>, J.M. Vance<sup>2</sup>, J.R. Oksenberg<sup>4</sup>, S.L. Hauser<sup>4</sup>, A. Compston<sup>3</sup>, M.A. Pericak-Vance<sup>2</sup>.* 1) Vanderbilt University Medical Center, Nashville, TN; 2) Duke University Medical Center, Durham, NC; 3) Cambridge University, Cambridge, UK; 4) University of California, San Francisco, CA.

We previously reported an effect of the apolipoprotein E (APOE) locus on progression of MS, with the APOE-4 allele associated with a more severe disease course, and the APOE-2 allele associated with mild MS. While the APOE polymorphism may be the causal variant influencing MS expression, the results could also be due to linkage disequilibrium (LD) of APOE alleles with one or more causal variants in another gene. The APOE region harbors several other candidate genes for MS expression, including the poliovirus receptor (PVR), the poliovirus receptor-related gene (PRR2), and a gene coding for an outer mitochondrial membrane protein (TOMM40). To date, we have genotyped a total of 27 SNPs in a 1 Mb interval around APOE in an effort to identify the most likely functional variant. Association signals of similar strength ( $p=0.003$  to  $0.007$ ) with MS severity, but not MS risk, were observed for variants in TOMM40 and APOE, but not PVR and PRR2. To test this association and further resolve the localization, we genotyped an additional 780 MS parent-child trios evaluated using similar diagnostic criteria. Our combined data set of almost 1500 MS patients and their family members is the largest one available for examining MS modifier genes on chromosome 19q13. Preliminary data strengthen the association of mild MS with APOE-2 is ( $p=0.001$ ), but not the association of severe MS with APOE-4 ( $p=0.43$ ). Genotyping of TOMM40 and APOE promoter SNPs is in progress for additional single-locus and haplotype-based analyses.

**The serotonin transporter polymorphism, 5HTTLPR, is associated with a faster response time to sertraline in an elderly population with Major Depressive Disorder.** *S.M. Webb<sup>1</sup>, L.K. Durham<sup>2</sup>, P.M. Milos<sup>1</sup>, C.M. Clary<sup>3</sup>, A.B. Seymour<sup>1</sup>.* 1) Genomic and Proteomic Sciences, Pfizer, Groton, CT; 2) Nonclinical Biostatistics, Pfizer, Groton, CT; 3) Clinical Development, Pfizer, New York, NY.

A common polymorphism (5HTTLPR) within the promoter region of the serotonin transporter gene (SLC6A4) has been shown to influence response time to paroxetine in elderly depressed and overall response to fluoxetine in younger subjects with major depressive disorder (Pollock et al., 2000; Smeraldi et al., 1998). Based on these findings we hypothesized that a similar effect in response time to sertraline would be observed and that no effect would be seen in a placebo arm. We tested the hypothesis that subjects homozygous for the Long allele (LL) at 5HTTLPR would respond more rapidly to sertraline than subjects carrying one or two copies of the Short allele (SS/LS). LL subjects showed a significant increase in response at weeks 1 and 2 as assessed by the CGI-I scale compared with SS/LS subjects. No significant difference was observed in the placebo group. These results suggest that genetic variation in the serotonin transporter gene affects the response time to sertraline and provides complementing evidence to previous reports that this polymorphism affects response time to other SSRIs.

**Cohort and age of onset analysis of female breast cancer in non-Spanish surnamed Whites and three Asian ethnic groups in Los Angeles County, from 1975 to 1999.** *B.A. Corey<sup>1</sup>, J. Setyawati<sup>2</sup>, Y.F. Yu<sup>2</sup>, J.N. Weitzel<sup>1</sup>*. 1) Clinical Cancer Genetics, City of Hope Medical Center, Duarte, CA; 2) Univ of Southern California, School of Pharmacy, Dept. of Pharmaceutical Economics and Policy, Los Angeles, CA.

Rates of cancer are subject to cultural factors. As immigrant groups become assimilated to lifestyle in the United States their rates of breast cancer alter from that of their native lands. Of interest is the population of Asian women living in Los Angeles County who traditionally have low rates of breast cancer. Utilizing data collected on 115,436 subjects by the Cancer Surveillance Program of Los Angeles County from 1975 to 1999, we describe the epidemiology of female breast cancer in four population groups through cohort analysis and analysis of age at diagnosis. Cohort analysis was carried out in non-Spanish surnamed whites (NSSW) and 3 Asian ethnic groups: Chinese, Filipino and Japanese. Age cohorts were selected at 20-year intervals and their age-specific incidence of breast cancer was followed from 1975 to 1999. Age at diagnosis of ductal, lobular and medullary neoplasms and of all histologies were analyzed for proportion of breast cancers diagnosed prior to menopause. In cohort analysis, the youngest cohort of each group (age 45-49) showed increased incidence of breast cancer compared to women of the same age from the preceding cohort. Youngest cohorts of Japanese and Filipinos showed a faster rate of increase in breast cancer incidence relative to Chinese and were similar to NSSW. Proportion of diagnoses before 50 years of age was greatest in Chinese and Filipino women (> 40%), intermediate in Japanese women (28.5%) and lowest in NSSW women (19%). The data show increasing rates of breast cancer, and a higher proportion of early onset disease in Asians compared to NSSW, and suggest that mammography should be considered at an earlier age for Asian women. Supported (in part) by the National Cancer Institute Grant #R25 CA85771.

**Genotyping of colorectal cancer patients to genotypically define clinical outcomes and phenotypic features. E.**

*Friedman<sup>1,3</sup>, S. Starinsky<sup>1,3</sup>, R. Geva<sup>2</sup>, A. Figer<sup>2,3</sup>.* 1) Oncogenetics Unit, Inst Gen, Chaim Sheba Medical Ctr, Tel Hashomer, Israel; 2) The Oncology Institute, Elias Sourasky Medical Center, Tel-Aviv, Israel; 3) The Sackler School of Medicine, Tel-Aviv University, Ramat Aviv, Tel-Aviv, Israel.

Colorectal cancer (CRC) is the fourth most common cancer and the lifetime risk for developing CRC is 3-5% in the general population. Clinical outcome and therapeutic response is highly dependent on disease stage, tumor invasion, and tumor size and site. Yet it is likely that genetic factors play a major role in determining the clinical outcome and therapeutic response of CRC patients. In order to gain insight into this issue, we genotyped 456 consecutive Israeli patients with histopathologically confirmed CRC, who were unselected for family history of cancer, for 17 single nucleotide polymorphisms (SNPs) or missense mutations in 12 candidate genes: APC, beta-catenin, K-RAS, DCC, P16, PTEN, RB1, P15, APOE, ERCC2, P53, hMSH2. Correlation with disease outcome parameters, tumor location, stage and grade, was carried out by applying the chi test, determining the Hardy Weinberg equilibrium, Armitage trend test, and the Kaplan Meir test for survival. For the entire patient population, a statistically significant association between a SNP in the APC gene and age at diagnosis was shown ( $P_{\text{genotype}}=0.0595$ ), beta-catenin and APOE SNPs and the existence of a positive family history of cancer (beta-catenin:  $PHWE=0.013269$ ,  $P_{\text{genotype}}=0.034$ , APOE:  $P_{\text{genotype}}=0.033$ ), and P53 R72P mutation and overall survival ( $P_{\text{Kaplan Meier}}=0.0336$ ). In analysis of the Ashkenazim, phenotypic features that were significantly associated with a specific genotype: ERCC2 SNP and the C677T polymorphism in the MTHFR gene with age at diagnosis above or below 50 years (ERCC2:  $P_{\text{alleles}}=0.025$ ,  $P_{\text{Armitage trend}}=0.03$ , MTHFR:  $P_{\text{genotype}}=0.0005$ ); A P53 intron 3 polymorphism and APOE SNP, were significantly associated with having a family history of colon cancer (P53:  $P_{\text{alleles}}=0.022$ ,  $P_{\text{genotype}}=0.034$ ,  $P_{\text{Armitage trend}}=0.016$ , APOE:  $P_{\text{alleles}}=0.049$ ,  $p_{\text{genotype}}=0.04$ ). The results of this preliminary study show that genetic factors do play a role in determining CRC phenotype.

**Analysis of AGTR1 gene in a non-hypertension population sample from Amazon-Brazil.** *L. Dolinsky*<sup>1, 2</sup>, *S. Roig*<sup>3</sup>, *M. Boia*<sup>4</sup>, *P. Cabello*<sup>3</sup>, *R. Moura-Neto*<sup>1</sup>. 1) Dept Gen, Inst de Biologia, Univ Fed do Rio de Janeiro, Rio de Janeiro, Brazil ; 2) Dept Biociências, Unigranrio, Rio de Janeiro, Brazil; 3) Dept Gen, Fundação Oswaldo Cruz, Rio de Janeiro, Brazil; 4) Medicina Tropical, Fundação Oswaldo Cruz, Rio de Janeiro, Brazil.

Cardiovascular diseases are the main important public health problem in Brazil with almost 25% of the Brazilian population having high blood pressure and mortality rate around 32%. Due to the high incidence of cardiovascular diseases in Brazil we studied a gene (AGTR1) of the renin angiotensin system, one of the most important in the maintenance of cardiovascular homeostasis. AGTR1 has a genetic polymorphism (A1166C) which is associated with essential high blood pressure, especially in pregnant women. In this work we compared two different populations for AGTR1 polymorphism: one from the North of Brazil (Amazon), with no hypertension individuals, and a control population. Our goal here is to verify if there are allelic frequency differences between these two samples, excluding pregnant women. To analyse 100 individuals per population we used PCR reaction followed by DdeI digestion. Genotype and allelic frequency, and statistical analysis were done using Genetic Data Analysis software.

Populations showed no deviation from Hardy-Weinberg equilibrium, but showed significant differences between allelic frequencies ( $\chi^2= 9.17$ ,  $p=0.0062$ ). These data corroborate the notion that C allele polymorphism from AGTR1 gene is associated with high blood pressure even when pregnant women were excluded from the analysis.

**Combined tests of linkage and association of 4 SNPs in the FXIII A-subunit gene to FXIII activity levels.** *M. de Lange*<sup>1</sup>, *T. Andrew*<sup>1</sup>, *H. Snieder*<sup>1,3</sup>, *R.A.S. Ariëns*<sup>2</sup>, *M. Stickland*<sup>2</sup>, *P.J. Grant*<sup>2</sup>, *T.D. Spector*<sup>1</sup>. 1) Twin Research Unit, St Thomas' Hospital, London, UK; 2) Academic Unit of Molecular Vascular Medicine, Leeds General Infirmary, Leeds, UK; 3) Georgia Prevention Institute, Department of Pediatrics, Medical College Georgia, Augusta GA, USA.

**Background.** Activated factor (F) XIII cross-links fibrin and thereby enhances the mechanical strength of a clot and increases the resistance to fibrinolysis. The prevalence of a common point mutation in the FXIII A-gene (FXIII Val34Leu) was lower in patients with MI than those without, suggesting a protective role of this polymorphism. This linkage and association study using several SNPs within the FXIII A-subunit gene aims to locate the functional polymorphism.

**Methods.** A total of 201 dizygotic twin pairs were genotyped for 4 SNPs in the FXIII A-subunit gene (FXIII -246 G/A, FXIII Val34Leu, FXIII 564 C/T and FXIII 651 G/C) and used for tests of linkage, association and combined linkage and association using QTDT software.

**Results.** Significant linkage of FXIII activity was shown to the SNPs Val34Leu ( $p=5.10^{-12}$ ) and 651 G/C ( $p=0.03$ ), but not for -246 G/A ( $p=0.18$ ) or 564 C/T ( $p=0.09$ ). Also, significant association was shown for -246 G/A ( $p=4.10^{-6}$ ), Val34Leu ( $p=3.10^{-49}$ ) and 564 C/T ( $p=0.001$ ), but not for 651 G/C ( $p=0.72$ ). Linkage in the presence of association only showed a drop in fit for the FXIII Val34Leu polymorphism (from  $\chi^2=47.55$ ,  $p=5.10^{-12}$  to  $\chi^2=1.30$ ,  $p=0.25$ ), indicating that this locus is either the functional polymorphism or in strong linkage disequilibrium with the genetic variant. No drop in fit was observed for FXIII 651 G/C. No linkage or association was detected for any of the SNPs to levels of FXIII A-subunit or FXIII B-subunit.

**Conclusion.** The results of this linkage and association test of multiple SNPs in the FXIII A-subunit gene indicate that the FXIII Val34Leu polymorphism is (close to) the functional polymorphism influencing FXIII activity.

