In the search for genetic variants affecting liability to complex diseases, haplotype data have received increasing recognition. When there are more than a few haplotypes, one way to assess the association between disease status and haplotypes is to reconstruct their evolutionary history, i.e. to build a tree that specifies the relative age of each haplotype. To achieve that goal, we combine information from two sources: (1) the inferred network relating haplotypes; and (2) the frequency and mutational history of each haplotype. The former resolves into a space of candidate trees while the latter entails probabilistic modeling to determine the absolute age of each haplotype. To maximize the 'tree likelihood', or the joint likelihood of absolute ages of haplotypes for a given tree, we develop a quasi-boundary procedure that enables us to compare trees consistent with the inferred network. These comparisons make explicit which trees are most likely to have generated the observed data and thus guide decisions for data analysis. We evaluate these methods using data on monoamine oxidase (MAO) haplotypes from two ethnic backgrounds, African-American and European-American. Our results show that the evolutionary trees exhibit consistency of relative ages among common haplotypes in the two ethnic groups.

**Progress toward the identification of origins of myotonic dystrophy type 1 mutation: worldwide study in the CEPH-Human Genome Diversity Project.** *T. Miki<sup>1</sup>, H. Yamagata<sup>1,2</sup>, S. Akiyama<sup>3</sup>, Y. Chen<sup>1</sup>, K. Kohara<sup>1</sup>, I. Kondo<sup>2</sup>.*

1) Dept Geriatric Medicine, Ehime Univ Sch Medicine, Ehime, Japan; 2) Dept Med Genetics, Ehime Univ Sch Medicine, Ehime, Japan; 3) Dept Clin Nursing, Sch Health Sciences, Univ Occupational and Environmental Health, Fukuoka, Japan.

Background: Although it is believed that a major ancient mutation underlying myotonic dystrophy type 1 (DM1) has originated from reservoir pool (CTG19-37), the molecular mechanisms underlying repeat instability are not well understood. Objectives: To understand the origins of DM1 mutations and the evolution of modern humans. Samples and Methods: 1064 normal individuals from 51 different world populations in 21 countries (CEPH-HGDP) and Japanese DM1 samples were analysed. We determined CTG-repeat number and examined 8 SNPs at the 20kb DMPK-SIX5 region. Determination of genotypes included GeneScan (CTG repeat) and PCR-RFLPs (SNPs). Linkage disequilibrium and haplotype analysis were carried out. Results and Discussion: As for CTG repeat distributions, the results were similar to those reported by Tishkoff et al.(1998). Some populations showed trimodal distribution (CTG5, 6-17, 18-37) and others did not. Frequencies of CTG5, 11-13, >19 were grouped. As expected, DM1 rare populations (sub-Saharan African, China etc) had no CTG>19 repeats. As for Amerindians (Karitiana, Maya etc), a major genetic bottleneck from Asia to the Americas was seen. The SNPs in promoter region of DMPK showed an evenly distributed pattern when normal alleles were grouped according to CTG repeat length. Even for CTG>20 alleles there were different haplotypes according to SIX5 locus SNPs. It suggests that CTG>20 alleles are also comparatively stable and not all >20 repeat allele will increase its size in successive generations. Common DM1 founder chromosome region was postulated to be within about 17kb including CTG repeat. Our data suggest founder chromosomes rather than predisposing alleles.

**Integration of association statistics over genomic regions using BARS.** *K. Roeder<sup>1</sup>, X. Zhang<sup>2</sup>, D. Wallstrom<sup>1</sup>, B. Devlin<sup>3</sup>.* 1) Dept Statistics, Carnegie Mellon Univ, Pittsburgh, PA; 2) Dept of Biometrics Research Merck Research Laboratories; 3) Dept of Psychiatry, University of Pittsburgh School of Medicine.

In the search for genetic determinants of complex disease, two approaches to association analysis are most often employed, testing single loci or testing a small group of loci jointly via haplotypes for association to disease status. It is still debatable which of these approaches is more favorable, and under what conditions. The former has the advantage of simplicity but suffers severely when alleles at the tested loci are not in linkage disequilibrium (LD) with liability alleles; the latter should capture more of the signal encoded in LD, but is far from simple. The complexity of haplotype analysis could be especially troublesome for association scans over large genomic regions, which in fact is becoming the standard design. For these reasons, we have been evaluating statistical methods that bridge the gap between single-locus and haplotype-based tests. In this article we present one such method, which uses non-parametric regression techniques embodied by Bayesian Adaptive Regression Splines (BARS). For a set of markers falling within a common genomic region and a corresponding set of single locus association statistics, the BARS procedure integrates these results into a single test by examining the class of smooth curves consistent with the data. The non-parametric BARS procedure generally finds no signal when no liability allele exists in the tested region (i.e., it achieves the specified size of the test) and yet it is sensitive enough to pick up signals when an liability allele is present. The BARS procedure provides a robust and potentially powerful alternative to classical tests of association, diminishes the multiple testing problem inherent in those tests, and can be applied to a wide range of data types, including genotype frequencies estimated from pooled samples.

Program Nr: 1206 from 2003 ASHG Annual Meeting

**Mitochondrial haplotypes revealed genetic connection between Sino-Tibetan and Japanese.** *Y. Qian, L. Jin, B. Su.*  
Center for Genome Information, Dept. Env. Health, Univ Cincinnati, Cincinnati, OH.

To investigate genetic affinity among East Asian populations, a total of 515 mtDNA lineages of 14 Eastern Asian populations, including 6 Sino-Tibetan speaking populations, 2 Japanese populations from East and West Honshu respectively, and 2 Altaic, 1 Daic and 3 Astro-Asiatic speaking populations were involved in this study. Ten Eastern Asian-specific RFLP markers in coding region were typed and non-coding region HVS-I (16042-16569 following 1-41) were sequenced to determine haplotypes of each mitochondrial lineage. Based on published data and our dataset, a phylogenetic tree of haplogroups was generated and allowed us to describe matrilineal relationships of these populations. Our results showed that all mtDNA lineages are affiliated with two macrohaplogroup M and N, however, the distribution of sub-haplogroup frequency showed differences between Daic, Astro-Asiatic populations which are genetically close to Southeast Asian populations and Sino-Tibetan, Altaic, Japanese populations. By contrast, Japanese exhibited similar haplogroup frequency distribution with Sino-Tibetan and Altaic populations, especially for a few geographic specific haplogroups, such as F1b, D, G1 and G2a, indicating close genetic affinity with Northern Chinese populations. Principal components analysis also suggested such genetic connection between Japanese and these Chinese populations. Interestingly, the mitochondrial data indeed support our previous observation that inferred migration from Himalayas to Japan using Y chromosome polymorphic markers typing.

**Haplotype analysis of the M390R mutation within *BBS1*, the most common locus for Bardet-Biedl syndrome.** A.J. Ross, B.E. Hoskins, P.J. Scambler, P.L. Beales. Molecular Medicine Unit, Institute of Child Health, London, United Kingdom.

Bardet-Biedl syndrome (BBS) is a heterogeneous disorder with primary features that include age-related retinal dystrophy, obesity, polydactyly, renal dysplasia, reproductive tract anomalies and cognitive impairment. It is genetically heterogeneous and has at least seven loci, with mutations identified in five genes to date (*BBS1*, *BBS2*, *BBS4*, *BBS6* & *BBS7*). The *BBS1* gene is the locus most frequently involved with this disorder, with mutant alleles present in 20% of all patients. M390R, a missense mutation within exon 12 of *BBS1*, is the most common BBS mutation and has been shown to be involved in 18-32% of all BBS cases. This single mutation, which accounts for the vast majority (75%) of all *BBS1* associated alleles, is found almost exclusively in patients of European origin. Therefore, it has been suggested that M390R may be an ancient mutation that has arisen from a single common ancestral event, which has subsequently been fixed within this population. In support of this, results from a recent study typing STRP markers from an approximately 450Kb region flanking the *BBS1* gene in patients from 22 families have indicated that there may be a common M390R haplotype. Here, we present the results of haplotype analyses of BBS patients with the M390R mutation from 24 unrelated families of European origin using the same STRP markers to facilitate direct comparison. Our results provide further evidence to suggest that M390R is likely to be an ancient mutation, which has possibly been maintained in the European population through positive M390R heterozygous advantage.

Program Nr: 1208 from 2003 ASHG Annual Meeting

**The use of SNP-based haplotypes and LD blocks to positionally clone modifying determinants of expansion of the Fragile X triplet repeat.** *S. Ennis, A. Collins, N.E. Morton.* Human Genetics Division, Duthie Building (MP808), Southampton General Hosp, Southampton, United Kingdom.

Unstable germline transmission of the FRAXA CGG triplet repeat at Xq27.3 results in transcriptional silencing of the adjacent FMR1 gene when the repeat tract exceeds 200 units. The resulting Fragile X phenotype is the most common form of inherited mental retardation affecting ~1/5500 males. Purity and length of the CGG array influence stability but other cis-acting factors are postulated to exist. Over the last decade, three microsatellite repeats (DXS548, FRAXAC1 and FRAXAC2), have been commonly applied to characterise the haplotypic background upon which a FRAXA allele occurs. Although high-risk haplotypes have been identified using these markers, causal determinants of expansion remain elusive.

We have typed a panel of 22 single nucleotide polymorphisms (SNPs) across 650 kb of the FRAX region on a panel of 877 independent male chromosomes that span the range of FRAXA repeat sizes. The resultant haplotypes confirm and extend the information gleaned from microsatellite haplotypes. A metric linkage disequilibrium map of the region was created to identify discrete regions of elevated recombination and extended regions containing contiguous SNPs in high LD.

These SNP data were then used in a program recently developed for the ALLASS suite of software, which reads data from SNP haplotypes, and uses linkage disequilibrium to positionally clone disease genes. As the causal mutation for fragile X syndrome is already known, the program was instead used to examine the regional marker data for: 1) evidence for and; 2) the location of a modifier of dynamic mutation. Results indicate a region 3 of the FMR1 gene is significantly associated with expanded CGG repeats. Further examination of this associated region using SNPs at increased density may reveal some genetic component of the FMR1 CGG repeat expansion.

**MJD haplotypes unequally distributed throughout mainland Portugal.** *S. Martins*<sup>1,2</sup>, *C. Gaspar*<sup>3</sup>, *I. Silveira*<sup>2</sup>, *F. Calafell*<sup>4</sup>, *G. Rouleau*<sup>3</sup>, *P. Coutinho*<sup>5</sup>, *A. Amorim*<sup>1,6</sup>, *J. Sequeiros*<sup>2,7</sup>. 1) IPATIMUP, Portugal; 2) UnIGENe, IBMC, Univ Porto, Portugal; 3) Centre for Research in Neuroscience, McGill Univ, Montreal General Hosp, Canada; 4) Unitat de Biologia Evolutiva, Fac Ciències Salut Vida, Univ Pompeu Fabra, Spain; 5) Serv Neurologia, Hosp S Sebastião, St<sup>a</sup> M<sup>a</sup> Feira, Portugal; 6) Fac Ciências, Univ Porto, Portugal; 7) ICBAS, Univ Porto, Portugal.

Machado-Joseph disease (MJD) is an autosomal dominant neurodegenerative disorder, caused by an unstable CAG expansion in the *MJD1* gene. The disease was first described in families of Portuguese-Azorean ancestry, but the origin of the mutation(s) has been a matter of debate since it was suggested its introduction in northeastern Portugal, spreading later to the Azores archipelago, and from there to the rest of the world. More recently, a haplotype study, using three intragenic SNPs, showed the association of an A-C-A and a G-G-C haplotypes with MJD in Azorean families, respectively from the islands of Flores and S. Miguel. Worldwide, the majority of the families shared the A-C-A haplotype, suggesting a major founder mutation. In order to clarify the origin and spread of the MJD mutation(s), we have (1) performed a haplotype analysis, including the CAG polymorphism and the intragenic SNPs A<sup>669</sup>TG/G<sup>669</sup>TG, C<sup>987</sup>GG/G<sup>987</sup>GG, TAA<sup>1118</sup>/TAC<sup>1118</sup> and a newly identified one, in MJD mainland Portuguese families, and (2) searched for microsatellites flanking the CAG repeat. The new intragenic polymorphism is located in intron 7 (IVS7-86TG). Strong linkage disequilibrium was noted between T and G alleles, from IVS7-86TG and A<sup>669</sup>TG/G<sup>669</sup>TG, respectively. The preliminary haplotype analysis showed a heterogeneous distribution over mainland Portugal. Interestingly, the most frequent haplotype was G-G-C (in contrast to the rest of the world), except in northeastern Portugal, where A-C-A seems to be over-represented. In addition, we found a polymorphic GT repeat, 227 kb from the CAG, with five alleles in the MJD population. By sequencing four of them, we have identified three different lineages caused by nucleotide substitutions. These results are compared with those in a large control population.

Program Nr: 1210 from 2003 ASHG Annual Meeting

**Evidence for epistasis between chromosome 2p and 13q in human obesity.** *C. Dong, W.D. Li, D. Li, R.A. Price.*  
Dept Psychiatry, Univ Pennsylvania, Philadelphia, PA.

We employed several model-free approaches to conduct multipoint analyses and look for epistatic interactions in human obesity using our second-generation genome scan data in 1297 individuals from 260 European American families. For assessment of epistasis, we found the strongest evidence between chromosomes 2p24-p25 and 13q12-q14 with a correlation score of 0.213 (N=247, p=0.0008) for BMI 35 and 0.406 (N=115, p=6.6-E6) for BMI 40 based on alleles shared identical by descent (IBD) for affected sib pairs (ASP) and with a correlation score of 0.306 (N=201, p=1.0-E5), 0.339 (N=161, p=1.1-E5) and 0.426 (N=98, p=1.2-E5) for BMI 30, 35 and 40, respectively, based on family-specific nonparametric linkage (NPL) scores. We also conducted NPL score-based conditional logistic regression analyses and found a significant interaction between the two regions with a regression coefficient for the interaction term of 0.706 (p=0.0002), 0.810 (p=0.0002) and 1.258 (p=0.0001) for BMI 30, 35 and 40, respectively. We performed conditional analyses using the ALLEGRO program and found that the LOD score at 2p rises from 0.06 in the baseline analyses to 2.00, 2.36 and 1.96 for BMI 30, 35 and 40, respectively, when families were weighted by evidence for linkage at 13q (26 cM) using zero-one weights. For a continuous BMI phenotype, we conducted Haseman-Elston regression analysis based on a two-locus epistatic model, which yielded significant evidence for interaction between 2p (28 cM) and 13q (LOD=4.11), compared with a two-locus model (LOD=1.20). Results from variance component analysis also supported the observed interaction between the two regions by showing an epistatic effect of p=0.004. Our findings suggest that genetic loci on chromosomes 2p and 13q may interact to influence human obesity. (This study was supported in part by NIH grants R01DK44073, R01DK48095, and R01DK56210 to RAP.).

**Combined and sex-specific linkage analyses of thyroid hormones in Mexican Americans.** *N. Gouin<sup>1</sup>, M.M. Barmada<sup>2</sup>, G. Perez<sup>2</sup>, C. Kammerer<sup>2</sup>, S. Cole<sup>1</sup>, H. Göring<sup>1</sup>, J. Blangero<sup>1</sup>, L. Almasy<sup>1</sup>, D. Finegold<sup>3</sup>, T.P. Foley<sup>3</sup>, P. Samollow<sup>1</sup>.* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Endocrinology, UPMC Health System, Pittsburgh, PA.

Thyroid hormones play major roles in the regulation of protein synthesis, basal metabolism, and lipid metabolism. In an effort to understand the genetic regulation of thyroid hormone levels, we performed variance components linkage analyses to detect quantitative trait loci (QTLs) using data on six thyroid hormone or thyroid hormone related traits (free and total thyroxine (FT<sub>4</sub> & TT<sub>4</sub>), free and total triiodothyronine (FT<sub>3</sub> & TT<sub>3</sub>), thyroxine-binding globulin (TBG), thyrotropin (TSH), and on insulin-like growth factor 1 (IGF1). Phenotypic and genotypic data were available on 1022 individuals (428 male and 595 females) from 33 Mexican-American families collected as part of the San Antonio Family Heart Study. Prior to performing linkage analyses over both sexes and within male and female subgroups, significant effects of measured external environmental components were identified via multivariate linear regression. Overall, we detected suggestive evidence for QTLs influencing TT<sub>3</sub> on chr 16q (LOD=2.78), FT<sub>4</sub> on chr 11p (LOD=2.43), and IGF1 on chr 8 (LOD=2.57). Sex-specific analyses indicated that evidence for the overall IGF1 QTL was mostly from the subgroup of women, whereas each sub-group contributed to evidence for the TT<sub>3</sub> and FT<sub>4</sub> QTLs. We also detected a QTL for FT<sub>4</sub> levels on chr 16q (LOD=3.14) in women, which was not evident in men or the combined group; this QTL is within 20cM of the TT<sub>3</sub> QTL. Our results illustrate that analyses performed overall and within subgroups will enhance our understanding of genetic control of thyroid hormone variation and also facilitate the identification of possible QTLs that influence thyroid hormone function.

**Results from web-based recruitment of subjects for study on the genetics of absolute pitch.** *B. Levinson<sup>1</sup>, J. Zemansky<sup>1</sup>, A. Athos<sup>1</sup>, A. Kistler<sup>1</sup>, N. Freimer<sup>2</sup>, J. Gitschier<sup>1</sup>*. 1) Dept. of Medicine and Pediatrics, University of California, San Francisco and HHMI; 2) Center for Neurobehavioral Genetics, Neuropsychiatric Institute, and Dept. of Human Genetics, University of California, Los Angeles.

Absolute pitch (AP), also known as perfect pitch, is the ability to identify the pitch of a tone without use of a reference. Previous studies by our group and others have shown evidence for both a genetic and environmental contribution to the development of AP. To map the gene(s) responsible for AP, we are collecting affected relative pairs and trios. For efficient recruitment of subjects, we rely on a web-based survey and pitch-identification test (<http://perfectpitch.ucsf.edu>). From 7/31/02 to 6/17/03, 764 people completed the survey and took the acoustical test, which includes both pure tones and piano tones. Of these, 316 scored sufficiently high in pitch-recognition (AP-1) to be included in our study. Subjects were accurate in their self-description, with 80% of subjects who indicated AP ability testing AP-1, and only 11% of those answering no or don't know testing AP-1. Age range for subjects entering the study is 6 to 79, with 60% falling between ages 14 and 30, a skewed distribution most likely reflecting increased use of the web in this age group. Subjects testing AP-1 ranged from 12 to 67 with a similarly skewed distribution. 28% of responding AP-1 subjects report a relative with AP ability (more than 50% indicated a sibling), with an additional 34% unsure. AP-1 subjects also proved to be quite accurate in their assessment of their family members' pitch abilities, as only a handful of reported relatives failed to test AP-1. Confirmed families were invited to contribute a blood sample, collected by a mobile phlebotomy service. Samples have been immortalized and stored. Our large data set also allows us to analyze the errors in AP-1 subjects tests. Subjects tend to err sharp more than flat. Of interest was a common error in perception in multiple octaves of the pure tone G# as an A. This error was not found in the piano tone test. Errors were also more frequent in older participants.

**The Role of CARD15/NOD2 variants G908R, R702W and L1007fsins in a pediatric Crohn's Disease cohort.** *K.L. Maresso<sup>1</sup>, N. Collins<sup>2</sup>, R. Kraemer<sup>1</sup>, S. Kugathasan<sup>2</sup>, U. Broeckel<sup>1</sup>.* 1) Human & Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 2) Department of Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

Three single nucleotide polymorphisms (SNPs) within the CARD15/NOD2 (G908R, R702W, L1007fsins) gene have been strongly associated with susceptibility to Crohn's Disease (CD) in various adult populations. While there are distinct clinical patterns between adult- and pediatric-onset CD, no study has yet to examine the role of these SNPs in childhood CD using a population-based, pediatric cohort. Consequently, we aimed to determine allele frequencies of G908R, R702W and L1007fsins within children and to test for their linkage and association with pediatric-onset CD. Determining the role of these mutations within pediatric CD will assist in identifying molecular genetic differences between adult and childhood forms of the disease. A total of 159 patients have been recruited from a population-based, pediatric CD registry in southeastern Wisconsin. We have parental DNA for 40% of these patients, constituting 63 complete mother-father-child trios. All patient and parental DNA samples were genotyped for the three SNPs using direct fluorescence-based sequencing. Allele frequencies were calculated for all patients and the Transmission-Disequilibrium-Test (TDT) was used to assess linkage and association within the trios (GeneHunter, v.2.0). Allele frequencies within the affected children were as follows: G908R, 5.2%; R702W, 7.6%; and L1007fsins, 10.1%. These frequencies are similar to those found in adult populations. Results of both the single-locus ( $\chi^2 = 7.36$ ,  $p = 0.007$ ) and two-locus ( $\chi^2 = 4.5$ ,  $p = 0.03$ ) TDT demonstrated that the L1007fsins allele is preferentially transmitted from parent to affected offspring. Based on this preliminary analysis, the L1007fsins appears to play a role in pediatric CD. However, it is likely there are additional genetic determinants influencing susceptibility to pediatric CD, as allele frequencies within this population are similar to those of adult CD populations. This is the first such study of Crohn's Disease-associated polymorphisms in a population-based, pediatric cohort.

Program Nr: 1214 from 2003 ASHG Annual Meeting

**Worldwide genetic variation in human bitter taste receptor genes.** *U.-K. Kim, J. Larsen, D. Drayna.* NIDCD/NIH, Rockville, MD.

Common allelic variants of a member of the TAS2R bitter taste receptor gene family underlie variation in the ability to taste phenylthiocarbamide (PTC). To extend these results to other bitter receptors, we have sequenced 22 of the 24 known TAS2R genes in a series of populations worldwide, including Hungarians, Japanese, Cameroonians, Pygmies, and South American Indians. All 22 TAS2R genes contain common SNPs within their coding sequence, and we identified an average of 4.4 SNPs per TAS2R gene. Fifteen variants listed in dbSNP were not observed to be polymorphic in our sample. 77% of the SNPs we observed cause an amino acid substitution in the encoded receptor protein, giving rise to a very high degree of receptor protein variation in the population. Four SNPs specify one allele that introduces an in-frame stop codon in the gene. The frequency of these stop codon alleles indicates that there are a significant number of individuals who are homozygous null for some bitter taste receptors. Overall, African samples displayed higher diversity of alleles. This is consistent with the view that the majority of human genetic variation resides within older African populations, and a fraction of this variation emerged and subsequently spread across the remainder of the world.

**Linkage disequilibrium and haplotype structure of four SNPs of the Interleukin-1 gene cluster in seven South Asian populations.** *S.M. Raju<sup>1</sup>, R. Govindaraju<sup>1</sup>, N. Wang<sup>2</sup>, R. Chakraborty<sup>2</sup>.* 1) 4 Marshall Road, Lexington, MA; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati College of Medicine, Cincinnati, OH.

We investigated the extent and pattern of genetic variations at four single nucleotide polymorphism sites (SNPs: IL-1A 4845, IL-1B 3954, IL-1B 511, and IL1-RA 2018) of the interleukin-1 gene cluster among 280 unrelated individuals, representing seven caste groups (Bunt, Havyak, Iyenger, Lingayath, Smartha, Vaishya, and Vokkaliga) from the state of Karnataka, India, and one European American community of Boston area, US. In terms of allele frequencies at these sites, two- to four-fold differences were found among these eight populations. Genotype frequencies at these sites were, by and large, in Hardy-Weinberg equilibrium in all populations. Linkage disequilibrium (LD), examined by  $D$ ,  $R^2$ , and Fishers exact test, showed significant allelic associations between sites, but the strength of LD varied by site-pairs as well as across populations. Haplotype frequency distributions and haplotype diversity, inferred by the E-M algorithm, also showed considerable differences across populations, some of which were statistically significant. The frequency of the most common haplotype ranged from 15 to 40 percent. Presence of more than 5 segregating haplotypes (e.g., 7 in the Bunt, and 11 in the Caucasian sample) in multiple populations provides evidence of historical recombinations between sites. Together, these observations indicate a substantial inter-population variation of the extent and pattern of polymorphisms of the interleukin-1 genes, suggesting that these polymorphisms may differentially influence susceptibility to autoimmune diseases among the studied populations. Differences of community sizes, and traditions of consanguinity may account for the observed population differentiation within small geographic areas at these functionally relevant SNP sites. These observations also imply that factors responsible for such population differentiation may impact inference regarding haploblock structures in specific genomic regions. (Research supported by US Public Health Service Research grants to RC).

**Ipf-1 D76N mutation is present in Italian late-onset type 2 diabetics.** *J.F. Brittman<sup>1</sup>, J.F. Habener<sup>1,2,3</sup>, C. Gragnoli<sup>1,2,4</sup>*. 1) Molecular Endocrinology, MGH, Boston, MA; 2) Med. School., Harvard. Univ., Boston, MA; 3) HHMI, Boston, MA; 4) Univ. Tor Vergata of Rome, Italy.

Maturity onset diabetes of the young (MODY) is a monogenic autosomal-dominant subform of type 2 diabetes mellitus (T2DM). It has an onset before age 25 and is due to mutations in at least six different genes. MODY gene mutations are also a cause of late-onset T2DM. Genetic variations in insulin promoter factor-1 (Ipf-1/MODY4) are uncommon but when present contribute to diabetes as part of a polygenic background. IPF-1 is a homeodomain transcription factor required for pancreas development and transcriptional regulation of pancreatic beta cell genes. Our goal was to investigate whether ipf-1 mutations are responsible for late-onset T2DM in the Italian population. We recruited and screened 89 late-onset T2DM Italian probands for Ipf-1 mutations in exon 1-2 and flanking introns. We identified one subject with a single nucleotide substitution GAC to AAC at AA Asp76. 50 Italian controls with negative family history for T2DM and normal fasting glucose were directly sequenced for the presence of Ipf-1 Asp76Asn. We excluded variations in exon 1 in the 100 normal chromosomes. The affected T2DM sib of the mutant proband is also a D76N mutation carrier. This mutation D76N has been already identified in the French, UK, Swedish and Danish late-onset T2DM population and it is known to be located in the transactivation domain of IPF-1 and to affect the IPF-1 transactivation and DNA-binding activities. Furthermore, the AA 76 is highly conserved in hamster, rat and mouse. This is the first screening of Ipf-1 gene performed in the late-onset T2DM Italian population, while a previous screening in an early-onset T2DM Italian population identified a P33T mutation. So far in multiple population screenings of the Ipf-1 gene, 12 different mutations have been identified. D76N Ipf-1 has a prevalence of 1.1 per cent in the late-onset T2DM Italian population and represents the most common mutation present in Ipf-1, and contributes to late-onset T2DM with a prevalence of 1.9 per cent in the European population (combined estimate from published data and this described study).

**Gene diversity of mitochondrial DNA in Russians.** *O.P. Balanovsky*<sup>1, 2</sup>, *R. Villems*<sup>2</sup>, *M.I. Churnosov*<sup>3</sup>, *E.A. Pocheshkova*<sup>4</sup>, *E.V. Balanovska*<sup>1</sup>. 1) Research Centre for Medical Genetics, Moscow, Russia; 2) Estonian Biocenter, Tartu, Estonia; 3) Belgorod State University, Belgorod, Russia; 4) Kuban Medical Academy, Maikop, Russia.

We have analyzed mtDNA variability in 640 Russians to evaluate degree and patterns of intra-ethnic variability of mitochondrial genome. The studied sub-populations are: northern (from Arkhangelsk region), western (Smolensk region), eastern (Kostroma region), southern (Belgorod region) and the Kuban Cossacs, with a median distance between the groups more than 1000 km. The first hypervariable segment was sequenced in all samples and a set of informative RFLP sites was typed. We have found that the other East Slavonic people Ukrainians and Belorussians - have the largest number of maternal lineages, shared with Russians, whereas western and southern Slavs differ in their haplotype composition from Russians more. Finnic ethnoses, both the Baltic and Volga-Finnic, encompass somewhat more lineages, shared with Russians, than western and southern Slavs do. This can be interpreted in terms of a significant Finno-Ugric substratum in Russians. Multidimensional scaling (MDS) analysis revealed two clusters - Finnic and Slavic, with Baltic language speakers as intermediate. The MDS plot shows that differentiation between maternal lineages of Finnic-speaking ethnoses is greater than that between Slavic populations. However, among the Slavic-speaking people, intra-Russian variability of mtDNA is as high as that among all Slavic ethnoses studied here: northern and southern Russians occupy two poles of the intra-Slavic variation. The northern Russians are the most distant because of specific features of their mtDNA haplogroup composition. We conclude that large geographic distances between Russian sub-populations have resulted in a high level of intra-Russian mtDNA variability that is comparable with inter-ethnic differences in East Europe in general. Several substratum populations, including Finnic-speaking tribes, have likely facilitated the creation of a diversity that can be observed in the extant Russian-speaking people of the East Europe. The work was supported by RFBR (grants 01-06-80085, 01-07-90041).

**Molecular genetic analysis of suballeles of the ABO blood group system in a Kuwaiti population using multiplex PCR-RFLP.** *M.M. El-Zawahri<sup>1</sup>, Y.A. Luqmani<sup>2</sup>, G.C. Abraham<sup>2</sup>, A.A. Al-Bashir<sup>3</sup>*. 1) Dept Biological Sci, Fac Sci, Kuwait Univ, Kuwait; 2) Dept Pharmaceutical Chemistry, Fac Pharmacology, Kuwait Univ, Kuwait; 3) Kuwait Central Blood Bank (KCBB), Kuwait.

The ABO blood group system is one of the conventional polymorphisms that are important in transfusion medicine, forensic serology and anthropological genetics. The Kuwaiti population is a relatively young that has roots originating mainly from Saudi Arabia, Iraq, and Iran. The present study is the first demonstration of an extensive variability linked to suballeles of the ABO locus in a Kuwaiti population. Molecular genetic analysis of suballeles of the ABO blood group system and their distribution were studied by multiplex PCR-RFLP method in 355 unrelated Kuwaiti individuals. DNA was extracted from EDTA blood samples. With multiplex PCR, fragments of 252 (251 for O<sup>1</sup>) and 843 (842 for A<sup>2</sup>) bp were amplified in the same tube using two pairs of specific primers. The amplified fragments cover the two major exons 6 and 7, and constitute 91% of the translated gene. After simultaneous digestion with restriction endonucleases HpaII and KpnI, a conclusive interpretation of the expected fragment pattern obtained could be made in all cases. Fifteen different genotypes could be identified when combining the A<sup>1</sup>, A<sup>2</sup>, B, O<sup>1</sup> and O<sup>2</sup> suballeles from the digestion patterns. The serologic phenotypes of the 355 blood samples used in this study were: A (77), B (97), AB (10) and O (171). The genotypes determined were 1 A<sup>1</sup>A<sup>1</sup> (0.28%), 6 A<sup>1</sup>A<sup>2</sup> (1.69%), 38 A<sup>1</sup>O<sup>1</sup> (10.71%), 1 A<sup>1</sup>O<sup>2</sup> (0.28%), 1 A<sup>2</sup>A<sup>2</sup> (0.28%), 30 A<sup>2</sup>O<sup>1</sup> (8.45%), 6 A<sup>1</sup>B (1.69%), 4 A<sup>2</sup>B (1.13%), 12 BB (3.38%), 79 BO<sup>1</sup> (22.25%), 6 BO<sup>2</sup> (1.69%), 167 O<sup>1</sup>O<sup>1</sup> (47.04%) and 4 O<sup>1</sup>O<sup>2</sup> (1.13%). Two of the combinations (A<sup>2</sup>O<sup>2</sup>, O<sup>2</sup>O<sup>2</sup>) were not found amongst the 355 samples tested. All genotypes determined were consistent with the observed phenotypes. These frequency data may provide useful additional information for forensic medicine, organ transplantation and phylogenetics in Kuwaiti population. Supported by grant SZ 01/00 from Kuwait University.

**Y chromosome haplotype diversity in insular and mainland populations from Croatia.** *L. Barac<sup>1</sup>, M. Pericic<sup>1</sup>, I. Martinovic Klaric<sup>1</sup>, S. Rootsi<sup>2</sup>, B. Janicijevic<sup>1</sup>, T. Kivisild<sup>2</sup>, J. Parik<sup>2</sup>, P. Rudan<sup>1</sup>.* 1) Institute for Anthropological Research, Zagreb, Croatia; 2) Department of Evolutionary Biology, Institute for Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

Y chromosome haplotypes have become invaluable tools for determination of parentage and kinship in forensic casework and population genetics. Eight short tandem repeat (STR) polymorphic systems mapped on the human Y chromosome (DYS19, DYS388, DYS389I, DYS389II, DYS390, DYS391, DYS392, DYS393) were typed in mainland (n = 109) and four insular (n = 348) populations. A general allelic frequency distribution in the overall Croatian sample corresponds to other European populations with the exception of the loci DYS19 and DYS389II. The most frequent DYS19 allele was 16, while at the DYS389II the most frequent were alleles 30 and 31. Complete typing was obtained for 457 chromosomes that showed two hundred forty one different Y chromosome haplotypes. The most frequent Y chromosome haplotype (16-13-13-31-24-11-11-13) was found in 33 individuals (7.22%). One hundred seventy four haplotypes (38.07%) were observed in single copies. Comparison of insular and mainland populations showed a statistically significant difference in allele frequencies at 4 out of 8 loci. Moreover, the haplotype 16-13-13-32-24-11-11-13 was noticed exclusively in two islands. The haplotype diversity ranged from 0.9749 (island of Korcula) to 0.9913 (mainland). Observed differences between mainland and insular populations could be explained by specific population histories, unlike settling patterns involving different gene boundaries and more pronounced effects of genetic drift in island.

**Cytochrome P450 2D6\*2, \*3, and \*4 polymorphisms in a Mexican population.** *J.L. Guerrero<sup>1</sup>, M. Lopez<sup>2</sup>, G. Galicia<sup>1,2</sup>, E. Alonso<sup>1</sup>.* 1) Genetics and Molecular Biology, Nac. Inst. Neurol. Neuroc., Mexico City, Mexico City, Mexico; 2) Biologic Systems, UAM-X, Mexico, D.F.

Cytochrome P450 2D6 (CYP2D6) catalyzes the oxidative metabolism of several clinically important classes of drugs. The CYP2D6 gene is highly polymorphic, and more than 70 different alleles have been identified. These genetic variants have been correlated to 3 classes of phenotypes based on the extent of drug metabolism: ultra-extensive (UEM), extensive (EM) and poor (PM) metabolizers resulting in low, normal and high blood levels of parent drugs. In addition to individual variation in drug response, there are interethnic differences. Among Caucasians, 5-9% lack functional CYP2D6 enzymes, whereas the incidence of PMs among Asians and Africans is <2%. Molecular analysis of the CYP2D6 locus has also revealed interethnic differences in allele frequencies. The most common mutations in Caucasians are CYP2D6\*4 (G1934A) and CYP2D6\*3 (A2637 del), these alleles are rarely found among Chinese, Koreans, black Americans and black Zimbabweans. The CYP2D6\*2 allele is the most common allele encoding intermediate enzyme activity in Caucasians, and results have a strong effect on the metabolic phenotype when present in combination with a null allele. We studied 152 unrelated healthy Mexican volunteers, between 18 and 55 years old. The leukocyte DNA was isolated and CYP2D6\*1, \*2, \*3 and \*4 sequences were amplified by PCR, followed by digestion with Cfo I, Msp I and Mva I, respectively. DNA fragments were analyzed by electrophoresis. The allelic frequency found was 63.4%, 24.8%, 11.0% and 0.8% for CYP2D6\*1, CYP2D6\*2, CYP2D6\*4, and CYP2D6\*3, respectively. We identified one subject who was homozygous for the CYP2D6\*4 allele, and another individual who had a combination of CYP2D6\*3 and CYP2D6\*4 alleles. The population frequency of the CYP2D6 poor metabolizer phenotype was estimated to be 2%. This study will extend the literature attesting to ethnic differences with respect to CYP2D6 polymorphism. The polymorphic CYP2D6 enzyme activity in Mexican population could have important implications for the use of drugs that are substrates for CYP2D6 and have a narrow therapeutic window. CONACYT, 37103 M.

**Y chromosome and mitochondrial DNA variation and the origin of Lithuanians.** *V. Kucinskas*<sup>1</sup>, *D. Kasperaviciute*<sup>1</sup>, *D. Ambrasiene*<sup>1</sup>, *M. Stoneking*<sup>2</sup>. 1) Dept. of Human and Medical Genetics, Vilnius Univ, Vilnius, Lithuania; 2) Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.

There are conflicting anthropological findings regarding the origins of Indo-Europeans and formation of Baltic tribes in Eastern Baltics. The Lithuanians and the Latvians are the only Baltic cultures that survived until today, therefore molecular genetic characterisation of these populations may help to reconstruct the prehistory and ethnogenesis of the people in this area. We have analysed mitochondrial DNA and Y chromosome diversity in six ethnolinguistic groups of Lithuanians. Analysis of molecular variance shows that all variation in Lithuania is due to variation within groups, and no variation was detected among groups neither in mtDNA nor Y-chromosome markers. Comparisons of mtDNA sequences with other European populations have not revealed significant differences, however, more lineages are shared with populations of northern Europe. Y-chromosome analysis shows Lithuanian population to be closest to Latvians and Finno-Ugric speaking Estonians, all three populations being indistinguishable in frequencies of biallelic markers. Interestingly, Lithuanians have a high frequency (~37%) of TatC allele, which is frequent in Uralic speakers of northern Eurasia. However, the analysis of Y chromosome 9 different microsatellite markers on TatC allele background in Lithuanians and Estonians revealed significant differences, thus indicating different histories of these populations. Lower gene diversity and nearly star-like median joining network of Lithuanian TatC chromosomes indicates a recent population bottleneck, however major Lithuanian haplotypes are rare in Estonians, suggesting that these populations have different origins or have differentiated before Indo-Europeanization took place in Eastern Baltics.

**Microsatellite genetic variation in the Indian Subcontinent.** *S.S. Mastana*<sup>1</sup>, *G. Sun*<sup>2</sup>, *S.S. Papiha*<sup>3</sup>, *R. Chakraborty*<sup>2</sup>, *R. Deka*<sup>2</sup>. 1) Dept Human Sciences, Human Genetics Lab, Loughborough University, Loughborough, United Kingdom; 2) Department of Environmental Health, University of Cincinnati, Cincinnati, OH 45267. USA; 3) Institute of Human Genetics, University of Newcastle on Tyne. United Kingdom.

We have analysed genetic variation at 13 STR loci (CODIS core loci) in a sample of 18 ethnically and geographically diverse endogamous caste and tribal populations of the Indian subcontinent. A wide spectrum of allelic distribution at different loci was observed in different geographical and ethnic populations. Overall populations within geographical regions showed greater degree of similarity. Statistically significant differences were observed in a large number of inter-population comparisons. D18S51, FGA and D21S11 loci were the most polymorphic in all populations. FGA locus had the highest average heterozygosity (86%) and the lowest was observed for TPOX (69%). Average heterozygosity for all loci was 0.79. Coefficient of genetic diversity showed a narrow range for different loci (0.007 to 0.026) with an average of 1.4%, which indicates that these populations are at an early stage of micro-differentiation. Phylogenetic trees and principal component analysis computed from microsatellite allele frequencies provide support for socio-cultural and geographical assignment of these populations. Lowest match probability and highest exclusion probability was observed for the FGA locus in majority of the populations. Combined match probability was low (1 in  $1.55 \times 10^{-15}$  to 1 in  $7.47 \times 10^{-16}$ ), and combined exclusion probability was > 99.99%. There was no evidence of allelic association between loci studied, so these loci seem to comprise a suitable group of markers for population genetic purposes and for paternity and forensic testing. This research was supported by NIH grant GM45861, NIJ grant 98-LB-VX-002 and funds from Loughborough University.

**Principal Component Analysis for Selection of Optimal SNP-sets that Capture Intragenic Genetic Variation.** *B.D. Horne<sup>1,2</sup>, N.J. Camp<sup>1,2</sup>*. 1) Genetic Epidemiology, University of Utah School of Medicine, Salt Lake City, UT; 2) LDS Hospital, Intermountain Health Care, Salt Lake City, UT.

Association analysis results are often inconsistent across studies. A source of inconsistency can be the limited genetic data analyzed -usually one single nucleotide polymorphism (SNP) per gene. A solution would be to choose a set of SNPs which comprehensively covers the total genetic diversity of the gene. We introduce a novel method that defines sets of SNPs that comprise linkage disequilibrium (LD) groups and selects SNPs that encompass the intragenic genetic diversity. Principal component analysis (PCA) is performed on the SNP haplotypes in two stages. First, PCA is performed on all SNP haplotypes to determine the number of principal components (LD-groups) needed to describe the data. An LD-group is defined as a set of SNPs which all have substantial weighting in the same principal component. Second, PCA is performed on the SNP haplotypes for SNPs within each LD-group to establish an optimal set of genetic information content SNPs (gicSNPs) that sufficiently account for the diversity within each LD-group. The final set of gicSNPs will consist of at least one SNP from each LD-group, and should comprehensively cover the intra-genic diversity. This PCA method differs from other methods in that an LD-group need not consist of continuous DNA fragments or be mutually exclusive. As an example, we analyzed 19 SNPs in the ELAC2 gene spanning the gene and its promoter. Four LD-groups were identified in ELAC2 which accounted for 94% of the total variation. All except 2 very rare SNPs were represented in these LD-groups. Next, gicSNPs were chosen such that at least 90% of variation within each LD-group was maintained. The optimal gicSNP set included eight SNPs in total, 4 in the promoter region. Results of the PCA gicSNP method compared well with existing htSNP methods, but also provided advantages including better tagging of LD-groups, and quantification of the optimal number of SNPs to adequately describe a gene. This suggests that PCA may be useful in establishing optimal SNP sets which maximize the amount of genetic variation captured while using a minimal number of SNPs.

**Genetic variation at nine short tandem repeat loci in the Croatian populations.** *I. Martinovic Klaric<sup>1</sup>, M. Pericic<sup>1</sup>, L. Barac<sup>1</sup>, B. Janicijevic<sup>1</sup>, M. Kubat<sup>2</sup>, D. Pavicic<sup>1</sup>, R. Chakraborty<sup>3</sup>, L. Jin<sup>3</sup>, R. DeKa<sup>3</sup>, P. Rudan<sup>1</sup>.* 1) Institute for Anthropological Research, Zagreb, Croatia; 2) Department of Forensic Medicine and Criminology, University of Zagreb, School of Medicine, Zagreb, Croatia; 3) Division of Epidemiology and Biostatistics, Department of Environmental Health, University of Cincinnati Medical Center, Cincinnati, OH, USA.

The aim of this study is to analyze genetic variation at nine autosomal short tandem repeat loci (D3S1358, vWA, FGA, THO1, TPOX, CSF1PO, D5S818, D13S317, D7S820) in six populations from Croatia, five of which are distributed in the islands of the eastern Adriatic coast and one is drawn from the mainland. The purpose is to investigate genetic structure of the Croatian populations and to evaluate the usefulness of the studied loci in regional level genetic differentiation. This investigation demonstrates a substantial genetic homogeneity of the Croatian gene pool as revealed by distribution of allelic frequencies, heterozygosity values, number of alleles and allele size variance, allele and genotype sharing data and the coefficient of gene differentiation. Even though a larger sample sizes for villages within islands could have provided a greater power of autosomal STRs in resolving patterns of microevolutionary structuring at regional level, the greatest discriminating power will certainly result when all classes of genetic markers, paternal, maternal and autosomal, will be jointly considered.

**The prevalence of methylenetetrahydrofolate reductase (MTHFR) gene polymorphisms (C677T) and prothrombin 3-untranslated region variant (G20210A) in Mexican Cerebral Venous Thrombosis patients. A.**

*Jara, L. Martinez, H. Gonzalez, C. Cantu, A. Rasmussen, E. Alonso.* Genetics and Molecular Biology, Inst. Nal. Neurol. Neuroc., Mexico, City, Mexico, City, Mexico.

Cerebral venous thrombosis (CVT) is a serious disease, characterized by the severity of the clinical manifestations and the high mortality rate. It is a multifactorial disease caused by the interaction of acquired and genetic factors. CVT arises as a result of alterations in coagulation pathways. Recently, two genetic factors were described, the prothrombin gene variant and methylenetetrahydrofolate reductase polymorphism. A GA transition in position 20210 in the 3-UT region of the prothrombin gene is associated with elevated plasma prothrombin levels. The second factor described is a mutation (C677T) in the methylenetetrahydrofolate reductase (MTHFR) gene. MTHFR polymorphism is significantly associated with reduced enzyme activity and increased circulating levels of homocysteine. In this study, we examined the prevalence of prothrombin (G20210A) and MTHFR C677T gene variants in control subjects and in patients with CVT and determined the association between these variants and the presence of CVT. Fiftythree CVT patients and 456 healthy controls were recruited. Blood samples were collected for DNA analysis for the identification of the prothrombin and MTHFR gene (G20210A and C677T respectively) variants by PCR, followed by digestion with Taq I and Hinf I respectively. The resulting fragments were analyzed by electrophoresis and visualized with UV light. The frequency of the heterozygous variant G20210A was 1.5 % in the patients and 8.7 % in the controls, and the prevalence for the homozygous polymorphism MTHFR C677T was 16.4% and 12.7%, respectively. We also found an association between the prothrombin gene G20210A transition and the risk of CVT (OR=5.36, 95% CI=1.11-5.36). However, we did not find an association between MTHFR C677T mutation and the risk of CVT. These findings suggest that the G20210A variation could be a more important risk factor for CVT in Mexican population than the MTHFR mutation. However it would be important to increase the sample in order to support these findings.

**Beta globin haplotypes of three Mediterranean beta-thalassemia mutations observed in Mexican patients.** *B. Ibarra, M.T. Magaña, F.J. Perea.* Division de Genetica, Centro Invest Biomed Occte, Guadalajara, Jalisco, Mexico.

Beta thalassemia in Mexico has a wide spectrum of mutations, characteristic of the populations with low frequency of thalassemias, since to date 17 different mutations have been observed in 80 unrelated studied chromosomes. Mediterranean, Asian and rare alleles have been observed, the most common was GLN39TER (31.4%), followed by IVS1, G-A, +1 and IVS1, G-A, +110 (14.5% each). The beta globin haplotype (BH<sub>p</sub>) performed by RFLPs, was studied in 28 families with beta thalassemia, (13 with the mutation GLN39TER, 8 with IVS1, G-A, +1 and 5 with IVS1, G-A, +110), with the aim to search the genetic background of these alleles in Mexican population. All chromosomes with the IVS1, G-A, +1 mutation showed the same haplotype (1, + - - -), while for the 5 with the IVS1, G-A, +110 mutation, four had haplotype 1 and one haplotype 9 ( - - - - ), suggesting that its presence in Mexico has a single origin. On the other hand, the GLN39TER mutation showed a diversity of RFLP haplotypes since six were observed on haplotype 1, four with haplotype 2 ( - + + - +), two with haplotype 4 ( - - - - +) and one with haplotype 3 ( - + - + +). A great heterogeneity of BH<sub>p</sub>s with the GLN39TER mutation has also been observed in several Mediterranean countries like Algeria, which could be explained as a high mutation susceptibility at the second exon of the beta globin gene leading to a recurrent mutations on different chromosomal background.

**Correlation between apolipoprotein E and lipid levels in the three ethnic groups in Malaysia.** *W.T. Seet<sup>1</sup>, J.A. Tan<sup>2</sup>, S.Y. Tan<sup>1</sup>*. 1) Department of Medicine, University of Malaya, 50603 Kuala Lumpur, Malaysia; 2) Department of Molecular Medicine, University of Malaya, 50603 Kuala Lumpur, Malaysia.

Apolipoprotein E, a polymorphic gene located on chromosome 19, has three common alleles: 2, 3 and 4. Studies have shown that individuals with at least one 2 allele tend to have lower cholesterol levels than those with homozygous 3 alleles and individuals with at least one 4 allele tend to have higher cholesterol levels than those with homozygous 3 allele. The objective of this project was to determine the correlation between apoE genotype and lipid levels (total cholesterol, triglyceride, high-density lipoprotein and low-density lipoprotein) in the Malay, Chinese and Indian populations in Malaysia. EDTA and plain blood were collected from 1127 blood donors. All of the subjects were screened for total cholesterol levels. Seventy nine subjects were screened for triglyceride (TG), high-density lipoprotein (HDL) and low-density lipoprotein (LDL) levels. The ApoE gene sequence was amplified by the polymerase chain reaction (PCR) method and ApoE genotyping was performed by restriction enzyme digest with Hha I. One-way analysis of variance (ANOVA) was used to test the significance of total cholesterol, TG, HDL and LDL levels between the different apoE genotypes and gender. The results showed that there was a significant difference between the different apoE genotypes and total cholesterol levels in the Malay (n=345), Chinese (n=563) and Indian (n=219) populations with a p-value of 0.0001, 0.0001 and 0.009 respectively. Individuals with the E2/E2 and E2/E3 genotypes were found to have lower mean cholesterol levels than those with the E3/E4 and E4/E4 genotypes. No significance was found between gender and total cholesterol levels. Significant difference between the apoE genotypes and LDL levels in the 79 subjects (p=0.018) was also observed. However, no significance was found between genotypes and TG and HDL. Our study indicates that the apoE2 isoform is related to lower LDL and serum cholesterol levels whereas the apoE4 isoform tends to increase these values.

**Genetic structure of Sao Miguel's population (Azores) revealed by Y-Chromosome STR analysis.** *P.R. Pacheco, C.C. Branco, S. Costa, R. Cabral, T. Cymbron, B.R. Peixoto, L. Mota-Vieira.* Genetics & Molec Pathol Unit, Hosp Divino Espirito Santo, Azores Islands, Portugal.

The Azorean archipelago (Portugal) is located in the Atlantic Ocean, 1500 Km from the European mainland. The islands had no native population when Portuguese navigators first arrived from mainland in the XV century. Sao Miguel is the biggest and most populated (131,609 inhabitants) island of the Azores. In order to understand the genetic structure of Sao Miguel's population, we analysed seven Y-chromosome STR loci (DYS385, DYS389I, DYS389II, DYS390, DYS391, DYS392 and DYS393) in 100 unrelated individuals. Father's birthplace was used to select the samples: Nordeste (n=4), Povoacao (n=5), Vila Franca do Campo (n=8), Lagoa (n=11), Ribeira Grande (n=22) and Ponta Delgada (n=50), representing all the municipalities in Sao Miguel. The samples were typed by PCR with fluorescently labelled primers and products run in a CEQ8000 DNA Sequencer (Beckman Coulter). In a total of 100 complete seven-locus haplotypes, we observed 71 different haplotypes of which 54 appear only once. The mean heterozygosity per locus in the overall sample was 0.59, with the highest value in Nordeste (0.71) and the lowest in Ponta Delgada (0.56). On average the mean pairwise difference between two random haplotypes ranged from 4.49 in Ponta Delgada to 5.66 in Nordeste. The mean  $F_{st}$  value over all 7 loci was very low (-0.00758), denoting the absence of heterogeneity among the municipalities of the island. Pairwise genetic distances were computed for all six municipalities and no genetic heterogeneity was detected. AMOVA analysis shows that the percentage of variation attributable to differences within municipalities is extremely high compared to the differences between municipalities. These results provide evidence for reduced levels of Y-chromosome variability in the male lineages of Sao Miguel's population. We are currently analysing 4 SNPs (sY81, Tat, SRY1532 and SRY2627) and 1 indel polymorphism (YAP), in order to characterize the frequency and distribution of Y-chromosome haplogroups in the population of Sao Miguel. Funded by DRCT, Azores. (paulapacheco@hdes.pt).

**Genetic and environmental influences on racial/ethnic health disparities.** *N. Risch*<sup>1,2</sup>, *A. Karter*<sup>2</sup>. 1) Dept Genetics, Stanford Univ, Stanford, CA; 2) Division of Research, Kaiser Permanente, Oakland, CA.

The initiative Healthy People 2010 aims to reduce health disparities between racial/ethnic (R/E) groups. While Mendelian diseases typically show R/E variation, an unanswered question is the degree to which genetic versus non-genetic factors contribute to disparities in the prevalence of more common, complex diseases. To address this question, we considered a quantitative trait (QT) influenced by multiple additive loci and environmental factors. For discrete traits, we imposed a threshold model on the QT. Using published data on SNP frequencies and their differences in several R/E groups, we calculated how much difference could occur between R/E groups for average value of the QT and prevalence of the threshold trait. Model parameters included number of loci (N) and total heritability (H). We found that mean differences in QT between groups depends only on H and not N. The average difference in trait mean between R/E groups is about .6 standard deviations (sds) at high H (80%) and .3 sds at low H (20%). Similarly, prevalence differences were also a function of H but not N. For a 1% prevalence trait, the average prevalence ratio at high H was 2.3-3.0-fold, but only 1.2-1.5-fold at low H. These results suggest that genetic differentiation can play an important role in prevalence differences between R/E groups. Environmental factors, particularly R/E differences in access to preventive health care, are also clearly important. Here we compared R/E-specific disease prevalences for various diseases derived from the general California population to those from Kaiser Permanente (KP), a health plan offering uniform access to health care. We also examined R/E disparities in KP before and after adjustment for a wide range of environmental factors. For some disease outcomes, differences were attenuated with access to uniform care or after adjusting for environmental factors. In other cases R/E differentials persisted, suggesting residual factors, possibly genetic, are influential. Because no single piece of evidence is definitive, understanding the relative contribution of genes and environment to R/E health disparities requires a family of methodologic approaches.

**APOE distribution in World populations with new data from the Indian and the British populations.** *P. Singh<sup>1</sup>, M. Singh<sup>1</sup>, S.S. Mastana<sup>2</sup>*. 1) Dept Human Biololgy, Punjabi Univ, Patiala Punjab, India; 2) Human Sciences Department, Loughborough University, Loughborough, UK.

Human apolipoprotein E (APOE\*E) plays a major role in lipoprotein metabolism. Three common variants (\*E2, \*E3, & \*E4) of APOE gene show genetic variation. Epidemiological studies have found that the \*E4 allele is associated with longevity, increased cholesterol level, increased prevalence for cardiovascular and Alzheimer diseases. Apolipoprotein E genotypes (n =1065) were determined in four population groups (Punjabi Sikhs, Punjabi Hindus, Gonds and Koch) of India and three regionally sub-divided populations (Nottinghamshire, East Midlands and West Midlands) of UK. The extent and distribution of APOE allele frequencies were compared with 265 populations of the world. Three alleles APOE\*E2, APOE\*E3 and APOE\*E4 were observed with the contrasting variation. One interesting feature is low incidence or absence of \*E4 allele in many caste and tribal populations, even though cardiovascular diseases are relatively common. Higher values of \*E2 allele displayed similitude in Africa and Oceania (0.099 0.083 and 0.0990.057 respectively). Similarly highest value of \*E4 is sojourned in Oceania (0.2380.004) followed by Africa (0.1920.008). Intriguingly, coefficient of gene differentiation was found to be highest in South America (10.2%), though the highest gene diversity was observed in African populations (45.9%). APOE\*E2 revealed statistically significant decreasing cline towards North in Asia ( $r = -0.511$ ,  $y = -0.0013x + 0.1053$ ,  $df = 55$ ,  $p < .05$ ), which is not compatible with the coronary heart disease statistics in this continent. Correspondence analyses exhibited that Indians are in between European and Asian populations. Spatial autocorrelation analysis shows that the variation at this locus is influenced by isolation by distance with a strong positive correlation for lower distances upto 1313 kilometres. Large, intricate and unanticipated heterogeneity of this locus in its global perspective have insightful ramifications. The data presented also suggests that autochthon groups (like tribes) in India may throw better insight on the role of apolipoproteins in disease.

Program Nr: 1231 from 2003 ASHG Annual Meeting

**Recent natural selection on human populations detected by haplotype analysis of over 5,000 genes.** *G. Ruano, B.A. Salisbury, J.C. Stephens.* Genaissance Pharmaceuticals, New Haven, CT.

Intense interest exists in the detection of natural selection acting in the recent history of the human species. One reason for this interest is that polymorphisms currently or recently driven by natural selection may have important health consequences. Here we focus on a systematic, genome-wide approach to detecting gene variants that have been acted upon by geographically localized selection or by balancing selection. We introduce the use of gene-based haplotypes as a particularly sensitive resource for the detection of selection, and apply this analysis to haplotype data from over 5000 genes resequenced in 59 humans representing three continental populations (African, Asian, and European). A measure of genetic differentiation among populations,  $F_{ST}$ , is used to gauge which genes are most likely to have been under recent natural selection by their position within the empirical  $F_{ST}$  distribution. From this set of genes, we detail the findings for five whose haplotype  $F_{ST}$  values place them in the top 2.5% of the  $F_{ST}$  distribution, where one would expect to find haplotypes that had been favored by geographically-restricted natural selection. We also present a gene that may be a case of balancing selection, from the lower 2.5% of our empirical  $F_{ST}$  distribution. This empirical, gene-based haplotype approach is a promising strategy for identifying genes whose variation has been shaped in response to localized environmental challenges and genes whose variants are functionally distinct yet selectively co-maintained. Genes whose variation has been critical in the past are the lynchpins for a better understanding of human biology and our interactions with the world.

**Nucleotide diversity and linkage disequilibrium patterns in three regions marked by *Alu* insertion events. S.**

*Watkins*<sup>1</sup>, *J.A. Walker*<sup>2</sup>, *G.E. Kilroy*<sup>2</sup>, *M.A. Batzer*<sup>2</sup>, *L.B. Jorde*<sup>1</sup>. 1) Dept Human Genetics, Univ Utah, Salt Lake City, UT 84112; 2) Dept of Biological Sciences, Louisiana State University, Baton Rouge, LA 70803.

To test hypotheses about the evolutionary dynamics of *Alu* insertions, we have characterized three unlinked genomic regions, each containing a polymorphic *Alu* insertion and nine to twelve closely-linked, common, single nucleotide polymorphisms (SNPs), in a panel of 152 Africans, 77 E. Asians, and 116 Europeans. As expected, chromosomes bearing the Ya5NBC148 (frequency [f] = 0.26) or Yb8NBC589 (f = 0.64) *Alu* insertions showed 45% and 26% reductions, respectively, in pairwise nucleotide diversity compare to non-*Alu* bearing chromosomes. In contrast, chromosomes containing *Alu* Yb8NBC120 (f = 0.52) showed a 41% increase in diversity. Age estimates for the *Alu* insertion event using closely linked microsatellite loci were 9 to 37 thousand and 88 to 394 thousand years ago for Ya5NBC148 and Yb8NBC589. In agreement with expectations, microsatellite variance was lower for haplotypes marked by the low frequency *Alu* insertion.

Haplotypes for a region of ~85 kb surrounding the Yb8NBC120 polymorphic *Alu* insertion were constructed using common SNPs that were 1) chosen randomly from the dbSNP database (8 loci) or 2) identified by resequencing of 21 ethnically diverse samples (9 loci). Haplotypes generated from dbSNP loci show higher diversity estimates for Europeans (2.51) than for Africans (2.20). In contrast, Africans show higher within-group diversity (2.81) than Europeans (2.07) when haplotypes were constructed using SNPs identified by resequencing. Elevated African diversity was also observed for the 2 other regions, where SNPs were also obtained by resequencing. These results suggest incomplete representation of human variation in the dbSNP database that may influence diversity estimates and haplotype construction for populations studies. For the 3 regions, *Alu*-bearing chromosomes did not show high levels linkage disequilibrium, possibly due to the age of the insertions or effects of the elements on recombination. Grant sponsorship: NIH GM59290.

**Genetic Structure of the population of Zulia State, Venezuela, based on Autosomal Hypervariable Loci.** *W. Zabala, L. Pineda, L. Borjas, E. Fernandez, C. Castillo, A. Socca.* Medical Genetic Unit, University of Zulia, Maracaibo, Zulia, Venezuela.

The genetic relationships between population groups can be studied through a comparison of their own genotypic and allele similarities. On this investigation, value is given to the utility of the microsatellite markers (STRs) for the study of the genetic structure of the population of Zulia. By Polymerase Chain Reaction under multiplex format, seven (7) autosomal systems were amplified into 688 different chromosomes of not-related individuals, from five populations of Zulia State: Maracaibo, Isla de Toas, San Jos de Heras, Bari y Yukpa. It was determined the allele and genotypic frequencies, Hardy-Weinberg equilibrium and other population estimators like the Wrights F-statistic, genetic distances and ethnic Admixture as well. It was proved that these markers were useful in the study of the genetic structure of the population in Zulia. It was shown that it does exist a clear genetic difference among these groups. The distribution of the genetic differences that were found, were in accordance with the history and behavior of each population. It was also proved the existence of a general tendency of not random crosses that causes a departure from panmictic in the studied population. The populations in Maracaibo and Isla de Toas showed a tri-racial origin, with a high European contribution, followed by the amerindian and with an African component in a lower value. The indigenous groups Bari and Yukpa showed exclusively an amerindian component and the San Jos de Heras an African one. The results of this investigation become a valuable tool for the molecular anthropology, the same, regional and world wide, providing important information about the origin and genetic comparison of the current population of Zulia.

**Genetic and Environmental Determination of Renal Function in Young Adult Twins.** *R. Vlietinck*<sup>1, 2</sup>, *M. Gielen*<sup>1</sup>, *R. Loos*<sup>2</sup>, *C. Derom*<sup>2</sup>, *S.J. Pinto-Sietsma*<sup>3</sup>, *M. Zeegers*<sup>1</sup>, *G. Beunen*<sup>4</sup>, *R. Fagard*<sup>5</sup>. 1) Population Genetics, Genomics & Bioinformatics, University of Maastricht, (Netherlands); 2) Human Genetics, University of Leuven, (Belgium); 3) Internal Medicine, University of Maastricht, (Netherlands); 4) Physical Education, University of Leuven, (Belgium); 5) Hypertension and Cardiovascular Revalidation, University of Leuven, (Belgium).

Genetic and environmental contribution of renal function was determined in 200 monozygous and 122 dizygous twinpairs, aged 18-34 years. Creatinin clearance (Ccr) was calculated from the creatinin in serum and 24-hour urine. It was also estimated with the Cockcroft-Gault formula. Genetic and environmental contribution was calculated using variance component analysis (VCA). Adjusted values were calculated from residuals by regressing on sex, age, lean bodyweight, smoking, glycemia and blood pressure.

The correlations of unadjusted calculated Ccr in MZ was higher ( $r_{MZ}=0.5$ ) than in DZ pairs ( $r_{DZ}=0.31$ ). These were significantly lower than of the estimated Ccr ( $r_{MZ}=0.77$ ,  $r_{DZ}=0.38$ ) and of the calculated Ccr after adjusting for the mentioned variables ( $r_{MZ}=0.89$ ,  $r_{DZ}=0.33$ ).

VCA showed that 20% of the unadjusted calculated Ccr was caused by genes, 26% by environment common to both twins and 54% by specific environment. For the estimated Ccr these were 80%, 0% and 20% respectively. After adjustment for the mentioned variables the genetic determination rose to 89%.

This study shows that the genetic determination of the estimated creatinin clearance is higher than that of the calculated clearance. After adjustment for the mentioned variables, the genetic contribution increased to 89% and the common environment disappeared. This shows that these variables account for most of the environmental determination of the Ccr. Accounting for them raises the heritability from 20% to 89%, which shows that this strategy may dramatically improve the chances of finding genes for renal function.

**Heritability of Prostate Related Phenotypes in Men of African Ancestry: The Tobago Family Prostate Study.**

*J.M. Zmuda<sup>1</sup>, C.M. Kammerer<sup>1</sup>, A.L. Patrick<sup>2</sup>, I. Miljkovic-Gacic<sup>1</sup>, D. Rodriguez<sup>1</sup>, C.H. Bunker<sup>1</sup>.* 1) Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) The Tobago Regional Health Authority, Scarborough, Tobago, Trinidad & Tobago.

Benign prostatic hyperplasia (BPH) is a prevalent condition with unknown etiology. Family history is an important risk factor for BPH suggesting a genetic component, but the genetics of BPH remains poorly defined, especially among men of African ancestry. In the present study, we determined the relative contribution of genetics and environmental factors to anatomical (prostate size), clinical (lower urinary tract symptoms) and biochemical (prostate specific antigen; PSA) surrogates of BPH in 287 Afro-Caribbean families consisting of 532 male siblings aged 38-89 years (meanSD; 5510 yrs). All men completed a digital rectal examination (DRE), serum PSA and were administered a questionnaire about the frequency of nocturia as part of a population-based prostate screening evaluation in over 3,000 Afro-Caribbean men. Men with a history of prostate cancer were excluded from the present analyses. Prostate volume was estimated from sagittal and transverse dimensions. Maximum likelihood methods were used to partition the variance of each prostate related phenotype into components attributable to measured covariates (age, height, weight, hypertension, diabetes, smoking) and additive genetic effects (heritability). MeanSD prostate volume and PSA were 2823 cubic centimeters and 1.61.4 ng/ml, respectively. Measured covariates accounted for 11% and 18% of the total variance in PSA and nocturia, but explained less than 1% of the variation in prostate size. PSA and nocturia demonstrated significant residual heritability ( $P < 0.01$ ). The heritability (meanSEM) of PSA and frequency of nocturia were 0.300.13 and 0.290.13. Our preliminary analyses suggest that there is a significant genetic component to clinical and biochemical measures of BPH among men of African descent. The high heritability of these prostate related phenotypes suggests that their inclusion in family-based studies might advance our understanding of the genetic mechanisms underlying BPH.

**Sequence Variation of Bradykinin Receptors B1 and B2 and association with hypertension.** *J. CUI<sup>1</sup>, E. Melista<sup>1,2</sup>, I. Chazaro<sup>1,4</sup>, Y. Zhang<sup>3</sup>, A.L. DeStefano<sup>3,4</sup>, A.J. Manolis<sup>5</sup>, C. Baldwin<sup>2</sup>, H. Gavras<sup>1</sup>.* 1) Hypertension Section, Boston University School of Medicine, Boston, MA; 2) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 3) Department of Neurology, Boston University School of Medicine, Boston, MA; 4) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 5) Cardiology Division, Tzanio Hospital, Piraeus, Greece.

The two subtypes of Bradykinin Receptors B1 and B2 (BDKRB1, BDKRB2) mediate the function of Bradykinin, which is involved in the regulation of blood pressure and hence are attractive candidate genes for hypertension. To better understand the genetic variations in these genes, we sequenced a 64.4 kb genomic region containing the entire BDKRB1 and BDKRB2 in 16 hypertensive and 14 normotensive African American individuals. A total of 282 single-nucleotide polymorphisms (SNPs) were identified. We selected 18 SNPs for study in our complete cohorts, of African Americans, American Caucasians, and Greek Caucasians. Pairwise linkage disequilibrium (LD), measured by  $r^2$ , demonstrated a general pattern of decline with increasing distance. This pattern of decline did not vary among the three groups but we observed less LD in African Americans. The percent of  $r^2$  values larger than 0.1 in the three populations are 7.19%, 18.95% and 16.99% for African American, American Caucasian, and Greek Caucasian, respectively. We also evaluated 18 SNPs for differences in genotypic frequency between hypertensives and normotensives. One SNP in BDKRB1 and 3 SNPs in BDKRB2 were associated with hypertension status ( $p$ -values range between .026 and .0004) in American Caucasians, but not associated in African Americans or Greek Caucasians. Haplotypes were built using these 4 SNPs which were in high LD. There is a significant haplotype frequency difference between hypertensive and normotensives among our American Caucasian ( $p=0.035$ ) sample, but not in African Americans or Greek Caucasians. These results support the hypothesis that the African American population is an older population compared to the other samples and the two bradykinin receptors may play a role in blood pressure regulation.