**Frequency of PvuII (LPL) genetic polymorphism in patients with Arterial Coronary Disease from Mexican population.** *L. Arnaud Jr<sup>1,2</sup>, M.P. Gallegos<sup>2</sup>, R.P. Mariaud<sup>1,2</sup>, L.J. Ramirez<sup>1,2</sup>, L.E. Figuera<sup>3</sup>, A.J. Ventura<sup>4</sup>, R. Gaxiola<sup>5</sup>, T.J. Beltran<sup>2</sup>, G.M. Zuniga<sup>2</sup>.* 1) Doctorado en Genetica Humana, UDG; 2) Division de Medicina Molecular, CIBO; 3) Division de Genetica Molecular, CIBO; 4) Servicio de Cardiologia; 5) Servicio de Epidemiologia, HE, CMNO, IMSS, Guadalajara, Jalisco.

**INTRODUCTION:** The Arterial Coronary Disease is the principal cause in morbidity and mortality in the world. It is considered a multifactorial disease. In the development of the ACD influence genetics and environmental factors. Between the risk factors most important is find abnormalities in the lipids metabolism whose provide correlation with ACD. Some studies have described the PvuII polymorphism association between gene Lipoprotein Lipase (LPL) and ACD, even so this association is contradictory in others parts of the world. This association is unknown in Mexican population. **OBJECTIVE:** To determine the genotypic frequency of PvuII polymorphism in the gene LPL in case-control study in Mexican population with Arterial Coronary Disease. **MATERIAL AND METHODS:** In this study, genomic DNA from 59 ACD patients and 46 controls were genotyped. Analysis of PvuII polymorphism was done by PCR amplification of a segment of 430 bp witch is localized in the intron 6 of the LPL gene in the chromosome 8. This has a recognition site for the PvuII restriction enzyme followed by PAGE at 6% and stained with silver nitrate. Genotypes were identified as A1/A1 (430bp), A2/A2 (218 and 212 bp). **RESULTS:** The presence of the A1/A1 genotype was identified in 43.5% of the controls and 17.8% of the patients with ACD, whereas 21.7% of the controls and 29.7% of the cases were homozygous A2/A2. Statistical difference was found when both group were compared ( $p < 0.05$ ). **CONCLUSIONS:** It was clear an increased frequency of allele A2 in patients group as in other parts of the world, this could demonstrate the contribution to the pathogenesis of the ACD.

**Association of apolipoprotein B signal peptide polymorphism in patients with myocardial infarction from**

**Mexican population.** *M. Gallegos Sr<sup>1</sup>, Y. Valdez<sup>1</sup>, L.E. Figuera<sup>2</sup>, A. Ventura<sup>3</sup>, F. Pérez<sup>3</sup>, T.J. Beltrán<sup>4</sup>, M.R. Arechavaleta<sup>5</sup>, L. Arnaud<sup>1</sup>, R.P. Mariaud<sup>1</sup>, G.M. Zuñiga<sup>1</sup>.* 1) División de Medicina Molecular, CIBO, IMSS; 2) División de Genética, CIBO, IMSS; 3) Departamento de Cardiología; 4) Departamento de Urgencias; 5) Departamento de Endocrinología, HE, CMNO, IMSS, Guadalajara, Jalisco, Mexico.

The three amino acid insertion/deletion (I/D) polymorphism in the apoB signal peptide (27 amino acids versus 24 amino acids signal peptide) was evaluated as a possible risk factor for myocardial infarction (MI) in a case-control study, population comprising 114 MI patients and 132 controls. In controls, homozygotes for the deletion allele (D/D) had the highest average levels of both total cholesterol and low density lipoprotein cholesterol, the homozygotes for the insertion allele (I/I) had the lowest average values, while the heterozygotes (I/D) had intermediate average levels. In MI patients, the trend was similar with no differences statistically significant were observed. However statistically differences in genotype frequencies (genotypes D/D in controls 0.09 and cases 0.29, I/I 0.42 in controls and 0.34 in cases and I/D 0.49 in controls and 0.37 in cases) were detected between cases and controls ( $p < 0.05$ ). Several studies have shown that the frequency of D/D is higher in hyperlipidemic than in normolipidemic groups. This marker is probably in linkage disequilibrium with some other atherogenic gene(s). Our study shows that differences, in both apoB signal peptide alleles and D/D and I/D genotypes distributions, are statistically significant ( $p < 0.05$ ). This marker had probably a predictive value in patients with IM in our populations.

**Heritability of Venous Function in Humans.** *A. Busjahn*<sup>1</sup>, *M. Brinsuk*<sup>2</sup>, *J. Tank*<sup>2</sup>, *F.C. Luft*<sup>2</sup>, *J. Jordan*<sup>2</sup>. 1) HealthTwiSt GmbH, Berlin, Germany; 2) Franz-Volhard Zentrum fuer Herz-Kreislaufforschung, Charité, Berlin, Germany.

**Introduction:** Venous function contributes to the pathogenesis of thrombophlebitis, venous thrombosis, and possibly to orthostatic intolerance. Venous disease is highly heritable; however, the genetic variance of venous function is unknown.

**Methods:** We determined the heritability of venous function in 46 twin pairs (24 monozygotic, age 35+/-11 yrs, 14 men, 34 women, and 22 dizygotic, age 30+/-8 yrs, 19 men, 25 women). All studies were conducted in the morning hours. After a resting phase in the supine position, we determined venous function in both legs by impedance plethysmography. Venous capacity was determined by a standardized protocol. In addition, we obtained venous pressure volume curves by slowly deflating a thigh cuff from 60 to 0 mmHg. Venous compliance was determined by linear regression analysis at the steepest part of the venous pressure volume curve. Heritability (h) was estimated using a path modeling approach.

**Results:** Venous capacity was 6+/-2.2 ml/100ml in monozygotic twins and 5.1+/-2.3 ml/100 ml in dizygotic twins. Venous compliance was 0.24+/-0.14 %/mmHg in monozygotic twins and 0.18+/-0.12 %/ mmHg in dizygotic twins. Unadjusted heritability (h<sup>2</sup>) was 0.6 (p<0.05) for venous capacity and 0.9 (p<0.05) for venous compliance. The heritability estimates remained essentially unchanged after adjustment for gender and age.

**Conclusions:** Venous function is strongly influenced by genetic factors. The genes involved may influence venous disease states. Moreover, they may contribute to variability in orthostatic tolerance. Currently we extend the dataset and initiate candidate gene studies.

**Association analysis of  $\alpha_2$ -adrenoceptor haplotypes with essential hypertension in White and Black Americans. X.**

*Bao*<sup>1</sup>, *A. Joyner*<sup>1</sup>, *P. Mills*<sup>3</sup>, *J. Dimsdale*<sup>3</sup>, *P. Cadman*<sup>2</sup>, *F. Rao*<sup>2</sup>, *B.K. Rana*<sup>3</sup>, *N. Schork*<sup>3</sup>, *D. O'Connor*<sup>2</sup>, *M. Ziegler*<sup>1</sup>. 1) Medicine, UCSD Medical Center, San Diego, CA; 2) Nephrology and Hypertension, UCSD VA Medical Center, San Diego, CA; 3) Psychiatry, UCSD Medical Center, San Diego, CA.

To investigate the relevance of genetic variants in  $\alpha_2$ -adrenergic receptor (ADRB2) to essential hypertension, 11 single-nucleotide polymorphisms (SNPs) in the promoter and coding region of ADRB2 gene were genotyped in an unrelated population (356 hypertensives, 665 normotensives). Using a maximum likelihood method, 12 haplotypes out of the theoretically  $2^{11}$  (=2048) possible combinations were found distributed divergently in Caucasian (n=659) and African-American (n=362) groups ( $p < 0.0001$ ). In the Caucasian group, three common haplotypes accounted for 96% of all haplotypes. They were analyzed as six haplotype pairs (diplotypes). African-Americans had more diversity in ADRB2 gene with five common haplotypes and 11 diplotypes accounting for 95% of all haplotypes. Mean lymphocytes  $\alpha_2$ -adrenergic receptor density and the low frequency spectrum of heart rate variability were significantly related to diplotype ( $P < 0.01$ ) but not to a single haplotype or individual SNPs in Caucasians. In both White and Black groups, the frequency of individual SNPs and haplotypes as well as diplotypes did not differ overall between the hypertensive and the normotensive. However, the diplotype frequency did differ by post hoc analysis among young Caucasians (age < 40,  $p < 0.05$ ). The diplotypes were related to a family history of hypertension in African-Americans ( $p < 0.05$ ). These results suggest important interactions of multiple SNPs within a haplotype and between haplotypes. We did not confirm prior reports of a relationship between individual SNPs and hypertension among Caucasians, but there may be a relationship between diplotype and hypertension among young Caucasians.  $\alpha_2$  adrenergic diplotype did relate to a family history of hypertension among African-Americans.

**High-throughput genotyping for identification of genes underlying coronary heart disease: Cumulative perspective from 222 polymorphisms in 111 candidate genes.** *J.J. McCarthy<sup>1</sup>, A. Parker<sup>2</sup>, D.J. Moliterno<sup>3</sup>, W.J. Rogers<sup>4</sup>, L.K. Newby<sup>5</sup>, R. Cannata<sup>3</sup>, K. Glatt<sup>2</sup>, E.J. Topol<sup>3</sup>, The GeneQuest Investigators.* 1) GSPH, San Diego State University, San Diego, CA; 2) Millennium Pharmaceuticals, Inc., Cambridge, MA; 3) Cleveland Clinic Foundation, Cleveland, OH; 4) University of Alabama Medical Center, Birmingham, AL; 5) Duke University, Durham, NC.

**BACKGROUND AND METHODS:** Widespread access to SNPs has facilitated genetic association studies of coronary artery disease (CHD) on a large scale. Here we present data for 222 common SNPs in 111 candidate genes typed in 352 Caucasians with familial, premature CHD (onset <45 males, <50 females) and 418 Caucasian population controls. Genotype frequencies were compared between cases and controls using logistic regression. **RESULTS:** SNPs in 30 genes previously associated with CHD were evaluated in our study and significant ( $p < 0.05$ ) associations were found in the following: APOE, CYBA, F7, FGB, GP1BA, IL1RN, MTHFR, F2, F5 and SELP. In addition, novel associations were found with SNPs in 13 genes: ANXA4, ECE1, HRG, LRP1, PAI2, PLCG1, PLOD2, PROC, SDC4, THBS1, THBS2, THBS4, THPO. The most significant CHD association was found with FGB R478K ( $p < 0.0005$ ), one of four tightly linked SNPs, along with 455G/A, -655G/A and S189S, in the Beta Fibrinogen gene for which genetic associations with CHD have been previously described. Individuals who carried the K allele were at decreased odds of CHD (OR 0.59; 95% CI 0.41, 0.85), even after adjusting for age, gender, diabetes, hypertension and body mass index and population stratification. Restricting the cases to those with MI enhanced many associations, the strongest being with THBS4 A387P ( $p < 0.004$ ) where presence of the variant allele increased odds of MI. We also identified a region of strong linkage disequilibrium on 1q22-q25 that spans a number of candidate genes including F5, SELP and SELL. **CONCLUSIONS:** Despite concerns regarding false positives from multiple testing, and false negatives, from incomplete assessment of SNPs, large-scale association analysis can be an effective means of hypothesis generation and offers a complementary strategy to classic linkage studies of the genetic basis of CHD.

**A Comprehensive Analysis of a Missense Mutation in the Rho-kinase Gene that Potentially Causes Coronary Vasospastic Ischemic Heart Disease in the Japanese.** *H. Kamiunten, G. Koike, J. Mashiba, H. Shimokawa, A. Takeshita.* Cardiovascular medicine, Kyushu University, Fukuoka, Fukuoka, Japan.

**Background** Coronary vasospasm is one of the major causes of ischemic heart disease (IHD) and its prevalence is known to be higher in the Japanese than that in the western population. We have shown that Rho-kinase (also known as ROCK2) plays a crucial role in coronary vasospasm in humans. However, the genetic impact of Rho-kinase gene variation on coronary vasospasm remains to be examined. **Methods and Results** We have recently identified a novel single nucleotide polymorphism (SNP), G930T (K310N), in the catalytic domain of Rho-kinase. Japanese patients with IHD (n=215) and Caucasian ones from the ENCORE I trial (n=318) were genotyped for the Rho-kinase SNP and also for additional 4 polymorphisms of interest, including ACE I/D, angiotensinogen C704T, angiotensin II type 1 receptor A1166C, and eNOS C-786T polymorphisms in each population. The Japanese patients were classified into 3 groups based on their coronary responses to intracoronary acetylcholine administration; large epicardial coronary artery spasm group (LAS), microvascular spasm group (MVS), and normal group (N). The frequency of the T930 allele is higher in the LAS+MVS group (4/111 for the LAS group and 2/53 for the MVS group) than in the N group (0/51) and the general population (1/98,  $p=0.008$ ) in the Japanese. Interestingly, no Caucasian patients had the T930 allele. There was no remarkable association between coronary vasospasm and the other 4 polymorphisms. Human coronary artery smooth muscle cells were infected with adenoviruses expressing the wild type (G930) or the mutant (T930) Rho-kinase. Western blot analysis revealed no increase in phosphorylation level of ERM in cells infected with the mutant Rho-kinase compared to that in cells infected with the wild type. The similar result was observed in F-actin staining. **Conclusions** The G930T variation of Rho-kinase have a significant association with coronary vasospasm in the Japanese. The functional analyses indicated that the mutant Rho-kinase may induce hyperresponse to vasoconstrictive stimuli resulting in coronary vasospasm. Further analysis is now ongoing.