**DNA typing from limited quantities of genomic DNA using whole genome amplification.** *G. Sun, R. Kaushal, M. Wolujewicz, D. Smelser, H. Cheng, M. Lu, L. Jin, R. Deka.* Dept Environmental Health, Univ Cincinnati, Cincinnati, OH.

Whole genome amplification (WGA) is a critical method for DNA analysis from limited quantities of genomic DNA. Several strategies for WGA have been developed during the past decade, each with variable fidelity, yield and coverage of the genome. In search for a reliable WGA method for typing VNTR, STR and SNP markers, we initially tested three popular methods, viz., degenerate oligonucleotide primed PCR (DOP), improved-primer extension preamplification (I-PEP) and multiple displacement amplification (MDA), typing the 13 CODIS STR loci. The results showed that both I-PEP and MDA have good coverage (13/13). However, DOP failed to provide satisfactory coverage with a dropout of 11 out of 13 loci. Since then, we have focused on I-PEP and MDA and typed an additional 33 dinucleotide repeat markers from the ABI linkage mapping (v2.5) panels 25, 26 and 27, the amelogenin locus, one VNTR and 19 SNP markers. The results show comparable coverage (67/67) using both methods, as well as fidelity, genotyping results completely matching with the results using native genomic DNA. Based on the amplification of the CODIS STR loci, we find that the yield of MDA is slightly higher than I-PEP (5 ng of input DNA). However, I-PEP products result in more uniform amplification. If the input DNA for WGA is too low or degraded, differential amplifications occur causing allelic imbalance. MDA products induce higher allelic imbalance. With an initial input amount of 5~50 ng of genomic DNA, both methods produce high fidelity DNA sufficient for 1000~1500 PCR amplifications. Genotype fidelity of 67 loci using both I-PEP and MDA products demonstrate that WGA methods can play significant role in DNA marker analysis from limited amount of native genomic DNA. Our analysis also demonstrates that blood spots on FTA cards are a good source of DNA suitable for both strategies.

**Bardet-Biedl Syndrome 1 and obesity in the Newfoundland population.** *W.S. Davidson<sup>1</sup>, Y. Fan<sup>1</sup>, P. Rahman<sup>2,3</sup>, L. Peddle<sup>2</sup>, D. Hefferton<sup>2</sup>, N. Gladney<sup>2</sup>, S.J. Moore<sup>3</sup>, J.S. Green<sup>3</sup>, P.S. Parfrey<sup>3</sup>.* 1) Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada; 2) Newfound Genomics, 187 LeMarchant Road, St. John's, NF, Canada; 3) Faculty of Medicine, Health Sciences Centre, Memorial University, St. John's, NF, Canada.

Obesity is one of the primary clinical features of Bardet-Biedl Syndrome (BBS), a genetically heterogeneous disorder that is usually inherited as an autosomal recessive trait. It has been suggested that heterozygous carriers of BBS are predisposed to obesity. We set out to identify the common mutation in BBS1 families from southwest Newfoundland and to examine the relationship between this mutation and obesity in the general population. All affected members of the six Newfoundland BBS1 families were homozygous for the most common BBS1 mutation (M390R). BMIs were calculated for affected individuals, carriers, and non-carriers from these families. The affected individuals were more obese than the carriers ( $p < 0.05$ ) and the non-carriers ( $p < 0.01$ ) whereas the carriers and non-carriers are not statistically different ( $p > 0.25$ ). The contribution of the M390R BBS1 mutation to obesity in the general population was assessed by screening 200 obese individuals ( $BMI > 30 \text{ kg/m}^2$ ) and 200 ethnically matched, unrelated controls from the same region ( $BMI < 29 \text{ kg/m}^2$ ). The frequency of the M390R BBS1 mutation was identical in each group (0.0075). Our data do not support the hypothesis that BBS1 plays a significant role in the frequency of obesity in the general public in Newfoundland.

**Accuracy and Efficiency of Bayesian and EM Inference of Haplotypes in the Presence of Gene Conversion. R.**

*Adkins*<sup>1</sup>, *C. Campese*<sup>2</sup>, *R. Vaidya*<sup>2</sup>, *J. Krushkal*<sup>3</sup>, *T. Boyd*<sup>4</sup>. 1) Dept Pediatrics, Le Bonheur Hosp, Memphis, TN., USA; 2) Dept. Biology, Univ. Mass., USA; 3) Dept. Preventive Medicine, Univ. Tenn. Memphis, USA; 4) Dept. Pathology, Baystate Med. Center, USA.

Gene conversion creates a nonstandard pattern of correlation among nucleotide sites. Instead of patterns of linkage disequilibrium being simply the consequence of normal recombination, correlations in polymorphisms among sites are determined by the extent of gene conversion and the identity of the gene donating variants. Pituitary growth hormone (GH) is an excellent system within which to study the impact of gene conversion on computational inference of haplotypes. GH is one of 5 tightly-linked and highly-similar genes and is unusually polymorphic in that 27 SNPs occur in the span of 1,750 nucleotides. First we demonstrate that the high polymorphism and complex haplotype structure of GH is the consequence of recurrent gene conversion. Then, we compare the efficiency and accuracy of Bayesian and EM inferences of haplotypes. For validation of inferences we use an empirically determined set of haplotypes from a large independent study. Our results demonstrate that Bayesian inference of haplotypes as implemented by the program PHASE is superior to the most popular implementations of the EM algorithm when levels of polymorphism are high and gene conversion is present. Separately, we present evidence that polymorphism upstream of GH is associated with variation in term birth weight. This is a surprising finding given the accepted wisdom that pituitary GH is not involved in regulating fetal growth.

**Instability of Expanded CAG/CAA repeats in Spinocerebellar Ataxia Type 17.** *R. Gao<sup>1</sup>, M. Coolbaugh<sup>2</sup>, C. Zuhlke<sup>3</sup>, K. Nakamura<sup>4</sup>, A. Rasmussen<sup>5</sup>, T. Matsuura<sup>6</sup>, M. Siciliano<sup>2</sup>, T. Ashizawa<sup>1</sup>, X. Lin<sup>1</sup>.* 1) Neurology, University of Texas Medical Branch, Galveston, TX; 2) Department of Molecular Genetics, MD Anderson Cancer Center, Houston, Texas; 3) Institut für Humangenetik, Universität Lubeck, Lubeck, Germany; 4) Department of Neurology, The University of Tokyo School of Medicine, Tokyo, Japan; 5) Department of Neurogenetics and Molecular Biology, Instituto Nacional de Neurología y Neurocirugía, Mexico City, D.F. Mexico; 6) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas.

Expanding trinucleotide repeats are dynamic mutations causing many neurological conditions. Among the many factors that are implicated in repeat instability is the configuration of repeats: pure repeats are more prone to expand and/or contract than interrupted repeats. However, this hypothesis still lacks direct evidence. Here, we attempt to test the hypothesis in spinocerebellar ataxia type 17 (SCA17), which is caused by CAG repeat expansion coding for polyglutamine tract in TBP (TATA binding protein). SCA17 is unique among polyglutamine diseases in that the expanded CAG repeats in many patients are interrupted by CAA, and there are two types of repeat configurations: the simple configuration with long stretches of pure CAGs and the complex configuration containing CAA interruptions. By small pool PCR (SP-PCR) analysis of blood DNA from SCA17 patients of distinct racial backgrounds, we quantitatively assessed the instability of these two types of expanded alleles with similar length of repeat expansion. We observed that the mutation frequency in patients harboring pure CAGs is 2-3 folds of those having a complex repeat configuration. Interestingly, the less interrupted CAG repeats showed both expansion and deletion while more interrupted repeats exhibited mostly deletion. These data clearly demonstrated that repeat configuration is a critical determinant for instability in SCA17. Further studies of the underlying mechanisms will provide insights into understanding how the stability of repetitive sequences is maintained.

**Polymorphisms at VDR and DRD3 genes moderate the effect of lead exposure on postural balance in children.**

*B.M. Chakraborty, M. Wolujewicz, J. Mallik, K.N. Dietrich, A. Bhattacharya, R. Deka, R. Chakraborty.* Department of Environmental Health, University of Cincinnati, Cincinnati, OH.

Adverse effects of lead exposure, even at low levels, on neuromotor function have been observed in developing children. Also, some genes are known to moderate lead toxicokinetics. We investigated the possible involvement of several genes in inducing differential associations of lead exposure on neuromotor functions in developing children. In the Cincinnati Lead Study cohort, average blood lead level during the first 5 years of life (AvPb05) was taken as the measure of early exposure. Postural balance, an indicator of neuromotor function, was measured in four testing conditions, resulting in two variables, postural sway length, SL; and postural sway area, SA; in each testing condition. Height and age-adjusted log(SL) values were positively correlated with log AvPb05 ( $r = 0.249$  to  $0.260$ ;  $p < 0.001$ ) in all testing conditions, indicating a trend towards impaired postural balance with increasing blood lead levels in the 189 children examined. Neither blood lead level, nor any of the postural sway measures showed any significant difference by genotypes at the eight loci studied. However, the regression coefficients of log(AvPb05) on adjusted log(SL) showed significant differences ( $p < 0.01$ ) across genotypes of the DRD3 (Gly/Gly, Gly/Ser, and Ser/Ser) and VDR (TT, Tt, and tt) genes. For DRD3, the heterozygotes showed a significant positive regression effect, while for VDR, only the homozygous (TT, tt) children showed significant positive regression coefficients. This heterogeneity of regression coefficients represents a gene-environment interaction, and the pattern of the three-way relationship of genotype, blood lead, and postural sway measures suggests that the polymorphisms at DRD3 and VDR genes may moderate the effects of lead exposure on neuromotor functions in children. (Research supported by a pilot project of the NIEHS-funded program project P01-ES06096 awarded to the Center for Environmental Genetics at the University of Cincinnati).

**Pharmacogenetic association between 2AR haplotypes and lower bronchodilator responsiveness in Puerto Rican than in Mexican asthmatic subjects from the Genetics of Asthma in Latino Americans (GALA) Study.** *E.G.*

*Burchard<sup>1</sup>, S. Choudhry<sup>1</sup>, N. Ung<sup>1</sup>, K. Salari<sup>1</sup>, E. Ziv<sup>1</sup>, S. Nazario<sup>1</sup>, J. Casal<sup>2</sup>, J. Torres<sup>2</sup>, J. Rodriguez-Santana<sup>3</sup>, J. Senter Sylvia<sup>4</sup>, J. Salas<sup>5</sup>, M. Selman<sup>5</sup>, R. Chapela<sup>4</sup>, H.A. Boushey<sup>1</sup>, S.T. Weiss<sup>4</sup>, J. Ford<sup>6</sup>, D. Sheppard<sup>1</sup>, W. Rodriguez-Cintron<sup>2</sup>, J.M. Drazen<sup>4</sup>, E.K. Silverman<sup>1</sup>.* 1) University of California, San Francisco, San Francisco, CA; 2) University of Puerto Rico, San Juan, Puerto Rico; 3) Pediatric Pulmonary Program, Cardiovascular Center of Puerto Rico, San Juan; 4) Brigham and Womens Hospital, Boston, MA; 5) Instituto Nacional de Enfermedades Respiratorias, Mexico City, MX; 6) Harlem Lung Center, Harlem Hospital and Columbia University, NY.

Puerto Ricans (PR) and Mexicans (MX), represent the U.S. populations with the highest and lowest asthma prevalence, morbidity and mortality, respectively. We hypothesized that genetic variants in the beta 2 adrenergic receptor (2AR) gene contributed to differences in asthma and asthma severity. The Genetics of Asthma in Latino Americans (GALA) Study included 684 MX and PR asthmatic probands and their biologic parents (trios) recruited from Puerto Rico, Mexico and the U.S. We genotyped 430 trios and tested for association between 2AR haplotypes with asthma, asthma severity and bronchodilator responsiveness. Asthmatic Puerto Ricans had lower lung function, greater asthma morbidity, and longer asthma duration than asthmatic Mexicans. Puerto Ricans had on average 7.3% ( $p < 0.001$ ) lower bronchodilator reversibility in FEV1, higher risk of an Emergency Department visit in the previous year ( $OR = 2.63$ ,  $p < 0.001$ ), and of previous hospitalization for asthma ( $OR = 1.94$ ,  $p = 0.009$ ) than Mexicans. 2AR haplotypes were associated with asthma severity and bronchodilator responsiveness in Puerto Ricans ( $p = 0.01-0.001$ ) but not in Mexicans. Pharmacogenetic differences in bronchodilator responsiveness exist between PR and MX asthmatics. The 2AR locus may contribute to the observed differences in asthma prevalence, morbidity and mortality. These findings underscore the need for additional research on racial/ethnic differences in asthma morbidity and response to therapy.

**Human Pressor Responses: Heritability Estimations in White American Twins and Genotypic Associations at Adrenergic Loci.** *R. Chandran<sup>1</sup>, F. Rao<sup>1</sup>, D. King<sup>1</sup>, P. Cadman<sup>1</sup>, A. Chen<sup>1</sup>, K. Nguyen<sup>1</sup>, A. Bolotnikova<sup>1</sup>, G. Zhang<sup>2</sup>, B. Rana<sup>2</sup>, A. Joyner<sup>1</sup>, M. Robinson<sup>2</sup>, P. Insel<sup>1</sup>, N. Schork<sup>2</sup>, D. O'Connor<sup>1</sup>.* 1) Dept. of Medicine, UCSD and VASHDS, San Diego, CA; 2) Department of Psychiatry, UCSD, San Diego, CA.

It has been hypothesized that transient, repeated pressor responses may lead to long-term sustained hypertension in individuals at genetic risk. The Cold Pressor Test (CPT) consists of immersion of the non-dominant hand in ice water (0°C) for 1 minute, with continuous, non-invasive recording of BP and HR in the contralateral arm. Sensory afferent nerves relay the information to the hypothalamus. Vasoconstriction and an increase in HR & BP are mediated by adrenergic efferents. The Heart Rate (HR) response to cold stress is augmented in individuals with a genetic risk of hypertension, compared to family history negative normotensives. The study population was composed of 298 White Americans, 198 monozygotic (66%), and 100 dizygotic (34%) twin pairs. 48% of the participants had a positive family history of hypertension, while 52% did not. The average age of the population was 40 years, with a median of 45. Genotypic data for the ADRB1, ADRB2, and ADRB3 polymorphisms was available on a minimum of 189 individuals. The genetic analysis program SOLAR was used to compute heritability and the percentage of variability of the phenotype contributed by covariates. Age was the greatest contributing mechanism to variability in basal sbp, basal dbp, post cold pressor test sbp and dbp phenotypes in contrast to sex and family history of hypertension,  $H^2=37.81, 33.51, 31.11,$  and  $34.5$  respectively, with  $p=0.0000131, 0.0002779, 0.000293,$  and  $0.0000534$  respectively. Of the twelve ADRB polymorphisms used as covariates in this analysis, ADRB2 -654 and -47 made the greatest contribution to phenotypic variability. ADRB2 -654 contributed to 6.78%, 5.01%, and 5.65% to the variability of basal dbp, post test hr, and change in sbp. ADRB2 -47 contributed 5.53% to the change in sbp. Human twin heritability computations suggest that cardiovascular responses (blood pressure and heart rate) to an environmental stressor (cold stress test) are heritable.

**Variation in the Resistin Gene is Associated with Diabetes-Related Phenotypes in Finns.** *K.N. Conneely<sup>1</sup>, K. Silander<sup>2</sup>, K.N. Lazaridis<sup>3</sup>, K.L. Mohlke<sup>3</sup>, L.J. Scott<sup>1</sup>, T.T. Valle<sup>2</sup>, R.M. Watanabe<sup>4</sup>, T.A. Buchanan<sup>4</sup>, R.N. Bergman<sup>4</sup>, J. Tuomilehto<sup>2</sup>, F.S. Collins<sup>3</sup>, M. Boehnke<sup>1</sup>.* 1) U. Michigan, Ann Arbor, MI; 2) Nat'l Public Health Inst., Helsinki, Finland; 3) NHGRI, Bethesda, MD; 4) U. Southern California, Los Angeles, CA.

Resistin is a peptide hormone produced by adipocytes that is present at higher levels in obese mice and may be involved in glucose homeostasis, possibly through regulation of insulin sensitivity. Human studies have found associations between polymorphisms of the resistin gene and BMI, insulin-related variables, and blood pressure. Associations between resistin and type 2 diabetes (T2D) have been reported, but not in all studies. The aim of the Finland-U.S. Investigation of NIDDM Genetics (FUSION) Study is to identify genetic variants that contribute to the development of T2D. We analyzed 781 T2D cases and 409 controls for association between resistin and T2D and related traits. Three previously identified common, non-coding SNPs were typed: one from the promoter region (-420CG) and two from intron 2 (+156CT, +298GA). The three SNPs were in strong linkage disequilibrium and formed two main haplotypes: CCG (76.9%) and GTA (21.6%). We found no significant association between the SNPs and T2D ( $p = .55$ ), but did find associations with T2D-related phenotypes. For cases, the number of copies of the CCG haplotype was positively associated with weight-related traits. Mean BMI was 29.0, 29.6, and 30.4 kg/m<sup>2</sup> for cases with 0, 1, or 2 copies of CCG ( $p = .025$ , all tests based on age-sex adjusted additive effects of haplotypes on transformed variables.) Mean waist circumference was 99.5, 101.0, and 103.9 cm for cases with 0, 1, or 2 copies of CCG ( $p = .001$ ). Positive associations were also found for weight ( $p = .006$ ), weight change since age 20 ( $p = .014$ ), and waist-hip ratio ( $p = .022$ ). We saw similar results for individual SNPs. For controls, the C allele of SNP -420CG was associated with lower insulin sensitivity ( $p = .008$ ) and higher acute insulin response ( $p = .017$ ) assessed by intravenous glucose tolerance test. Our results provide evidence that resistin is associated with variation in weight, fat distribution, and insulin resistance.

**Association Between Frizzled Related Protein Polymorphisms and Osteoporosis Phenotypes in Older Women.**

*W.-C. Hsueh<sup>1</sup>, J.M. Zmuda<sup>2</sup>, L. Lui<sup>1</sup>, K.L. Stone<sup>1</sup>, J.A. Cauley<sup>2</sup>, T.A. Hillier<sup>3</sup>, J. Li<sup>4</sup>, R. Higuchi<sup>4</sup>, D.R. Greene<sup>4</sup>, S. Germer<sup>4</sup>, B. Fijal<sup>4</sup>, S. Kwon-Ro<sup>4</sup>, J. Mangacat<sup>4</sup>, N. Umblas<sup>4</sup>, J.D. Allard<sup>5</sup>, T. Nikolcheva<sup>5</sup>, G. Peltz<sup>5</sup>, S.R. Cummings<sup>1</sup>.*  
1) UCSF, San Francisco, CA; 2) University of Pittsburgh, Pittsburgh, PA; 3) Kaiser Permanente Center for Health Research Northwest/Hawaii, Portland, OR; 4) Roche Molecular Systems, Alameda, CA; 5) Roche Palo Alto, Palo Alto, CA.

Frizzled related protein (FRZB) acts as a soluble Wnt-binding protein that antagonizes Wnt signaling, a secreted growth factor implicated in skeletal morphogenesis. Our recent studies showed that FRZB is involved in the determination of bone mineral density (BMD) in mice and a single nucleotide polymorphism (SNP) (Arg324Gly) is associated with vertebral fracture among Caucasian women aged 65 years or older in the Study of Osteoporotic Fractures. Here we report results from studies investigating association between multiple SNPs in this gene and osteoporosis phenotypes using a case-control study design. A total of 9 SNPs (denoted as SNP1-9, the Arg324Gly SNP is SNP8) were typed in 51 cases with hip fracture and lowest 5% BMD, 262 cases with incident vertebral fracture, and 276 cases with low hip BMD (T score < -2.5). These case groups were compared to 278 fracture-free controls with normal BMD. All but 1 SNP are in untranslated regions. In <sup>2</sup> tests using single SNPs, there was a weak association between SNP1 (near exon 3) and fractures (hip and vertebral) (p=0.04-0.09). SNP9, which is in tight linkage disequilibrium with SNP8, also showed an association with vertebral fracture (p=0.01). There was no association between any other SNP and fractures, nor was there association between any SNP and low hip BMD. Haplotype analyses using various SNP combinations also supported findings using single SNPs. Only haplotypes containing SNP1 were associated with hip fracture (p=0.02-0.06), but the same haplotypes were not associated with vertebral fracture. We conclude that FRZB variants may play a role in osteoporosis, and that different allelic variants may influence clinically different manifestations of osteoporosis. Confirmation studies using a larger sample are underway.

**Social functioning in male premutation carriers of Fragile X (FRAX) syndrome.** *A.S. Rigby<sup>1</sup>, J. Turk<sup>2</sup>, A.C. Mills<sup>2</sup>, N. James<sup>3</sup>, C. Hollis<sup>3</sup>, K. Cornish<sup>4</sup>, A. Dalton<sup>5</sup>, T. Manly<sup>6</sup>.* 1) Children's Hospital, University of Sheffield, Sheffield, S Yorkshire, UK; 2) Department of Clinical Development Sciences, St Georges Hospital Medical School, London, UK; 3) Division of Psychiatry, University of Nottingham, Nottingham, UK; 4) Department of Education and Counselling Psychology, McGill University, Montreal, Canada; 5) Department of Molecular Genetics, North Trent Molecular Genetics Service, Sheffield UK; 6) MRC Cognition and Brain Sciences Unit, Addenbrookes Hospital, University of Cambridge, UK.

Previous small studies suggest males with FRAX premutation may show a phenotype similar to full mutation males. We assess if such males show phenotypic features similar to high functioning autism/Asperger syndrome. We report a large national UK study of adult premutation carriers recruited through regional genetics centres and the British Fragile X Society. Each case was IQ and age matched to 1 familial and 1 non-familial control. To date we have recruited 42 premutation males, 14 familial and 24 non-familial controls. All completed a new self-assessment screening test, the Autism-Spectrum Quotient (ASQ) consisting of 5 subscales; social skills, attention to detail, communication, attention switching and imagination. High scores imply poor performance. Premutation males scored highest on the ASQ (mean 20.2). Non-family controls scored the lowest (15.3). Family controls were intermediate (19.3). Subscale analysis showed no significant differences between premutation males and family controls. However, both groups had significantly higher scores than non-family controls on the attention switching and communication subscales. Premutation males also had significantly higher scores than non-family controls on the imagination subscale. These findings indicate that premutation males are more impaired than the general population in terms of the total ASQ score and in particular with attention switching. However, a familial tendency cannot be excluded given the intermediate performance of the family controls. The findings are consistent with premutation FRAX males having specific developmental difficulties with social and communication skills as well as attention skills.

**Study of apolipoprotein E genotypes in end-stage renal failure patients using a rapid molecular screening technique.** *S.Y. Tan<sup>1</sup>, W.T. Seet<sup>1</sup>, J.A. Tan<sup>2</sup>*. 1) Department of Medicine, University of Malaya, Kuala Lumpur, Malaysia; 2) Department of Molecular Medicine, University of Malaya, Kuala Lumpur, Malaysia.

In end-stage renal failure (ESRF), lipid abnormalities are frequently observed. Abnormal lipid metabolism may play an important role in the progression of renal disease. Apolipoprotein E2 (ApoE2), a variant of the common apoE3 caused by a change of residue 158 from Arg to Cys, has a lower affinity for the LDL receptors (less than 5% of apoE3) and the apoE receptors. Therefore they are cleared at a slower rate compared to apoE3 and thus contribute to the accumulation of remnant particles in the plasma, which is derived from partial catabolism of triglyceride-rich lipoproteins. In this study, the association of apolipoprotein E polymorphism with renal failure, especially the apoE2 genotype, was investigated in 123 end-stage renal failure patients. EDTA blood was collected from ESRF patients at the Renal Unit of University of Malaya Medical Centre. Characterization of the apoE variants was carried out by a rapid molecular screening method consisting of DNA amplification followed by restriction enzyme digestion using *Hha* I. Digested products were electrophoresed on 3% Molecular Screening Agarose to separate the DNA fragments. The restriction enzyme digested fragments were observed as distinct and well separated bands on MS Agarose and thus proved the horizontal gel system to be an efficient electrophoresis medium for the separation and detection of the six apoE genotypes. The frequencies of the three apoE alleles (2, 3 and 4) from our diseased population were found to be 0.037, 0.865 and 0.098 respectively. The allele frequency for the control population (n=123) was found to be 0.077 (p=0.080), 0.825 (p=0.262) and 0.098 (p=0.879) respectively. The results indicated that the frequencies of the three apoE alleles from control individuals were almost identical to the ESRF patients with exception of the 2 allele which was slightly lower in the ESRF population. Our study found no correlation between apoE alleles and ESRF. The slight decrease in the 2 allele found in the ESRF population in this study is not significant enough (p=0.080) to be conclusive.

**APOLIPROTEIN E GENOTYPING IN PATIENTS WITH ALZHEIMERS DISEASE IN RISARALDA, COLOMBIA, SA.** *L. Rengifo, M.Y. Sánchez, P.A. Osorio, R.P. Alarcón, L.H. García, J. Rodríguez, M. Castañeda, H. Serrano, A.H. Alegría, Centro de Biología Molecular y Biotecnología-CENBIOTEP. Basic Sci, Fac Med, Favi II, Univ Technologica de Pereira, Pereira, Risaralda, Colombia, SA.*

Apolipoprotein E isoforms have been associated with different risks for late onset Alzheimers disease (AD). Individuals with the 4 allele have a higher probability of acquiring the disease and the age for the appearance of the first symptoms is an earlier one. The 2 allele seems to have a protective effect. In Colombia, SA, no studies have been carried out to determine if these associations are still valid. A study was performed on a group of patients with clinically diagnosed Alzheimers disease and a comparison made with the results obtained for a normal population in the Department of Risaralda, Colombia SA. A fragment of the ApoE gene corresponding to 244 bp was amplified by PCR. The fragment was later digested with HhaI for distinguishing the 3 alleles. 54 patients (22 men and 32 women, 40.7% and 59.3% respectively) with ages between 49 and 92 years were genotyped. A group of 654 normal people was used as a control. In the AD group the 4 allele had a relative frequency of 18.5% while the control group had 8.93%, a result statically significant ( $P=0.022$ ). The 4 allele was more frequent in males than in females (10.0% and 8.0%). The 4/3 genotype was present in the AD group with 22% and 14.07% in the control group. The 4/4 genotype was 5.5% in the AD patients and 1.19% in the control group. The most frequent allele was 3 with 79.63% in the AD group and 83.78% in the control. The 3/3 genotype was present in 68.5% and 72.5% respectively. No allele correlation was detected with age or the initiation of symptoms.

**Association of the AGT 174 and 235 Polymorphisms with Blood Pressure in Ghana.** *M. Robinson*<sup>1</sup>, *S. Williams*<sup>2</sup>. 1) Univ California, San Diego, La Jolla, CA; 2) Vanderbilt Univ, Nashville, TN.

Genetic analysis of hypertension has revealed complex and inconsistent results, making it difficult to draw clear conclusions regarding the impact of specific genes on blood pressure regulation in diverse human populations. Using a different approach, we examined the contributions of variations in two Angiotensinogen (AGT) polymorphisms, in a monogenic and polygenic analysis, in conjunction with the age of the subjects, to assess their association with blood pressures. A total of 177 subjects (51 normotensives and 126 hypertensives) were recruited in Accra, Ghana. Blood pressures were determined using an automatic blood pressure reader on the right arm in a seated position. Blood samples were collected, the DNA was isolated and genotyped for each of the AGT T174M and M235T polymorphisms using standard PCR/RFLP methods for these polymorphisms. In our analysis, the AGT polymorphisms were the independent variables, blood pressure measurements were the dependent variables, and age was assigned as the covariate. We observed a significant association of the AGT T174M polymorphism with average systolic and diastolic blood pressures ( $p=0.000$ , and  $p=0.010$ , respectively). Also, we observed a significant association of the AGT M235T polymorphism with systolic and diastolic blood pressures ( $p=0.000$  and  $p=0.014$ , respectively). Finally, we observed a simultaneous significant association of the AGT T174M and M235T polymorphisms with systolic and diastolic blood pressure ( $p=0.000$ , and  $p=0.026$ , respectively). Age was used as a covariate in all models. Our results indicate that combinations of alleles at these two AGT sites, in conjunction with age, may be significantly associated with elevated systolic and diastolic blood pressures. Also, our data demonstrate the utility of the monogenic and polygenic analysis as a method of analyzing blood pressure variation. We suggest that inconsistent results from previous association studies on the Angiotensinogen polymorphism with blood pressure regulation in African derived populations may have resulted from an incomplete model in the different study populations.

**HEREDITARY HEMOCHROMATOSIS: GENOTYPE/PHENOTYPE CORRELATIONS FOR THE MAIN HFE1 MUTATIONS.** *V. Scotet<sup>1</sup>, MC. Merour<sup>2</sup>, AY. Mercier<sup>2</sup>, B. Chanu<sup>2</sup>, T. Le Faou<sup>3</sup>, O. Raguene<sup>1</sup>, G. Le Gac<sup>1</sup>, C. Mura<sup>1</sup>, JB. Nousbaum<sup>4</sup>, C. Ferec<sup>1,2</sup>.* 1) Dept de Genetique Moleculaire, INSERM EMI 01-15, Brest, France; 2) EFS-Bretagne, Brest, France; 3) EFS-Bretagne, Quimper, France; 4) Dept d'Hepato-Gastroenterologie, Brest, France.

Characterized by iron overload, hereditary hemochromatosis (HH) is the most common autosomal recessive disorder in Caucasian populations. A candidate gene for HH was cloned in 1996 (HFE1). It includes a main mutation (C282Y), two susceptibility factors (H63D, S65C) and a tenth of private mutations. HH presents a large genetic and allelic heterogeneity, and the aim of this study was to describe the phenotypic expression of the main HFE1 genotypes. We retrospectively analyzed a cohort of HH patients from western Brittany, France. A clinical questionnaire, completed at the time of onset, provides data on biochemical and clinical signs, genotype and treatment. This study included 585 patients: 433 C282Y/C282Y, 114 C282Y/H63D and 38 H63D/H63D. The age at onset was significantly lower in the two last groups (50.7 y. and 52.4 y. vs. 47.9 y. -  $p=0.02$ ). Serum iron, ferritin and transferrin saturation levels were also significantly lower in those two groups ( $p<0.001$  for each parameter). The C282Y/H63D and H63D/H63D genotypes were associated with lower frequency of arthritis (26.7% and 25.7% vs. 44.0% -  $p=0.0012$ ) and of skin pigmentation (3.7% and 13.9% vs. 24.0% -  $p<0.0001$ ) in comparison with the C282Y/C282Y genotype. Moreover, higher proportions of metabolic disorders (41.2% and 56.7% vs. 26.5% -  $p<0.0001$ ) and of high blood pressure (29.2% and 34.4% vs. 19.4% -  $p=0.02$ ) were observed in the patients carrying those genotypes. The comparison of the C282Y/H63D and H63D/H63D genotypes showed no significant difference, excepted a significantly higher proportion of skin pigmentation among the H63D-homozygous patients (13.9% vs. 3.7% -  $p=0.028$ ). This study highlights the correlation between HFE1 genotypes and phenotype in HH. The results confirm that the two less common genotypes are associated with a milder form of HH, and show that the patients carrying those genotypes present more frequently metabolic disorders.

**Association of a regulatory intronic polymorphism in the *PDCDI* gene with the risk of sporadic systemic lupus erythematosus and the occurrence of antiphospholipid antibodies.** *D.K. Sanghera*<sup>1</sup>, *S. Manzi*<sup>2</sup>, *F. Bontempo*<sup>2</sup>, *C. Nestlerode*<sup>1</sup>, *M.I. Kamboh*<sup>1</sup>. 1) Department of Human Genetics, GSPH, University of Pittsburgh, Pittsburgh, PA; 2) Department of Medicine, University of Pittsburgh, Pittsburgh, PA.

Systemic lupus erythematosus (SLE) is a chronic multifactorial autoimmune disease associated with diverse clinical manifestations. Although a significant amount of genetic component is involved in the etiology of SLE, the precise role of specific genes is yet to be identified. A regulatory polymorphism in intron 4 (G/A) of the programmed cell death 1 (*PDCDI*) gene has recently been shown to be associated with SLE risk in familial and sporadic cases from European, European American and Mexican origin. In this investigation we examined the role of this polymorphism in a biracial case-control cohort from Pittsburgh comprising 276 US White and 35 African American SLE patients and age matched healthy 359 US White and 31 African American controls. The frequency of the A allele was significantly higher in US White controls than African American controls (0.107 vs. 0.048;  $p=0.046$ ). There was no significant difference in the frequency of the A allele between SLE cases and controls in the white (0.107 vs. 0.129;  $p=0.84$ ) and black (0.048 vs. 0.100;  $p=0.25$ ) cohorts. However, a regression model including antiphospholipid antibodies (APA) as a covariate revealed that both APA ( $p=0.00001$ ) and *PDCDI* genotype ( $p=0.0385$ ) were independent risk factors for SLE. APA-adjusted odds ratio (OR) between A allele carriers (AA + AG genotypes) versus the GG genotype showed modest association in whites (OR = 1.52, 95% CI: 1.12 1.92;  $p=0.039$ ) and African Americans (OR = 2.91, 95% CI: 1.52 4.31;  $p=0.139$ ). Furthermore, we observed that the A allele carriers were associated with protection against the occurrence of APA in both controls (OR = 0.339, 95% CI: 0.19 0.82;  $p=0.0098$ ) and SLE cases (OR = 0.57, 95% CI: 0.32 1.01;  $p=0.054$ ). In conclusion, our data indicate that the *PDCDI* intron 4 polymorphism affects the occurrence of antiphospholipid antibodies and that it may slightly modify the risk of sporadic SLE.