**Contribution of a promoter polymorphism in the AGTR1 gene to Hypertension in African Americans and Latinos in Los Angeles, California.** *S. Henderson*<sup>1,2</sup>, *C. Haiman*<sup>2</sup>, *W. Mack*<sup>2</sup>. 1) Department of Emergency Medicine, Keck School of Medicine of the University of Southern California, Los Angeles, CA; 2) Dept. of Preventive Medicine, Keck School of Medicine of the University of Southern California, Los Angeles, CA.

**OBJECTIVE:** African Americans have excess hypertension (HTN), and its associated complications, when compared to other U.S. populations, and this excess is particularly significant in younger individuals. The Renin-Angiotensin-Aldosterone system (RAAS) is critical to the maintenance of blood pressure and genetic variants in the Angiotensin II Type 1 Receptor (AGTR1) genes have been associated with the risk of HTN in some populations. We theorized that a polymorphism in the AGTR1 gene would contribute to HTN risk in AAs when compared to another racial-ethnic group with a similar socioeconomic status, specifically Latinos. **METHODS:** We genotyped 1252 African American and 1042 Latino members of a large multiethnic cohort to determine the frequency of the C(-535)T variant in the AGTR1 gene, and its association with HTN. **RESULTS:** There was a significant increase in risk of HTN for African Americans associated with the AGTR1 T allele (OR =2.62 (95%CI: 1.46,4.72) for the heterozygote and OR =2.67 (95%CI: 1.51,4.74) for the homozygote:  $p = 0.03$  for the trend). No such trend was seen among Latinos (OR=0.91 (95%CI: 0.68,1.20) for the heterozygote and 1.31 (95%CI: 0.78,2.18) for the homozygote,  $p=0.79$  for the trend). **CONCLUSION:** There is a significant risk of hypertension associated with the (-535)T allele of the AGTR1 (-535) gene in the AA population, a finding not seen in the Latino population.

**Genetic and clinical factors in PR pediatric patients with thromboembolic disease (TED) at the UPR Pediatric Hospital.** *N.I. Lopez-Molina<sup>1</sup>, J.Y. Renta<sup>1</sup>, M.A. Ayala<sup>1</sup>, A. Rivera<sup>1</sup>, I. Rivera<sup>1</sup>, J.R. McFaline<sup>1</sup>, P.J. Santiago-Borrero<sup>2</sup>, C.L. Cadilla<sup>1</sup>.* 1) Biochemistry Department, UPR School of Medicine, San Juan, PR; 2) Pediatrics Department, Hereditary Diseases Program, UPR School of Medicine, San Juan, PR.

Many studies have demonstrated a relatively high prevalence of thromboembolic disorders (TED) in neonates and children, especially in very-low-birth weight newborns and very sick children. These clinical findings have been associated with deficiencies of antithrombin, proteins C and S and plasminogen; and the presence of common mutations in the prothrombin (G20210A), factor V (G1691A, Leiden), and the methyltetrahydrofolate reductase (MTHFR, C677T) genes. We studied twenty seven (27) Puerto Rican (PR) TED pediatric patients between the ages of one (1) and nineteen (19) years that were treated at the Thromboembolic Clinic of the UPR Pediatric Hospital, both or one of their parents and twenty-two (22) control subjects, to determine the role of genetic or environmental factors in TED. The TED patients had at least one thromboembolic event confirmed by imaging studies and were not on anticoagulation treatment at the time of the thromboembolic event. The control patients had the same age range as the TED patients, and were chosen at random at the Pediatric Emergency Clinic. We found eight (8) carriers of the MTHFR C677T among 18 TED patients. Nine out of 19 controls carried the MTHFR C677T mutation, and three were homozygous for the mutation. The MTHFR carrier frequencies in TED patients and control subjects compare well with previous studies on 400 PR newborns where the carrier frequency for the C677T mutation was found to be ~50%, and the frequency of homozygotes was 14%. None of the TED patients had FV Leiden alleles. In 122 PR newborns the allele frequency of the FV Leiden mutation was 0.41%. These data suggest that the MTHFR C677T mutation is not more frequently found among PR children with TED, and that the FV Leiden mutation is not frequently found among Puerto Ricans. This study was supported in part by grants from RCMI G12RR03051, MBRS RISE R26GM61838 and SCORE S06GM08224.

**Analysis of ACE gene in a non-hypertension population sample from Amazon-Brazil.** *S.R.S. Roig<sup>1</sup>, L. Dolinsky<sup>2, 3</sup>, M. Boia<sup>4</sup>, R. Moura-Neto<sup>2</sup>, P. Cabello<sup>1</sup>.* 1) Genetica, Fundacao Oswaldo Cruz, Rio de Janeiro, Brazil; 2) Genetica, Univ Fed Rio de Jan, Rio de Janeiro, Brazil; 3) Biociencias, Unigranrio, Rio de Janeiro, Brazil; 4) Medicina Tropical, Fundacao Oswaldo Cruz, Rio de Janeiro, Brazil.

High blood pressure affects almost 10 million Brazilian people and it is an important risk factor for cardiovascular diseases. Hypertension etiology involves both genetics and environmental factors. The Renin-Angiotensin System (RAS) plays a role in the physiology of vascular diseases, and genes involved in this system may be related to hypertension development. Actually exists many reports demonstrating the association of renin-angiotensin system gene polymorphism with blood pressure regulation in different populations. In order to test this association, we analyzed the angiotensin I converting enzyme (ACE) D/I gene polymorphism in two different populations from Brazil. We performed an association study with this polymorphism in 100 individuals from Amazon and a control population. Genotyping was performed using PCR reaction. Allelic frequencies and statistical analysis were done using Genetic Data Analysis software.

Allelic frequencies showed significative differences between the two analyzed populations ( $X^2=71.77$ ,  $p=0.00$ ). These data corroborate that I allele is associated with normal to low blood pressure.

**Pleiotropic effect of genes influencing hemostasis phenotypes on type 2 diabetes status.** *D. Warren<sup>1</sup>, J.M. Soria<sup>2</sup>, J.C. Souto<sup>2</sup>, J. Fontcuberta<sup>2</sup>, J. Blangero<sup>1</sup>, L. Almasy<sup>1</sup>.* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Type 2 diabetes is a complex disease influenced by multiple genes and environmental factors, both of which are largely unknown. Hypercoagulation often occurs in diabetic patients, suggesting possible pleiotropy of genes influencing both hemostasis-related phenotypes and diabetes status. These pleiotropic effects may contribute to the increased risk of thrombosis, myocardial infarction, retinopathy, and nephropathy observed in diabetics. Whether increased clotting in diabetics occurs because of hyperactivity of procoagulants, depressed anticoagulant or fibrinolytic activity, or a combination of factors, is unclear. To better understand the mechanisms behind hypercoagulation in diabetics, we used bivariate variance-components methods to examine the correlation between diabetes status and 16 quantitative hemostasis-related traits in randomly ascertained Mexican Americans participating in the San Antonio Family Heart Study. Data were available for 811 subjects from 39 extended families. 155 diabetics were identified by WHO criteria or previous diagnosis. Quantitative traits examined include clotting factors II, V, VII, VIII, X, XI, and XII, activated protein C ratio (APCR), activated partial thromboplastin time (APTT), free and total protein S (fPS & tPS), protein C, prothrombin time, tissue factor pathway inhibitor (TFPI), thrombin activable fibrinolysis inhibitor, and von Willebrand factor (vWF). Additional covariates include age, sex, and exogenous hormone use. Analyses indicate positive genetic correlations (0.38-0.51,  $p < 0.05$ ) between diabetes status and levels of proteins that enhance (factors II & VIII, vWF) and inhibit (tPS, TFPI) coagulation. Two measures of hypercoagulability, APTT and APCR, correlate negatively (-0.38 & -0.49,  $p < 0.05$ ) with diabetes status. Our results suggest that genes influencing hemostasis-related traits pleiotropically influence risk of diabetes. Although both pro- and anticoagulant levels are elevated in diabetics, the hypercoagulability observed in this disease suggests genes that promote clotting have the greater impact on disease phenotype.

**Heritability associated with candidate polymorphisms for cardiovascular risk factors.** *M.-H. Roy-Gagnon<sup>1,2</sup>, S.H. Jee<sup>3</sup>, A.F. Wilson<sup>1</sup>*. 1) Genometrics Section, IDRB, NHGRI, NIH, Baltimore, MD; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Epidemiology and Health Promotion, Graduate School of Public Health, Yonsei University, Seoul, Korea.

Quantitative traits, such as plasma levels of coagulation factors, may determine risk factors for cardiovascular disease (CVD). Understanding the genetic mechanisms underlying these traits may help to unravel the complex etiology of CVD. In this study, the contribution of known candidate polymorphisms to the heritability of CVD-related traits is estimated. The Regression of Offspring on Mid-Parent (ROMP) approach was used to investigate heritability in 87 Korean families (508 individuals) of probands who underwent elective coronary arteriography. ROMP is an extension of the traditional regression of offspring on mid-parent used to estimate trait heritability. ROMP also provides a test of association and an estimate of the heritability attributable to a candidate locus. Total and locus-specific heritability estimates were obtained for 14 traits including coagulation factors VII and fibrinogen, plasminogen activator inhibitor - 1 (PAI-1), total and HDL cholesterol. Five candidate polymorphisms for PAI-1, factor VII and fibrinogen were considered. Estimates were adjusted for age, sex, smoking and alcohol drinking. Parent-of-origin effects were also investigated. Estimates of total heritability for factor VII, PAI-1, HDL cholesterol and triglyceride levels were significant ( $p < 0.0001$ ) and ranged from 45 to 66%. The estimated heritability of fibrinogen levels was 14 10%. Three linked fibrinogen polymorphisms were associated with fibrinogen and PAI-1 levels (locus-specific heritability estimates of 1 0.3% and 3 1%, respectively;  $p < 0.015$ ). Clotting factor VII was associated with the factor VII polymorphism with a locus-specific heritability estimate of 2 0.8% ( $p = 0.01$ ). These polymorphisms account for only a small percentage of the heritability of the traits (3-7%). This suggests that several other genes and/or shared familial and environmental factors may be responsible for the high heritability of these traits.

**COMPLEX SEGREGATION ANALYSIS OF BLOOD PRESSURE IN THREE MIDDLE DALMATIAN ISLANDS, CROATIA.** *T. Skaric-Juric*<sup>1</sup>, *E. Ginsburg*<sup>2</sup>, *E. Kobyliansky*<sup>2</sup>, *I. Malkin*<sup>2</sup>, *N. Smolej Narancic*<sup>1</sup>, *M. Pericic*<sup>1</sup>, *P. Rudan*<sup>1</sup>. 1) Institute for Anthropological Research, Zagreb, Croatia; 2) Department of Anatomy and Anthropology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Complex segregation analyses of systolic and diastolic blood pressure have been performed on family data from the populations of the island of Brac, Korcula and Vis (Middle Dalmatia, Croatia), separately, with the purpose to elucidate a potentially promising population for the search of the genes responsible for high prevalence of hypertension. According to the criteria for developed hypertension (systolic BP $\geq$ 160 and/or diastolic BP $\geq$ 95 mm Hg), the prevalence ranged from 31% on Brac, to 38% on Korcula and 41% on Vis (36% for all islands). Complex segregation analysis has been performed by implementation of the program package MAN. The sample encompassed 928 individuals, aged 17-85 yr. (490 from Brac, 282 from Korcula and 156 from Vis). By applying the usual transmission probability tests, the major gene (MG) hypothesis for systolic and for diastolic blood pressure has been accepted only in the sample from the island of Vis. For both blood pressures, the major gene as well as environmental hypotheses have been rejected in the sample from Korcula, while on the sample from Brac, along with the rejection of MG model, the environmental model - indicating action of polygenetic and environmental family factors - could not be rejected. According to the estimates revealed from the non-constrained MG model, in the sample from Vis, the proportion of (age and sex adjusted) variance of blood pressure that could be attributed to the effect of a hypothetical major gene (H<sub>2</sub>) is 41.0% for systolic and 42.3% for diastolic blood pressure. The respective values for total genetic variance (h<sup>2</sup>) are 76.5% and 59.7%. High prevalence of hypertension combined with the results of the complex segregation analyses of blood pressure in three isolated Middle Dalmatia islands point to the island of Vis, as a potentially promising target population for incoming molecular genetic studies of hypertension.