**Increased risk of idiopathic chronic pancreatitis in cystic fibrosis carriers.** *J. Yan*<sup>1</sup>, *J. Cohn*<sup>2,3</sup>, *J. Neoptolemos*<sup>4</sup>, *J. Feng*<sup>1</sup>, *Z. Jiang*<sup>1</sup>, *W. Greenhalf*<sup>4</sup>, *I. Ellis*<sup>5</sup>, *S. Sommer*<sup>1</sup>. 1) Dept Molecular Genetics, City of Hope, Duarte, CA; 2) Duke Univ., Dept. of Medicine, Durham, NC; 3) V.A. Med. Ctr., Durham, NC; 4) Univ. of Liverpool, Dept. of Surgery, Liverpool, UK; 5) Alder Hey Children's Hosp., Liverpool, UK.

Idiopathic chronic pancreatitis (ICP) is associated with having mutations in both copies of CFTR, the CF gene. In this study, 52 ICP patients were comprehensively tested for rare CFTR mutations. This analysis detected common CF-causing mutations in 8 patients. Seven patients were CF carriers who had a normal second CFTR allele (4.8 times expected frequency,  $p < 0.001$ ). Thus, ICP differs from other CFTR-related conditions in that it is associated with CF carriers who have one documented normal CFTR allele. CF carriers are frequent. For ICP, the data suggest that carriers of one CF mutation have a higher attributable risk, while compound heterozygotes for a CF-causing mutation and another milder mutation have a higher relative risk.

**The Roles of Selection and Demography in Shaping Patterns of Variation in Vitamin D-Binding Protein.** *M. Pilkington, M.F. Hammer.* The Genomic Analysis and Technology Core, The University of Arizona, Tucson, AZ.

Relatively few genes have been identified in humans to be the targets of natural selection in response to environmental challenges. This work focuses on examining patterns of genetic variation at vitamin D-binding protein (DBP). DBP is a critical component of the vitamin D synthesis, metabolic, and activation pathway. The three major DBP alleles, termed Gc\*1F, Gc\*1S and Gc\*2, are distributed clinally across all continents, and their frequencies appear tightly correlated to skin pigmentation and latitude. The vitamin D hypothesis posits that humans have developed dark skin near the equator to protect from the over-absorption of vitamin D, and lighter skin further from the equator to protect from the under-absorption of vitamin D. Therefore, it is hypothesized that the vitamin D pathway is tightly regulated to maintain calcium homeostasis in humans. The goal of this study is to further characterize geographic patterns of DBP polymorphism to test hypotheses about the relative roles of demography and natural selection in shaping patterns of variation at this locus. Partial correlations between skin pigmentation, Gc allele (1F,1S and 2), and latitude were generated and Pearson's r statistic calculated for approximately 30 globally distributed populations (N=6983). Partial correlations between skin pigmentation and DBP allele frequency, holding latitude constant, indicated marginal statistical significance for the 1F and 1S alleles ( $p=0.072$  and  $0.071$ , respectively), but not for the 2 allele ( $p = 0.375$ ). In contrast, partial correlations between latitude and allele frequency, holding skin pigmentation constant, were not statistically significant; while correlations between latitude and skin pigmentation, holding allele frequency constant, were highly statistically significant (i.e.,  $p < 0.001$ ). Additionally, the residuals from plots of allele frequency against latitude, and skin pigmentation against latitude (which are not expected be correlated if allele frequencies are distributed randomly) result in highly significant correlations. These analyses indicate complex interactions between various components of the vitamin D synthesis and activation pathway.

**MC1R gene, nevus phenotypes and sun-related covariates modify CDKN2A penetrance in french melanoma-prone families.** *V. Chaudru*<sup>1</sup>, *A. Chompret*<sup>2</sup>, *A. Minire*<sup>2</sup>, *K. Laud*<sup>2</sup>, *M.F. Avril*<sup>2</sup>, *B. Bressac-de Paillerets*<sup>2</sup>, *F. Demenais*<sup>1</sup>. 1) INSERM EMI 00-06, Evry, France; 2) Institut Gustave Roussy, Villejuif, France.

Germline mutations in the cyclin-dependent kinase inhibitor gene, CDKN2A, are melanoma-predisposing alleles that confer high but incomplete penetrance, suggesting risk modification by other genetic and/or environmental factors. Variants of melanocortin-1 receptor gene, MC1R, have been shown to be associated with red hair, fair skin as well as melanoma independently of skin type. Other factors including nevus phenotypes (total number, dysplastic nevi), pigmentary traits (skin, hair and eye color), skin reactions to sunlight and degree of sun exposure, also influence melanoma risk. Our goal was to examine the joint effects of MC1R variants (R151C, R160W, D294H), nevus phenotypes, pigmentary traits and sun-related covariates on CDKN2A penetrance. Clinical, genetic, and covariate data were recorded in 53 French melanoma-prone families of which 20 had co-segregating CDKN2A mutations. Analysis of the co-transmission of CMM and CDKN2A alleles was conducted by likelihood based-methods using the regressive logistic models which can account for a variation of disease risk with age and can include the aforementioned risk factors as covariates. Tests for significant risk factors were conducted using a stepwise procedure. The factors that influence significantly CMM risk in carriers and non-carriers of CDKN2A mutations, in the whole family sample, include sunburns (OR=4.7), MC1R variants (OR=2.3), number of nevi (OR=2.1), dysplastic nevi (OR=1.8), sun exposure (OR=1.7) and fair skin (OR=0.8). In the subset of 20 families with CDKN2A mutations, the three significant factors modifying CDKN2A penetrance are: sunburns (OR=3.97), dysplastic nevi (OR=3.49) and MC1R variants (OR=2.64). In CDKN2A mutation carriers, the cumulative risk of melanoma is 0.58 by age 80 years and reaches 0.97 by adding presence of MC1R variants and 1.0 with dysplastic nevi or history of sunburns. This study shows that several pathways (cell-cycle pathway, nevus pathway, UV-sensitivity pathway, and cell-signaling pathway) are likely involved in the development of malignant melanoma.

**The influence of HLA on acute lymphoblastic leukemia of childhood.** *W. Klitz<sup>1</sup>, E. Trachtenberg<sup>1</sup>, M. Maiers<sup>2</sup>.* 1) Children's Hospital Oakland Research Institute, Oakland, CA; 2) National Marrow Donor Program, Minneapolis, MN.

Acute lymphoblastic leukemia of childhood (cALL) is the most common childhood cancer and the most common single disease for which bone marrow transplantation is employed, yet few clearly established etiological factors are known. Genetic predisposition according to HLA type might suggest an underlying infectious etiology. With this context in mind, we examined a large series of cALL patients of European American background drawn from the National Marrow Donor Program (NMDP) database. Two controls for each of 1,904 cALL patients, drawn from the NMDP donor registry, were matched for ethnicity and year of HLA typing from 1997 to 2002. Despite the limitations of low resolution DNA typing performed on the HLA A, B and DRB1 loci, and serological typing on a portion of the HLA class I typings, strong protective and predispositional effects were evident at both the HLA class I and class II regions. Among the 15 HLA A alleles recorded in the sample, the alleles A\*11, A\*24 and A\*30 were each predisposing, while A\*01 was associated with disease protection. Of 28 HLA B locus alleles only protective effects could be demonstrated, including the alleles B\*07, B\*08, B\*44, B\*62, B\*14, B\*60 and B\*57. At the 12 low resolution alleles examined at the DRB1 locus, DRB1\*03 was protective and DRB1\*11 was predisposing. The common extended HLA haplotype A\*01-B\*08-DRB1\*03 is the single best explanation for the protective effects of each of the constituent alleles. Further analysis revealed the allele B\*08 is most closely identified with the protective effect of the haplotype. It was possible to identify several additional genetic effects operating at the genotypic level. We conclude that the substantial impact of HLA on cALL predisposition deserves further examination in order to determine its implications for a role of pathogens or immune surveillance in the disease.

**Genetic linkage and association of single nucleotide polymorphisms in the IL10 region and HCV clearance.** T.K. Oleksyk<sup>1</sup>, C.L. Thio<sup>2</sup>, A.L. Truelove<sup>1,3</sup>, J.J. Goedert<sup>4</sup>, S. Donfield<sup>5</sup>, D.L. Thomas<sup>2,6</sup>, S.J. O'Brien<sup>1</sup>, M.W. Smith<sup>1,3</sup>. 1) Laboratory of Genomic Diversity, NCI, Frederick, MD; 2) Department of Medicine, Johns Hopkins University, Baltimore, MD; 3) Basic Research Program, SAIC, NCI, Frederick, MD; 4) Viral Epidemiology Branch, NCI, Bethesda, MD; 5) Rho, Inc., Chapel Hill, NC; 6) Department of Epidemiology, Johns Hopkins University, Baltimore, MD.

Hepatitis C virus (HCV) is an infectious blood-borne pathogen that is infrequently cleared from the host (approximately 15% of the time) while usually persisting as a chronic infection. Host differences are likely critical in determining HCV clearance, and showing their involvement will give insights into HCV pathogenesis. The inflammatory response is crucial in HCV infection and previous reports have implicated interleukin 10 (*IL10*) polymorphisms with successful anti-HCV therapy; however they have not been studied in natural viral clearance. *IL10* is a cytokine synthesis inhibitory factor that balances TH1 and TH2 immune response, and is involved in many aspects of human disease. We tested 67 SNPs in the *IL10* region, which included the *SRGAP2*, *IKKE*, *NORE1*, *MAPKAPK2*, and *PIGR* genes along with the *IL10* paralogs *IL19*, *IL20* and *IL24*, for association with HCV clearance versus persistence during infection. 32 SNPs were sampled within *IL10*, and 35 more from the surrounding 300kb region. Of those, 38 had minor allele frequencies 3%. A total of 274 African Americans (91 clearance cases and 183 chronically infected matched controls) and 353 European Americans (108 clearance and 245 chronic) were examined. In African Americans two linked regions, one at *IL10* and the other from *IL19/IL20*, were associated with the HCV clearance as viewed by allelic, codominant, and dominant models using conditional logistic regression ( $p=0.03-0.002$ ). We used the EM algorithm to reconstruct haplotypes within genes, and associations with clearance remained ( $p=0.05-0.01$ ). These analyses were not significant in European Americans. Our results indicate that *IL10* and *IL19/IL20* gene variants may be involved in clearance of HCV in the African American population. Funded in part by DHHS#N01-CO-12400.

**Comparative Genetic Study of Tuberculosis and Asthma Susceptibilities.** A. Poon<sup>1, 7</sup>, C. Laprise<sup>2</sup>, A. Jimnez-Corona<sup>3</sup>, M. Palacios-Martnez<sup>3</sup>, J. Sifuentes-Osornio<sup>4</sup>, A. Ponce-de-Len<sup>4</sup>, M. Bodadilla<sup>4</sup>, M. Kato<sup>4</sup>, M. Lemire<sup>5</sup>, A. Montpetit<sup>5</sup>, Y. Renaud<sup>5</sup>, P.M. Small<sup>6</sup>, M.L. Garca Garca<sup>3</sup>, T.J. Hudson<sup>5, 7</sup>, E. Schurr<sup>7</sup>. 1) Dept Biochemistry, McGill University, Montreal, QC, Canada; 2) Universit du Qubec Chicoutimi, Chicoutimi, QC, Canada; 3) Instituto Nacional de Salud Pblica, Cuernavaca, Mexico; 4) Instituto Nacional de Ciencias Mdicas y de Nutricin Salvador Zubirn, Mexico City, Mexico; 5) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada; 6) Medicine, Stanford University, CA, USA; 7) McGill Centre for the Study of Host Resistance, Montreal, QC, Canada.

Epidemiologic evidence suggests that on the population level tuberculosis (TB) is protective for asthma/atopy. Consequently, genetic variants predisposing to TB may have been selected due to their protective effect for asthma susceptibility. We tested this hypothesis (i) by analysing bi-allelic genetic variants in four selected candidate TB susceptibility genes for association with asthma/atopy and (ii) by studying a hypothesized inverse association of asthma associated polymorphism with TB in a TB case control group. We analyzed gene-specific panels of 37 single nucleotide polymorphisms (SNPs) for *NRAMP1* (4 SNPs), *TNFA* (1 SNPs), *VDR* (19 SNPs) and *CARD15* (13 SNPs) in a panel of 421 nuclear asthma families. Haplotype structures for the asthma families were established for *NRAMP1*, *VDR* and *CARD15* and a clear linkage disequilibrium block structure was found across all three genes. We then selected several SNPs within these genes for further analysis in a group of TB cases and controls: No significant association with TB was observed for *NRAMP1*, *CARD15* and *TNFA* polymorphisms. However, two *VDR* markers, a *FokI* polymorphism located at the translational start site of *VDR* and a *TaqI* polymorphism located in the 3' region of the gene, showed evidence for association with TB. Specifically, homozygous carriers of the rare allele for the *TaqI* polymorphism were found associated with TB susceptibility ( $p = 0.027$ ). This polymorphism had previously been linked with altered expression levels of the *VDR* gene and is associated with altered bone mineral density.

**What causes early onset breast cancer in a population-based sample of Australian women with a strong family history?** *M.C. Southey<sup>1</sup>, A.A. Tesoriero<sup>1</sup>, S.G. Royce<sup>1</sup>, L. Smith<sup>1</sup>, P. MacAulay<sup>1</sup>, J. Cui<sup>1</sup>, M.A. Jenkins<sup>1</sup>, G.S. Dite<sup>1</sup>, R.L. Milne<sup>1</sup>, G. Chenevix-Trench<sup>2</sup>, A. Spurdle<sup>2</sup>, G.G. Giles<sup>4</sup>, M.R.E. McCredie<sup>3</sup>, D.J. Venter<sup>1</sup>, J.L. Hopper<sup>1</sup>, Australian Breast Cancer Family Study.* 1) University of Melbourne, Melbourne, Victoria, Australia; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) The University of Otago, New Zealand; 4) The Cancer Council, Victoria, Australia.

The Australian Breast Cancer Family Study (ABCFS) includes a population-based case-control-family study of 856 women diagnosed with breast cancer before the age of 40 years. Eight percent of cases had a strong family history, defined by having two or more first- or second-degree relatives on the same side of the family with breast or ovarian cancer, compared with one percent of controls. Of these 66 cases with a strong family history: 8 (11%) would be expected by chance alone based on the age distribution of the relatives and the population incidence rates; 14 (20%) were found to carry a germline mutation in the coding or splice site regions that were likely to be pathogenic by sequencing the coding and exon-flanking intronic regions of BRCA1 and BRCA2; 3 (4%) carry a large deletion in BRCA1; 1 (1%) is known to be part of a Li-Fraumeni kindred and carries a germline p53 mutation; 2 (3%) carry specific mutations in ATM (IVS10-6 T>G and T7271G); and 1 (1%) carries a mutation in CHK2 (1100delC). Segregation analyses of the ABCFS families have suggested that there may be as yet undetected mutations associated with a high dominantly-inherited risk. Two-loci segregation analyses also suggest that there may be genetic loci involved with a very high recessively-inherited risk. These segregation analyses cannot discount that there may also be a polygenic background of multiple genes with small effects. In summary, more than two-thirds of these population-based multiple-case breast cancer families are not explained by mutations in BRCA1, BRCA2, or other known or suspected susceptibility genes, and most of these unexplained families may be explained by recessive or polygenetic inheritance, rather than dominant inheritance or chance.

**CCR5 Pathway candidate genes susceptible to HIV-infection.** *S. Shrestha*<sup>1,2,5</sup>, *S.A. Strathdee*<sup>2</sup>, *N. Galai*<sup>2</sup>, *D. Thomas*<sup>3</sup>, *D. Vlahov*<sup>4</sup>, *S.J. O'Brien*<sup>5</sup>, *M.W. Smith*<sup>1,5</sup>. 1) Basic Research Program, SAIC, NCI-Frederick, MD; 2) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 3) Division of Infectious Diseases, School of Medicine, Johns Hopkins University, Baltimore MD; 4) Center for Urban Epidemiologic Studies, The New York Academy of Medicine, New York, NY; 5) Laboratory of Genomic Diversity, NCI-NIH, Frederick, MD.

We are conducting a nested case control study within the ALIVE cohort in Baltimore to study candidate genes (CCR5, Rantes, MIP-1a, MIP-1b, MCP-2, IL10, IFNG, MCSF and IL2) involved in the CCR5 pathway of HIV infection. HIV-1 strains responsible for infection predominantly use CCR5 as a co-receptor. Homozygosity for a 32 bp deletion of CCR5 encodes a non-functional receptor preventing viral entry. However, the affect is not absolute and the allele frequency is 11% among European descent population but rare (<3%) among African Americans and absent in native Africans and Asians. We are examining other genes that up-regulate, down-regulate or bind as ligands affecting the CCR5 expression and host susceptibility to HIV infection among African American cohort with measured risk behavior. A total of 299 African American HIV-seroconverter cases and two controls per case matched for duration in the cohort using incidence density sampling are being examined for these genes. A set of informative SNPs at IL2, IL10 and IFNG have been identified and genotyped using the Taqman protocol. Single-locus association was conducted directly with cSNPs, and indirectly with other SNPs as linkage disequilibrium surrogates for functional polymorphisms. A multi-locus analysis is being conducted to test the associations between haplotypes, HIV-infection and cumulative risk exposure based on questionnaire data using conditional logistic regression. Haplotypes for informative SNP combinations at each gene are estimated via an Expectation-Maximization algorithm. Preliminary univariate analyses indicate significant ( $p < 0.05$ ) genotype association at a few loci in all three genes and also significant haplotype association in IL2, but need further analysis. Funded in part by DHHS#N01-CO-12400.

**Phylogenetic Analysis of Slavic Lebers Hereditary Optic Atrophy (LHON) Cases: The Role of Population Genetic Markers for mtDNA Human Pathology.** *S.I. Zhadanov<sup>1, 2</sup>, T.G. Schurr<sup>1</sup>*. 1) Dept Anthropology, University of Pennsylvania, Philadelphia, PA; 2) Institute of Cytology and Genetics, Novosibirsk, Russia.

One of the most puzzling features of the numerous common mtDNA diseases is the difference in population distribution and disease expression related to ethnic and genetic factors. It has been shown that certain polymorphic genetic markers in some mtDNA haplogroups promote the phenotypic expression of human diseases. The interaction between population-specific mtDNA variation and pathogenic mutations is particularly evident in LHON. Numerous studies have demonstrated that LHON cases occur in patients with haplogroup J mtDNAs six to eight times more frequently than expected based on normal control haplogroup frequencies and a random pattern of pathogenic mutation distribution in Caucasian populations. However, much less is known about such patterns in Slavic populations. For this reason, we analyzed the mtDNA genetic population background for about 30 clinical LHON cases in persons of Slavic origin. The majority of these cases occurred in individuals having common West Eurasian haplogroups (HV, TJ, UK, XI), while a small portion occurred in Eastern Eurasian haplogroup D, which is nearly absent in Slavs. One-fourth of the LHON cases (~25%) fell within haplogroup TJ, a pattern consistent with that previously seen for Caucasian populations. In addition, we observed a number of LHON cases without known mtDNA mutations, with these being distributed more randomly across mitochondrial backgrounds. When the distribution of primary LHON mutations was considered, haplogroup JT was associated with these mutations over three times higher (40%) than with cases caused by unknown mutations. Such striking geographic and population differences suggest that ancient genetic backgrounds could affect the expression of different LHON mutations. At the same time, they may also indicate that specific population-specific mtDNAs are functionally different and, hence, might have been influenced by selection. The probable interaction of the genetic background with pathogenic mtDNA mutations further supports a polygenetic model for OXPHOS disease development.

**Complex Inheritance and Possible Imprinting in Juvenile Myoclonic Epilepsy.** *D. Pal<sup>1</sup>, M. Durner<sup>1,2</sup>, I. Klotz<sup>2</sup>, E. Dicker<sup>2</sup>, S. Shinnar<sup>3</sup>, S. Resor<sup>4</sup>, J. Cohen<sup>5</sup>, C. Harden<sup>6</sup>, S. Moshe<sup>3</sup>, H. Kang<sup>3</sup>, E. Bromfield<sup>7</sup>, D. Greenberg<sup>1,2</sup>, New York Epilepsy Study.* 1) Psychiatry, Columbia Univ, New York, NY; 2) Biostatistics, Columbia Univ, New York, NY; 3) Albert Einstein College of Medicine, NY; 4) Columbia Presbyterian Medical Center, NY; 5) Beth Israel Medical Center, NY; 6) Cornell University, NY; 7) Boston University College of Medicine.

**Background.** Juvenile Myoclonic Epilepsy (JME) is a common adolescent-onset idiopathic generalised epilepsy (IGE) with complex inheritance. A major susceptibility locus (EJM1) for JME has been localised on chromosome 6, with evidence of maternal inheritance in EJM1-linked families. EJM1 was recently identified as the BRD2 gene. We sought epidemiological support for imprinting in JME families with both positive and negative evidence for linkage at EJM1, and compared patterns of seizure inheritance between JME and other IGE families. **Methods.** We ascertained 89 families through a proband with typical JME and 50 families through a proband with a non-JME IGE. Family members were assessed for seizures and EEG abnormalities. Lineality was assessed in 43 multigenerational families. The crude prevalence of seizures, epilepsy and EEG traits in 806 family members was tabulated. **Results.** Multigenerational families showed evidence for preferential maternal transmission of JME, both in EJM1-linked and unlinked families. The sex ratio was extremely skewed in JME, with a female excess not seen in other IGEs (Risk Ratio 12.5). Proband seizure types and sex influenced the risk of seizures in relatives: i) absence seizures in JME probands increased (0.16 vs 0.07) the risk of absence and GTCS (but not myoclonic seizures) in first degree relatives; ii) overall risk of seizures was doubled in relatives of male compared to female JME probands (0.15 vs 0.07). **Conclusions.** Imprinting seems the best explanation of maternal inheritance in JME. We confirmed a striking female excess in JME which may be explained by sex-dependent trait penetrance. Absence and myoclonic seizures were inherited independently, and GTCS shared susceptibility with both absence and myoclonic seizures. Our results support an oligogenic model for adolescent-onset IGE.

**Familial aggregation of hyperemesis gravidarum.** *M. Schoenberg-Fejzo, K. MacGibbon, R. Schoenberg-Paik.*  
Hyperemesis Education and Research Foundation.

Nausea and vomiting in pregnancy, occurs in 50-90% of all pregnant women. When the symptoms are so severe that individuals require hospitalization and/or therapeutic intervention, pregnant women are diagnosed with hyperemesis gravidarum (HG). HG occurs in approximately 0.3-2.0% of pregnant women, and is characterized by severe nausea and vomiting in early pregnancy that rapidly leads to at least a 5% weight loss. Currently approximately 70% of patients are prescribed antiemetic drugs of unknown safety and efficacy to treat the symptoms of HG. In an attempt to learn more about HG, we wrote and collected surveys from over 260 affected individuals. Our study shows that the 3 most commonly prescribed antiemetics (phenergan, compazine, and tigan) are more strongly correlated with second trimester fetal demise than with having any positive therapeutic effect, suggesting a better understanding of the disease and new treatments is critical. To determine whether HG is amenable to genetic studies, we included a number of questions about family history. All patients were diagnosed by a medical professional to have hyperemesis gravidarum. Of the 260 respondents, 96 reported having at least one sister with a pregnancy history. Of the 96 sister pairs, 23 (24%) reported a sister with HG. In addition, 28 (11%) affected individuals reported having an affected mother, and 29 (11%) reported having an affected secondary relative. We have also identified 14 families with 3 or more affected individuals. This study shows the frequency of HG in families is way above the reported 0.3-2.0% in the general population. This is the first evidence that there may be a genetic component to the severe form of morning sickness, hyperemesis gravidarum, which may make it amenable to genetic studies of complex disease. We hope that this will lead to a new field of study to identify the genetic basis for hyperemesis gravidarum and lead to development of targeted therapy.

**The familial occurrence of Stuttering.** *R. Uppala<sup>1,3</sup>, D. Dasgupta<sup>1</sup>, J.V. Solanki<sup>2</sup>, R. Uppala<sup>3</sup>.* 1) Dept. of Biochemistry, Institute of Science, Mumbai; 2) Dept. of Animal Genetics & Breeding, Veterinary college, Anand, India; 3) GeneHealth, Green Cross Voluntary blood bank & Genetic Centre, Paldi, Ahmedabad,.

Stuttering is a speech disorder, which begins in childhood between the ages of 3-6 and is characterized by involuntary syllable repetitions, sound prolongations or interruptions (audible and silent). It is a painful symptom and is considered as society's hidden disability. Stuttering greatly interferes with a child's emotional and psychological development and also affects their daily social or occupational functioning. The incidence of stuttering among the general population is about 0.7-1.0% with a higher 4-5:1 ratio of male to females affected. Family, twin, and adoption studies strongly suggest a genetic predisposition/susceptibility to stuttering, but no genes have yet been identified. Associations between childhood and/or adult stuttering and brain disorders, such as Down syndrome, Parkinson's disease, Tourette syndrome and depressive illness, have been reported. We have studied nine large Indian pedigrees with stuttering (OMIM 184450) in which the anomaly segregates as an autosomal dominant trait. The onset is during early childhood. These families were identified from the old records of child psychiatrists and speech pathologists and extended with information from other family members. The pedigrees consist of 455 individuals with 105 affecteds (82 males/23 females). These include two large pedigrees with 32 and 37 affecteds. The age distribution of these affecteds is 8-70 years. Severity of the phenotype was quite variable among the families and skipping of a generation was observed in two pedigrees. In three families four members were affected with post stuttering epilepsy. No other associated anomalies were present in these families. The present study indicates a monogenic mode of inheritance with variable expression. Systematic genome-wide linkage analyses, using rare larger families that show autosomal dominant stuttering may reveal one or more chromosomal loci for the phenotype. The identification and characterization of this stuttering gene will contribute in determining molecular pathophysiological basis of this disorder Email: u\_c\_rao@hotmail.com.

**Linkage disequilibrium mapping in the Newfoundland population: a reevaluation of the refinement of the Bardet-Biedl Syndrome 1 critical interval.** *Y. Fan<sup>1</sup>, J.S. Green<sup>2</sup>, P.S. Parfrey<sup>2</sup>, W.S. Davidson<sup>1</sup>*. 1) Dept Molec Biol & Biochem, Simon Fraser Univ, Burnaby, BC, Canada; 2) Faculty of Medicine, Memorial University, St. John's, NF, Canada.

Two criteria must be met for linkage disequilibrium (LD) mapping: 1) there should be a single disease causing allele with a relatively high frequency in the population, and 2) the disease causing allele should have been introduced sufficiently long ago that recombinations have reduced the original haplotype around this allele. The island population of Newfoundland has the potential for LD studies based on the nature of its founding and its subsequent isolation. Young et al. (*Am J Hum Genet* 65: 1680-1687, 1999) used 6 families in a LD analysis to refine the critical region of Bardet-Biedl Syndrome 1 (BBS1) to 1 cM. However, when Myktyyn et al. (*Nat Genet* 31: 435-438, 2002) identified the BBS1 gene it was located outside this region. Possible reasons for this are: 1) another gene is responsible for BBS in these families, or 2) the Newfoundland population is not ideal for LD studies. We screened the 6 families for mutations in the BBS1 gene. All affected individuals in 5 of the families were homozygous for the most common BBS1 mutation, M390R. However, there was no evidence for any mutation in the coding regions or exon-intron boundaries of the BBS1 gene in the affected individual in family B12. Therefore, the first condition for an effective LD analysis was not met. It should be noted though that family B12 was not a key factor in predicting the critical region of BBS1. We then performed fine haplotype mapping on a 450 kb region surrounding the BBS1 gene. Haplotypes were constructed for 8 BBS1 patients homozygous for M390R, 31 heterozygous parents and siblings, 10 sibling non-carriers, 6 apparently unrelated individuals from the general population who were heterozygotes, and 6 non-carriers of M390R from the general public. All 53 chromosomes carrying the M390R mutation contained a common sub-haplotype defined by 5 markers. This provides evidence for a single ancestral founder for BBS1 in Newfoundland. However, the same sub-haplotype (apart from M390R) was also found in 13 of 69 normal chromosomes.

**The impact of inaccurate ages on a potential association between tuberculosis and NRAMP1. C.M.T.**

*Greenwood<sup>1,2</sup>, J. Beyene<sup>1,2</sup>, S. Malik<sup>3,4</sup>, T. Egualé<sup>3,5</sup>, A. Kifle<sup>6</sup>, A. Habte<sup>6</sup>, A. Tadesse<sup>6</sup>, I. Abraham<sup>6</sup>, S. Britton<sup>7</sup>, E. Schurr<sup>3,4</sup>.* 1) Hospital for Sick Children Research Institute, Toronto, ON, Canada; 2) Department of Public Health Sciences, University of Toronto, ON; 3) Research Institute of the McGill University Health Centre, Montreal, QC, Canada; 4) Department of Medicine, McGill University, QC; 5) Department of Epidemiology and Biostatistics, McGill University, QC; 6) Armauer Hansen Research Institute, Addis Abbaba, Ethiopia; 7) Department of Medicine, Karolinska Institute, Sweden.

Covariates can be incorporated into models testing for linkage/disequilibrium; one straightforward approach involves rewriting the standard TDT as a logistic model of transmissions versus non-transmissions for a particular allele from heterozygous parents. The dependence of any association upon factors measured in the child can then be investigated. When covariates are measured with error, it is well known that standard errors tend to be too small, and that the estimates of the covariate effects may be biased. However, measurement error is not always considered in family-based association studies. Proband with proven tuberculosis and their parents were enrolled into a study in Ethiopia investigating candidate genes for association with disease susceptibility. Four NRAMP1 markers were genotyped, and haplotypes were estimated. There were 43 heterozygous parent-child transmissions involving one particular haplotype, where all four markers were genotyped in both parents and the proband, and we identified a potential association that appeared to depend on age, so that a stronger association is apparent at younger proband ages (estimated increase in odds of transmission of the risk haplotype per 5 years younger = 2.25, significance=0.012). We were concerned that self-reported age was inaccurate, with the error increasing with the age of the individual. We therefore placed a log-normal distribution on the true age, and found that the association's dependence on age appeared slightly stronger (odds=2.50, significance=0.010), but that conclusions were not altered. The impact of risk factor measurement error should be evaluated in genetic studies.

**Odds-ratio regression models for testing joint transmission of candidate genes for tuberculosis.** *J. Beyene*<sup>1, 2</sup>, *C.M.T. Greenwood*<sup>1, 2</sup>, *S. Malik*<sup>3, 4</sup>, *T. Egualé*<sup>4, 5</sup>, *A. Kifle*<sup>6</sup>, *A. Habte*<sup>6</sup>, *A. Tadesse*<sup>6</sup>, *I. Abraham*<sup>6</sup>, *S. Britton*<sup>7</sup>, *E. Schurr*<sup>3,4</sup>. 1) Population Health Sciences, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Public Health Sciences, University of Toronto, ON; 3) Research Institute of the McGill University Health Centre, Montreal, QC, Canada; 4) Department of Medicine, McGill University, QC; 5) Department of Epidemiology and Biostatistics, McGill University, QC; 6) Armauer Hansen Research Institute, Addis Ababa, Ethiopia; 7) Department of Medicine, Karolinska Institute, Sweden.

There is growing evidence linking tuberculosis susceptibility with host genetics and a number of candidate genes have been identified. For the case-parental control design, marginal transmission rates for individual marker alleles can be investigated using standard regression models. However, in genetic studies joint association parameters are of interest and models that allow explicit specification of the association parameters and link them with covariates are useful. Data have been collected in Ethiopia from probands with proven tuberculosis and their parents to investigate candidate genes for association with disease susceptibility. We studied the joint association of marker alleles for one marker at surfactant protein gene 1 and four NRAMP1 markers. The generalized estimating equations (GEE) approach was applied to test for association using the odds ratio of joint allelic transmission as the parameter of interest. We found a marginal association between the surfactant marker and one of the NRAMP1 markers ( $p = 0.0539$ ). Further modeling of the association parameter stratified by gender showed a significant interaction between the two genes in females ( $p = 0.0365$ ). Such methods can be used to investigate interactions between genes and environmental factors.

**Efficacy of haplotype-based association approaches.** *J. Drake*<sup>1</sup>, *M. Loomer*<sup>2</sup>, *C. Newton-Cheh*<sup>2,3</sup>, *A. Lochner*<sup>2</sup>, *R. Levy*<sup>2</sup>, *H. Hirschhorn*<sup>1,2</sup>. 1) Genetics, Children's Hosp/Harvard Med, Boston, MA; 2) Whitehead/MIT Center for Genome Research, Cambridge, MA; 3) NHLBI.Framingham Heart Study, Framingham, MA; 4) Medicine, Boston University, Boston, MA.

The genome contains blocks of linkage disequilibrium (LD), within which most chromosomes carry one of a few common haplotypes (e.g. Gabriel et al. 2002). Single nucleotide polymorphisms (SNPs) that tag these haplotypes (htSNPs) should thus capture information about other common variants in blocks, and enable efficient association studies. We now directly test this approach in a large dataset.

We studied 29 genes (covering 1.1 Mb) using a set of 1094 SNPs ("set 1") from dbSNP (TSC and BAC overlap SNPs only) and Celera, genotyped in 96 European-derived chromosomes from CEPH pedigrees. All genes are candidates for cardiovascular traits. We compared 3 different algorithms for defining blocks of LD, and selected htSNPs using 3 different approaches; results below are from one of these algorithms and approaches.

Within blocks, there were on average 4 common (>5%) haplotypes. To test how well the htSNPs captured unmeasured common variation within blocks, we identified 156 additional SNPs ("set 2") discovered by resequencing of these genes. 120 of the 156 "set 2" SNPs (77%) fell in the blocks defined using "set 1" SNPs. The "set 1" htSNPs largely captured these 120 SNPs: 79% of the "set 2" SNPs that fell in blocks were correlated with at least one htSNP in the block or a neighboring block ( $r^2 > 0.5$ ). Consideration of haplotypes of htSNPs further strengthened this correlation; only 15% of the 120 SNPs created a new common haplotype.

We conclude that htSNPs from existing databases can efficiently capture most common variation within blocks (in this non-African-derived population). We are using this approach to test these genes for association with cardiovascular traits, and have identified preliminary associations (see [www.cardiogenomics.org](http://www.cardiogenomics.org)).

Supported by the NHLBI Programs for Genomic Applications 5U01 HL66582.

**Choosing subsets of SNP for genotyping in association studies: htSNP and ldSNP.** *R. Lazarus, E. Silverman, B. Raby, D. Kwiatkowski, S.T. Weiss.* Channing Laboratory, Boston, MA.

Genotyping costs nearly always limit the design of large, comprehensive disease association studies. Subsets of SNPs must be chosen, in the hope that linkage disequilibrium (LD) between genotyped SNPs and any causal SNPs not genotyped will permit an association to be demonstrated. Although no provably optimal method for selecting subsets of SNP for any given genotyping budget and set of samples is available, we illustrate two potential approaches: a haplotype-tagging SNP (htSNP) method, and a novel method based on capturing pairwise LD in subsets of SNP (ldSNP).

Minimal htSNP sets were identified using BEST in haplotypes inferred with SNPHAP for SNP  $\geq 10\%$  frequency (mean 10%SNP/gene=25.8, SD=22.8) in complete resequencing data for 23 European American subjects from 137 inflammatory and innate immunity genes. For haplotypes observed twice or more, haplotype diversity was captured with no information loss in relatively small subsets (mean htSNP/gene=5.1, SD=2.1). However, htSNPs may not be ideal for analyses which rely on LD to detect causal variations not genotyped, since the best LD with one or more 10% SNP not in the set was below 0.5 in 78 genes (worst case  $r^2$  mean=0.50, SD=0.32).

LD can be captured in sets of SNPs chosen to provide a user specified minimum LD level between at least one of the ldSNPs and each of the SNPs not in the set. An algorithm which selects the smallest sets of ldSNP satisfying a pre-specified worst case LD level is described. Applying this method to the same resequencing data 10% SNPs, a minimum  $r^2$  of 0.5 required a mean ldSNP set size of 8.6 (SD=7.2). A minimum  $r^2$  of 0.8 required a mean ldSNP set size of 11.8 (SD=10.2). Useful levels of minimum LD require larger ldSNP sets and thus increased genotyping costs, compared with the htSNP approach. A hybrid approach where htSNP sets are augmented to give prespecified minimum LD levels is described.

The benefit of a haplotype-based approach combined with a prespecified minimum level of LD at analysis may make the additional genotyping costs justifiable in some study design situations.

**Patterns of linkage disequilibrium in calpain-10.** *M.G. Hayes*<sup>1</sup>, *T. Tsuchiya*<sup>2</sup>, *L. del Bosque-Plata*<sup>2</sup>, *N.J. Cox*<sup>1,3</sup>. 1) Human Genetics, Univ Chicago, Chicago, IL; 2) Biochemistry and Molecular Biology, Univ Chicago, Chicago, IL; 3) Medicine, Univ Chicago, Chicago, IL.

The q-terminus of chromosome 2 achieves a genome wide level of significance for linkage to type 2 diabetes in Mexican-Americans, and subsequent positional cloning analyses yield calpain-10 (*CAPN10*) as the candidate gene within the region (*NIDDM1*). A combination of two different three-polymorphism (SNP43, INDEL19, SNP63) haplotypes has the highest risk in Mexican-Americans, although replication studies produce confounding results among several other populations examined. This suggests *CAPN10* (or at least 43-19-63) might not be the true disease-associated gene, and that these polymorphisms may simply be in strong linkage disequilibrium (LD) with the nearby true disease-associated locus. To better understand the complex association of type 2 diabetes to polymorphisms in this region, we calculated pairwise measures of LD ( $D'$  and  $r^2$ ) for 64 markers spanning 800kb in 110 patients and 112 randomly chosen controls from the Starr County Mexican-American study. Two adjacent LD blocks spanning 120kb were discernable, one containing *CAPN10*, and the other containing a neighboring gene, *GPR35*. Pairwise LD values within *CAPN10* are significantly greater than the LD values between any marker within *CAPN10* and any marker outside of *CAPN10*. Hence, LD decays rapidly outside *CAPN10*, and suggests that it is the true diabetes-susceptibility gene and not simply a marker for a closely linked unidentified diabetes-susceptibility locus. On average, patients have higher LD values than controls. This difference was examined further by comparing mean patient and control pairwise LD values within overlapping sliding windows (4.5kb in length and sliding 1.5kb/iteration), and mean patient and control pairwise LD values between the sliding window and the remainder of the region. Both comparisons yield a significant peak in the LD difference between patients and controls in the largest intron (13<sup>th</sup> of 15) of *CAPN10*. This peak is largely the result of decreased LD among the controls, not an increase in the LD among patients.

**Patterns of genetic variation and linkage disequilibrium of genes in the renal-dopaminergic system. K.E.**

*Lohmueller<sup>1</sup>, M.H. Liang<sup>1</sup>, H. Boudreau<sup>1</sup>, L.L. Liu<sup>1</sup>, E. Wilson<sup>1</sup>, R.A. Felder<sup>2</sup>, P.A. Jose<sup>3</sup>, S.M. Williams<sup>4</sup>, L.J.C.*

*Wong<sup>1</sup>.* 1) Inst Molec & Human Genetics, Georgetown Univ Med Ctr, Washington, DC; 2) Dept of Pathology, Univ of Virginia Health Sciences Ctr, Charlottesville, VA; 3) Dept of Pediatrics, GUMC, Washington, DC; 4) Div of Cardiovascular Med & Program in Human Genetics, Vanderbilt Univ School of Med, Nashville, TN.

Association studies using single nucleotide polymorphisms (SNPs) have the potential to help unravel the genetic basis of hypertension. Nevertheless, association studies of hypertension have yielded ambiguous results thus far. Consequently, it is becoming clear that these studies must be interpreted within the context of the genetic structure of the populations studied. With this in mind, we analyzed genetic variation in the G protein-coupled receptor kinase 4 (*GRK4*) gene whose product has recently been shown to inhibit the dopamine receptor D1 (*DRD1*) from increasing sodium excretion. We genotyped the three previously identified *GRK4* SNPs (G4448T, C679T and C1711T) as well as SNPs in *DRD1* (A-48G) and *DRD5* (G181A) in the following populations: African Americans, Asians, Hispanics and Caucasians. The SNPs in *GRK4* involve amino acid changes R65L, A142V and A468V, respectively. Levels of linkage disequilibrium (LD) between the *GRK4* SNPs varied among populations, with African Americans having lower levels of LD within the gene compared to levels in other populations. However, useful levels of LD ( $r^2 > 0.33$ ) extended over 15.5 kb in all populations studied and as far as 48.6 kb in Hispanics and Caucasians. While we noted limited haplotype diversity in the four populations studied, allele and haplotype frequencies differed among ethnic groups. Though preliminary, our results not only document different allele frequencies among populations, but differences in haplotype structure that may be important in evaluating association studies with hypertension and *GRK4*, *DRD1* and *DRD5*.

**The effect of natural selection on the pattern of linkage disequilibrium around the hemoglobin E variant. J.**

*Ohashi*<sup>1, 2</sup>, *I. Naka*<sup>1</sup>, *J. Patarapotikul*<sup>3</sup>, *H. Hananantachai*<sup>3</sup>, *S. Looareesuwan*<sup>3</sup>, *A.G. Clark*<sup>2</sup>, *K. Tokunaga*<sup>1</sup>. 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 3) Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand.

The carriers of the hemoglobin E variant (HbE; 26Glu->Lys) are considered to confer some protection against *Plasmodium falciparum* malaria. We analyzed biallelic markers surrounding the HbE variant in a Thai population to examine the effect of natural selection on the pattern of linkage disequilibrium (LD) and to infer the evolutionary history of the HbE variant. The pairwise LD analysis of 44 markers revealed that LD between HbE and markers distal to HbE extended beyond 100 kb, whereas no LD was observed between non-HbE variants and the distal markers. The inferred haplotype network suggested that HbE had a single origin. Forward-in-time computer simulations under a variety of selection models indicated that the HbE variant arose within the past 1,240 to 4,440 years. Our results support the conjecture that a mutation of HbE occurred recently, and the allele frequency has increased rapidly due to positive selection in malarial endemic areas of Southeast Asia.

**Maternal cigarette smoking and variants in GSTP1 and GSTT1 contribute to the etiology of orofacial clefting.** *M. Shi*<sup>1</sup>, *K. Christensen*<sup>2</sup>, *A. Lozada*<sup>3</sup>, *P. Romitti*<sup>4</sup>, *J. Murray*<sup>1,3,4</sup>. 1) Dept Biological Sci, Univ Iowa, Iowa City, IA; 2) Center for the Prevention of Congenital Malformations, Institute of Public Health, Univ Southern Denmark, 5000 Odense C, Denmark; 3) Dept Pediatrics, Univ Iowa, Iowa City, IA; 4) Dept Epidemiology, Univ Iowa, Iowa City, IA.

Orofacial Clefts (OCs) have a complex etiology involving both genetic and environmental factors. Maternal tobacco smoking has been associated with OCs in some studies but unconfirmed in others. These disparities may be due to the failure to consider inherited pharmacogenetic susceptibilities to tobacco smoke. In this study, maternal cigarette smoking and the effects of variants in genes involved in the detoxification pathway for smoke byproducts were evaluated in a collection of cases and controls of OCs. Variants in genes involved in both phase I and phase II detoxification were investigated. Nine SNPs in eight genes were genotyped on samples from a Danish population and an Iowa population. A total of 370 case and 360 control case-parent triad families, and an additional 300 case and 500 control individual samples were investigated in this study. Effects of the maternal and fetal genotypes as well as the interaction between genotypes and smoking status were tested. Logistic regression and log-linear modeling were applied in the analysis. In Danish samples, even though no significant associations were detected either for the maternal or fetal genotype alone, a significant effect of the interaction between GSTP1 A313G and maternal cigarette smoking was identified in the case-parent samples. In the case-control samples, interaction between the GSTT1 null mutation and maternal smoking was identified to have a significant effect on OCs. Genotyping has been completed on the Iowa samples and replication tests are underway. In summary, significant effects on OCs were detected in the interactions between the polymorphisms in two genes of the GST family, GSTT1 and GSTP1, and maternal cigarette smoking. These results suggest that there may be individuals at particular high risk for abnormal pregnancy outcomes in the context of maternal smoking and may be a target group for especially aggressive antismoking programs.

**Association of a DBH Intron 5 Taq I Polymorphism and Plasma Dopamine beta-hydroxylase Activity Results from Linkage Disequilibrium to a Putative Functional Variant, -1021C->T.** *Y. Tang<sup>1</sup>, S. Buxbaum<sup>2</sup>, M. Kohnke<sup>3</sup>, G. Anderson<sup>4</sup>, J. Cubells<sup>1</sup>, Lab of Human Genetics.* 1) Department of Psychiatry, Yale University School of Medicine VA Connecticut Health Care System, Psychiatry/116A2, 950 Campbell Avenue, West Haven, CT 06516; 2) Department of Human Genetics, University of Pittsburg, Pittsburg, PA; 3) University Hospital of Psychiatry and Psychotherapy, Tübingen, Germany; 4) Yale Child Study Center, Yale University, New Haven, CT.

Background: Plasma activity of dopamine beta-hydroxylase (DbetaH), the enzyme facilitating the conversion of dopamine to norepinephrine, is an important endophenotype. Plasma DbetaH is under genetic control by the structural locus encoding DbetaH protein, DBH. A common polymorphism, IVS5+192CT, which is located in exon 5 and is easily genotyped by restriction with Taq I, has been reported to associate with attention deficit hyperactivity disorder. Its relationship to functional variation at DBH is therefore of keen interest. This study tested the following hypotheses: (1) IVS5+192C->T associates with plasma DbetaH level; and (2) there is linkage disequilibrium between IVS5+192C->T and a putative functional polymorphisms, -1021C->T, located in the proximal 5 region of the DBH gene. Methods: Plasma DbetaH activity was measured in a mixed sample consisted of cocaine abusers, alcoholics, patients with affected disorders and normal controls (n=447). Genotypes were determined at Taq I and -1021c->T functional DBH polymorphisms. Results: (1) The mean square-root plasma DbetaH levels were 6.14+/-1.70, 5.72+/-1.81 and 4.40+/-2.07 nmol/min/ml for CC (n = 68), CT (n=223) and TT (n=156) groups respectively (F=29.692, p<0.000); (2) There was strong linkage disequilibrium between IVS5+192C->T and -1021C->T polymorphisms. (3) Multivariate analysis showed that IVS5+192C->T genotype did not explain significant additional variance in plasma DbetaH levels, beyond the effect of 1021C->T. Conclusions: IVS5+192C->T is associated with plasma DbetaH activity, with the T allele associating with lower plasma DbetaH activity. This association reflects linkage disequilibrium between IVS5+192CT and 1021C->T.

**Patterns of gametic disequilibrium between microsatellite loci on human chromosomes Xq and 11p.** *E. Sande<sup>1</sup>, J. Hermida<sup>1</sup>, L. Rodríguez<sup>1</sup>, S. Rodríguez<sup>1</sup>, C. Martín<sup>2</sup>, C. Zapata<sup>1</sup>.* 1) Departamento de Genética, Universidad de Santiago, 15782 Santiago de Compostela, Spain; 2) Departamento de Dermatología y Otorrinolaringología, Universidad de Santiago, 15782 Santiago de Compostela, Spain.

Knowledge on distribution of nonrandom associations between alleles at different loci (gametic disequilibrium) along human genome is essential for understanding its multilocus architecture as well as for designing and interpreting an experience of localization of disease genes. Here, we report a comparative study of levels of disequilibrium between microsatellite loci located spread across extensive anonymous regions on human chromosomes Xq and 11p, from a large sample of the Galician population (northwest Spain). We found that significant disequilibrium between microsatellite pairs is substantially higher along Xq and 11p than that previously reported for different human chromosomes in populations with similar demographic history, although the proportion of interallelic non-random associations was smallest over chromosome X. Moreover, patterns of disequilibrium depend on allele frequencies and their sizes. In particular, rare alleles (frequency 3%) and alleles of extreme size tend to exhibit greater disequilibrium than the other alleles. Distribution of disequilibrium along these extensive regions of human chromosomes seems to be complex and it does not follow simple rules depending on between-locus recombination frequency. In fact, significant correlation between the intensity of GD and recombination frequency and physical distance was not detected. Our observations suggest that the high rate of mutation of microsatellite loci together with their complex mutational dynamics are probably the main causal factors contributing to the origin and distribution of disequilibrium detected across Xq and 11p. Consequently, patterns of disequilibrium between microsatellites on human chromosomes seems to be rather unspecific of chromosome or chromosome region.

**A common founder mutation in *FKRP* causes limb girdle muscular dystrophy type 2I (LGMD2I) in both Hutterite and European populations.** P. Frosk<sup>1</sup>, C.R. Greenberg<sup>1, 2</sup>, A. Poulin<sup>1</sup>, R. Lamont<sup>1</sup>, E. Nylen<sup>1</sup>, M. Zaik<sup>3</sup>, V. Straub<sup>3</sup>, K. Bushby<sup>4</sup>, D. Frappier<sup>5</sup>, N.M. Roslin<sup>5</sup>, K. Morgan<sup>5, 6</sup>, T.M. Fujiwara<sup>5, 6</sup>, K. Wrogemann<sup>1, 2</sup>. 1) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, Canada; 2) Department of Pediatrics, University of Manitoba, Winnipeg, Canada; 3) Department of General Pediatrics and Neuropediatrics, University of Essen, Essen, Germany; 4) Institute of Human Genetics, University of Newcastle upon Tyne, Newcastle upon Tyne, UK; 5) Departments of Human Genetics and Medicine, McGill University, Montreal, Canada; 6) The Research Institute of the McGill University Health Centre, McGill University, Montreal, Canada.

The limb girdle muscular dystrophies (LGMDs) are a clinically and genetically heterogeneous group of disorders characterized by weakness and wasting in the pelvic and shoulder girdles. They are relatively rare worldwide, ranging from 1/14,500 to 1/123,500. They are common in the Hutterite population of North America with a prevalence of approximately 1/500. Using samples from Hutterite families, we have identified a putative disease-causing mutation in each of two autosomal recessive LGMDs: a *TRIM32* missense mutation (c.1459G>A, D487N) in LGMD2H and a *FKRP* missense mutation (c.876C>A; L276I) in LGMD2I. The LGMD2H mutation appears to be private to the Hutterite population and no other *TRIM32* mutations have been reported. In contrast, the LGMD2I mutation may be the most frequent LGMD-causing mutation in European patients. A single common haplotype surrounding the *FKRP* gene was identified in the Hutterite LGMD2I patients. Thirteen non-Hutterite LGMD2I patients of northern European origin share a core 2-marker haplotype of 0.19 Mb with the Hutterite haplotype. The occurrence of the L276I mutation on a common core haplotype suggests that it is a founder mutation which is widely dispersed in populations of European ancestry.

**Selecting a minimal set of SNPs for whole-genome association studies.** *M.A. Eberle<sup>1</sup>, C.S. Carlson<sup>2</sup>, D.C. Crawford<sup>2</sup>, M.J. Rieder<sup>2</sup>, D.A. Nickerson<sup>2</sup>, L. Kruglyak<sup>1</sup>.* 1) Department of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA.

Roughly 6 million sites in the human genome are polymorphic in the human population with frequency of both alleles above 5-10%. These common SNPs include the genetic variants proposed to be involved in disease susceptibility under the common disease-common variant hypothesis. The most straight-forward approach to test for associations between genetic variants and common diseases would be to compare the frequencies of all 6 million common SNPs in a large case-control study. Because this is not feasible with current or near-future technologies (at least not at a reasonable cost), a key goal of human genetics is defining a subset of SNPs that effectively assays the entire set through linkage disequilibrium (LD) between those SNPs included in the subset and the rest. Two central issues of this goal are: (1) finding the minimal number of SNPs that must be included in the subset in order to preserve high power to detect phenotypic association with any SNP and (2) deciding how to most effectively select this subset from the entire set of 6 million SNPs. We have examined these issues by performing coalescent simulations using population parameters that match empirically observed patterns of LD. For each series of population simulations we compare the power to detect association between common genetic variants and disease with subsets of SNPs chosen on the basis of random selection, pairwise LD, allele frequency and haplotype blocks. Initial results indicate that while a minimal subset of ~200,000-500,000 SNPs will have 80-90% power to detect associations realistic selection strategies will require larger numbers of SNPs.

**Oligogenic segregation analysis of obesity-related traits in hypertensive families from a French-Canadian isolate.**

*F. Gagnon<sup>1</sup>, J. Freil<sup>1</sup>, D. Gaudet<sup>2</sup>, J. Tremblay<sup>2</sup>, A.W. Cowley<sup>3</sup>, Z. Pausova<sup>2</sup>, P. Hamet<sup>2</sup>.* 1) Epidemiology and Community Med, University of Ottawa, Ottawa, Canada; 2) Centre de recherche du CHUM, Montreal, Canada; 3) Medical College of Wisconsin, Milwaukee, USA.

Obesity (Ob) is strongly related to morbidity and mortality and is drastically rising in North America. Ob is a complex disorder with multiple genes likely to be involved. Several genome scans of Body Mass Index have been performed but linkage results are inconsistent across studies. Little work has been done to identify better Ob-related quantitative traits (QT) prior linkage analysis. Physiological and statistical relationships between Ob and blood pressure are well established, and genetic pleiotropic effects on these traits have been suggested. In this study, we used 97 hypertensive families (n=1180) from a relative isolate population with the purpose of identifying the most promising QT for genome scan analyses of Ob-related traits in hypertension (HT). More than 600 phenotypes have been collected. Since body water regulation has been suggested to be involved in Ob-related HT, 2 body water measures as estimated by bioimpedance, in addition to 5 anthropometric measures, have been analyzed in n=242-792 individuals. Using novel oligogenic segregation analysis based on Bayesian Markov chain Monte Carlo methods, our analyses provide evidence in support of at least 1 locus with an individual contribution > 10 % to each trait variance. Contributions of the largest loci to the variance of anthropometric QT are ~ 41-64 %, and ~ 11-30 % for body water QT. Among the QT studied, subscapular skinfold is the best QT candidate because of the small number of loci implicated (mean 3.9), with the 3 largest loci contributing ~55, 20 and 7 %, respectively, to the variance. Age and sex were included as covariates in all QT analyses. A strong sex effect (21-42 %) on the variance was estimated for body water QT. Careful analyses of QT related to weight and water regulation prior linkage analyses will be useful in mapping genes implicated in Ob-related hypertension. Analysis of more Ob-related QT is under way.

**A cost-effective statistical and experimental approach to the analysis of candidate genes in complex disease using haplotype tag SNPs.** C.E. Lowe, J. Cooper, B.J. Barratt, E.A. Green, D. Clayton, J.A. Todd. JDRF/WT Diabetes and Inflammation Laboratory, CIMR, University of Cambridge, UK.

Owing to the high cost of single nucleotide polymorphism (SNP) typing, the search for common variants that may be expected to underlie common complex traits is currently restricted to candidate genes selected on the basis of function and data from linkage studies and animal models. Nevertheless, there may be hundreds of candidates. We have attempted to optimise the interrogation of any single gene in order to reduce costs while retaining as much statistical power as possible. To investigate whether the *RANK* or *TRANCE* immune response genes are associated with T1D we sequenced the exons and 3 kb 5' and 3' of both genes in 48 parents of diabetics and 48 controls. In *RANK*, 24 SNPs were identified, of which 16 were common (frequency >3%). In *TRANCE*, 26 polymorphisms were identified, 12 of which were common. From these common polymorphisms we determined an optimal set of haplotype tag SNPs (htSNPs), which captured the allelic variation of the untyped SNPs with a minimum  $r^2$  of 0.8. Six and four htSNPs were chosen for *RANK* and *TRANCE*, respectively. We then employed a two-stage procedure for genotyping. Phase 1 involved genotyping 666 multiplex families and testing for association using a multi-locus transmission/disequilibrium test (mlTDT). The mlTDT *P*-values for *TRANCE* and *RANK* were 0.295 and 0.112, respectively. For *RANK* we proceeded to phase 2: genotyping htSNPs in 1,695 additional T1D families. Phase 2 analyses were then performed on the entire dataset (Phase 1 and Phase 2 data combined) for which the mlTDT *P*-value was 0.286. Power calculations indicated that there was little loss in power in this two-stage process compared to a single stage approach, although it vastly reduces the genotyping requirement. We conclude there is little evidence in these data for association between the common variants identified in these genes and T1D. However, the combination of htSNPs and a two-stage design results in an effective and efficient framework for candidate gene studies. In this study, for example, the required genotyping was reduced by approximately 75%.

**Mapping multiple sclerosis (MS) susceptibility to the HLA-DR locus in African-Americans.** *J.R. Oksenberg<sup>1</sup>, L.F. Barcellos<sup>1</sup>, B.A.C. Cree<sup>1</sup>, T.L. Bugawan<sup>2</sup>, O. Khan<sup>3</sup>, E. Mignot<sup>4</sup>, L. Lin<sup>4</sup>, S. Schmidt<sup>5</sup>, G. Thomson<sup>6</sup>, D. Reich<sup>7</sup>, M.A. Pericak-Vance<sup>5</sup>, J.L. Haines<sup>8</sup>, S.L. Hauser<sup>1</sup>, MS Genetics Group.* 1) Dept of Neurology, UC San Francisco; 2) Roche Molecular Systems, Inc., Alameda, CA; 3) Wayne State University School of Medicine, Detroit, MI; 4) Stanford University, CA; 5) Duke University Med Center, Durham, NC; 6) UC Berkeley, Berkeley, CA; 7) Whitehead Institute/MIT Center for Genome Research; 8) Vanderbilt University, Nashville, TN.

An association with the HLA-DRB1\*1501-DQB1\*0602 (DR2) haplotype in MS has been repeatedly demonstrated in high-risk (Northern European or NE) groups. However, further localization within this haplotype has been difficult since it is unknown whether the effect is explained by DRB1 or DQB1, which are in strong linkage disequilibrium (LD). Compared to NE, Africans are characterized by greater HLA haplotypic diversity and distinct patterns of LD. To localize the HLA MS gene, we analyzed DRB1 and DQB1 alleles in a large dataset of self-reported African-American MS cases (n=336), family members (n=357) and controls (n=310). Using informative SNP markers, an average of 19.1% European ancestry was present in both cases and controls. Global testing for DRB1 and DQB1 in cases and controls revealed significant differences ( $p=4.0 \times 10^{-4}$  and  $p=0.02$ , respectively). While the DQB1 effect was restricted to DQB1\*0602 only, associations with DRB1\*15 ( $p=6.0 \times 10^{-4}$ ) and DRB1\*0301 ( $p=0.01$ ) alleles were identified. As observed in NE datasets, an increased risk for DRB1\*1501 ( $p=0.03$ ) and the DR2 haplotype ( $p=0.049$ ) were both present. In addition, DRB1\*1503 was also increased in patients ( $p=0.015$ ). Remarkably, the DRB1\*1501 and 1503 associations were independent of DQB1\*0602, as chromosomes carrying this allele with other DRB1 alleles were present in cases and controls at identical frequencies (4.0% each,  $p=0.77$ ), and conversely, DRB1\*15 haplotypes without DQB1\*0602 were increased in cases ( $p=0.01$ ). Family based analyses also supported a role for DRB1, but not DQB1. Our results provide strong evidence for DRB1 in MS and underscore the power of using ethnically defined datasets to identify disease genes.

**LRP5, low density lipoprotein receptor-related protein 5, is a bone-mineral-density determinant.** *T. Mizuguchi*<sup>1</sup>, *Y. Watanabe*<sup>1</sup>, *K. Tsukamoto*<sup>2</sup>, *H. Tomita*<sup>3</sup>, *N. Niikawa*<sup>1</sup>, *K. Yoshiura*<sup>1</sup>. 1) Human Genetics, Nagasaki University, Nagasaki, Japan; 2) Departments of Pharmacotherapeutics, Nagasaki University, Nagasaki, Japan; 3) Nagasaki Prefectural Medical Health Center, Nagasaki, Japan.

Osteoporosis is a multifactorial trait with low bone mineral density (BMD) determined by bone formation and resorption. We report results of association study between BMD and candidate genes: TGFB1, TGFBR2, SMAD2, SMAD3, SMAD4, INFB1, IFNAR1, FOS and LRP5. Samples included 481 general Japanese women who had a health checkup. There was no association between their genotypes and BMD values ( $p > 0.10$ ) in any of the first 8 genes. The LRP5 gene is another candidacy, because its mutations cause autosomal recessive osteoporosis-pseudoglioma syndrome (OPPG) characterized by osteoporosis and a high-bone-mass trait, and *Lrp5*<sup>-/-</sup> mice showed phenotype similar to OPPG. With 21 (7 known and 14 novel) SNPs in LRP5, we genotyped 77 of the samples to analyze linkage disequilibrium (LD) within the gene region. We chose 9 of the 21 SNPs showing minor allele frequency  $> 0.2$ , and identified a strong LD region between two SNPs, LRP5-7 and LRP5-21. Using 15 SNPs within this LD region, we constructed 4 common haplotypes ( $> 5\%$  frequency), accounting for 89 % of all chromosomes. Association study revealed that women with one or two copy (heterozygotes or homozygotes) of Haplotype 3 had significantly lower BMD than those without it ( $p < 0.03$ ). Of 4 LRP5-SNPs that located in this LD block, three gave relatively significant results. Women with C/C genotype at LRP5-9 SNP site had higher BMD value, compared to C/T and T/T women ( $p < 0.022$ ). Likewise, G/G at LRP5-20 and C/C women at LRP5-21 showed higher BMD than those with G/A or A/A ( $p < 0.038$ ) and with C/T or T/T ( $p < 0.051$ ), respectively. Comparison between diplotypes and genotypes showed that these 3 SNPs represent Haplotype 3. LRP5-9 and LRP5-21 are both cSNPs, but result in synonymous change and A1330V, respectively. Since alterations of gene function by them are unlikely, a SNP that affects LRP5 gene function may exist within or nearby the LD region.

**The MMP3 Gene and High Myopia.** *C.C. Liang<sup>1,2</sup>, H. Xu<sup>2</sup>, H.T. Chan<sup>3</sup>, M.L. Sun<sup>4</sup>, K.S. Hung<sup>4</sup>, S. Lee<sup>2</sup>, C.W. Chou<sup>1</sup>, M.J. Wu<sup>3</sup>, W.T. Huei<sup>1</sup>, J.Y. Su<sup>1</sup>, C. Gilliam<sup>2</sup>, E. Yen<sup>1</sup>, S.H. Juo<sup>2</sup>.* 1) Kaohsiung Municipal United Hospital, Kaohsiung, Taiwan; 2) Columbia University, Genome Center, New York, USA; 3) Sun Yat-Sen University, Kaohsiung, Taiwan; 4) Chang-Gung Memorial Hospital, kaohsiung, Taiwan.

Myopia is a leading cause of loss of vision, and its prevalence is increasing. Strong genetic contribution (heritability estimated from 0.6 to 0.9) towards the development of myopia has been suggested in several twin studies. However, genetic studies to map the susceptibility genes for myopia are sparse.

In experimental myopia, eye growth is accompanied by altered proteolytic activities which could serve to remodel the structural components of the scleral extracellular matrix (ECM). The MMP3 gene is involved in tissue remodeling scleral ECM. Recent gene expression studies suggested that mRNA levels and protein activities of MMP3 changed in the induced myopic eyes. The 1612 5A/6A polymorphism of the MMP3 gene has been shown to have different expression activity in cultured cells. This polymorphism has been studied in several complex diseases, but has not been tested in myopia yet.

We investigated the relationship between the 5A/6A polymorphism and myopia in the unrelated young (aged between 17 and 45) Taiwanese population. The study participants included 179 high myopes (5D or higher) and 209 controls (1 D or lower). Genotyping was performed using the fluorescent polarization method. The 5A allele frequency was 12.3% in the cases and 13.6% in the controls. The number of participants among the three genotypes 5A/5A, 5A/6A and 6A/6A was 5, 47 and 179 in the case group, and 1, 55 and 153 in the control group. The genotypic distribution was not deviated from the Hardy-Weinberg Equilibrium in either cases or controls. The chi-square test for three genotypes between cases and controls was not significant with a p value of 0.12. The 5A frequency between cases and controls was not significantly different ( $p=0.37$ ) either. These data indicated that the 5A/6A polymorphism at the MMP3 gene may not play an important role in developing myopia in the Taiwanese population.

**A straightforward approach to evaluate false positive associations in studies of gene interaction.** *C.M. Van Duijn<sup>1</sup>, J.J. Hottenga<sup>1,2</sup>, G. Roks<sup>1</sup>, B. Dermaut<sup>3</sup>, C. Van Broeckhoven<sup>3</sup>.* 1) Epidemiology & Biostatistics, Erasmus MC, Rotterdam, Netherlands; 2) Department of Medical Genetics, Leiden University Medical Center (LUMC), Leiden, The Netherlands; 3) Department of Molecular Genetics, Flanders Interuniversity Institute for Biotechnology Born-Bunge Foundation, University of Antwerp (UIA), Antwerp, Belgium.

Research of gene-gene interactions will be important in unraveling genetic risk factors involved in complex traits. However, gene interaction studies have shown to be susceptible to false positive findings as well as false negative ones. One of the reasons may be over-stratification of a limited number of cases and controls leading to a small number of subjects in the stratum of carriers of both risk alleles. In particular the number of controls who have both risk alleles is often small, even for common polymorphisms. We present a straightforward approach to reveal spurious associations due to over-stratification in controls that can be applied in gene-gene interaction studies. Basically we propose to reformulate the data and analyse cases and controls separately. In controls, the association between two unlinked genes will indicate bias in the findings of the study. From this approach it also follows that one may improve the statistical power of the study and reduce the probability of false positive findings by genotyping controls for the second gene in the limiting stratum specifically, i.e., control carriers of the risk allele of the first gene studied. This approach may be useful in large-scale epidemiological studies in which multiple genes often have been characterized. We will illustrate the approach using an example of a study of interaction of the apolipoprotein E gene and presenilin-1 gene in relation to Alzheimer's disease. In this study a false positive association was detected using this method.

**Evidence for extensive transmission distortion in the human genome.** *S. Zöllner<sup>1</sup>, X. Wen<sup>1</sup>, N.A. Hanchard<sup>2</sup>, M.A. Herbert<sup>2</sup>, C. Ober<sup>1</sup>, J. Pritchard<sup>1</sup>.* 1) Department of Human Genetics, University of Chicago, Chicago, IL. 60637, USA; 2) Department of Paediatrics, University of Oxford, JohnRadcliffe Hospital, Oxford, OX3 9DU, UK.

It is a basic principle of genetics that each chromosome is transmitted from parent to offspring with a probability that is given by Mendel's laws. However, several known biological processes lead to skewed transmission probabilities among surviving offspring and, therefore, to excess genetic sharing among relatives. Examples are in utero selection against deleterious mutations, meiotic drive, and maternal-fetal incompatibility. Although these processes affect our basic understanding of inheritance, little is known about their overall impact in humans or other mammals. In this study we examined genome screen data from 148 nuclear families, collected without reference to phenotype, in order to look for departures from Mendelian transmission proportions. Using singlepoint and multipoint linkage analysis, we detected a modest but highly significant genome-wide shift towards excess genetic sharing among siblings (average sharing of 50.52% for the autosomes;  $p=0.001$ ). Our calculations indicate that many loci with skewed transmission are required to produce a genome-wide shift of this magnitude. We have explored possible mechanisms for the transmission distortion, and find that viability selection in utero is likely to be the most important. Since transmission distortion loci are subject to strong selection, this raises interesting questions about the evolutionary forces that keep them polymorphic. Finally, our results also have implications for mapping disease genes and the genetics of fertility.

**Multivariate diplotype analyses in genetic association studies - association of Insulin Degrading Enzyme (IDE) gene with Late Onset Alzheimer's Disease (LOAD).** *K. Lau*<sup>1</sup>, *C. Rowland*<sup>1</sup>, *A. Grupe*<sup>1</sup>, *A. Goate*<sup>2</sup>, *J.C. Morris*<sup>2</sup>. 1) Celera Diagnostics, Alameda, CA; 2) Washington U., St. Louis, Missouri.