**Study of the Isolated Populations in the National Park of Cilento and Vallo di Diano and Comunita Montana**

**Ufita.** *M. Persico*<sup>1</sup>, *M. Ciullo*<sup>2</sup>, *V. Colonna*<sup>1</sup>, *M. Astore*<sup>1</sup>, *A. Calabria*<sup>1</sup>, *T. Nutile*<sup>1</sup>, *W. Longo*<sup>1</sup>, *A. Fierro*<sup>2</sup>, *R. Pacente*<sup>1</sup>, *G. Antoniol*<sup>3</sup>, *J. Guardiola*<sup>1</sup>. 1) IGB A. Buzzati Traverso, CNR, Napoli, Italy; 2) BioGeM s.c. a r.l., Ariano Irpino (Av), Italy; 3) Research Centre on Software Technology, Benevento, Italy.

One approach useful to identify loci and genes responsible for complex diseases takes advantage of populations of small villages that have been geographically isolated for centuries. We looked at the villages on the hills and mountains of the National Park of Cilento e Vallo di Diano and of the Comunita Montana Ufita, two areas in Southern Italy. We chose some of these villages on the basis of a history of high endogamy (marriages between people born in the same village). In the Comunita Montana Ufita, we have chosen the village of Montaguto where the collection of anagraphic data is in progress. In the Cilento region, we have already collected the last three centuries genealogical data of the population in three villages, Campora, Cardile and Gioi, in order to build their genealogy. These villages have at the present a population of about 600/800 habitants. All genealogical informations have been stored in a relational database. Although the villages are located in the same area, historical data report a different origin of these populations. Moreover, the plague in Southern Italy in the 1656 strongly hit these villages determining a population bottleneck. Computational analysis of genealogical male and female hereditary lines was carried out to determine the ancestral villages founders. This analysis allowed to identify 51 unrelated males and 48 unrelated females. Further, the analysis of mitochondrial (mtDNA) and Y chromosomal DNA performed on these individuals allowed a further reduction of the number of hypothetical founders. In order to establish the homogeneity of the population we are evaluating the extent of linkage disequilibrium (LD) by the analysis of a number of microsatellites in chromosome region Xq13.3. We will present preliminary data on the health of the population of Campora village: clinical analyses of blood samples, medical interviews and examination.

**Influence of vascular endothelial growth factor gene polymorphisms on cardiac defects in 22q11 deletion syndrome.** *E.J. Seo<sup>1,2</sup>, J.J. Lee<sup>1</sup>, S.M. Park<sup>1</sup>, J.Y. Yang<sup>1</sup>, Y.H. Kim<sup>1,3</sup>, J.K. Ko<sup>1,3</sup>, H.W. Yoo<sup>1,3</sup>, S.J. Kim<sup>4</sup>, H.B. Oh<sup>2</sup>, K.J. Lee<sup>5</sup>, I.S. Park<sup>1,3</sup>.* 1) Genome Research Ctr for BDGD, Asan Medical Center, Seoul, Korea; 2) Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 4) Department of Pediatrics, Sejong Hospital, Seoul, Korea; 5) Department of Statistics, Dongguk University.

The phenotype of 22q11 deletion syndrome is extremely various among del22q patients, even within same family. Cardiac defects are found in 75% of 22q11 deletion syndrome. Recent report has shown that vascular endothelial growth factor (VEGF) gene is a modifier of cardiovascular birth defects in this syndrome. VEGF is a potent regulator of vasculogenesis and angiogenesis. Aim of the present study was to determine whether the VEGF gene polymorphisms are associated with cardiac defects in 22q11 deletion syndrome. We examined five common polymorphisms in the promoter region, 5'UTR and 3'UTR of the VEGF gene in 63 patients with 22q11 deletion, 22 families of 22q11 deletion, 53 control subjects and 16 control families. Allele frequencies of -2578C>A, -1498T>C, -1154G>A, -634C>G and 936C>T in controls were 0.314, 0.276, 0.245, 0.546, and 0.093, respectively. Any genotype distribution did not differ significantly between del22q patients with and without cardiac defects, and between controls and del22q patients with cardiac defects. Association studies were performed in families of del22q patients with cardiac defects and control families using transmission disequilibrium test (TDT) and haplotype based haplotype relative risk (HHRR) statistics. TDT analysis showed no evidence of preferential transmission of any VEGF alleles studied. We did not identify the important associations between VEGF gene polymorphisms and cardiac defects in del22q patients, which might be caused by limited number of subjects. Extended study for larger populations will be required to confirm that VEGF gene increase the risk for cardiac defects in 22q11 deletion .

**Unexpected discordance of lung disease severity between monozygous twins with cystic fibrosis.** *G.R. Cutting<sup>1</sup>, R. McWilliams<sup>1</sup>, J. Hoover-Fong<sup>1</sup>, S. Beck<sup>2</sup>, K. Naughton<sup>1</sup>, C. Yurk<sup>1</sup>, C. Gruver<sup>1</sup>, P. Cornwall<sup>1</sup>, D. Fallin<sup>1</sup>, A. Hamosh<sup>1</sup>.*  
1) Johns Hopkins Univ, Balt, MD; 2) St. Chris Hosp for Children, Phila, PA.

To identify factors independent of the disease-causing gene that contribute to cystic fibrosis (CF) phenotype variability, we have undertaken a multicenter study of CF-affected twins. Thus far, blood samples, clinical and environmental data have been collected from 25 monozygous (MZ) twin pairs and 14 dizygous (DZ) twin pairs. Five sets of twins were excluded in this analysis (3 DZ sets of opposite sex, 1 DZ and 1 MZ set with a member with other significant medical problems) yielding 13MZ/8DZ male pairs and 11MZ/2DZ female pairs. All DZ and 22 MZ pairs are both alive, 1 MZ pair are both dead, and 1 MZ pair is discordant for vital status. There were no differences between MZ and DZ pregnancies in gestational age, complications or mode of delivery. Similar portions of MZ (74%) and DZ (80%) twins were homozygous for F508, the common CF mutation. Concordance was assessed using Fishers Exact Test for categorical data and within pair differences were examined using t-tests and ANOVA for continuous data. As expected, MZ twins were more concordant than DZ twins for height at diagnosis (within twin diff: MZ 1.00.8 cm, DZ 4.63.2 cm;  $p < 0.02$ ), current height, and meconium ileus (MZ 23 concordant/1 discordant, DZ 9/4;  $p < 0.04$ ). Unexpectedly, MZ twins were no more concordant than DZ twins for measures of lung disease severity (current FEV<sub>1</sub>, FVC, and latest chest X-Ray). Furthermore, inspection of longitudinal pulmonary function tests on 17 MZ pairs and 7 DZ pairs revealed 3 MZ pairs who had notably different lung function throughout their lives. Despite sharing similar environments, MZ and DZ twins were discordant for pathogens that commonly infect CF patients (*P. aeruginosa* and *B.cepacia*). Interestingly, MZ twins had greater exposure than DZ twins to environmental agents likely to affect lung disease progression, including wood stoves, passive smoke, cockroaches, rodents and history of exercise. Taken together, these data indicate that environmental and stochastic factors play a substantial role in variation of lung disease, the major cause of morbidity and mortality in CF patients.

**Haplotype analysis suggests the wild-type allele is a modifier of the severity of the nail dysplasia in Nail Patella Syndrome.** *J. Dunston*<sup>1</sup>, *J.W. Park*<sup>1,2</sup>, *M. Malbroux*<sup>1</sup>, *I. McIntosh*<sup>1</sup>. 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Dept Epidemiol. Bloomberg School of Public Health, Johns Hopkins Univ, Baltimore, MD.

Nail Patella Syndrome (NPS) results from haploinsufficiency of the LMX1B gene, which codes for a LIM-homeodomain transcription factor. NPS is typically characterized by nail dysplasia, elbow dysplasia, absent/hypoplastic patellae and exostoses of the ilia. Nail dysplasia decreases in severity from thumb to fifth finger and is variable in severity both within and between families. Previous genetic evidence suggested that the allele inherited from the unaffected parent might influence the severity of the nail dysplasia. To test this hypothesis, we applied a quantitative scoring system to the nail dysplasia in 89 individuals from 41 families with NPS. Mutations in LMX1B have been identified in 40/41 families. Possible nail scores range from 0 to 6.32, with 0 representing no nail changes and 6.32 representing the complete absence of all nails. The observed scores ranged from 0 to 5.70 with a mean of 2.32 and standard deviation of 1.06. The presence or absence of the creases over the distal interphalangeal (DIP) joint was noted; 93 % of individuals were missing 1 or more creases. Neither age, sex, mutation type, absence of DIP joint creases or sex of the parent from whom the disease-causing mutation was inherited is a predictor of the nail score. To test the effect of the LMX1B allele inherited from the unaffected parent, six SNPs, including two newly identified SNPs, were genotyped across the LMX1B gene. Haplotypes were constructed using family data to set phase. For singletons, haplotypes were predicted using the population frequencies. Haplotypes with a population frequency greater than 0.05 were included in subsequent analyses. Simple linear regression was used to test the total effect of each haplotype on the nail score. Two of six haplotypes gave a significant result. One haplotype appears to be protective ( $\beta=-0.93$ ,  $p=0.041$ ) and the other appears to increase risk ( $\beta=0.93$ ,  $p=0.041$ ), supporting the hypothesis that the wild-type LMX1B allele is a modifier of this aspect of the NPS phenotype.

**Polymorphisms of the C677T and A1298C of the MTHFR gene in Alzheimer's diseases.** *I. Kara<sup>1</sup>, E. Eker<sup>2</sup>, T. Ertan<sup>2</sup>, F. Engin<sup>2</sup>, A. Sazci<sup>3</sup>, E. Ergul<sup>3</sup>, G. Akpinar<sup>3</sup>, G. Kaya<sup>1</sup>.* 1) Department of Neuroscience, Institute for Experimental Medical Research, Istanbul University, Istanbul, Turkey; 2) Department of Psychiatry, Cerrahpasa Faculty of Medicine, Istanbul University, Istanbul, Turkey; 3) Department of Medical Biology and Genetics, Faculty of Medicine, University of Kocaeli, Kocaeli, Turkey.

Alzheimers disease (AD) is a progressive neurodegenerative disorder of the central nervous system and resulting in dementia in more than 65 years old individuals. Although a number of genes has been shown involved in familial and sporadic AD, mutations in these particular genes are responsible for only 1 percent of all AD patients. The methylenetetrahydrofolate reductase (MTHFR) gene has been suggested to be a candidate gene for AD. The MTHFR C677T and A1298C polymorphisms may cause hyperhomocysteinemia by reducing 5-methyltetrahydrofolate availability. The aim of the study was to investigate the contribution of MTHFR polymorphisms; C677T and A1298C to AD. A PCR-RFLP method was used in the analysis of the genotypes followed by a statistical analysis. We examined 94 AD patients (mean age 72.76 plus minus 10.44) and 225 healthy control subjects (mean age 70.39 plus minus 11.99). Clinical diagnosis of AD patients was made according to the NINCDS-ADRDA and DSM-IV criteria. The allelic frequencies of the MTHFR T677 and MTHFR C1298 were 34.57 percent; and 31.38 percent; in the AD patients and 34 percent; and 29.11 percent; in the controls respectively. The allelic distribution was not significant in the MTHFR T677 ( $\chi^2=0.614$ ;  $P=0.736$ ) whereas it was significant in the MTHFR C1298 ( $\chi^2=7.588$ ;  $P=0.023$ ). Frequencies for MTHFR C677C, C677T and T677T were 39.4 percent; 52.1 percent; and 8.5 percent; in the AD patients and 42.2 percent; 47.6 percent; and 10.2 percent; in the control subjects respectively. Likewise, frequencies for MTHFR A1298A, A1298C and C1298C were 41.5 percent; 54.3 percent; and 4.3 percent in the AD patients and 51.6 percent; 38.7 percent; and 9.8 percent in the controls respectively. The MTHFR A1298C genotype showed increased risk for AD ( $OR=1.881$ ; 95 percent  $CI=1.157-3.060$ ;  $\chi^2=6.564$ ;  $df:1$ ;  $P=0.010$ ). The MTHFR C677C/A1298A compound genotype was protective for AD ( $OR=0.397$ ; 95 percent  $CI=0.160-0.981$ ;  $\chi^2=4.240$ ;  $df:1$ ;  $P=0.039$ ). In conclusion, the MTHFR A1298C genotype is associated with AD.