In case-control studies, comparing diplotype (pair of haplotypes in diploids) frequencies can be more powerful than comparing haplotypes, especially when the mode of inheritance (MOI) is recessive. Multivariate analyses using diplotypes, assessing joint effects of multiple loci, environmental factors and interactions, can be performed using multiple logistic regression. The main issues involve the choice of SNPs, diplotype inference and dealing with rare diplotypes. We illustrate the analysis methods using a case-control study with 419 LOAD cases and 375 controls. 3 SNPs within the IDE gene have been genotyped. APOE genotypes, gender, age of onset and years of education are important factors for LOAD. Genotypic association tests for individual markers reveal that SNPs IDE-A and IDE-B are associated in the APOE4+ stratum when a recessive MOI is used. P-values are 0.051 and 0.073 while odds ratios OR are 0.36 (0.12-1.0 95% CI) and 0.42 (0.16-1.08) for IDE-A and B, which are in strong LD ( $R^2=0.74$ ,  $D'=0.98$ ). Haplotype and diplotype analyses were performed on IDE-A & B only as the third SNP is not in LD ( $R^2<0.5$ ). No significant differences in haplotype frequencies were found using the program HAPLO.SCORE (Schaid et. al. AJHG 70:425-434, 2002). A multiple logistic regression model was built with IDE-AB diplotypes, age of onset, gender, years of education, APOE4 status and APOE4xIDE-AB interaction. Diplotypes were inferred using SNP HAP (D.Clayton's website) and weighted with the inference probabilities in analyses using SAS. Recessive MOI was used to construct design variables for IDE-AB. APOE4xIDE-AB interaction term was significant (p-val.=0.006). In stratum specific analyses, IDE diplotypes were not significantly associated in the E4- stratum. For the E4+ stratum, the p-value for the diplotype association, adjusted by other factors, is 0.019, OR=0.28 (0.099-0.81). Exact logistic regression has been performed but results do not change significantly. While diplotype analyses show significant association between IDE SNPs and LOAD, haplotype analyses do not.

**Mitochondrial DNA haplogroups and maternal transmission of type 2 diabetes.** *M.L. Langdown<sup>1</sup>, M.R. Nelson<sup>1</sup>, N.J. Markward<sup>1</sup>, C. Herrnstadt<sup>2</sup>, S. Kammerer<sup>1</sup>, T. Haak<sup>3</sup>, H. Northoff<sup>4</sup>, A. Braun<sup>1</sup>, P. Meyer<sup>5</sup>.* 1) Sequenom Inc., San Diego, CA; 2) San Diego, CA; 3) Research Institute of the Diabetes Academy, Bad Mergentheim, Germany; 4) Department of Transfusion Medicine, University Hospital of Tuebingen, Germany; 5) Institute of Human Genetics, University Hospital of Tuebingen, Germany.

Many studies have implicated that maternal transmission may influence the etiology of type 2 diabetes and that the mitochondrial genome, which is strictly maternally inherited, might play a significant role. In a collection of unrelated patients with type 2 diabetes from Germany, we observed a significant increase in the number of individuals reporting a history of maternal diabetes (40%) compared to paternal diabetes (21%). This excess was not seen in age- and gender-matched controls (10%). Thus, we tested whether the major European mitochondrial DNA (mtDNA) haplogroups are associated with disease and/or maternal history of type 2 diabetes. MtDNA was extracted (498 cases and 498 controls) and genotyped at nucleotide positions which define the nine European mtDNA haplogroups (H, I, J, K, T, U, V, W, X), the two predominant Asian haplogroups (A, B) and the African/Asian superhaplogroup (M). As expected, the most predominant mtDNA haplogroup was H, with a frequency of 40%. The Asian and African mtDNA haplogroups were of low frequency (<1%) and were excluded from further analysis. Haplogroup frequencies were compared among cases and controls, yielding no significant evidence of an association between a specific mtDNA haplogroup and type 2 diabetes. Among type 2 diabetic cases, maternal history of diabetes was significantly reduced from 40% to 20% in the IXW cluster ( $P < 0.01$ ). We found no significant difference in paternal history of diabetes. This study leads us to conclude that the maternal inheritance of type 2 diabetes may not be solely dependent upon the transmission of mtDNA. Rather, other genetic phenomena such as interaction of mitochondrial and nuclear DNA polymorphisms, maternal imprinting or intrauterine environment may predispose an individual to type 2 diabetes and contribute to the onset and severity of the disease.

**Screening of the neurofilament M Gene Gly336Ser mutation in a French-Canadian population with Parkinson's disease.** *F. Han*<sup>1</sup>, *D.E. Bulman*<sup>1,3</sup>, *M. Panisset*<sup>2</sup>, *D.A. Grimes*<sup>1,3</sup>. 1) Molecular Medicine, Ottawa Health Research Institute, Ottawa, Ontario, Canada; 2) McGill Centre for Studies in Aging, McGill University, Montreal, QC, Canada; 3) Department of Neurology, University of Ottawa, Ottawa, ON, Canada.

Neurofilament M is one of the three neurofilament subunits—the light, medium, and heavy neurofilaments (NF-L, NF-M and NF-H) which are the most abundant intermediate filaments (IFs) in neurons. Abnormalities in these proteins have been associated with neurological diseases in humans and animal models. Recently, a single base pair substitution (G1747A) mutation of the NF-M gene was reported in a French-Canadian patient with early onset Parkinson's disease (PD). This mutation resulted in the amino acid substitution Gly336Ser. Three unaffected siblings were found to be heterozygotes for the NF-M Gly336Ser mutation but to date no other affected PD individuals have been found with a similar mutation. The Gly336Ser mutation creates a new restriction site for FspI. In order to explore whether this mutation could have arisen from a founder mutation within the French-Canadian PD population, we screened 102 French-Canadian patients with definite PD and 45 French-Canadian controls by PCR and restriction enzyme digestion. Oligonucleotide primers covering the NF-M G1747A mutation were designed according to the reported primer sequences. PCR products were digested with the restriction enzyme FspI and then electrophoresed on agarose gel. None of the patients nor controls had this mutation, indicating that this mutation is not common even in a PD population of similar ethnic background and suggests this change could represent a rare polymorphism. However, these results do not exclude the possibility that other mutations in this gene could be present.

**Association of *CCR5* and *CCL5* polymorphisms with Coal Workers' Pneumoconiosis.** R. NADIF<sup>1</sup>, A. JEDLICKA<sup>2</sup>, M. MINTZ<sup>2</sup>, F. KAUFFMANN<sup>1</sup>, S. KLEEBERGER<sup>3</sup>. 1) INSERM U472, VILLEJUIF, FRANCE; 2) Johns Hopkins University, MD, USA; 3) NIEHS, Research Triangle Park, NC, USA.

The role of C-C chemokines and their receptors in the pathogenesis of human lung inflammatory diseases is not clearly understood. The effect of functional polymorphisms in *CCR5* and its ligand *CCL5*, and their interactions with environmental exposure, were investigated in Coal Workers' Pneumoconiosis (CWP), a chronic inflammatory respiratory disease. In a longitudinal epidemiological study, 212 coal miners (aged 34-50 years in 1990) from the Lorraine Bassin (France) were genotyped for polymorphisms in *CCR5* (32 bp deletion) and *CCL5* (C-28G). Chest *x* rays scored according to International Labor Office classification of CWP, and subclinical computed tomography (CT) scores were performed in 1990 and 1994. Cumulative and current exposure to coal mine dust and smoking were recorded. *CCR5* 32 polymorphism was significantly associated with CT score in 1990 (1.27 1.83 vs. 2.12 2.27 p=0.01) and in 1994 (1.79 2.37 vs. 2.98 3.52 p=0.01), miners with wt/32 or 32/32 genotype having the highest score. No significant interaction with occupational exposure was found. *CCL5* -28 polymorphism was unrelated to CT score. Associations of *CCR5* 32 polymorphism with CT score in 1990 and in 1994 remained significant after adjustment for occupational exposure. The difference in adjusted CT scores according to *CCR5* genotype was 2.2 greater in miners with *CCL5* CG or GG genotype than in those with CC genotype of the ligand, but a formal test for interaction was not statistically significant. Significant interactions of *CCR5* 32 polymorphism with current smoking on CT score in 1990 and in 1994 were observed (p=0.03 and p=0.04), with CT scores significantly higher in smoker or ex-smoker miners with *CCR5* wt/32 or 32/32 genotype, whereas no association was found in non smokers. Results suggest the role of *CCR5* 32 polymorphism in the etiology of CWP with a potential interaction with smoking. Studies considering simultaneously *CCR5* with its ligand *CCL5* are of interest in inflammatory diseases.

**A pharmacogenetic study of response to a 5-lipoxygenase inhibitor in a Phase II clinical trial.** *S. Lewitzky<sup>1</sup>, G. Barnes<sup>2</sup>, P. Garg<sup>3</sup>, J. Metivier<sup>1</sup>, M. Chang<sup>3</sup>, B. Rosengren<sup>3</sup>, J. Meyer<sup>1</sup>.* 1) Dept of Molecular Epidemiology, Millennium Pharmaceuticals Inc., Cambridge, MA; 2) Dept of Molecular and Cellular Pharmacology, Millennium Pharmaceuticals Inc., Cambridge, MA; 3) Dept of Clinical Development, Millennium Pharmaceuticals Inc., Cambridge, MA.

LDP-977 is a candidate asthma drug that inhibits leukotriene production by antagonizing the enzyme 5-lipoxygenase. We hypothesized that clinical response to LDP-977 is associated with genetic polymorphisms. In a sample of 137 patients in a Phase II clinical trial, 136 polymorphisms in 39 candidate genes were genotyped and tested for association with response to LDP-977 in 99 Caucasian patients. Response was defined as achieving a 20% increase in forced expiratory volume in one second (FEV) from baseline to 2 hours after dosing; nonresponse was defined as failing to achieve a 15% increase. The 39 candidate genes include 14 genes in the leukotriene pathway (including 5-lipoxygenase), 7 drug metabolizing enzymes, and 18 genes in other known inflammation pathways. The 136 polymorphisms include 131 SNPs, 4 insertion/deletions, and 1 microsatellite. Each polymorphism was tested for evidence of pharmacogenetic association by standard single-point association tests, both allele-based and genotype-based. Each gene was also tested for evidence of pharmacogenetic association by a novel haplotype association test for unphased genotype data based on the principle that haplotype similarity should be greater within a response group than between response groups. Several tests yielded nominally significant p-values ( $p < .05$ ). A summary of the statistical results is presented.

**Asthma pharmacogenetics: Association of sequence variants in CRHR1 and improved lung function in asthmatics treated with inhaled corticosteroids.** *K.G. Tantisira<sup>1</sup>, S.L. Lake<sup>1</sup>, E.S. Silverman<sup>1</sup>, R. Lazarus<sup>1</sup>, E.K. Silverman<sup>1</sup>, S.B. Liggett<sup>2</sup>, S. Gabriel<sup>3</sup>, E. Lander<sup>3</sup>, J.M. Drazen<sup>1</sup>, S.T. Weiss<sup>1</sup>.* 1) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Pulmonary Division, University of Cincinnati, Cincinnati, OH; 3) Whitehead Institute, Massachusetts Institute of Technology, Cambridge, MA.

The response to treatment of asthma shows high inter-individual variability. We hypothesized that a significant proportion of the variation in response to inhaled corticosteroids, the most commonly used asthma controller therapy, could be genetic. We genotyped 131 single nucleotide polymorphisms (SNPs) from 14 genes related to the biological action of inhaled steroids to evaluate the pharmacogenetic effect of treatment in an eight week clinical trial of 470 adults with moderate-to-severe asthma. Single SNP analyses revealed three genes with an association with the eight week change in lung function, as measured by the forced expiratory volume in one second (FEV1). We subsequently genotyped these three genes in DNA from 308 childhood asthmatics treated with inhaled corticosteroids. One gene, corticotropin releasing hormone receptor 1 (CRHR1, NM\_000756), demonstrated multiple single SNP associations within each of the populations. Three CRHR1 SNPs captured most of the haplotypic variation in both populations. One haplotype derived from these three SNPs was associated with over twice the lung function response in both populations ( $p = 0.02$  and  $0.04$  for the adults and children, respectively) compared to absence of this haplotype. Finally, we genotyped those three CRHR1 SNPs in a third clinical trial sample of 339 adult asthmatics and found a strong positive association with response to inhaled corticosteroids. Replication of the initial association between CRHR1 variation and response to inhaled corticosteroids in two additional independent samples of asthmatics may provide opportunities for improved asthma therapy planning.

**Nicotinic acetylcholine receptor gene polymorphisms, adolescent smoking, and attention deficit hyperactivity disorder (ADHD) subtypes.** *R.J. Neuman, E.A. Lobos, C.A. Joyner, H.-C. Ji, L. Sun, W. Reich, R.D. Todd.* Washington Univ Med Ctr, St Louis, MO.

Recent population based studies of ADHD have demonstrated the existence of heritable latent class subtypes of ADHD (Todd et al., 2001; Rasmussen et al., in press). In addition, associations between cigarette smoking and inattentive ADHD symptoms have frequently been reported in clinic-based studies. Using systematic mutation screening approaches, we found a significant association of an exon2/intron 2 junction polymorphism of the neural nicotinic acetylcholine receptor alpha-4 subunit gene, CHRNA4 with the latent class defined inattentive ADHD subtype (Todd et al, 2003).

We used logistic regression to test for an association between regular smoking with DSM and latent class ADHD subtypes while controlling for age, sex, ethnicity, zygosity, and comorbid traits (e.g., conduct disorder, alcohol abuse and marijuana use, major depression) in 800 male, female and opposite sex twin pairs recruited via Missouri birth-records. After correcting for comorbid conditions and other variables, there was a strong association of the latent class defined inattentive ADHD ( $p=0.002$ ) with regular smoking. Correcting for covariates the odds ratio for regular smoking in latent class inattentive ADHD was 4.7 (95% CI 1.8-12.4). However, no significant association of regular smoking was found with the DSM-IV defined primarily inattentive ( $p=0.10$ ) or combined subtypes ( $p=0.38$ ) ADHD. There was a weak association with the latent class defined combined subtype ADHD ( $p=0.04$ ). The average age of onset of smoking was not significantly different for this subtype of ADHD contrasted with non-ADHD controls (12.3 years for each). Although our current ADHD subtype sample size is not large enough to definitively implicate abnormalities in nicotinic genes for increased tobacco use in the latent class inattentive ADHD subtype, the current findings are compatible with the strong association between latent class inattentive ADHD subtype and smoking being related to polymorphisms in nicotinic acetylcholine receptor genes.

**Domains of speech-sound disorder and dyslexia are pleiotropically influenced by chromosome 3 region.** *C.M. Stein<sup>1</sup>, J.H. Schick<sup>1</sup>, H.G. Taylor<sup>2</sup>, L.D. Shriberg<sup>3</sup>, A. Kundtz-Kluge<sup>1</sup>, C. Millard<sup>1</sup>, K. Reading<sup>1</sup>, N. Minich<sup>2</sup>, A. Hansen<sup>2</sup>, L.A. Freebairn<sup>2</sup>, R.C. Elston<sup>1</sup>, B.A. Lewis<sup>2</sup>, S.K. Iyengar<sup>1</sup>.* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Pediatrics, Rainbow Babies & Childrens Hospital, Case Western Reserve Univ, Cleveland, OH; 3) Waisman Center on Mental Retardation and Human Development, Univ. of Wisconsin-Madison, Madison, WI.

Speech-sound disorders (SSD) are characterized by deficiencies in articulation, phonologic coding and memory, and language. It has recently been proposed that these early problems in spoken language predict development of dyslexia in later years. The correlation between speech-sound and dyslexia phenotypes suggests that these disorders may share some common genetic etiology. A previous study identified a candidate region on chromosome 3 that was linked to developmental dyslexia in a large Finnish family. We hypothesized that this region may be linked to domains shared by SSD and dyslexia. We utilized quantitative test scores that measure several processes underlying speech-sound production, including articulation, phonologic coding, and phonologic memory, to examine linkage to markers in the pericentrometric region of chromosome 3 in 77 families ascertained through a child with SSD. We also assessed linkage to traits measuring language and reading skills. Model-free linkage analysis was followed by identification of sibpairs that contributed most to the linkage effect, and construction of core shared haplotypes in these sibpairs. Our multipoint linkage analyses of measures associated with phonologic coding/decoding demonstrate the strongest linkage (D3S2465,  $P=5.6 \times 10^{-5}$ ; D3S3716,  $P=6.8 \times 10^{-4}$ ). The corresponding dyslexia phenotypes also demonstrated linkage (single word reading, D3S2465,  $P=.004$ ; nonsense word reading, D3S1595,  $P=.005$ ). The minimum shared haplotype in sibpairs with similar trait values spans 4.9 cM and is bounded by markers D3S3049 and D3S3045. Our results suggest that phonologic skills, which predispose to dyslexia, are influenced by a quantitative trait locus on chromosome 3, implying a pleiotropic effect on both disorders.

**Disentangling the autism phenotype; a sib-pair analysis.** *P. Szatmari*<sup>1</sup>, *C. Merette*<sup>2</sup>, *C. Emond*<sup>2</sup>, *L. Zwaigenbaum*<sup>3</sup>, *M. Maziade*<sup>2</sup>, *MA. Roy*<sup>2</sup>, *R. Palmour*<sup>4</sup>. 1) Dept Psychiatry, McMaster Univ, Hamilton, ON, Canada; 2) Dept of Psychiatry, Laval Univ, Quebec City, PQ, Canada; 3) Dept of Pediatrics, McMaster Univ, Hamilton, ON, Canada; 4) Dept of Psychiatry, McGill Univ, Montreal, PQ, Canada.

There are several dimensions that show familial aggregation among sib pairs with autism spectrum disorders. These include non-verbal IQ and communication skills. Since, these skills are highly correlated, it is not clear whether variation in IQ and communication arise from a common genetic background or from independent genetic mechanisms. We assembled 80 sib pairs with an autism spectrum disorder such as autism, Asperger syndrome and atypical autism based on standard diagnostic instruments and best-estimate. Within affected individuals there was a strong correlation ( $r=0.70$ ) between non-verbal IQ (as measured by the Leiter performance scale) and communication (as measured by the Vineland Communication Scale). In addition, there was strong familial correlation between sibs from the same family on both measures; intraclass correlations of 0.37 and 0.34, respectively. To see whether, the familial correlation on one measure was accounted for by the familial correlation on the other, we used multiple regression models. First, we calculated residual communication scores for each member of the sib pair based on their IQ score controlling for the age and gender of the affected individual. The process was repeated using IQ as the dependent variable and communication scores, along with the covariates, as the independent variables. These residual scores were then used to calculate intraclass correlations (ICC) between affected sibs. Strong familial correlations were still seen on the residual scores indicating that non-verbal IQ (ICC=0.39) and communication (ICC=0.36) may arise from independent genetic mechanisms in autism spectrum sib pairs. These data suggest that non-verbal IQ and communication should be tested as separate quantitative phenotypes in linkage analysis of autism sib-pairs, a strategy may improve power to find autism susceptibility genes.

**Autoimmunity related genes and their evolutionary fate as reflected in three inbred ethnic groups.** *I. Grossman*<sup>1</sup>, *C. Singer*<sup>2</sup>, *N. Avidan*<sup>2</sup>, *M. Chemla*<sup>2</sup>, *A. Miller*<sup>1</sup>, *D. Lancet*<sup>2</sup>, *J.S. Beckmann*<sup>2</sup>. 1) Division of Neuroimmunology and Multiple Sclerosis Center, Technion Israel Institute of Technology, Haifa; 2) Department of Molecular Genetics, Crown Human Genome Center, Weizmann Institute of Science, Rehovot, Israel.

To elucidate conservational forces shaping autoimmunity related genes, we examined the frequency of Single Nucleotide Polymorphisms (SNPs) in such genes in three healthy inbred Israeli ethnic groups. We considered genes reflecting, amongst others, immunological pathways common to autoimmune conditions, including cytokines, chemokines, apoptotic agents, proteases, etc. A total of 73 SNPs representing a diverse range of minor allele frequencies in each gene were selected from public databases, and typed using the Sequenom MassArray in Ashkenazi Jews, Sephardic Jews and Israeli-Palestinians. Allele frequencies of both SNPs and inferred haplotypes were compared by various statistical methods. The allele frequency of only one SNP was statistically significant in discerning the three groups from one another. However, comparison of inferred haplotypes showed significant distinction in 14 out of the 22 genes tested. These results suggest that a small set of SNPs with varied minor allele frequencies in each gene captures the greater part of the haplotypic diversity, even across recently diverged populations. The described strategy in SNPs selection may also be advantageous in association studies to seize differences between cases and controls. Though all the selected genes might be crucially involved in etiology of a vast variety of inflammatory and neuroimmunological diseases, allele frequencies in the above ethnic groups are generally unknown. The present study allows us to look for possible epistatic effects in autoimmunity related genes, according to population evolution. The pattern emerging from the results suggests that genes in processes more environmentally influenced, such as lipid metabolism and antiviral immunity, exhibit different haplotypic patterns in each ethnic group. In contrast, genes involved in more general pathways, such as proteases and apoptotic agents, show substantial similarity across all groups.

**Investigation of genotype frequencies of candidate genes for coronary atherosclerosis in dependence of the sexual hormone status in healthy female blood donors.** C. Glaeser<sup>1</sup>, S. Schulz<sup>1</sup>, U. Mueller-Werdan<sup>2</sup>, K. Werdan<sup>2</sup>, I. Hansmann<sup>1</sup>. 1) Inst Human Genetics, Univ Halle, Halle, Germany; 2) Dep Internal Med, Univ Halle, Halle, Germany.

Atherosclerosis is a very complex disease influenced by a variety of factors. Among this the sexual hormone status is established to be an important modulator of CAD. Further established genetic risk markers are involved in processes leading to the development of CAD like e.g. PM in the ACE-, ApoE-, CD-14- and E-selectin-gene as well as the Leiden-PM in the factor V-gene. We investigated the genotype distribution of these PM in a group of 174 healthy female blood donors without any coronary risk factors (> 3y in medical monitoring; mean: 39.7y). The group was divided into 1 group of 118 young women (<45y) whose hormone level is not already altered corresponding to their age and in a second group of 56 elderly women (>45y) who are adjusted hormonally in terms of age. For evaluation of the genotype distributions the DD- (ACE), the 3/4- (ApoE), the TT- (CD-14), the Arg/Arg+Arg/Ser- (E-selectin) as well as the AA+AG-genotype (factor V) were considered pathological in terms of coronary atherosclerosis in common consent. Investigating the genotype frequencies in dependence of the hormone status we could not detect any significant differences in the score of so called pathological genotypes between the hormone protected young and the elderly group (ACE: p=0.49; Apo-E: p=0.61; CD-14: p=0.54; E-selectin: p=0.68; factor V: p=0.38). Since it is well established that there is a first order cardioprotective effect of female sexual hormones like e.g. oestrogen it is conceivable that the number of pathological risk markers in healthy female persons who are no longer protected by their hormones should be obviously decreased because of the supposing higher cardiovascular susceptibility of persons carrying these genotypes. Our results suggest that the investigated genetic markers are not predictors for the incidence of coronary atherosclerosis in general. These findings do not rule out that these PM could be markers for the progress and therefore for a practicable clinical therapy of the complex CAD.

**Resequencing analysis of the Mannose-binding lectin gene (MBL2) demonstrates substantial genetic diversity with functional implications.** *T. Bernig*<sup>1</sup>, *B. Staats*<sup>2</sup>, *M. Yeager*<sup>2</sup>, *J.G. Taylor*<sup>1</sup>, *C.B. Foster*<sup>3</sup>, *S. Chanock*<sup>1</sup>. 1) Pediatric Oncology Branch, National Cancer Institute-ATC, Gaithersburg, MD; 2) Core Genotyping Facility, National Cancer Institute-ATC, Gaithersburg, MD; 3) Johns Hopkins University, Department of Pediatrics, Division of Infectious Diseases, Baltimore, MD.

The human mannose-binding protein (MBL) is an important component of the innate immune system that protects organism against pathogens in the first line of host defence preceding the beginning of the adaptive immune response by T and B-lymphocytes. There are seven described secretor haplotypes of the MBL2 gene based on 3 strongly linked promoter SNPs and a set of non-synonymous SNPs (known as B, C and D) in exon 1, which influence both serum levels and functional activity. Overall, select haplotypes, which correlate adequately with levels have been associated with increased susceptibility to a spectrum of infections and complications of immunodeficiency states; interestingly, these variants are also protective against other infections (i.e. tuberculosis). Complete resequencing analysis of MBL2 revealed that it is highly polymorphic with 87 variants across the gene (about 10.0 kb) in 4 separate populations: African American, Caucasian, Hispanic and Pacific Rim. Analysis of linkage disequilibrium appears to be complete across the entire gene but shows distinct differences between Caucasians and African Americans, with greater complexity in both structure and distribution of haplotypes in the latter. Moreover, there is evidence for gene conversion in the 3 region of the gene that disrupts LD in the latter. This suggests a functional implication for the 3 region and could have substantial implications for investigation of the importance of genetic variation within MBL2 in disease. These findings imply that future association studies with MBL2 require a locus wide approach with a much denser map of polymorphic sites and that the exclusive use of the classical secretor haplotypes is insufficient to detect the diversity in MBL2. Lastly, we have determined that the B, C and D structural alleles (which are central to the 7 secretor haplotypes) lie on restricted haplotypes, suggesting that they have arisen recently.

**IL10 polymorphisms and risk of cardiovascular disease in the CHOICE cohort.** *Y. Berthier-Schaad*<sup>1, 2</sup>, *L. Plantinga*<sup>1</sup>, *Y. Liu*<sup>1</sup>, *N. Fink*<sup>1</sup>, *M.J. Klag*<sup>1</sup>, *J. Coresh*<sup>1</sup>, *M.W. Smith*<sup>3</sup>. 1) Johns Hopkins Medical Institutions, Baltimore, MD; 2) Laboratory of Genomic Diversity, NCI, Frederick, MD; 3) Basic Research Program, SAIC, NCI, Frederick, MD.

Accumulating evidence suggests that inflammation plays an important role in the development of cardiovascular disease (CVD). IL10 is an anti-inflammatory cytokine and polymorphisms in the IL10 promoter region have been associated with lower IL10 and inflammatory markers levels and decreased risk of CVD in some but not all studies. We tested the relationship between IL10 genotypes, inflammatory markers levels and CVD incidence in a cohort of 1041 dialysis patients where subclinical inflammation is common and strongly predictive of CVD. Using a 5'exonuclease assay, genotypes were obtained for six loci: -3575 T/A, -1082 A/G, and -592 C/A in the promoter region, 4467 G/A in intron 4, 5016 T/C and 5351 A/G in the 3' UTR region. Haplotypes were estimated using resequencing data and PHASE analysis of the genotypes. Adjusted differences of inflammatory markers and relative hazards of CVD and mortality associated with IL10 variants were calculated overall as well as stratified by race and smoking history. There was no association between any polymorphism and relative hazard of CVD over the entire population. However, in race-stratified analyses, alleles -1082G and 5016C were associated with higher levels of IL6 and CRP in patients of European descent (ED) ( $P < 0.05$ ), while alleles -3575A and 4467A were associated with lower levels of IL6, CRP and fibrinogen in patients of African descent (AD) ( $P < 0.05$ ). One haplotype was associated with lower relative hazard of CVD [RH 0.31 (0.12-0.83)] in AD patients. In analyses stratified by smoking history, there was no association between any haplotype and relative hazard of CVD. We find no strong and constant association between the six IL 10 variants and the levels of inflammatory markers and CVD incidence. The slightly protective effect of one haplotype in AD patients is consistent with previous literature. Funded in part by RO1 L62985, AHA EI01-40197ND & DHHS#N01-CO-12400.

**T102C 5-Hydroxytryptamine (5-HT<sub>2A</sub>) receptor polymorphism in late-onset cardiovascular diseases and its risk factors.** *I.B.M. DaCruz<sup>1</sup>, C.H.A. Schwanke<sup>2</sup>, M. Taufer<sup>1</sup>, G. Oliveira<sup>1</sup>, L. Bittencourt<sup>2</sup>, G.A.L. Flores<sup>1</sup>, A.A.M. Cruz<sup>1</sup>, J. Siviero<sup>1</sup>, I.E.C. Jung<sup>1</sup>, E.H. Moriguchi<sup>1</sup>, GENESIS RESEARCH PROGRAM.* 1) IGG, PUCRS, Porto Alegre, RS, Brazil; 2) Faculdade de Biociencias, PUCRS, Porto Alegre, RS, Brazil.

Serotonin (5-HT) is involved in cardiovascular pathophysiology. In addition to platelet aggregation and vascular contraction, 5-HT induces hyperplasia of artery smooth muscle cells. Previous studies suggested that the T102C (5-HT<sub>2A</sub>) polymorphism is related to cardiovascular and psychiatric disorders. However, the data are still controversial. This case-control study was designed to analyse possible associations between DNA polymorphisms in the serotonin (5-HT<sub>2A</sub>) receptor with late-onset (>60 years) cardiovascular diseases and risk factors. 725 living community subjects were recruited from Genesis Research Program that investigate gene-environment interaction on aging and related diseases in the Brazilian population. The T102C polymorphism was detected by PCR-RFLP using HpaII restriction enzyme. The average age was 68.056.35 years. The genotype frequency was TT= 22.9 (167), CC=21.8 (158) and CT=55.2 (400). The allelic frequency was T=0.506 and C=0.494. The frequencies were in Hardy-Weinberg equilibrium. No cardiovascular disease association (myocardial infarction, angina pectoris and stroke) with the T allele was found. However we found CC independent risk association with DM [OR=2.16 (1.10-4.28)]; obesity [OR=1.69 (1.00-3.11)] and smoking habit [OR=1.63 (1.10-2.51)]. The associations could be better explained by the neurological role other than by the vascular role of the 5-HT<sub>2A</sub>. Additionally, it is important to consider that serotonin metabolism studies have been reporting association with several clinical conditions as early-onset no-fatal myocardial infarction, hypertension, eat disorders and compulsive behaviour. Also, the serotonin re-uptake drugs are extensively used in clinical setting. Therefore, complementary studies could help to elucidate the complex associations reported in the literature and here.

**Risk of female breast cancer and the *BRCA2* N372H polymorphism: a population-based case family study.** *M.A. Jenkins<sup>1</sup>, R.L. Milne<sup>1</sup>, M.C. Southey<sup>1</sup>, A.B. Spurdle<sup>2</sup>, G. Chenevix-Trench<sup>2</sup>, J.L. Hopper<sup>1</sup>, Australian Breast Cancer Family Study.* 1) University of Melbourne, Australia; 2) Queensland Institute of Medical Research, Brisbane, Australia.

Two large case-control studies have shown that the *BRCA2* 372 *HH* genotype was associated with a 30% to 50% increased risk of female breast cancer. We have used a population-based case family study, the Australian Breast Cancer Family Study, to estimate the age-specific risks of breast cancer in carriers of this genotype. Genotyping was conducted on 1353 women diagnosed with breast cancer before age 60 years (half under 40 years) who were incident cases sampled from cancer registries, and 1827 of their adult first- and second-degree relatives. Families with an identified carrier of a *BRCA1* or *BRCA2* mutation were excluded. Personal and family history of breast cancer was obtained from all participants and attempts were made to validate all cancer reports. The hazard ratio (ratio of age-specific incidence of breast cancer in women with the *HH* genotype (carriers) to that in women without the genotype (non-carriers)) and the age-specific cumulative risk (penetrance) were estimated by a modified segregation analysis. Familial aggregation was modelled by adjusting for the breast cancer status of each individual's mother. Models were fitted under maximum likelihood theory using the statistical package MENDEL. The allele frequency was fixed at 0.27 based on 775 controls. Under a recessive model (superior fit to dominant model), women with the *HH* genotype were 1.3 (95% CI 1.1 - 1.6) times more likely to be diagnosed with breast cancer, independently of a 2.5 (1.8 - 3.4) fold risk for having an affected mother. The cumulative risks of breast cancer to age 70 were: 5.7% (non-carriers with unaffected mother); 7.3% (carriers with unaffected mother); 13.3% (non-carriers with affected mother); and 16.9% (carriers with affected mother). These results, using family data that are not subject to population stratification, confirm that the allele is associated with a small, recessively inherited increased risk of breast cancer, or is in linkage disequilibrium with a disease predisposing variant.

**Association of angiotensin I-converting enzyme polymorphisms with obesity in Nigerians, Jamaicans, and African Americans.** *Y. Jiang<sup>1</sup>, H. Kramer<sup>1</sup>, X. Zhu<sup>1</sup>, A. Luke<sup>1</sup>, N. Bouzekri<sup>2</sup>, C. Mckenzie<sup>3</sup>, T. Forrester<sup>3</sup>, A. Adeyemo<sup>4</sup>, M. Farrall<sup>5</sup>, S. Anderson<sup>2</sup>, R. Cooper<sup>1</sup>, R. Ward<sup>2</sup>.* 1) Department of Preventive Medicine and Epidemiology, Stritch School of Medicine, Loyola University, Maywood, IL, USA; 2) Department of Biological Anthropology, University of Oxford, Oxford, UK; 3) Tropical Metabolism Research Institute, University of the West Indies, Mona, Jamaica; 4) Department of Pediatrics/Institute for Child Health, College of Medicine, University of Ibadan, Nigeria; 5) Department of Cardiovascular Medicine, University of Oxford, The Wellcome Trust Center for Human Genetics, Oxford, UK.

We report an association analysis of obesity with the angiotensin I-converting enzyme (ACE) polymorphisms in Nigerians, Jamaicans, and African Americans. Thirteen single nucleotide polymorphisms (SNPs) expanding 25 kb of the ACE gene were genotyped in each of the three population samples. Fifteen major haplotypes were grouped into 4 clads, I, II, III, and IV, from the most frequent to the least frequent, by Templeton algorithm (Templeton et al. 1987, 1988). Haplotype analysis of multiple SNPs was conducted by TRANSMIT (Clayton 1999) which contrasts the observed number versus the expected number of a haplotype (under H<sub>0</sub>) transmitted from parents to his or her obese children. Different sets of multiple SNPs were found in each of the three population samples. Each population sample has two significant haplotypes ( $p < 0.06$ ), one was over transmitted and the other was under transmitted. The over transmitted haplotype belongs to clad I and/or IV. The under transmitted haplotype belongs to clad II and/or clad III except the one in the African Americans with very low frequency. The common SNP in the three sets is ACE8 which has the strongest association with ACE levels among the 13 SNPs genotyped in all three samples. In conclusion, we found some evidence of association of the ACE polymorphisms with obesity in three black population samples through a cladistic analysis using multiple ACE polymorphisms.

**Genetic variation in TNF (G-308A) is associated with measures of body composition in older women.** *S.P. Moffett<sup>1</sup>, J.M. Zmuda<sup>1</sup>, J.A. Cauley<sup>1</sup>, K.L. Stone<sup>2</sup>, M.C. Nevitt<sup>2</sup>, K.E. Ensrud<sup>3</sup>, M.C. Hochberg<sup>4</sup>, T.A. Hillier<sup>5</sup>, G. Joslyn<sup>6</sup>, P. Morin<sup>6</sup>, S.R. Cummings<sup>2</sup>, for the SOF Research Group.* 1) Univ Pittsburgh, Pittsburgh, PA; 2) Univ California, San Francisco, CA; 3) Veterans Affairs Medical Center, Minneapolis, MN; 4) Univ Maryland, Baltimore, MD; 5) Kaiser Permanente, Portland, OR; 6) Axys Pharmaceuticals, CA.

Tumor necrosis factor (TNF) is a proinflammatory cytokine that regulates adipose, muscle and bone metabolism and thus has been targeted as a potential candidate gene for alterations in body composition. The G-308A polymorphism in the TNF promoter has been associated with alterations in mRNA and plasma levels where the A allele corresponds to increased TNF. In the present study, we evaluated the relationship between the TNF G-308A polymorphism and measures of body composition in 3376 women aged 65 years and older participating in the Study of Osteoporotic Fractures. The frequency of the -308A allele was 0.167. Using analysis of covariance, we found that women with the AA genotype were significantly taller and heavier than the GG homozygotes (mean height in cm (standard error): GG=158.5 (0.1), GA=159.1 (0.2), AA=159.7 (0.6),  $p=0.003$ ; weight in kg: GG=66.4 (0.3), GA=67.5 (0.4), AA=68.2 (1.3),  $p=0.034$ ). These relationships remained significant after adjusting for study center, age, current estrogen use, health status, exercise, steroid use and smoking. Fat mass (FM) and fat free mass (FFM), measured using bioelectrical impedance, were also higher in the AA homozygotes; however, FM did not reach statistical significance when the three genotypes were considered separately (FM in kg: GG=26.6 (0.2), GA=27.4 (0.3), AA=27.6 (0.9),  $p=0.061$ ; FFM in kg: GG=39.8 (0.1), GA=40.2 (0.1), AA=40.5 (0.5),  $p=0.032$ ). In addition, AA homozygotes had higher spine and hip BMD (measured with dual energy x-ray absorptiometry) compared to the GG women (spine in  $g/cm^2$ : GG=0.852 (0.004), GA=0.876 (0.006), AA=0.874 (0.018),  $p=0.002$ ; hip in  $gm/cm^2$ : GG=0.756 (0.003), GA=0.760 (0.004), AA=0.766 (0.014),  $p=0.586$ ), but findings reached significance at the spine only. Our results support a link between allelic variation at the TNF locus and body composition regulation.

**Nucleotide diversity in the *DC-SIGN* gene.** *J.J. Martinson*<sup>1</sup>, *C. Eddy*<sup>2</sup>, *J. Chambers*<sup>1</sup>, *C. Bannerjee*<sup>1</sup>. 1) Inf. Diseases & Microbiology, University of Pittsburgh, Pittsburgh, PA; 2) Institute of Genetics, University of Nottingham, Nottingham UK.

Dendritic Cells (DCs) are highly specialized antigen-processing cells that can activate both naive and memory T-lymphocytes, and play a pivotal role in the initial presentation of many of pathogens, including HIV, ebola virus and mycobacteria. Both processes require the involvement of the DC-specific ICAM-grabbing nonintegrin protein DC-SIGN. This protein has recently been shown to be of critical importance in the early stages of cellular infection with HIV, as virus particles bound to DC via DC-SIGN are maintained in a viable state for long periods of time, and can infect target cells in trans.

Much is now known about the genomic organization of the *DC-SIGN* gene, its closely-related homolog *DC-SIGNR*, and other similar genes in primates. The gene is known to be alternately spliced, producing proteins with differences in lineage tropism, and possibly in cellular localization. Despite this, little is known sequence variation within the gene and the effect such nucleotide diversity may have on the ability of the DC-SIGN protein to bind pathogens and interact with T-lymphocytes. We present data here on an initial survey of sequence variation in the *DC-SIGN* gene in a random sample of Caucasian and Asian individuals.

The *DC-SIGN* gene consists of 1202bp in seven exons located in a 4.4kb region. We obtained full sequence data on each exon, and a 1840bp of intron sequence, from a total of 90 individuals. We found a total of 17 SNPs, evenly distributed between coding and noncoding regions. Four coding SNPs were found, in exons 4, 6 and 7, and all of these altered the amino acid sequence of DC-SIGN. Minor allele frequencies ranged from singleton observations to 14%, with the commonest SNPs located in the introns. The estimated nucleotide diversity was higher than observed for many genes, being  $10^{-3}$  for the exons and  $1.45 \times 10^{-3}$  in the introns. Thus there is a great deal of nucleotide diversity within *DC-SIGN*, including many coding variants whose biological significance remains to be elucidated.

**Allele frequencies of the short and long tetra-nucleotide repeat [TTTA] n in the CYP-19 gene in African-American and Caucasian women.** *C. Lara-Castro, U. Desai, S.M. Sell.* Nutrition Sciences, Univ Alabama, Birmingham, AL.

A tetranucleotide repeat polymorphism in the fourth intron of the CYP19 gene is associated with different conditions in women. The short allele is associated with increased risk of osteoporosis and breast cancer. The longer allele (187 bp) is associated with decrease risk of obesity in women. Because the burden of these diseases is different among women of different ethnic groups, it is important to determine allele frequencies of polymorphisms in relevant candidate genes, such as the CYP19 gene, across women of different ethnic backgrounds. To determine differences in allele frequencies of the short (167bp) and long allele (187bp) of the CYP19 polymorphism in women of Caucasian and African-American backgrounds, DNA from a bi-ethnic sample (n=242) was genotyped. We are reporting preliminary data on 36 normal controls (12 Caucasian and 24 African-American). MapPair primers, specific for the CYP19 tetra nucleotide repeat were obtained and PCR amplification was conducted following their specifications. The larger allele (187bp) was more common than the shorter allele (167bp) in this group of women, 31% vs. 16%. Table 1 shows allele frequencies by ethnic group. These results suggest that frequencies of the short and long alleles in the aromatase gene varied between ethnic groups. Further research is necessary to determine the role of these differences as they relate to disease phenotypes in women. Table 1

Allele size (bp)	167 n (%)	187 n (%)
African-American (N=24)	10 (21)	9 (19)
Caucasian (N=12)	2 (8)	13 (54)
Total (N=36)	12 (17)	22 (31)

N=number of subjects, n=number of alleles.

**Human chromogranin A (CHGA): discovery of both frequent and rare functional polymorphisms at a locus governing catecholamine storage and release.** *G. Wen*<sup>1</sup>, *S.K. Mahata*<sup>1,2</sup>, *P. Cadman*<sup>1,2</sup>, *M. Mahata*<sup>1,2</sup>, *S. Ghosh*<sup>1,2</sup>, *N.R. Mahapatra*<sup>1,2</sup>, *F. Rao*<sup>1,2</sup>, *M. Stridsberg*<sup>3</sup>, *D.W. Smith*<sup>4</sup>, *P. Mahboubi*<sup>1,2</sup>, *D.T. OConnor*<sup>1,2</sup>, *B.A. Hamilton*<sup>1</sup>. 1) Department of Medicine,UCSD,La Jolla,CA; 2) VA San Diego Healthcare System, San Diego,CA; 3) Department of Medical Sciences, University Hospital, Uppsala, Sweden; 4) Division of Biology,UCSD,La Jolla,CA.

Chromogranin A (CHGA) is a central regulator of catecholamine vesicle storage and release. CHGA is also a candidate gene for autonomic dysfunction syndromes, including intermediate phenotypes that contribute to human hypertension. In order to identify genetic variants in CHGA that might alter its function, we resequenced all 8 exons and adjacent intronic regions, ~1.2 kbp of 5 promoter, and two intronic conserved noncoding regions from 180 ethnically diverse human subjects. We identified 53 single nucleotide polymorphisms (SNPs) and 2 single base insertion/deletions in this ~5.7 kb footprint. Of these, 20 SNPs were common in our samples. Surprisingly, 8 of the common SNPs occur within less than 1.2 kb in the proximal promoter. The estimated nucleotide diversity ( $\pi$ ) in the promoter region (0.0021) is ~3 fold higher than in other regions of CHGA. Tajimas T and H tests showed significant departure from neutrality in the promoter region, but not in other regions. Among these polymorphisms, we inferred 6 common haplotypes in promoter region. Promoter strength assessed in vitro is markedly reduced in two closely related haplotypes compared with all other haplotypes. Phylogenetic analysis shows that the high and low-expressing haplotype groups also mark the deepest division of the human lineage for this gene. Two amino acid substitutions, Gly364Ser and Pro370Leu, are rare variants in functionally important catestatin peptide. Interestingly, the Gly364Ser substitution results in a 4.7-fold loss of potency, while the Pro370Leu substitution produces a 2.3-fold gain of potency for inhibition of nicotine-evoked catecholamine secretion. Our data demonstrate that both common and rare variants contribute to functional variations in CHGA. Genetic and functional analysis suggests that the level of CHGA and catestatin is under positive selection.

**Angiotensin-Converting Enzyme Gene Polymorphism, Carotid Artery Wall Thickness and Cardiovascular Mortality; Findings from the Rotterdam Study.** *F.A. Sayed-Tabatabaei<sup>1</sup>, A. Arias-Vásques<sup>1</sup>, Y. Aulchenko<sup>1</sup>, A. Hofman<sup>2</sup>, J.C.M. Witteman<sup>2</sup>, C.M. van Duijn<sup>1</sup>.* 1) Genetic Epidemiology Unit, Department of Epidemiology & Biostatistics, Erasmus MC, Rotterdam, The Netherlands; 2) Department of Epidemiology & Biostatistics, Erasmus MC, Rotterdam, The Netherlands.

*Introduction:* Although angiotensin-converting enzyme (ACE) plays a major role in blood pressure regulation, the role of the gene in the risk of atherosclerosis and vascular mortality is unclear. We performed an association study on the insertion/deletion (I/D) polymorphism of the ACE gene and carotid intima media thickness (IMT) and risk of cardiovascular and total mortality in 6869 subjects from the Rotterdam Study. The follow-up data for overall mortality was assessed until the year 2003 and for cardiovascular mortality until the year 2000.

*Results:* There was a small increase in IMT in carriers of the D allele when analysed in the total 5394 subjects for whom IMT measurements were available. The association was limited to smokers. In current smokers there was a significant trend ( $p = 0.04$ ), with the highest IMT in the DD genotype (mean difference DD vs. II =  $0.26 \text{ mm} \times 10^{-1}$ ,  $p = 0.03$ ). The observed difference remained after adjustment for blood pressure.

During the follow-up, 2304 all-causes deaths and 575 cardiovascular deaths were recorded. The hazard ratio (HR) of total mortality in DD carriers compared to II carriers was increased only in smokers who had the event before age 75 (HR=1.52, 95% confidence interval (CI) 1.03-2.25,  $p=0.03$ ). An increased risk for the DD carriers compared to II carriers was also seen for cardiovascular mortality (HR=3.22, 95% CI 1.06-9.77,  $p=0.04$ ).

*Conclusion:* We found a positive association of the D allele of the I/D polymorphism with carotid IMT and risk of cardiovascular mortality among smokers. The findings suggest that the gene may be an important determinant of cardiovascular disease in smokers.

**The deletion/insertion polymorphism of the angiotensin converting enzyme gene and primary palmar**

**hyperhidrosis.** Z. Yamagata<sup>1</sup>, T. Kakinuma<sup>2</sup>, H. Uchino<sup>3</sup>. 1) Dept Health Sci, University of Yamanashi, Yamanashi, Japan; 2) Department of Anesthesiology, Tokyo Medical University, Tokyo, Japan; 3) Department of Anesthesiology Hachiohji Medical Center Tokyo Medical University, Tokyo, Japan.

Palmar hyperhidrosis (HH) is a distressing condition that can impair quality of life causing social, psychological, educational and occupational problems. It has been reported that the hyperactivity in skin sympathetic nerve activity of HH patients that involves contains sudomotor as well as vasoconstrictor nerve activity. Recently, it has been reported that chronic pain due to herpes zoster is associated with the polymorphism of the angiotensin converting enzyme gene and this gene could be a new landmark of the sympathetic function. In this study, we have explored the association between the ACE gene polymorphism and primary HH.

**Materials and Methods:** 40 consecutive patients (9 men, 31 women) with primary HH were included in the study. Serum ACE, angiotensin I, II, were measured in both groups. Blood samples were collected from both 40 patients and 40 healthy subjects. The insertion/deletion DNA polymorphism detected by human ACE.

**Result:** The mean age of HH subjects were 25.1 in II, 23.3 in ID, and 22.3 in DD. On the other hand, The mean age of controls healthy subjects were 26.1 in II, 26.1 in ID, and 25.1 in DD. The distribution of Genotypes in healthy subjects (II=0.20, ID=0.55, DD=0.25) and HH subjects (II=0.05, ID=0.425, DD=0.525) were in agreement with the Hardy-Weinberg proportion. Allele frequency of controls healthy subjects was 0.48 of I allele and 0.52 of D allele. In HH subjects, allele frequency was 0.26 of I allele and 0.74 of D allele. The D allele was significantly more frequent in HH subjects. The association was stronger in both homozygous and heterozygous patients (odds ratio DD/II was 8.4(95% CI, 1.49-47.04) and ID/II was 3.1(95% CI, 0.57-16.48), respectively. The ACE activity in DD genotype showed significant differences compared to the II and ID genotype of HH subjects.

**Genetic susceptibility and gastric cancer risk in a Colombian population.** *M.M. Torres, C.P. Acosta, D.M. Sicard, H. Groot de Restrepo, Laboratorio de Genética Humana. Departamento de Ciencias Biológicas, Universidad de los Andes, Bogota, Colombia.*

The main cause of cancer mortality in Colombia is due to gastric cancer (GC). The risk to develop GC has been associated with environmental factors and *Helicobacter pylori* (Hp) infection. The tumor necrosis factor (TNF- ) is a potent proinflammatory cytokine, and its levels are increased in patients infected with Hp. A G/A transition in the position -308 of the promoter of the TNF- has an increased expression of the gene, and this has been associated with the susceptibility of GC. Glutathione S-transferase (GST) enzymes are involved in the detoxification of many environmental carcinogens. The homozygous deletions of GSTT1 and GSTM1 have been associated with some types of cancer. In the present study, the association of genetic polymorphisms of TNF- at position -308 of the promoter and the deletion polymorphisms of GSTT1 and GSTM1 with GC were investigated in a south western region of Colombia. The interaction of these polymorphisms and other risk factors such as Hp infection, alcohol consumption, smoking and some dietary habits were explored. The information was collected in a questionnaire, and the blood samples were obtained from all the subjects: 50 patients with GC and 96 controls. The logistic regression model was used and the independent effect of each of the polymorphisms on the risk of GC and their potential interaction with other factors was assessed. The frequency of the G/A transition in the TNF- promoter was 18% in the GC population infected with Hp, and 7% in the control group. This transition was not significantly associated with Hp infection and GC. The frequencies of the deletion polymorphisms for both populations (patients and controls) respectively were as follows: GSTM1 65.2%; and 37.5%; GSTT1 17.4%; and 14.6%;. Our results suggest that the GSTM1 deletion polymorphism may be associated with an increased risk of gastric cancer (OR of 5.5; 95%;CI, 1.7-17.2). Also, our data showed that other risk factors such as Hp infection and alcohol intake are associated with this type of cancer (OR of 5.57; 95%;CI, 1.7-17.7; and 3.27; 95%;CI, 1.1-9.4) respectively.

**Association of the D2 dopamine receptor gene with opium-addiction in Iran.** *M. Shahmoradgoli N.<sup>1, 2</sup>, M. Ohadi<sup>1</sup>, F. Valaie<sup>1</sup>, Y. Riazalhosseini<sup>1</sup>, M. Mohammadbeigi<sup>1</sup>, H. Najmabadi<sup>1</sup>.* 1) Genetics Research Center, The Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 2) Young Researchers Club, Azad University, Tehran, Iran.

Dysfunction of central Dopaminergic neurotransmission has been suggested to play an important role in the etiology of certain neuropsychiatric disorders such as drug abuse. It has been shown that the Dopamine D2 Receptor (DRD2) gene dysfunction is associated with multi-drug addiction. Addiction to opium is the most common form of drug abuse in Iran. We studied the allelic association between DRD2 Taq I A polymorphism in 100 opium-dependent patients and 80 unrelated controls. A 310 bp region surrounding Taq I site at the DRD2 locus was amplified by polymerase chain reaction (PCR) and the PCR product was incubated with Taq I restriction enzyme. The A1 allele remained intact while the A2 allele was cut. Significant association was observed between A1 allele and addiction in the patients group ( $P=0.0001$ ). Moreover, the frequency of A1A1 genotype was significantly higher in opium users than controls ( $P=0.0001$ ). Our result further indicates that DRD2 may be involved in the pathophysiology of opium addiction.

Program Nr: 1308 from 2003 ASHG Annual Meeting

**Characterization of human variation panels from African American, Caucasian, Han Chinese and Mexican American populations.** *L. Toji, P. Bender, C. Beiswanger, D. Coppock, J. Beck.* Coriell Cell Repositories, Coriell Inst Med Res, Camden, NJ.

Panels of 100 DNA samples isolated from cell cultures in the Human Genetic Cell Repository at the Coriell Cell Repositories from apparently healthy individuals of African American and Caucasian origins have been available for investigators studying human variation since January, 2000. Because of interest in larger sample sets, a second, non-overlapping set of 100 Caucasian samples has been identified from within the NIGMS collection and made available to investigators in the past year. To extend these panels to other major populations found in the US, blood samples have been collected from Chinese Americans and Mexican Americans under the "Policy for the Responsible Collection, Storage, and Research Use of Samples from Identified Populations for the NIGMS Human Genetic Cell Repository." Epstein-Barr virus-transformed lymphoblastoid cultures have been established and frozen, and DNA has been isolated from these anonymous samples. The Han People of Los Angeles Panel of 100 is a selection of 50 male and 50 female samples. Each sample is from an individual of Han ethnicity unrelated to all others in the Panel and has all four grandparents born in Taiwan, China, or Hong Kong. The Mexican-American Community of Los Angeles Panel of 100 is a selection of 50 male and 50 female samples. Each sample is from an individual unrelated to all others in the Panel and has either three or four grandparents born in Mexico. As part of the routine quality control procedure of the CCR, a set of six highly polymorphic microsatellite markers was determined for each of the 500 DNA samples in these panels. The cumulative profiles for each marker for each panel have been compared; the similarities and differences between panels will be discussed along with additional data on occurrence of the COII/tRNA(Lys) intergenic 9-bp mitochondrial DNA deletion in these populations. Information about these resources may be found at <http://ccr.coriell.org/nigms>.

**Val16Ala Polymorphism of the gene of the manganese(SOD2)-dependent enzyme Superoxide Dismutase, could contribute to increase the predisposition to age-associated diseases?** *M. Tauffer<sup>1</sup>, I.B.M. DaCruz<sup>1</sup>, A.L. Frasson<sup>3</sup>, C.H.A. Schwanke<sup>2</sup>, G. Oliveira<sup>1</sup>, A.R. Santos<sup>1</sup>, P. Jobim<sup>1</sup>, M.E.P. Canto<sup>1</sup>, D. Mussel<sup>1</sup>, J. Maia-Filho<sup>1</sup>, J.E. Piccoli<sup>1</sup>, L. Vieira<sup>1</sup>, I.E.C. Jung<sup>1</sup>, E.H. Moriguchi<sup>1</sup>.* 1) IGG, PUCRS, Porto Alegre, RS, Brazil; 2) Faculdade de Biociencias, PUCRS, RS, Brazil; 3) Faculdade de Medicina, PUCRS, Porto Alegre, RS, Brazil.

Several factors associated to aging stands out the crucial role that oxidative stress plays on macromolecules. This fact associated to differential responses of the anti-oxidant defense system, due to the presence of genetic polymorphisms, as is the case of the Val16Ala SOD2 polymorphism, could contribute to increase the predisposition to age-associated diseases. The association between the SOD2 Val16Ala polymorphism and chronic-degenerative diseases (cardiovascular-CVD and breast and prostate cancer-NEOPL) were investigated in a case-control study, with elderly participants of the Genesis Research Program (n=1158). To proceed, the following groups were selected: 1) healthy elderly individuals without diseases (HE) control group; and 2) elderly with cardiovascular diseases (ECVD) and breast and prostate cancer (NE) case group. Subjects with plurimorbidities were excluded. Besides, a control group of healthy adults was selected (HA). The SOD2 polymorphism was detected by PCR-RFLP using MspI enzyme restriction. The genotypic frequencies were AA=13%, VV=23.8% and AV=63.2%, and they were at Hardy-Weinberg equilibrium. In the control groups the frequency of AA individuals was significantly lower (HA=7.0% and HE=9.8%, NE=15.0%, ECVD=19.1%) (p=0.03). The AA genotype associated to the affected group (case), with an odds ratio of the individuals with the AA genotype presenting CVD and NEOPL of the 2.50 (1.24-5.05). The results suggest SOD2 polymorphism association as risk for these diseases. The present study also allowed the elaboration of mathematical models of possible association between the gene polymorphism, early and late diseases, and aging.

**The "Twins of mistaken zygosity" (TOMZ) study design: Evidence for a genetic contribution to dietary choices.**

*E. Gunderson*<sup>1</sup>, *A. Tsai*<sup>1</sup>, *M. Austin*<sup>2</sup>, *E. Mayer-Davis*<sup>3</sup>, *N. Risch*<sup>1,4</sup>. 1) Division of Research, Kaiser Permanente, Oakland, CA; 2) U Washington; 3) U South Carolina; 4) Stanford U.

Twin designs, comparing correlations in MZ versus DZ twins, have an extensive history. A major confounder in such studies is that MZ twins may share postnatal environmental influences more than DZ twins. To avoid such confounding, twins separated at or soon after birth have sometimes been studied, but their scarcity often makes this approach impractical. Another method has been to measure the degree of contact twins have maintained over time, and adjust observed correlations for degree of contact.

Here we propose another complementary approach to remove the effect of confounding in twin studies. Presumably, postnatal environmental sharing between twins is a function of their perceived zygosity. DNA zygosity testing of twin pairs has shown that about 10% of twins are mistaken in their self-perceived zygosity. This discrepancy between biological and self-perceived zygosity provides an opportunity to separate environmental from genetic sources of twin similarity.

We demonstrate the power of this method by an analysis of preferences for 15 food types obtained from 351 female twin pairs of the Kaiser Permanente female twin registry. In this group, 176 pairs were MZ by self-report and DNA testing (MZC); 136 pairs were DZ by self-report and DNA testing (DZC); 30 pairs were MZ by DNA but not by self-report (MZW); 9 pairs were DZ by DNA but not by self-report (DZW). The average intraclass correlations across 15 food types were MZC: .361.123; MZW: .334.166; DZC: .204.071; DZW: .258.296. These results show that correlations are largely determined by biological rather than self-perceived zygosity. Comparing MZC with DZW and MZW with DZC groups gives average heritability estimates of 21-26%; comparing MZC with MZW and DZW with DZC groups gives a component due to greater environmental sharing of MZ than DZ twins of 3-5%.

Studying twins of mistaken zygosity provides a powerful alternative approach to dealing with confounding within the classic twin design.

**Analysis of CFTR gene mutation frequency in a random African population.** *C. Bombieri*<sup>1</sup>, *B.M. Ciminelli*<sup>2</sup>, *F. Belpinati*<sup>1</sup>, *C. Ciccacci*<sup>2</sup>, *D. Salvi*<sup>2</sup>, *P.F. Pignatti*<sup>1</sup>, *G. Modiano*<sup>2</sup>. 1) Section Biol & Genetics, DMIBG, Univ Verona, Italy; 2) Dpt Biol E.Calef, Univ Roma-Tor Vergata, Italy.

In a previous collaborative research project we analysed Cystic Fibrosis Transmembrane Regulator (CFTR) gene variation among random European healthy subjects (Hum Genet 106:172, 2000; AJHG 71-suppl4: abs.2236, 2002). In order to identify variants that could be used as anthropogenetic markers and to verify the classification of the 21 non CF-causing mutations found in the European population, we enlarged this analysis to a sample of 59 individuals from Burkina Faso (Africa). All the exons plus the intronic flanking regions of the CFTR gene were screened by DGGE and sequencing. Ten variants were found: 94C/T, R74W, IVS6a-GATT, M470V, 1716G/A, 2694T/G, 3030G/A, 3041-71G/C, 4002A/G, 4521G/A. Moreover, an anomalous DGGE pattern not yet characterized by sequencing was found in 2/31 subjects in exon 14b. 94C/T was only found in the African population. The other mutations were found in the European population too. Four variants showed a frequency very different in the two populations, therefore they can be considered good anthropogenetic markers: 94C/T found in 4/112 African genes and absent in 924 European genes; M470V found with a frequency of 0.027 in the African genes compared with 0.618 in the European genes; 4002A/G found with a frequency of 0.172 in African and of 0.036 in European population; and the not yet characterized variant of exon 14b, found in 2/62 African genes and absent in the European genes.

**Frequencies of normal and disease SMN1 alleles, SMN1-SMN2 haplotypes, and de novo SMN1 mutations: implications in SMA genetic risk assessment and molecular evolution of SMN.** *S. Ogino*<sup>1, 2, 3</sup>. 1) Pathology, Brigham and Women's Hospital, Boston, MA; 2) Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 3) Harvard Medical School, Boston, MA.

Approximately 94% of clinically typical spinal muscular atrophy (SMA) patients lack both copies of SMN1 by gene deletions/conversions (0-copy alleles). Genetics of SMA is complex because of the presence of small intragenic SMN1 mutations (1D alleles), two copies of SMN1 on one chromosome 5 (normal 2-copy allele), a high de novo mutation rate, and the SMA modifier gene SMN2 that is highly homologous to SMN1. Because of the genetic complexity and the high carrier frequency (~1/50), genetic counseling and risk assessment are very important. However, previous studies on SMN1 allele frequencies were based on relatively limited amount of data. For the most accurate genetic risk assessments, using all available and reliable data, I calculated various normal and disease SMN1 allele frequencies as follows: 0-copy, 0.0099; normal 1-copy, 0.95; 2-copy, 0.043; and 1D, 0.00018. The paternal and maternal de novo mutation rates were  $2.1 \times 10^{-4}$  and  $4.2 \times 10^{-5}$ , respectively. For the better understanding of molecular evolution of the SMN genes, I also estimated frequencies of various SMN1-SMN2 haplotypes [designated as (SMN1 copy number)-(SMN2 copy number)] as follows: 0-0, 0.00037; 0-1, 0.0066; 0-2, 0.0032; 1-0, 0.26; 1-1, 0.67; 1-2, 0.013; 2-0, 0.033; and 2-1, 0.010. In conclusion, the calculated SMN1 allele frequencies and de novo mutation rates can be utilized for accurate genetic risk assessments. The relatively high frequency of the 0-2 haplotype among disease haplotypes, and of de novo conversion mutations, implies that nucleotide position 840 (the location of an essential difference between SMN1 and SMN2) may constitute a mutation hotspot. The presence of rare 3-copy-SMN1 alleles was also suggested.

**Linkage disequilibrium and polymorphism of HLA genes in the Shona of Zimbabwe.** *D. Meyer*<sup>1</sup>, *K.A. Mather*<sup>1</sup>, *R. Jackman*<sup>2</sup>, *C. Yiu*<sup>2</sup>, *M. Sohsman*<sup>2</sup>, *V. Nguyen*<sup>2</sup>, *D. Katzenstein*<sup>3</sup>, *P. Mason*<sup>4</sup>, *G. Thomson*<sup>1</sup>, *L. Louie*<sup>2</sup>. 1) Integrative Biology, UC Berkeley, Berkeley, CA; 2) CHORI, Oakland, CA; 3) Stanford University Medical School, CA; 4) U of Zimbabwe Medical School, Zimbabwe.

Genetic studies of African populations have established that they present high levels of genetic diversity, relative low levels of linkage disequilibrium, and harbor variation that gave rise to that seen in non-African populations. These patterns are usually interpreted to reflect the demographic history of African populations, which are likely to have experienced larger effective population sizes and have older population histories. In this study, we use a sample of 229 Shona individuals from Zimbabwe to investigate whether these features hold for a set of genes that are known to be experiencing natural selection, the HLA classical genes. Heterozygosity levels at HLA genes range from 0.79 for HLA-DQA to 0.94 for HLA-B. These heterozygosities are higher than nuclear non-HLA genes in human populations (Stephens et al. 2002), and are among the highest HLA heterozygosity values among worldwide populations. All 3 loci within the class I region (1.6Mb) are in significant LD with each other. Excluding DPB1 (which is not in significant LD with any other locus), all class II loci (spanning 75kb) are also in significant pairwise LD. Spanning class I and II (distances of ~1.2Mb), a few pairs of loci are in significant LD: B with DRB1, DQA1 and DQB1, and C with DRB1, demonstrating that LD in the Shona exists over distances longer than the size of haplotype blocks. The CEPH (Sanchez-Mazas et al., 2000) and three Oaxacan Amerindian populations (Hollenbach et al., 2001) shows similar patterns of pairwise LD. However, the strength of LD is higher in the Oaxacan populations than either the Shona or CEPH, consistent with the expectation of higher LD in small constant sized populations than those that have expanded. This comparison of an African to non-African populations shows that HLA gene LD and diversity are shaped by demographic history in a similar manner to the remainder of the genom.

**Linkage Disequilibrium in the CEPH, Yoruba, Southern Han and Mixe populations in six genomic regions.** *K.A. Mather*<sup>1</sup>, *M. President*<sup>1</sup>, *S. Easton*<sup>2</sup>, *J. Hollenbach*<sup>1</sup>, *W. Klitz*<sup>3</sup>, *G. Huttley*<sup>2</sup>, *G. Thomson*<sup>1</sup>. 1) Integrative Biology, Univ California, Berkeley, Berkeley, CA; 2) Australian National Univ., Canberra, Australia; 3) CHORI, Oakland, CA.

Analysis of linkage disequilibrium (LD) in the CEPH population revealed a pattern consistent with the action of natural selection; a few large genomic regions with a high density of markers in significant LD. In ten regions of the genome, this clustered LD exceeded that found in the HLA (Human Leukocyte Antigen) region (Huttley et al. 1999). The high LD regions were hypothesized to be experiencing selection in the CEPH. However, if selection pressures vary among populations, patterns of LD may differ between populations. In order to determine if the LD pattern is conserved across populations, we analyzed microsatellite LD. We examined six genomic regions (5 - 10 Mb in size) on chromosomes 6 (the HLA region), 3 and 20 (two control region without high LD in the CEPH), 7 - one region on each arm and 22 (three CEPH high LD regions) in four populations: Mixe Amerindians (n=49), Southern Han Chinese (n = 47), CEPH (n = 49) and Yoruba Africans (n = 50). We quantified LD by the proportion of marker pairs with  $D'$  exceeding the 90th percentile of  $D'$  between unlinked markers in that population. We find evidence for LD between markers separated by several Mb, distances which are much greater than the sizes of the recently described haplotype blocks (Daly et al. 2001, Jefferys et al. 2001, Gabriel et al. 2002). Across all regions, the Mixe population have the highest LD levels, followed by the southern Han and CEPH populations and the Yoruba have the lowest LD, consistent with the theoretical expectation (Slatkin 1994) that small populations will have more LD than large populations which have expanded. The ordering of five regions by amount of LD is similar in all populations (but distinct from that of the earlier CEPH study): 6>3>22>20>7p, suggesting that LD levels in these regions may reflect a similar ordering in selection intensities across populations. The LD levels of the region on chromosome 7q vary between populations, suggesting that selection intensities in this region vary between populations.

**Evolution of Class I ADH haplotypes in worldwide human populations.** *Y. Han, M.V. Osier, A.J. Pakstis, H. Oota, J.R. Kidd, K.K. Kidd.* Genetics, Yale University, New Haven, CT.

The seven human Alcohol dehydrogenase (ADH) genes code for a family of enzymes that catalyze the reversible oxidation of alcohols to aldehydes. The three Class I ADH genes (ADH1A, ADH1B, ADH1C) share 95% sequence identity and are believed to play a major role in ethanol metabolism. Variants of different Class I ADH genes are associated with a protective effect against alcoholism. We have typed nine Class I ADH SNPs (ADH1C EcoR I, HaeIII, Arg271Gln, Ile349Val, Pro351Thr, ADH1B Arg47His, RsaI, Arg369Cys, ADH1A BccI) spanning > 68kb of the > 77kb Class I cluster, in samples of 38 populations. Most of the haplotypes that are common in Sub-Saharan Africa can be accounted for by a simple multibranching tree of nucleotide substitutions starting from the rare ancestral haplotype. The most common haplotype in the world differs from the ancestral haplotype by two nucleotide substitutions; the intermediate differing from the ancestor at only one of those sites is rare but present in African populations. The second most common haplotype differs from the most common haplotype at two additional changes; again, the intermediate differing at only one of those sites is found only in Africa. Thus, the haplotype frequencies suggest that most haplotypes were generated in Africa before modern humans migrated out of Africa. The haplotype that harbors a functional substitution associated with protection against alcoholism (ADH1B\*47His) is seen exclusively and at high frequency (>60%) in East Asia and appears to be a crossover product involving two haplotypes common in Western Asia. This crossover haplotype is not found in indigenous Africans suggesting it arose from a recombination event among modern humans who had already left Africa. Regionally restricted functional variants also exist in Africa and the Americas suggesting selection is operating on these genes probably related to adaptation in each geographical region. [Supported in part by NIH grant AA09379].