**Autism: Incidence of Cytogenetic abnormality and Fragile-X syndrome.** *K. Reddy, The Diagnostics Team.*  
Genzyme Genetics, Orange, CA.

A total of 434 patients with an indication of autism were referred for genetic diagnosis. The median age was 4.1 years. Sex ratio was 4.4 males to 1 female. Fragile-X testing (Southern blot & PCR) found 6/316 [1.89%] with abnormal results. The mutations were: A full mutation (fM) and abnormal methylation in 3 [50%] and mosaic mutations with partial methylation of variable clinical significance in 3 [50%]. The mosaic mutations were: a fM [200-900 repeats(r)]/deletion mutation [30 r] with partial methylation, 2 size mosaics had permutation (pM) [150 r]/fM [400 r], and pM [155 r]/fM [800 r] with normal and abnormal methylation. A premutation mosaic female carrier with atypical EcoR1 and Eag1 pattern and a typical BssH1 pattern gave 2.8, 3.0, 5.2-5.4 Kb bands. PCR gave reproducible bands corresponding to 29, 65, 80 repeats and a faint band for 39 repeats. This probably indicates somatic mosaicism. Family studies may provide insight into the clinical implication. A Chromosome (cs) abnormality was found in 14/421 [3.33 %] cases. The aberrations were: 4/14 [28%] supernumerary markers from cs15 [3] and cs2 [1]; 4/14 [28%] deletions of 2q37.3, 3q25, 12q21.2q23.3 and 13q13.2q14.1; 1/14 [7%] duplication of 15q11.2q13; 3/14 [21%] inversions of 10p11.2q21.2, 17q23q25 (de novo) and 14q11.2q33 (mosaic); 2/14 [14%] translocations, one balanced t(1;14) and one unbalanced der(14;18). A cs15 was involved in 4/14 [28%] rearrangements (2 de novo & 1 mosaic), of which 3/4 had an extra copy/copies of D15S11 & GABRB3 and a 2q37 deletion support the association of autism with duplication 15q11.2q13 and in some cases 2q37 deletion. The frequency of a cs abnormality (3.33%) and FRAXA (1.89%) are at the lower end of other reported surveys (cs 2.8-11.5%, FRAXA 2-4%). The limitations of this study are: the retrospective nature of our study and absence of defined clinical criteria. Conclusions: when the indication is autism a higher incidence of mosaic FRAXA mutations with partial methylation [50% vs 15-20% in FRAXA patients] suggests faint bands and atypical Southern band pattern may be anticipated. The partial methylation may be the cause of deviant features like autism. Since 28% of the cs abnormalities were subtle, high resolution analysis is indicated.

**Evidence supporting the MFTM in autism.** *C.M. Wolpert<sup>1</sup>, J. Grubber<sup>1</sup>, S.L. Donnelly<sup>1</sup>, G.R. DeLong<sup>1</sup>, S.A. Ravan<sup>2</sup>, R.A. Abramson<sup>2</sup>, H.H. Wright<sup>2</sup>, J.R. Gilbert<sup>1</sup>, M.L. Cuccaro<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Duke Univ Medical Ctr, Durham, NC; 2) Univ of South Carolina, Columbia, S.C.

The genetic basis of autism is complex, with a sex difference in incidence (male:female ratio 4:1). Applying the multifactorial threshold model to autism we thus hypothesize that females would have a higher genetic load than males. Impaired adaptive behavior and age at onset (AAO) can both be used as indicators of severity. We analyzed a data set (N=234; Fhx- = no family history of autism (N=139); Fhx+; = family history of autism (N=95)) ascertained for genetic studies. All individuals met diagnostic criteria for autism as confirmed by the Autism Diagnostic Interview-Revised (ADI-R). The Vineland Adaptive Behavior Scales (VABS) was used to assess adaptive functioning. Lower VABS scores reflect greater severity. Between group comparisons (Mann-Whitney U-test) showed females (n=56) had lower communication (p=0.03) and adaptive behavior composite (ABC; p=0.03) scores than males (n=178). The data set was then stratified by family history status. Females from Fhx- families (n=28) had significantly lower scores than males from Fhx- families (n=111) on communication (p=0.002), daily living skills (p=0.013) and ABC (p= 0.009) scores while no gender differences were noted in Fhx+ families. No difference was noted between Fhx- and Fhx+ groups when collapsed across gender. ADI-R items 5 and 94 measure AAO. Earlier AAO is an indicator of greater severity. Between group comparisons revealed no gender differences on either item. However, when stratified by family history status, Fhx- females showed a significantly earlier AAO than Fhx- males (item 5, Chi-square p-value =0.03; item 94, Wilcoxon p-value=0.05). No differences were noted in Fhx+ families. Finally, no AAO difference was noted between Fhx- and Fhx+ groups when collapsed across gender. In summary, females from Fhx- families show an earlier AAO and more impaired adaptive behaviors. We believe these indices may have etiologic relevance in autism in isolated or sporadic cases of autism. The current findings suggest a complex relationship between severity, gender, and family history status in individuals with autism.

**Discovering haplotype blocks in the human genome.** *A. Rinaldo<sup>1</sup>, B. Devlin<sup>2</sup>, L. Wasserman<sup>1</sup>, K. Roeder<sup>1</sup>.* 1) Dept of Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Dept of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Haplotype blocks are segments of chromosomes that apparently have been transmitted through many generations without experiencing substantial effects of recombination (i.e., segments behave as blocks). The identification of haplotype blocks can substantially reduce the cost of finding genetic variants associated with increased risk of disease by decreasing the number of polymorphisms required to screen genomic segments. In this work we provide a statistical characterization of haplotype blocks and develop a methodology to identify them. The algorithm possesses two main features: (1) Shannon's entropy is used as a measure of multivariate correlation among SNPs to locate groups of consecutive SNPs that are likely to belong to the same block; and (2) the physical boundaries of the blocks are found by implementing a model selection procedure that estimates the penalty for model complexity based on biological justification. The methodology performs well when evaluated by simulated data. Results obtained by using data from the UW-FHCRC Variation Discovery Resource (SeattleSNPs) indicate that the regions found by our procedure exhibit the expected characteristics of a haplotype block.

**Estimating main effects and interactions of genes through a structured stepwise dimension reduction (SSDR) of measures of association.** *N. Wang, R. Chakraborty.* Center for Genome Information, University of Cincinnati, Cincinnati, OH.

Recent literature supports the notion that identification of all components of genetic control of complex disease phenotypes is difficult without that a structured strategy of multipoint/multilocus linkage/association analysis. This is intimately connected with the complexity of phenotypes, which makes their familial resemblance deviate from the predictions of principles of simple Mendelian rules. As a consequence, deconvolution of multilocus genotype data into haplotypes, and/or deciphering multilocus/multi-site association results into a minimal set of markers, which explain the association results, constitutes a critical component of identifying the main effects as well as interaction of the genetic factors controlling any complex phenotype. Using classical measures of association applied to data of case-control study designs, we used a structured stepwise dimension reduction (SSDR) technique to attribute an overall significant association to a minimal set of classes, which in turn detects main effects as well as interactions of genes that can explain an observed phenotype-genotype association. This method is more general than the traditional haplotype inference methods, since the different sites of the SSDR method do not necessarily have to be genetically linked. Thus, the SSDR technique is argued to be helpful in determining gene-gene interactions, useful in studying gene ontology relationships. When the sites belong to linkage groups, this technique can also infer the antiquity of haplotypes and the history of populations in which they are observed. Through applications of such SSDR techniques, we show that phenotypes such as susceptibility to food allergies may be under genetic control through interactions of genes, rather than main effects of individual genetic polymorphisms. In addition, an application of SSDR to two sets of haplotype data from multiple populations is shown to be consistent with the Out-of-Africa origin of modern humans. (Research supported by US Public Health Service Research grants).

**A Significant Association between Nonsyndromic Oral Clefts and Arylhydrocarbon Receptor Nuclear Translocator (*ARNT*).** K. Kanno<sup>1,2</sup>, S. Kayano<sup>1,2</sup>, A. Yamada<sup>1</sup>, S. Kure<sup>2</sup>, Y. Suzuki<sup>2</sup>, Y. Matsubara<sup>2</sup>. 1) Plastic/Reconstructive Surg, Tohoku Univ School of Med, Sendai, Miyagi, Japan; 2) Dept. Medical Genetics, Tohoku Univ School of Med, Sendai, Miyagi, Japan.

The etiology of nonsyndromic oral clefts (cleft lip; cleft palate; or cleft lip and palate) is still controversial, but is considered to involve both genetic and environmental factors. One of the suspected environmental factors is 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) found in tobacco, herbicides, contaminated food; TCDD administered during organogenesis in mice causes a high incidence of cleft palate in fetuses. Aryl hydrocarbon receptor (AHR), aryl hydrocarbon receptor nuclear translocator (*ARNT*), and cytochrome P450 1A1 (*CYP1A1*) are involved in TCDD metabolism, and it is noteworthy that AHR, *ARNT* and *CYP1A1* mRNA is expressed during the craniofacial tissue development of mice and human fetuses. When TCDD was administered to pregnant mice, almost all wild-type fetuses suffered from cleft palate, whereas none of the AHR-null mutant fetuses were sensitive to the teratogenic effects of TCDD. This evidence suggests that genes *AHR*, *ARNT*, and *CYP1A1* may play a role in nonsyndromic oral clefts. In the present study, we assessed whether there is any association in the Japanese population of nonsyndromic oral clefts and single nucleotide polymorphisms (SNPs) in *AHR*, *ARNT*, and *CYP1A1* using the transmission disequilibrium test (TDT). We investigated SNPs in *AHR*(1661A/G), *ARNT*(567G/C, IVS12-19T/G), and *CYP1A1*(1384A/G), which were identified in Japanese. The SNPs were subjected to TDT for 148 patient-parents trios. The C allele of *ARNT* 567G/C was preferentially transmitted to patients ( $P=0.0334$ ). When *ARNT* haplotypes 567G/C and IVS12-19T/G were simultaneously considered, the preferential transmission of the CT (567C-IVS12-19T) haplotype was significant ( $P=0.0012$ ). Although the GG haplotype was transmitted to patients less than 50% of the time, the significance of this deviation was marginally significant ( $P=0.052$ ). Deviation of transmission rates for the other SNPs was not observed. Our results suggest that *ARNT* is involved in the development of nonsyndromic oral clefts in the Japanese population.

**Inherited Pathway for Exceptional Longevity.** *G. Atzmon<sup>1</sup>, P. Rabizadeh<sup>1</sup>, R. Gottesman<sup>1</sup>, A.R. Shuldiner<sup>2</sup>, N. Barzilai<sup>1</sup>.* 1) Institute for Aging Research, Dept Medicine, AECOM, New York, NY; 2) University of Maryland School of Medicine, and the Geriatrics Research and Education Clinical Center, Baltimore, MD.

Subjects with exceptional longevity have a lower incidence of age-related disease, and their family members may inherit biological factors that modulate aging processes and disease susceptibility. To identify specific genetic factors that predict the human longevity phenotype, we recruited Ashkenazi Jewish probands with exceptional longevity (n = 213; age 98.2±5.3 years), their offspring (n=242; age 68.3±6.7 years) and age-matched control group of Ashkenazi Jews (n=258). The odds ratio of reaching over the age of 90 was 6.9 in the proband's parent generation compared to controls (P<0.001), supporting the role of genetics in their longevity. The frequencies of only three SNPs in 3 candidate genes for cardiovascular disease (*Br J Haematol.* 114(3):718-20), were significantly different in long-lived probands compared to the ~70 year old control group. In particular, homozygosity for the 405 valine (V) allele of cholesteryl ester transfer protein (CETP) (VV genotype) was 25% in the proband group and 20% in the offspring group compared with only 5% in the control group (p<0.001 vs. proband and offspring). Those with the VV genotype also had ~30% lower serum CETP concentrations. Because CETP is involved in regulation of lipoprotein and their particle sizes, we determined these (by NMR technology), and found that HDL and LDL particle sizes were significantly larger in probands and their offspring compared with age-matched controls. Moreover, in CETP VV homozygotes, HDL and LDL particle sizes were significantly larger in offspring without hypertension, and cardiovascular disease (p<0.008), and in probands with better cognitive function (p<0.05). We conclude that the V allele of CETP has pleiotropic effects on lipoprotein and other cardiovascular traits as well as cognitive function that protect from cardiovascular disease and cognitive decline, and promote exceptional longevity in humans.

Program Nr: 1184 from 2003 ASHG Annual Meeting

**Epidemiology and Genetics of Duchenne muscular dystrophy in Northern Ireland.** *K. McKeever, A. Magee.*  
Regional Genetics Service, Belfast City Hospital Trust, Belfast, N Ireland, United Kingdom.

**Objective;** Creation of a database of affected males and their first degree relatives. This will facilitate study of the epidemiology and natural history of this devastating neuro-muscular disease and allow completion of molecular investigations for each pedigree. Carrier females have a significant risk of developing cardiac complications including cardiomyopathy, therefore identification of this group is imperative.**Methods;** Review of patient notes held in the department. Notes were identified with the use of a database, GENESIS, and with the help of the charity, Muscular Dystrophy Campaign.**Results;** Since 1980, 123 cases of Duchenne muscular dystrophy (DMD) have been diagnosed. There are 59 males and 3 manifesting carriers alive and resident in Northern Ireland. The prevalence is 3.5 per 100,000 population and incidence is 18.2 per 100,000 live births i.e. 1 in 5492 live births. The average age of surviving males is 12.21 years with a range of 3.3-26.1 years. The percentage survival at age 20 is 57.1% and mean life expectancy 17.42 years. Thirty-six (61%) of the current cases are sporadic and 23 (39%) are inherited. Thirty-five (59%) of the mutations are due to deletions of one or more exons; another 2 are contiguous gene deletions and there is 1 insertion. One further point mutation has been identified in muscle. In 20 cases the mutation is as yet unidentified. There are 23 confirmed carrier mothers from the population of 59 males and 17 mothers whose status is unknown. We have identified 93 other female first degree relatives of all cases of DMD identified since 1980 (both alive and deceased) whose carrier status is unknown; the family mutation is known in 46 (49%). **Conclusions;** We have created a database of Duchenne muscular dystrophy families in Northern Ireland. This has identified at risk females who can now be offered genetic counselling, testing, and cardiac assessment where appropriate. The survival of affected males at age 20 in Northern Ireland has now passed 50% creating a significant population in Adolescent and Adult Medicine.

**Allelic frequencies of nine loci STR in a sample of Bolivar City.** *J.A. Nastasi, A. Parrilla, H.O. Guzmán, A. Rodríguez, M. Suegart, G. Partidas, L. Eduard, M. López, O. Sánchez.* Unidad de Genética, Centro de Microscopía Electrónica, Esc. de Ciencias de la Salud, Universidad de Oriente, Ciudad Bolívar, Estado Bolívar, Venezuela.

The study of DNA polymorphism is extremely useful to anthropological and forensic sciences. The loci STR are extensively used because of their high informativity, heterozygosity, and easy reproducibility, and it has been preferred as a molecular tool in several areas of medicine and biology. We analyzed nine tetranucleotide loci STR highly informative in a sample of Bolivar City, Venezuela. The typing was performed by polymerase chain reaction (PCR), according with the conditions of the technical manual of GenePrint STR System of Promega. Denaturant polyacrilamide gel (6%) was used to resolve the amplified fragments of PCR, and reveled by silver staining technique. We calculated the allelic frequency of CSF1PO, TPOX, TH01, F13A01, FESFPS, vWA, F13B and LPL, as STR autosomic loci, and the locus HPRTB localized in X chromosome. We established allelic frequencies to our city, for every one of nine loci above mentioned, and these frequencies were compared with other published similar studies. Our allelic frequency are slight different to other Caucasian, American, African and Asian populations previously reported, but have higher similarity with other Latin-American populations. The matching probability including all nine loci STR studied for our population was  $5,42 \times 10^{-8}$ , and the typical paternity index to nine loci mentioned above was 184,5 and finally, the power of exclusion to all loci was 0,99759997. These results would be use in forensic casework and anthropological studies.

**Low cancer incidence rates in Ohio Amish.** *J.A. Westman, S.N. MacEachern, A.K. Ferketich, S. Lemeshow, R. Pilarski, R. Nagy, A. de la Chapelle, C.D. Bloomfield.* The Ohio State University Comprehensive Cancer Center, Columbus, OH.

Little is known about cancer in the Amish. The Amish of Holmes County, Ohio and neighboring areas is a unique founder population in north central Ohio and the largest Amish community in the world. The cancer incidence rate among the Ohio Amish was estimated for the reference years 1996-1999. A random sample of 92 households was interviewed and a detailed four- to five-generation cancer family history taken, resulting in a database of 27,580 unique individuals, with 26,679 living during the reference years. A total of 545 cancer diagnoses were documented with 108 diagnosed during the reference years, 35 of whom are still living. The population in the reference years had 18,201 adults over age 20 (9103 females and 9098 males) with 105 cancer occurrences in adults. Diagnoses were confirmed when possible with medical records, death certificates, and comparison to the state of Ohio cancer incidence surveillance system. The total person-time contribution to each of seven age categories was computed and crude rates estimated and compared to that seen in the general Ohio population. The cancer cases were classified using the National Cancer Institutes Surveillance, Epidemiology and End Results (SEER) classifications. An age-adjusted rate was computed for all cancer types, colon, breast, and prostate cancers in the Amish and compared to the Ohio rate. Age-adjusted rates were not computed for less common cancer types but the observed number of cases were compared with the expected number of cases for that age group. The age-adjusted cancer incidence rate for all cancers among the Amish was estimated to be  $192.2/10^5$  person-years (Ohio  $643.6/10^5$  person-years;  $Z = 12.99$ ;  $p < 0.0001$ ), or 30% of the general population incidence. The incidence of every SEER cancer type was lower in the Amish than in the general population. Lifestyle factors, generally considered responsible for 60% of cancer occurrences, are not likely to be the sole contributors to the observed reduction in cancer incidence since reduced tobacco and alcohol use is offset by increased obesity. Protective genetic factors may be present that reduce cancer susceptibility in the Ohio Amish.

**Large scale DNA variation as an aid to reconstruction of extended human pedigrees.** *S.R. Woodward<sup>1, 3</sup>, N. Myres<sup>3</sup>, J.B. Ekins<sup>3</sup>, J.E. Ekins<sup>3</sup>, K. Hadley<sup>3</sup>, L. Hutchison<sup>2</sup>, L. Layton<sup>3</sup>, U. Perego<sup>3</sup>, A. Sims<sup>3</sup>, A. Nelson<sup>3</sup>, M. Nelson<sup>3</sup>, A. Welch<sup>3</sup>.* 1) Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2) Computer Science, Brigham Young University, Provo, UT; 3) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT.

Reconstruction of pedigree structure from limited information is frequently required in studies of inherited diseases. To aid in this process, we have developed a database of genetic variation based on autosomal, mitochondrial, and Y chromosome DNA sequence. We have sampled a total of 37000 individuals of diverse ethnic origin, with an initial focus on European and Polynesian lineages verified by extended written genealogies. From 14000 of these individuals, we have typed 14 X chromosome microsatellites, 120 other autosomal microsatellites, 24 Y-chromosome microsatellites for more than 2.2 million locus tests. Markers were chosen in sets of 3 to 5 that are in tight disequilibrium and are distributed across the genome. In addition, we have sequenced from a subset of these samples 850 base pairs from the mitochondrial D-loop. The combination of genetic and genealogical data is maintained and managed in a mySQL based database from which input files for analysis programs including STRUCTURE and ARELIQUIN are generated. In addition, other analysis programs developed by us, YTYPEFINDER and HAPLOTYPYPER have been employed to generate modal haplotypes from the Y-chromosome data and to reconstruct phase in the X chromosome dataset where haplotyping algorithms can be assessed. We have employed the STRUCTURE program and additional analysis with HAPLOTYPYPER and YTYPEFINDER to measure genetic relationships across living individuals, and correlated these relationships with historical genealogical records. These analyses indicate that in Polynesian populations, clear assignment of living individuals to distinct historical lineages is feasible over the range of 3 to 6 generations, and similar assignments may be possible for living individuals in European populations.

**MTHFR polymorphism in patients with vascular dementia.** *E. L. Eker<sup>1</sup>, T. Ertan<sup>1</sup>, F. Engin<sup>1</sup>, A. Sazci<sup>2</sup>, E. Ergul<sup>2</sup>, G. Akpınar<sup>2</sup>, G. Kaya<sup>3</sup>, I. Kara<sup>3</sup>.* 1) Department of Psychiatry, Istanbul University, Istanbul, Turkey; 2) Department of Medical Biology and Genetics, Faculty of Medicine, Kocaeli University, 41900, Derince, Kocaeli, Turkey; 3) Department of Neuroscience, Institute for Experimental Medical Research, Istanbul University, Istanbul, Turkey.

Vascular dementia (VD) is the second most common form of dementia, following AD worldwide. VD is associated with a number of risk factors including MTHFR polymorphisms, resulting in hyperhomocysteinemia. MTHFR is an important risk factor for stroke. In the present study, MTHFR C677T and A1298C polymorphisms were examined as genetic risk factors for VD. Sixty-one patients (mean age 78.63 plus minus 8.78) with vascular dementia by the NINDS-AIREN criteria and 225 healthy control subjects (mean age 70.39 plus minus 11.99) were genotyped for MTHFR C677T and MTHFR A1298C polymorphisms using PCR-RFLP. The MTHFR T677 allele frequency was 36.07 percent in the VD patients and 34 percent in the control subjects. Frequencies for MTHFR C677C, C677T, and T677T were 32.8 percent, 62.3 percent and 4.9 percent in the VD patients and 42.2 percent, 47.6 percent and 10.2 percent in the control subjects. The allelic distribution by MTHFR C677T was insignificant ( $\chi^2=4.604$ ;  $df:2$ ;  $P=0.100$ ). The MTHFR C1298 allele frequency was 27.87 percent in the VD patients and 29.11 percent in the control subjects. Frequencies for MTHFR A1298A, A1298C, and C1298C were 50.8 percent, 42.6 percent and 6.6 percent in the VD patients and 51.6 percent, 38.7 percent and 9.8 percent in the control subjects. The allelic distribution of MTHFR A1298C was insignificant ( $\chi^2=0.743$ ;  $df:2$ ;  $P=0.690$ ). The MTHFR C677T genotype showed increased risk for VD (OR=1.822; 95 percent CI=1.020-3.255;  $\chi^2=4.171$ ;  $df:1$ ;  $P=0.041$ ). In conclusion, the MTHFR C677T genotype is a genetic risk factor for VD.

**Allele frequencies of 41 SNPs in 10 candidate genes for osteoporosis and obesity in a large Caucasian sample and comparison with the data from public databases and other studies.** *V. Dvornyk<sup>1</sup>, J.R. Long<sup>1</sup>, D.H. Xiong<sup>1</sup>, H.W. Deng<sup>1,2</sup>.* 1) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, NE; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan , P. R. China.

SNPs have become increasingly used in gene identification studies for complex traits. However, accuracy and suitability of SNP data for studies of some complex disorders, such as osteoporosis and obesity, have often not been validated. We analyzed allele frequencies of 41 SNPs of ten candidate genes for osteoporosis and/or obesity in a large US Caucasian sample (1,873 individuals of both genders) by PCR-invader assay and maximum likelihood method. Out of 41 SNPs studied, 13 were firstly reported for Caucasians and eight of them were monomorphic. A comparison of the other 28 SNP allele frequencies of the studied Caucasian population with the respective data for Caucasians from the literature and public databases revealed significant difference for six SNP markers. Further comparison of our data with other ethnic groups confirmed the commonly observed differences in SNP allele frequencies for the three major world ethnic groups: 3 of 19 loci differed significantly in Caucasians vs Africans, and so do 13 of 24 loci in Caucasians vs Asians. Significant differences in allele frequencies of three polymorphisms (out of five compared) were also observed between Caucasian and Pacific Rim samples. The results of this extensive study essentially confirmed the previously reported data on the SNPs for Caucasians, and suggested several new candidate SNPs for studying osteoporosis and obesity. The observed significant differences in allele frequencies of some SNPs in Caucasians may be due to population admixture and/or insufficient sample size in the other studies. Our results also showed that major ethnic groups are indeed highly differentiated at some SNP markers of a number of important genes, which may be associated with osteoporosis and/or obesity. This differentiation may underlie different rates of these disorders in the major ethnic groups.

**Defining haplotypes and tagging efficient SNPs for association studies of candidate genes and regions for Cleft Lip and Palate.** *T. Beaty*<sup>1</sup>, *M.D. Fallin*<sup>1</sup>, *J.B. Hetmanski*<sup>1</sup>, *R. Ingersoll*<sup>2</sup>, *I. McIntosh*<sup>2</sup>, *A.F. Scott*<sup>2</sup>. 1) Dept Epidemiology, Johns Hopkins University, School of Public Health, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Defining haplotype blocks and tagging SNPs that can identify these blocks has been proposed as one way to maximize the efficiency of genotyping for association studies while extracting the most genetic information. Characterizing haplotype structure should help identify the major variation in a candidate gene or region, so linkage disequilibrium information can be used to its greatest potential. Once haplotype structure is identified, only those SNPs that uniquely categorize chromosomes into common haplotypes need to be genotyped. This could substantially reduce the cost of a study while maximizing genetic association information. Before this strategy can be used for a particular candidate gene or region, however, haplotype blocks must be defined and SNP tags identified that best represent those blocks. We present analysis for 150 SNPs located in 27 genes and 2 extended chromosome regions (4p16, 22q11.21) selected as plausible candidates for cleft lip and/or palate. We first identified SNPs via sequencing and database searches, then genotyped SNPs in 145 unrelated Caucasian parents of cleft children. The number of SNPs identified per gene/region ranged from 1-30, spanning distances ranging from .05 kb 1.33 Mb. Analysis of allele frequencies, patterns of pair-wise linkage disequilibrium, haplotype block predictions and choices of tagging SNPs that would reconstruct the common haplotypes are presented. On average, only half of the original SNPs identified were needed for efficient typing. To contrast the set of informative SNPs for genotyping of these sample candidate genes in another population, the same strategy of defining haplotype blocks is being applied to an Asian control sample.

**Associations between Polymorphisms in the Steroid 5-Reductase Type II (SRD5A2) Gene and Benign Prostatic Hyperplasia and Prostate Cancer.** *M.T. Salam*<sup>1</sup>, *G. Ursin*<sup>1,2</sup>, *E.C. Skinner*<sup>3</sup>, *T. Dessissa*<sup>4</sup>, *J.K. Reichardt*<sup>1,4</sup>. 1) Preventive Medicine, University of Southern California, Los Angeles, CA; 2) Institute for Nutrition Research, University of Oslo, Norway; 3) Urology, University of Southern California, Los Angeles, CA; 4) Biochemistry & Molecular Biology, University of Southern California, Los Angeles, CA.

Genes affecting androgen synthesis and metabolism have been suggested to be involved in the development of both benign prostatic hyperplasia (BPH) and prostate cancer. We evaluated associations between three polymorphisms in the steroid 5-reductase type-II (SRD5A2) gene [A49T (alanine-49 to threonine), V89L (valine-89 to leucine) and a (TA)<sub>n</sub> dinucleotide repeat in the 3' UTR (untranslated region)] and both BPH and prostate cancer within a multiethnic population. Men between 60 and 86 years of age were recruited from annual prostate cancer screening programs and from a large urology clinic. We genotyped 606 men (412 Hispanic, 98 Caucasian, 73 African-American and 23 Asian) of whom 100 had prostate cancer, 393 had BPH (280 symptomatic and 113 asymptomatic) and 113 had normal prostates. Unconditional logistic regression was used to calculate the odds ratio (OR) and 95% confidence interval (CI) while adjusting for age and race. Overall, there was an association between V89L and BPH, with an OR for the LL (polymorphic) vs. VV (normal) genotype ( $OR_{LL/VV}$ ) of 1.9 (CI, 0.8-4.9,  $P_{trend} = 0.73$ ). This association was strongest in Hispanics ( $OR_{LL/VV} = 3.9$ ; CI, 0.9-17.3,  $P_{trend} = 0.03$ ). V89L was also associated with prostate cancer; the  $OR_{LL/VV}$  was 4.5 (CI, 1.2-16.1,  $P_{trend} = 0.01$ ) in the overall population and 7.3 in Hispanics (CI, 1.5-35.5,  $P_{trend} = 0.005$ ). Presence of at least one T allele at the A49T loci was associated with increased risk of BPH (OR = 4.5; CI, 0.6-37.0) and prostate cancer (OR = 4.1; CI, 0.4-49.0). These results suggest that the SRD5A2 gene may play an important role in both BPH and prostate cancer. Supported by CRP grant 99-000553V-10150.

**Multivariate genetic analysis of thyroid hormone traits.** *G. Perez<sup>1</sup>, N. Gouin<sup>2</sup>, C. Kammerer<sup>1</sup>, D. Finegold<sup>3</sup>, T.P. Foley<sup>3</sup>, S. Cole<sup>2</sup>, J. Blangero<sup>2</sup>, L. Almasy<sup>2</sup>, P. Samollow<sup>2</sup>, M.M. Barmada<sup>1</sup>.* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Department of Endocrinology, UPMC Health System, Pittsburgh, PA.

Thyroid hormones play major roles in the regulation of protein synthesis, basal metabolism, and lipid metabolism. In an effort to understand the genetic and environmental influences which contribute to variation in these hormones, we have conducted multivariate modeling, and report here biologically meaningful latent factors with high heritability. We evaluated variation in seven thyroid hormone or related traits (free and total thyroxine (T<sub>4</sub>), free and total triiodothyronine (T<sub>3</sub>), thyroxine-binding globulin (TBG), thyrotropin (TSH), and thyroglobulin (TG)). Phenotype and genotype data were obtained from members of 33 randomly selected Mexican-American families from the San Antonio Family Heart Study. Multivariate linear regression was used to correct for environmental components of variation, and the resulting residuals were analyzed for correlation and for higher-order structure using factor analysis. Similar analyses were conducted with the inclusion of other hormones, lipids, indicators of fat mass, and insulin related measures, and also individually for sex-specific subgroups. For all factor models, regression-derived factor scores were generated for each factor and subjected to variance component modeling. Significant heritabilities (>30%) were observed for most factors, so that genome-wide linkage analysis was subsequently undertaken. Linkage signals (LODs ranging from 2.0-2.5) were identified across most models for a factor representing the relationship between TSH, T<sub>3</sub>, and T<sub>4</sub> levels at a locus on chromosome 4, near albumin, which is associated with Euthyroid Hyperthyroxinemia - a disease that manifests with abnormal total T<sub>4</sub> and T<sub>3</sub> levels. This signal was not identified by separate univariate QTL analyses of the thyroid traits. These results illustrate that analyses of multivariate traits will enhance the identification of possible pleiotropic QTLs that influence thyroid hormone function.

**Association of the hCLCA1 gene with bronchial asthma.** *F. Kamada*<sup>1</sup>, *Y. Suzuki*<sup>1</sup>, *C. Shao*<sup>1,3</sup>, *M. Tamari*<sup>2</sup>, *K. Hasegawa*<sup>2</sup>, *Y. Aoki*<sup>1</sup>, *S. Kure*<sup>1</sup>, *G. Tamura*<sup>3</sup>, *T. Shirakawa*<sup>2,4</sup>, *Y. Matsubara*<sup>1</sup>. 1) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Miyagi, Japan; 2) Laboratory for Genetics of Allergic Diseases, SNP Research Center, The Institute of Physical and Chemical Research, Yokohama, Japan; 3) Department of Respiratory and Infectious Diseases, Tohoku University School of Medicine, Sendai, Japan; 4) Department of Health Promotion and Human Behavior, Kyoto University School of Public Health, Kyoto, Japan.

Bronchial asthma is a chronic illness characterized by reversible airway obstruction and airway hyperresponsiveness that are caused by bronchial inflammation. This inflammation involves mucus overproduction and hypersecretion. Recently, a mouse model of asthma showed that *Gob-5* is involved in the pathogenesis of asthma. The observation suggests that the human homologue of *Gob-5*, *hCLCA1*, may be involved in the human disease. We screened for SNPs in the *hCLCA1* gene in the Japanese population to examine whether the *hCLCA1* gene polymorphisms are associated with asthma. We identified 8 SNPs (intron 5; 908+246C>T, intron 5; 908+2199G>A, intron 6; 1086+589T>C, intron 6; 1087754C>A, intron 6; 1087705A>G, intron 8; 1533+997A>C, intron 8; 1534808G>C, exon 15; 2787T>C) in this gene, and performed association studies using 1091 asthma patients (562 childhood patients, 529 adult patients) and 1105 non asthmatic controls. Association of 2787T>C with childhood asthma (P=0.025) and that of 1533+997A>C with adult asthma (P=0.026) were detected in the single-SNP case control study. In the 8-SNP haplotype analysis, we found a different haplotype distribution pattern between controls and childhood asthma (P=0.000089). The TGCCAAGT haplotype was protective against childhood asthma (P=0.016). In the diplotype analysis, individuals who had this haplotype showed lower risk for childhood asthma when compared to those who did not (P=0.013). Our data are the first to suggest the association of the *hCLCA1* gene polymorphisms and human asthma.

**Environmental and genetic etiology factors in cleft lip and palate in Korea.** *S. Jee*<sup>1</sup>, *B. Park*<sup>2</sup>, *M. Kim*<sup>1</sup>. 1) Graduate School of Public Health , Yonsei Univ, Seoul, Korea; 2) Department of Plastic and Reconstructive Surgery, Yonsei University College of Medicine, Seoul, Korea.

This study was an investigation by questionnaire, from January 1997 to July 2002, of 453 people who had been diagnosed and treated with cleft lip and/or palate in one hospital. Among them, 107 participated in the study. According to priorities, we investigated the kinds of cleft etiologies considered by their parents. The analysis showed that the first priority was drug intake during early pregnancy, and the second was paternal smoking. This study showed 13.1% (14 people) heritable cases in clefts. Furthermore, among those with and without a family history of clefts, drug intake during early pregnancy was selected as the first priority risk factor. However, among those cases with a family history, parental genetic etiology was selected for the second and third priorities, while among those cases without a family history, parental smoking, environmental factors, and orofacial clefts were selected. Unfortunately, little is known regarding the etiology and embryology of these clefts in the Korean population. Especially, we cannot disregard the effect of genetic interaction in clefts in considering the 13.1% family heritable cases in this study. It is evident from the results of this study that further investigations into the environmental and genetic etiology in the Korean population are required.

Program Nr: 1195 from 2003 ASHG Annual Meeting

**Evidence of gene-gene interaction as a strong risk factor for myocardial infarction: Combined carrier status of prothrombin 20210A and factor XIII-A L34 alleles.** *Y.G. Xie, C. Butt, H. Zheng, D. Robb, P. Parfery, E. Randell.* Memorial University of Newfoundland, Disciplines of Laboratory Medicine, Genetics, Pediatrics, Medicine, St. Johns, NL, Canada. A1B 3V6.

Conflicting results have been obtained from studies associating the prothrombin 20210A (FII 20210A), Factor V Leiden (FVL), and Factor XIII L34 (FXIII-A L34) alleles with myocardial infarction (MI). These conflicting results may result from complicated gene-gene interactions in the pathogenesis of MI, inadequate sample size, heterogeneous genetic background of subject populations and focusing only on the role of individual genetic variants. These weaknesses could be overcome through simultaneous analysis of multiple gene variants in a large sample size from the genetically isolated population. We have genotyped 600 MI patients and 500 controls from this genetically isolated Newfoundland population to determine the association between the FII 20210A, FVL and FXIII-A L34 alleles and MI. We also focused on the analysis of possible gene-gene interactions involved in the pathogenesis of MI in this population. The prevalence of the FII 20210A allele was higher in MI patients (2.8%) than in controls (1.0%;  $P=0.031$ ). The FII 20210A allele was also 5.1 fold higher in MI patients younger than 55 years when compared with age-matched controls ( $P=0.009$ ). Furthermore, the prevalence of combined carriers of FXIII-A L34 and FII 20210A alleles was 13-fold higher in MI patients compared with controls ( $P = 0.002$ ) with 93% penetrance. There was disequilibrium of the FXIII-A L34 allele in MI patients carrying the FII 20210A allele as a genetic background. From these observations, we conclude that: 1) the FII 20210A allele is a risk factor for MI, possibly important for early onset; 2) interaction between the FII 20210A and FXIII-A L34 alleles form a synergistic co-effect which strongly predisposes for MI, placing combined carriers at high risk for MI. We are currently collecting and analyzing further patient samples, focusing on those under the age of fifty-five years.

**Diversity of paternal and maternal lineages in populations of South Siberia.** *M. Derenko*<sup>1</sup>, *B. Malyarchuk*<sup>1</sup>, *T. Grzybowski*<sup>2</sup>, *A. Lunkina*<sup>1</sup>, *I. Dambueva*<sup>3</sup>, *F. Luzina*<sup>4</sup>, *D. Miscicka-Sliwka*<sup>2</sup>, *I. Zakharov*<sup>5</sup>. 1) Institute of Biological Problems of the North, Magadan, Russia; 2) The Ludwik Rydygier Medical University in Bydgoszcz, Bydgoszcz, Poland; 3) Institute of General and Experimental Biology, Ulan-Ude, Russia; 4) Institute of Professional Diseases and Hygiene Problems, Novokuznetsk, Russia; 5) Vavilov Institute of General Genetics, Moscow, Russia.

Phylogeography of the non-recombining uniparentally inherited mitochondrial DNA (mtDNA) and Y-chromosome has been broadly used to shed light on different aspects of genetic history of human populations. To investigate the origin and evolution of aboriginal populations of South Siberia, a comprehensive mtDNA (HVR1 or HVR1/HVR2 sequencing combined with RFLP typing of informative coding region polymorphisms) and Y-chromosome binary markers (YAP, RPS4Y, SRY-8299, M89, 12f2, M9, M20, 92R7, SRY-1532, DYS199, LLY22g, Tat) analysis of 1538 individuals representing 15 different populations (Koryaks, Evens, Evenks, Yakuts, Tofalars, Tadjiks, Tuvinians, Khakassians, Altaians, Teleuts, Shors, Sojots, Buryats, Mongolians, Koreans) was performed. The phylogenetic networks based on obtained data were further investigated following the phylogeographic analysis of individual lineage clusters. The total sample revealed 81% of East Asian (M\*, M7, M8, M9, M10, C, D, G, Z, A, B, F, N9a, Y) and 17% of West Eurasian (R\*, HV, H, U, J, T, I, N1a, X) matrilineal genetic contribution, but with regional differences. The highest influx of West Eurasian mtDNAs was observed in populations of Altai region of South Siberia (up to 35%), whereas in other Siberian and East Asian populations it was markedly lower (less than 10%). On the contrary, our Y-chromosome data demonstrate that 67% of the South Siberian Y-chromosomes are of Eastern European descent. The Central/Eastern Asian influence has been estimated to be no more than 33%. Overall, the substantial degree of genetic differentiation within South Siberia region was demonstrated using both mtDNA and Y-chromosome haplogroup frequency data. Hierarchical analysis of genetic diversity reveals that geographic distances are the most important factor in genetic differentiation observed.

**An association study between Angiotensinogen (AGT) variants and AGT plasma level indicates functional evolution of the AGT gene.** *L. Fejerman<sup>1</sup>, N. Bouzekri<sup>1</sup>, X. Wu<sup>2</sup>, A. Adeyemo<sup>3</sup>, A. Luke<sup>2</sup>, X. Zhu<sup>2</sup>, R. Ward<sup>1</sup>, R.S. Cooper<sup>2</sup>.* 1) Dept. of Biological Anthropology, Oxford University, Oxford, UK; 2) Dept. of Preventive Medicine, Loyola University Medical Center, Maywood, IL; 3) Dept. of Pediatrics, University College Hospital, University of Ibadan, Ibadan, Nigeria.

During the last ten years, there has been an increasing interest in the associations between different angiotensinogen (AGT) variants and the predisposition to high blood pressure as well as in the relationship between AGT variants and AGT plasma levels. So far, evidence has emerged to support the relationship between AGT variants and the protein level. However, further analysis is needed to define which variants are more directly associated with AGT levels. An evolutionary approach that takes into account the phylogenetic relationship between all the polymorphisms along a given genetic region can enhance our understanding of the genetic nature of quantitative traits. In this study, we sequenced a 6.8 kb region in 57 Nigerian individuals (29 with high AGT plasma levels and 28 with low AGT plasma levels). Haplotypes were determined and grouped in 7 major haplogroups. Their phylogenetic relationship was established and the association of AGT levels and particular haplogroups were investigated. A significant correlation between the genetic distance and AGT levels for the 7 major haplogroups was detected. Our results indicate as plausible that the mutations that occurred during the evolutionary history of the AGT gene leading to the low and high phenotypes, have been accumulating progressively within the two main tree branches in a non-random manner. We propose a hypothesis of the functional evolution of the AGT gene based on this study.

**Geographic and haplotype structure of polymorphisms in *MTHFR*.** *M. Bamshad*<sup>1,2</sup>, *S. Wooding*<sup>2</sup>, *D. Dunn*<sup>2</sup>, *L.B. Jorde*<sup>2</sup>, *R. Weiss*<sup>2</sup>. 1) Dept of Pediatrics, U of Utah, Salt Lake City, UT; 2) Dept of Human Genetics, U of Utah, Salt Lake City, UT.

Polymorphisms in *MTHFR*, the gene encoding the enzyme, 5,10-methylenetetrahydrofolate reductase, influence the metabolism of folate and homocysteine, and are thought, in turn, to modulate the risk of neural tube defects, vascular dementia, and colon cancer. The two most common of these polymorphisms, C677T and A1298C, cause amino acid substitutions that reduce the enzymatic activity of *MTHFR* by ~65% and ~45%, respectively, in persons homozygous for the mutant genotype. As a consequence, these people may have higher folate requirements. The frequencies of C677T and A1298C vary substantially among populations, suggesting that differences in folate levels among environments might have exposed *MTHFR* to varying selective pressures. To investigate the effects of natural selection and population history on patterns of variation in *MTHFR*, we examined DNA sequence variation in 5.5 kb in all 11 exons and flanking regions from 156 chromosomes collected from African, Asian, and European populations. We found 38 single nucleotide substitutions including 5 non-synonymous and 9 synonymous changes in the coding region and 24 in non-coding regions. C677T and A1298C were both more frequent in Europeans. Of a total of 38 haplotypes discovered, C677T was found on two different haplotypes whereas A1298C occurred on 16 different haplotypes. Two haplotype clusters corresponding to haplotypes containing either C677T or A1298C were found. These clusters had different frequencies across Africa, Asia, and Europe. This suggested that natural selection might similarly have influenced both polymorphisms. Patterns of variation in the total population and each continental group did not, however, deviate significantly from expectations under a neutral model or under a model of population expansion.

**Detecting adaptive molecular polymorphism, lessons from the MHC.** *D. Garrigan*<sup>1,2</sup>, *P.W. Hedrick*<sup>2</sup>. 1) Genomic Analysis & Technology , University of Arizona, Tucson, AZ; 2) Department of Biology, Arizona State University, Tempe, AZ.

Predictions of the neutral theory have become the standard by which cases of balancing selection may be inferred. The immunologically important genes of the major histocompatibility complex (MHC) have long served as the canonical example of balancing selection operating in human populations. Human MHC sequence data are synthesized from a wide range of studies and the extraordinary levels of observed polymorphism are used as a benchmark to examine the power of many widely used tests of neutral evolution. These tests are categorized as being capable of detecting selection in the current generation, recent past, and more distant evolutionary past. We find that balancing selection on the human MHC is not detectable in every generation, population, or every evolutionary lineage. This suggests that either selection on the MHC is heterogeneous or that many of the current neutrality tests lack sufficient power to detect selection consistently. We also note an important inference problem that arises when tests reject long-term neutral evolution. We demonstrate that long-term signals of selection, such as the ratio of nonsynonymous to synonymous substitutions, develop quickly, yet persist for exceptionally prolonged periods of microevolutionary time, even in the absence of further selection. A novel, empirical test of selection is proposed that relies only on the observed distribution of neutral allele frequencies throughout the genome. This test bypasses the traditional population genetics assumptions made by many tests based upon the neutral theory.

**Evolution of human apolipoprotein H gene haplotypes and their significance in the production of antiphospholipid antibodies and binding to anionic phospholipid.** *M.I. Kamboh, D.K. Sanghera, H. Mehdi, C.S. Nestlerode, Q. Chen, C.H. Bunker.* Grad Sch Public Hlth, Univ Pittsburgh, Pittsburgh, PA.

Apolipoprotein H (APOH), also known as 2-glycoprotein I is a major autoantigen for the production of antiphospholipid antibodies (APA) in autoimmune diseases. APA is also recognized by a cryptic epitope generated following the interaction of APOH with anionic phospholipids (PL). The prevalence of APA in the general U.S. white population is about 10% but it ranges 30 - 70% in patients with lupus and antiphospholipid syndrome. Since the structural characterization of APOH from different mammalian species is important to identify the evolutionarily conserved regions that may be critical for its function, we have previously determined the chimpanzee APOH gene structure and the prevalence of APA. There is only two amino acid difference between the chimpanzee and human wild type APOH proteins. Chimpanzees have unusually high prevalence (64%) of APA. There is a common protein polymorphism in the human APOH gene with the occurrence of four alleles *APOH\*1*, *APOH\*2*, *APOH\*3* and *APOH\*4*, the latter being present only in blacks. Based on its differential reactivity with an APOH monoclonal antibody, the *APOH\*3* allele is further divided into *APOH\*3<sup>W</sup>* (present only in whites) and *APOH\*3<sup>B</sup>* (present only in blacks). In this study we have screened a large African population (n = 755) to determine the prevalence of APA and the molecular bases of the protein polymorphism. Almost 50% of the Africans were found to be positive for APA. The *APOH\*3<sup>B</sup>* allele was found to be identical to the chimpanzees wild type APOH. Novel two-site or three-site haplotypes, encoded in the third domain of APOH, explained the molecular basis of the *APOH\*3<sup>B</sup>*, *APOH\*3<sup>W</sup>* and *APOH\*4* alleles. Based on the comparison of the human and chimpanzee APOH DNA sequences, we suggest that the *APOH\*3<sup>W</sup>* and *APOH\*4* arose on the ancestral *APOH\*3<sup>B</sup>* haplotype after the split of human races in whites and blacks, respectively. We also found that these haplotypes are associated with the occurrence of APA. Recombinant APOH haplotypes, expressed in COS-1 cells, showed that these mutations also affect the binding of APOH to anionic PL.

**Mitochondrial DNA diversity in Slavonic-speaking populations.** *B. Malyarchuk<sup>1</sup>, T. Grzybowski<sup>2</sup>, M. Derenko<sup>1</sup>, A. Lunkina<sup>1</sup>, G. Denisova<sup>1</sup>, J. Czarny<sup>2</sup>, D. Miscicka-Sliwka<sup>2</sup>.* 1) Genetics Lab, Biological Probl of the North, Magadan, Russia; 2) The Ludwik Rydygier Medical University in Bydgoszcz, Bydgoszcz, Poland.

Maternally inherited mitochondrial DNA (mtDNA) sequence variation was examined by HVS1/HVS2 sequencing combined with SNP-RFLP typing in 885 individuals from European Slavonic-speaking populations inhabiting the territories from the Balkan Peninsula (on the south) to the Baltic Sea coast (on the north) and to the Volga river (on the east). Populations studied included ethnic groups from the West Balkans (Bosnians and Slovenians), Central-North Europe (Poles) and East Europe (Russians). Phylogenetic analysis suggested that maternal lineages were classified into 38 clusters representing the main West Eurasian mtDNA haplogroups. East Eurasian genetic contribution was found at frequency of 1.8% in Poles, 1.6% in Russians and 1.4% in Bosnians. The distribution of mtDNA lineages in Slavonic and the neighboring European populations revealed that the common genetic substratum appears to be characteristic for Central and Eastern European populations (such as Germans, Poles, Russians and Finns). Additionally, according to AMOVA results, South Slavonic populations were found to be significantly different from the neighboring South European populations (Italians, Albanians, and Greeks). It is noteworthy that Slavonic-speaking populations, including the Balkan ones, are characterized by a high frequency (30%-50%) of Y chromosome haplogroup R1a, which is rare in Western Europe. This pattern of mtDNA and Y chromosome distribution is compatible with the archaeological and historical data suggesting that the Slavonic migration waves from Central Europe reached the Balkans, as well as the East European plain, in the early Middle Ages. The work is supported by RFBR grant (03-04-48162).

**SNPSTR autosomal genohaplotypes by restriction site engineering: empirical gametic phase without allele-specific primers.** *A. Knight*<sup>1</sup>, *I.G. Udina*<sup>2</sup>, *B.M. Henn*<sup>1</sup>, *P.A. Underhill*<sup>3</sup>, *J.L. Mountain*<sup>1,3</sup>. 1) Anthropological Sci, Stanford Univ, Stanford, CA; 2) N.I. Vavilov Inst of General Genetics, Russian Academy of Sci, Moscow, Russia; 3) Genetics, Stanford Univ, Stanford, CA.

SNPSTRs have provided, for the first time, a method to simultaneously determine both genotype and phase (the genohaplotype) for compound single nucleotide (SNP) or indel polymorphisms and nearby linked short tandem repeat (STR or microsatellite) loci in autosomes using rapid, multiplex-capable, conventional fluorescent size analysis methods. A drawback to replacement of conventional STR analysis with SNPSTR analysis has been the technical difficulty of optimizing robust allele-specific PCR parameters for the SNP genotyping aspect of the standard SNPSTR approach. Although allele-specific difficulties may be overcome through experimentation, and large-scale population studies are well underway, we endeavored to develop a more reliable and straightforward alternative approach. Here we describe a simple method that entirely circumvents the inherent challenges of allele-specific PCR associated with SNPSTR methodology. This innovative restriction enzyme assay involves use of a forward PCR primer that incorporates a portion of a restriction endonuclease cleavage site (either native or engineered), followed by PCR and digestion, to diagnose the SNP and a fluorescent-labeled reverse primer to indicate STR length by capillary electrophoretic detection on a genetic analyzer. Analysis of SNPSTR genohaplotypes on human chromosome 8 demonstrates the technical ease and utility of the method.