**Gender-specific Association Between *IL10* Polymorphisms and the Rate of Decline of Lung Function in Smokers.**

*J-Q. He*<sup>1</sup>, *JE. Connett*<sup>2</sup>, *NR. Anthonisen*<sup>3</sup>, *PD. Paré*<sup>1</sup>, *AJ. Sandford*<sup>1</sup>. 1) Medicine/McDonald Research Lab, University of British Columbia, Vancouver, BC, Canada; 2) Division of Biostatistics, School of Public Health, University of Minnesota; 3) Faculty of Medicine, University of Manitoba.

Interleukin-10 (IL10) is a cytokine that has a wide spectrum of anti-inflammatory actions. IL10 concentrations are reduced in induced sputum from patients with COPD, indicating that this might be a mechanism for increasing lung inflammation. Several single nucleotide polymorphisms (SNPs) in the *IL10* promoter have been associated with the level of expression of IL10. Objective: To determine whether allelic variants of the *IL10* gene are associated with rate of decline of lung function in smokers. Methods: We used a case-control approach to study 585 Caucasians with the fastest decline in forced expiratory volume in 1 second (FEV<sub>1</sub>) (n=280, FEV<sub>1</sub> = -153 3ml/year) and with the slowest FEV<sub>1</sub> decline (n=305, FEV<sub>1</sub> = +15 3ml/year) selected from among 3,216 subjects who continued to smoke during 5 years of follow up in the NHLBI Lung Health Study. Genotyping was performed by TaqMan assay. The associations were analyzed by logistic regression to adjust for potential confounding factors. Results: We chose 3 SNPs from more than 20 SNPs of the *IL10* gene because of a minor allele frequency greater than 10% and because these 3 SNPs were able to define more than 80% of all haplotypes in the *IL10* gene. They were *IL10* -627 C/A (or -592 C/A), 734 T/G (perfect linkage disequilibrium with -1082 A/G) and 3368 G/A. Neither the genotype or haplotype frequencies were significantly different between groups with the fastest and slowest decline of lung function when the whole group was analyzed, however women who were homozygous for the 3368G allele were more likely to be in the fast decline group (70.3% vs 58.1% OR = 2.3, p = 0.02). To date there are no data testing whether the 3368 A/G transition has functional significance. Conclusion: Genetic polymorphisms in the *IL10* gene were associated with the rate of decline of lung function in woman smokers. Supported by the NHLBI and the CIHR.

**Mongolian populations as genetic resource: Challenges towards genetic study in Mongolians.** *B. Munkhbat<sup>1</sup>, K. Tounai<sup>1</sup>, T. Katoh<sup>1</sup>, S. Mano<sup>1</sup>, H. Ando<sup>1</sup>, S. Ando<sup>1</sup>, N. Baasanjav<sup>2</sup>, G. Batmunkh<sup>3</sup>, H. Inoko<sup>1</sup>, G. Tamiya<sup>1</sup>, N. Munkhtuvshin<sup>2</sup>.* 1) Molecular Life Science, School of Medicine, Tokai University, Isehara, Kanagawa, Japan; 2) Central Scientific Research Laboratory, National Institute of Medicine, Ulaanbaatar, Mongolia; 3) Department of Physiology, National Medical University of Mongolia, Ulaanbaatar, Mongolia.

To select the subject populations is a crucial factor for the genetic studies of the identification of genomic regions or genes predisposing to complex diseases. Because of reduced genetic and environmental variability, the genetic isolates have been thought to facilitate initial gene mapping of both complex and monogenic diseases. On the other hand, general outbred population better suit for the fine mapping of the complex and monogenic diseases. The National Institute of Medicine, Mongolia (NIMM) has started a scientific project on comprehensive genome wide analysis in contemporary Mongolians in collaboration with Tokai University, Japan. The project concentrates on cataloging DNA/cell-line samples from Mongolian populations and then disease association/linkage studies using these samples. Specific features of the Mongolians such as small population size (2.4 million people by 2000 population census), existence of nearly 20 closely related as well as genetically distinct ethnic groups in the vast territory (1.5 million km<sup>2</sup>), large families, cooperative people, and remote and centralized medical service make it an ideal population for the genetic studies of various purposes and consequently would offer an attractive scientific outcome. While presenting the genetic features of the Mongolian ethnic groups on the basis of a pilot study using STR and SNP markers, we will describe our project concept and also our efforts to attract potential corporate partners worldwide.

**SNP variation in a non-coding region of Xq13.3 in East Asia.** *T. Katoh<sup>1</sup>, K. Tounai<sup>1</sup>, S. Mano<sup>1</sup>, H. Ando<sup>1</sup>, B. Munkhbat<sup>1</sup>, N. Munkhtuvshin<sup>2</sup>, K. Tokunaga<sup>3</sup>, G. Jia<sup>4</sup>, H. Inoko<sup>1</sup>, G. Tamiya<sup>1</sup>.* 1) Molecular Life Science, School of Medicine, Tokai University, Isehara, Kanagawa, Japan; 2) Central Scientific Research Laboratory, National Institute of Medicine, Ulaanbaatar, Mongolia; 3) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 4) Harbin Red Cross Blood Center, Harbin, China.

It is well known that East Asia consists of various human populations. However, the genetic relationships among these populations are still unclear and an interesting subject in human genetics. To study the relationship among some East Asian populations including Chinese, Japanese, Korean, and Mongolian, we analyzed the SNP variations found within 10kb length at a non-coding region of Xq13.3. This region is thought to have an extremely low level of recombination rate, which is approximately one-eighth of the average of X chromosome, implying that it will be useful for evolutionary analyses. Frequency distributions of the Xq13.3 haplotypes showed that East Asian populations have the relatively low level of diversity than non-Asian populations, such as European American and African American, suggesting an occurrence of past bottleneck event in East Asia. On the whole, our study is compatible with the previous studies using Y chromosome, although somewhat different patterns are observed between Y chromosome and our studies.

**SNP-haplotype analysis in human chromosome region 3q27 in Japanese and European Americans.** *H. Morisaki*<sup>1</sup>, *E. Inoue*<sup>2</sup>, *Y. Kitamura*<sup>2</sup>, *N. Kamatani*<sup>2</sup>, *T. Morisaki*<sup>1,3</sup>. 1) Dept Bioscience, NCVI Research Inst, Suita Osaka, Osaka, Japan; 2) Inst Rheumatol, Tokyo Womens Med Univ; 3) Dept Mol Pathophysiol, Osaka Univ Grad Sch Pharm Sci.

SNP-haplotype analysis, along with the identification of haplotype-tagging SNPs, is believed to be a powerful tool to study genetic association with common diseases. We analyzed genetic variation and haplotype structure of human chromosome region 3q27, which has been shown to be associated with type 2 diabetes in several populations including Japanese. Fifty-six marker SNPs, spanning 1 Mb region of chromosome 3q27, were selected and genotyped in 94 Japanese control subjects and 95 European American subjects. To define haplotype blocks, we used  $D'$  confidence bounds instead of point estimates applying the same criteria defined by Gabriel, et. al. Among 56 marker SNPs, 53 SNPs were common (>10%) and shared between both populations, and more than 95% of SNP pairs were informative in terms of historical recombination. Ten and twelve haplotype blocks were defined in Japanese and European Americans, respectively. Six of them shared their boundaries and none of them were discordant between populations. The minimal span of the blocks varied from 2 kb to 51 kb, and the block-boundaries were not necessarily concordant with the gene-boundaries. Each haplotype block was consisted of 2 to 5 common (>5%) haplotypes. Most of them were shared in both populations, but differed in the haplotype constitution, resulting in different pairwise SNP correlation ( $r^2$ ) between populations. Haplotype-tagging SNPs were identified in two-thirds of the cases, which differ slightly between populations. We also found that the two SNPs in APM1 gene, one in promoter region reported to be associated with diabetes in French subjects, and the other in intron 2 which showed association in Japanese patients, were assigned to different haplotype blocks with the evidence of historical recombination between them. It may suggest a different mechanism of APM1 gene function affecting the diabetic phenotype.

**Strategy for a systematic genomic analysis of the Mexican population.** *G. Jimenez-Sanchez<sup>1,2,3</sup>, J.P. Lacleste<sup>1,4</sup>, J. Rosenkranz<sup>1</sup>, A. Serrano-Perez-Grovas<sup>1,5</sup>, M. Uribe<sup>1,6</sup>.* 1) Consortium Institute of Genomic Medicine, Mexico City, Mexico; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore MD, USA; 3) Mexican Health Foundation (FUNSALUD), Mexico; 4) National Autonomous University of Mexico, Mexico; 5) National Council of Science and Technology (CONACYT), Mexico; 6) Ministry of Health (SSA), Mexico.

Mexico prepares a nationwide platform to develop genomic medicine focused on medical problems of its population. One of the initial goals is to study the genomic structure of the Mexican population, with special interest in areas of the human genome directly related to health problems. Unlike any other population, Mexicans mostly result from the mixture of over 65 native Indian groups that arrived in Mesoamerica during the last 15 centuries, with Spaniards that arrived in Mexico about 500 years ago. Since 1999, over 100 biomedical investigators from different backgrounds in Mexico and abroad have joined efforts with government, academia and industry to identify priorities and goals for genomic medicine in Mexico. We recently reported the Mexican strategy to develop a nationwide platform on genomic medicine (*Science* 300; 5617, 2003). We have defined a five-year plan to achieve such goals, by developing a Mexican Institute of Genomic Medicine with strong intramural and extramural programs for basic and clinical research, professional and public education, and technology. Our feasibility study estimated an investment of \$190 Million USD in infrastructure and operations for the first five years. Initial candidate populations for genomic analysis have been identified and ethical, legal and social issues, along with technical requirements are being evaluated. This plan intends to serve as the bases for a nationwide platform in which genomic medicine can impact on national and regional health problems. Furthermore, we predict that the systematic genomic analysis of the Mexican population will have significant medical and financial benefits not only in Mexico, but also in the United States where Mexicans represent a significant part of the population. Detailed information is available at [www.inmegen.org.mx](http://www.inmegen.org.mx).

**Polymorphisms of five hypervariable autosomal loci in different ethnic groups of Eastern Europe. D.A.**

*Verbenko<sup>1</sup>, P.A. Slominsky<sup>1</sup>, E.K. Khusnutdinova<sup>2</sup>, V.A. Spitsyn<sup>3</sup>, N.A. Bebyakova<sup>4</sup>, A.I. Mikulich<sup>5</sup>, S.A. Limborska<sup>1</sup>.* 1) Human Molecular Genetics Department, Institute of Molecular Genetics, Moscow, Russia; 2) Institute of Biochemistry and Genetics, Ural Branch of Russian Academy of Sciences, Ufa, Russia; 3) Medical and Genetics Scientific Centre, Russian Academy of Medical Sciences, Moscow, Russia; 4) North State Medical University, Arkhangelsk, Russia; 5) Institute of Art History, Ethnography and Folklore, National Academy of The Republic of Belarus, Minsk, Belarus.

A study of DNA diversity is very important to understand the nature of human populations relationships. Here we present our results of East European ethnic groups relationships based on autosomal DNA markers with tandem repeat structure. These markers are extremely polymorphic and are widely used in medical and population genetics.

Eastern European region inhabited by a number of ethnic groups belongs both to two main anthropological types and to their admixtures. We considered Eastern Slavs as Europeans, whereas Kalmyks and Yakuts as Asians. Ural region ethnic groups (Komis, Mordvinians, Bashkirs, Udmurts) were regarded as admixture populations with different levels of an Asian component.

The analysis of DNA minisatellite polymorphisms (3'ApoB and D1S80 loci) was carried out using the PCR and subsequent electrophoresis followed by silver staining. The triplet microsatellites (DM, DRPLA, SCA1 loci) variability was investigated using 33P-labelling of PCR primers. All of the loci studied shown high polymorphism level. Genetic distance analysis was based on multidimensional scaling of Nei's pairwise genetic distance matrix. An UPGMA phylogenetic tree was also constructed. Observed cluster patterns reveal maximum distance between Europeans and Asians, while Uralic populations are most closely related to Europeans. As a part of the conclusion, we can strike very close relationship between Eastern Slavonic populations, namely Russians, Byelorussians, and Ukrainians. The data obtained are in agreement with ethno-historic and linguistic studies of the Eastern European region.

**Smoking-dependent effects of the Angiotensin-Converting Enzyme gene insertion/deletion polymorphism on blood pressure.** *A.F.C. Schut<sup>1,2</sup>, F.A. Sayed-Tabatabaei<sup>1</sup>, J.C.M. Witteman<sup>4</sup>, A.M. Bertoli Avella<sup>1</sup>, J.M. Vergeer<sup>1</sup>, H.A.P. Pols<sup>2,4</sup>, A. Hofman<sup>4</sup>, J. Deinum<sup>3</sup>, C.M. van Duijn<sup>1</sup>.* 1) Genetic Epidemiology, Erasmus MC, Rotterdam, The Netherlands; 2) Internal Medicine, Erasmus MC, Rotterdam, The Netherlands; 3) Internal Medicine, UMC Radboud, Nijmegen, The Netherlands; 4) Epidemiology & Biostatistics, Erasmus MC, Rotterdam, The Netherlands.

Studies on the role of the Angiotensin-Converting-Enzyme (ACE) gene in the development of hypertension have yielded conflicting results. Recent studies suggested that the ACE gene may have smoking-dependent effects on the development of cardiovascular disease. We studied the relation between the ACE insertion/deletion polymorphism, blood pressure and risk of hypertension in current, former and non-smokers in a population-based cohort.

We included 2414 non-smokers, 2794 former smokers and 1508 current smokers, all participants of the Rotterdam Study. In each group, we assessed the relation between the ACE I/D polymorphism, systolic (SBP) and diastolic blood pressure (DBP) and risk of hypertension. Mean blood pressure levels and prevalence of hypertension were compared between carriers and non-carriers of the D-allele. All analyses were adjusted for age, sex, BMI, diabetes mellitus, HDL-cholesterol, total cholesterol and anti-hypertensive medication use.

In non- and former smokers, blood pressure and the risk of hypertension did not differ significantly between genotypes. In smokers, we found a significant increase in SBP in DD-carriers (139.6 22.8 mmHg) compared to II-carriers (136.0 22.7 mmHg)( $p=0.04$ ). No effect of ACE genotype was observed for DBP. The risk of hypertension was significantly increased in smokers who carried one (OR: 1.4; 95% CI: 1.0-1.9;  $p=0.05$ ) or two copies of the D-allele (OR: 1.5; 95% CI: 1.1-2.2;  $p=0.02$ ).

The D-allele of the ACE polymorphism is associated with a modestly, but significantly, increased SBP and risk of hypertension in smokers. Our study underlines the importance of gene-environment interactions in the study of candidate genes for hypertension.

**The European ACP1\*C Allele has Recessive Deleterious Effects on Early Life Viability.** *J. Wilder, M. Hammer.*  
Division of Biotechnology, University of Arizona, Tucson, AZ.

The acid phosphatase locus (ACP1) is a classical polymorphism that has been surveyed in hundreds of human populations world-wide. Among individuals of European ancestry, the ACP1\*C allele occurs with an average frequency of 0.05, while it is nearly absent in all other human populations. It has been hypothesized that this allele is maintained by overdominant selection among European populations. Here we analyze ACP1 protein polymorphism data from over 46,000 individuals previously surveyed in 66 populations across Europe, as well as inheritance data from over 6000 European parent offspring pairings to assess the signature of natural selection on this allele. Although we see a significant excess of ACP1\*C heterozygotes relative to Hardy-Weinberg expectations, we find no evidence that natural selection favors ACP1\*C heterozygotes. Instead, ACP1\*C appears to have a strongly deleterious and recessive fitness effect, leading to only 48.6% of expected homozygous offspring from heterozygous parents, and significantly fewer homozygotes than expected among populations. Because parent offspring pairings indicate a significant deficiency of ACP1\*C homozygotes, we infer that viability selection is acting on ACP1\*C homozygotes very early in life, perhaps before birth. We estimate that approximately 1.1% of all couples of European ancestry are composed of individuals who both carry the ACP1\*C allele. As such, selection against ACP1\*C homozygotes may represent a non-negligible contribution to the overall number of spontaneous abortions among women of European ancestry, and may cause substantial fertility reductions among some combinations of parental genotypes.

**Angiotensin converting enzyme gene is associated with Alzheimers disease in women.** *K. Sleegers<sup>1</sup>, T. Den Heijer<sup>1,2</sup>, E.J. Van Dijk<sup>1,2</sup>, A. Hofman<sup>1</sup>, P.J. Koudstaal<sup>2</sup>, M.M.B. Breteler<sup>1</sup>, C.M. Van Duijn<sup>1</sup>.* 1) Epidemiology&Biostatistics, Erasmus MC, Rotterdam, The Netherlands; 2) Department of Neurology, Erasmus MC, Rotterdam, The Netherlands.

Despite strong evidence for a role of Angiotensin converting enzyme (ACE) in Alzheimers disease (AD), studies assessing the relation between the ACE I/D polymorphism and AD show conflicting results. A problem in the interpretation of findings is lack of power (Lohmueller et al, Nature Genetics 2003). Moreover, since ACE plays a pivotal role in vascular homeostasis, omitting cardiovascular status as a possible intermediate or confounder may lead to false associations. We evaluated the association between ACE and AD in a large population based cohort study (Rotterdam Study, n=6869) adjusting for confounding by cardiovascular risk. In addition we performed a meta-analysis of all studies conducted up to December 2002 including our data (3749 cases, 10495 controls). In the Rotterdam Study we further explored the underlying pathophysiology by analyzing the relation between ACE and early AD-related pathology on MRI, i.e. hippocampal and amygdalar atrophy, white matter lesions and infarcts, in 494 non-demented elderly. In the meta-analysis we found a modest but significantly increased prevalence of the I-allele in patients (OR 1.15 (95%CI 1.01-1.30)). In the Rotterdam Study, during 6 years of follow-up, subjects homozygous for the I-allele had a modestly increased risk of AD of 1.12 (95%CI 0.99-1.25; p=0.06) compared to subjects with a D-allele. This finding was strongest in women. After adjustment for cardiovascular confounders female carriers of the II genotype had a 1.39 fold increased risk of AD (p=0.001). Likewise women with the II genotype had lower hippocampal (p=0.02) and amygdalar (p=0.05) volumes on MRI. Vascular pathology on MRI was not associated with ACE. In conclusion the results of the meta-analysis, the follow-up study of AD and the study of early pathology on MRI consistently show an association of the ACE I-allele with AD in women independent of cardiovascular disease. Our findings underscore the value of large-scale epidemiological follow-up of (early) pathology for genetic research.

**Global distribution of the PRNP codon 129 polymorphism suggests an increased risk of CJD and vCJD in East Asia.** *M. Wolujewicz, R. Kaushal, A. Bhati, G. Sun, R. DeKa.* Environmental Health, University of Cincinnati, Cincinnati, OH.

The codon 129 polymorphism of the prion protein (PRNP) gene is characterized by an amino acid substitution of valine for methionine. Homozygosity at this locus has been described as influencing susceptibility to prion diseases, namely Creutzfeldt-Jakob disease (CJD). Additionally, individuals affected with vCJD, the variant form of the disease, understood to be transmitted by the bovine spongiform encephalopathy (BSE) epidemic, have all been identified as homozygous for methionine at this locus (Collinge et al. 1996, Lancet 348). The distribution of the polymorphism in European populations has been shown to be 40% Met/Met, 50% Met/Val, and 10% Val/Val. We examined the PRNP 129 polymorphism in 565 individuals comprising 15 global populations distributed over Africa, Europe, Asia, and Oceania. The populations of East Asia have significantly lower heterozygosity with an increased distribution of Met homozygosity (0.86-0.96), suggesting an increased risk for developing CJD in these populations. Also, recent reports of BSE in Japan (2001 Nature, 413) introduces the possibility for another vCJD epidemic, now with especial concern because of the Met/Met genotype frequency in the area. Projections of vCJD risk in Japan and other East Asian countries need to incorporate the high frequency of this genotype to more accurately ascertain risk. (Supported in part by NIH grant ES06096).

**Inferring intraspecific genealogy: a stepwise partitioning approach.** *G. Zhang, L. Jin.* Center for Genome Information, Dept. Environmental Health, University of Cincinnati, Cincinnati, OH.

In a population, a chromosome is delimited, by historical recombination events, into smaller blocks (i.e. haplotype blocks), each of which is captured by a genealogy representing a unique evolutionary history of the block. An efficient and accurate inference of such genealogy or phylogeny is essential in (a) understanding the evolutionary history and genetic structure of the population, (b) unraveling important biological processes such as recombination and mutation, and (c) applying such information in mapping and identifying the mutations and haplotypes underlying diseases and other traits. It also bears particular practical importance in inferring haplotype blocks and identifying haplotype-tagging SNPs (htSNPs). Based on the idea that any phylogenetic relationships of a DNA fragment without observable recombination can be represented by a primarily bifurcating tree with, to a less degree, multifurcating structure, we developed a stepwise partitioning algorithm for inferring such genealogy. In this method, all the sequences of a tree are partitioned (carrying one or a few specific mutations) by all the variations in a consecutive manner, and a unique nested partition can be obtained. And the final tree topology is solved by favoring the assumption that the number of mutations is proportional to the coalescent time. We have applied this method to simulated data sets and obtained reliable results that are superior to the existing maximum parsimony methods. Another major strength of this approach is its efficiency, much faster than any of the existing tree-making methods.

**HLA haplotyping in ethnic communities of Kerala, South India.** *R. Thomas, S.B. Nair, M. Banerjee.* Human Molecular Genetics Lab, Rajiv Gandhi Centre for Biotechnology, Thycaud P.O., Trivandrum, Kerala, INDIA.

Human Leukocyte Antigens (HLA) are glyco-proteins expressed on the surface of every cell in the body. The molecules form part of a system of immune recognition to distinguish "self" from "non-self". Their role is to present peptides, derived from foreign antigens, to cytotoxic T cells and to enable the specific destruction of "non-self" cells. Variations in these peptides between different individuals alter the nature of the antigen presented to the immune system. These antigenic variations could give a clinical advantage over some infectious diseases. It can also prove to be disadvantageous for some immune response diseases.

India has the worlds highest ethnic diversity with a hierarchical caste structure. The basis of reproductive isolation of these populations is also highly varied, comprising of geographic, religious, ethnic or occupational backgrounds. In the present study we selected eight ethnic communities namely Malapandaram, Paniya, Adiya, Kurichiya, Kanikkar, Kattunaikkar, Kuruma and Pulaya and one group consisting of individuals from the mainstream population of Kerala. These population groups are of Dravidian origin and are believed to be the earliest settlers of Southern India. We identified the distribution of HLA-B and HLA-C alleles in these communities using Polymerase Chain Reaction-Sequence Specific Primer (PCR-SSP) method based on the IHWC protocol. A total of 18 alleles HLA-B alleles were identified in the mainstream population while only 5-10 alleles were observed in the eight ethnic communities. B\*7, B\*44, B\*51 and B\*61 were the most common alleles observed. A total of 13 HLA-C alleles were identified with Cw\*07, Cw\*04, Cw\*14 and Cw\*15 occurring at a high frequency. It is interesting to note that Cw\*08 which was reported to be a characteristic feature of Indians of Indo European origin was present at a very low frequency in the present study which mainly comprises populations of Dravidian origin. Cw\*15 is believed to be of Dravidian origin as it was absent in Indians of Indo-European origin. The two-point haplotypes occurring at a high frequency were B\*07-Cw\*07, B\*35-Cw\*07, B\*44-Cw\*07, B\*58-Cw\*10, B\*61-Cw\*10 and B\*62-Cw\*14.

**Founder Mutations among the Dutch.** *M. Zeegers*<sup>1</sup>, *R. Vlietinck*<sup>1</sup>, *F. van Poppel*<sup>2</sup>, *L. Spruijt*<sup>1</sup>, *H. Ostrer*<sup>3</sup>. 1) Maastricht Univ, Maastricht, The Netherlands; 2) Netherlands Interdisciplinary Demographic Institute, The Hague, The Netherlands; 3) NYU School of Medicine, New York, NY.

Many genetic disorders demonstrate mutations that can be traced to a founder, sometimes a person who can be identified. These founder mutations have generated considerable interest, because they facilitate studies of prevalence and penetrance and can be used to quantify the degree of homogeneity within a population. This study reports on founder mutations among the Dutch and relates their occurrence to the history and demography of the Netherlands. International migration, regional and religious endogamy, and rapid population growth played key roles in shaping the Dutch population, a country that now includes 16 million inhabitants. Several different classes of founder mutations have been identified among the Dutch. Some mutations occur among people who represent genetic isolates within this country. These include mutations for benign familial cholestasis, diabetes mellitus, type I, infantile neuronal ceroid lipofuscinosis, L-DOPA responsive dystonia and triphalangeal thumb. Although, not related to a specific isolate, other founder mutations occur only within the Netherlands, including those predisposing for hereditary breast-ovarian cancer, familial hypercholesterolemia, frontotemporal dementia, hereditary paragangliomas, juvenile neuronal ceroid lipofuscinosis, malignant melanoma, protein C deficiency and San Filippo disease. Many of these show a regional distribution, suggesting dissemination from a founder. Some mutations that occur among the Dutch are shared with other European populations and others have been transmitted by Dutch migrants to their descendants in North America and South Africa. The occurrence of relatively limited genetic heterogeneity for many genetic conditions among the Dutch has resulted in short chromosomal regions that have remained identical by descent. These observations demonstrate the opportunity for gene discovery for other diseases and traits in the Netherlands.

**Meta-analysis of the evidence for sex-differential fitness of BRCA2 variant.** *D. Teare, A. Cox, C. Anderson, J. Shorto, C. Cannings.* Division of Genomic Medicine, University of Sheffield, Sheffield, South Yorks, UK.

Healey et al (2000) reported that a common variant (N372H) in exon 10 of the BRCA2 gene may affect foetal viability in a sex dependent manner. Their results suggested that females (adults and newborns) generally showed a similar excess of heterozygotes, whereas the single large sample of newborn males demonstrated decreased heterozygote fitness. Their study did not include adult males. While the original analysis reported the sex-specific fitness estimated under the assumption of equilibrium, no attempt was made to evaluate whether this equilibrium was stable.

In order to study the possible sex differential effect in more detail we have genotyped further series of adult males and females. Recent publications provided two further samples of female adult controls. A joint analysis of all 11 available female samples supports the original observation for female heterozygote advantage. However the evidence for reduced fitness in male heterozygotes is now less clear. In addition to this meta-analysis we have considered the range of stable sex-differential fitness models which would be consistent with observed data. The point estimates in the original publication were not consistent with a stable solution but the results of our presented meta-analysis are.

**GENOMEUTWIN - an integrated project of eight large twin cohorts for genetic studies on complex traits.** *L. Peltonen, M. Perola, D. Boomsma, K. Christensen, A. Evans, J. Harris, H. van Houwelingen, J. Kaprio, K. Kuulasmaa, K. Ohm Kyvik, J.E. Litton, N. Martin, N. Pedersen, T. Spector, A. Stazi, A.C. Syvanen.* National Public Health Inst, Finland.

Large population-based cohorts are of special significance for genomic research aiming to characterize the background of common human traits and diseases. European twin cohorts provide a unique opportunity for investigation of the role of genetics and environment/life style in the etiology of common traits. The EU-funded integrated project GenomeUtwinn ([www.genomeutwin.org](http://www.genomeutwin.org)) pools the expertise of eight twin cohorts (Australian, Danish, Dutch, Finnish, Italian, Norwegian, UK, Swedish) and a large European prospective epidemiological study of cardiovascular disease: MORGAM ([www.ktl.fi/morgam](http://www.ktl.fi/morgam)). The study population includes over 600.000 twin pairs and over 130.000 participants in MORGAM cohorts. So far over 200.000 biological samples have been collected for DNA analyses and major effort invested on the harmonization of database systems and phenotypic criteria. The GenomeUtwinn applies and develops new statistical strategies to utilise the unique, longitudinal information of health and life events of study participants to characterise the etiology of common traits and diseases, initially obesity, stature, longevity, migraine, coronary heart disease and stroke. The GenomeUtwinn operates via five intellectual cores on epidemiology, database, genotyping, statistics and ethics, which provide the infrastructure and expertise for the project. So far the twin cohorts have been mined for informative pairs and core families for ongoing genome scans. Putative loci are being fine mapped and SNP haplotypes constructed for the regional genes to determine the trait-associated alleles to be monitored in the prospective study cohorts to assess their contribution to survival and genetic risk. We have estimated heritability and the character of genetic component for traits listed above across the study populations. Examples of the data include the average heritability of 46 % for migraine in 31 410 twin pairs and evidence for different genetic effect of variations on BMI for males and females observed in 37 000 twin pairs.

**G Protein 3 Subunit (GNB3) C825T variation is correlated with latitude and climate: Is selection a source of differential susceptibility to hypertension?** *J.H. Young<sup>1</sup>, Y.-P. Chang<sup>2</sup>, J.-P. Chretien<sup>1</sup>, M. Ikeda<sup>2</sup>, J. Kim<sup>2</sup>, M.J. Klag<sup>1</sup>, M.A. Levine<sup>3</sup>, A. Chakravarti<sup>2</sup>.* 1) Dept of Medicine & Epidemiology, Johns Hopkins, Baltimore, MD; 2) Institute of Genetic Medicine, Johns Hopkins, Baltimore, MD; 3) The Children's Hospital, The Cleveland Clinic, Cleveland, OH.

Climatologic factors influence blood pressure and may have driven the evolution of genes involved in hypertension susceptibility. To test this hypothesis, we determined the extent to which latitude and climatologic factors contribute to worldwide variation in the GNB3 C825T, a functional polymorphism associated with hypertension. In the CEPH diversity panel, which includes 1064 people from 52 populations around the world, we genotyped C825T and five additional SNPs spanning a ~20 Kb region in and around GNB3. In order to compare variation in GNB3 versus the genome and assess the effect of demographic factors, over 400 microsatellite markers (STRs) were used to estimate genetic distance (Nei's D') among CEPH populations. Climate was characterized by average yearly temperature and precipitation. In univariate analysis, latitude explained 51% of C825T variation ( $\beta = -0.008$ ,  $R^2 = 0.5149$ ). Other GNB3 SNPs were only weakly associated with latitude (all  $|\beta| < 0.003$ , all  $R^2 < 0.0680$ ). No STR was as strongly correlated with latitude as C825T. In a separate model, temperature and precipitation together explained 38.9% of C825T variation ( $R^2 = 0.3893$ ). In the model containing latitude, temperature, and precipitation, each factor remained important ( $s$  were 0.010, -0.006, 0.002 respectively;  $R^2 = 0.5424$ ). Other GNB3 SNPs were also associated with climate but to a lesser degree (all  $R^2 < 0.1640$ ). Finally, C825T variation was not associated with relative genetic distance ( $R^2 = 0.003$ ). In addition, the inclusion of D' did not affect the association between C825T and latitude or climate. In summary, worldwide variation in C825T is largely explained by latitude and climatologic factors and shows a pattern distinct from the genome average. We speculate that differential exposure to selection pressures, most notably climate, during the out of Africa expansion contributed to GNB3 C825T variation and possibly differential susceptibility to hypertension.

Program Nr: 1332 from 2003 ASHG Annual Meeting

**Natural Selection on Haplotypes of MATP.** *J.C. Stephens, B.A. Salisbury, G. Ruano.* Population Genomics, Genaissance Pharmaceuticals, New Haven, CT.

We have used an empirical distribution of gene-based  $F_{ST}$  values to identify genes that may have been under intense natural selection in the course of modern human history. MATP, membrane associated transport protein, has the second highest  $F_{ST}$  in our analysis of thousands of genes. While our samples of African and Asian chromosomes are characterized by high levels of haplotypic diversity, the European sample is nearly fixed for a single, high  $F_{ST}$  haplotype. That haplotype is uniquely characterized by the derived amino acid Phe (Leu 374 Phe). The ancestral Leu allele is strictly conserved in all homologous proteins studied in other species, including the sucrose transporter in the celery plant. Had we only looked at a European population, we would have concluded that this gene is highly conserved and does not have much polymorphism. Furthermore, had we only looked at this one gene, we might have concluded that our European sample was too homogeneous, perhaps arising from a population bottleneck. The ability of this SNP to distinguish European from Asian and African ancestry has been noted before, but the haplotypic uniformity of European chromosomes containing this SNP is a novel finding illustrative of hitch-hiking at the haplotype level. This gene appears to affect melanin production or melanosome function according to studies in human, mouse, horse, and fish. Ultraviolet opacity of human skin is thought to be under strong selective pressure mediated by geographic variation in solar exposure and the contrasting pressures of the need for photo-induced vitamin D3 synthesis and the destructive effects of UV light exposure. If MATP's haplotypes are shown to affect human skin pigmentation, this gene's almost unrivalled selective signature would lend further support to these theories.

**Mitochondrial DNA Variation in Altaian Populations, the Putative Progenitors of Eurasian and Native American Populations.** *T.G. Schurr*<sup>1</sup>, *S.I. Zhadanov*<sup>1, 2</sup>, *L.P. Osipova*<sup>2</sup>. 1) Dept Anthropology, University of Pennsylvania, Philadelphia, PA; 2) Institute of Cytology and Genetics, Novosibirsk, Russia.

The Altai Mountain region has recently been suggested as the homeland for modern native Siberian and Native Americans whose common ancestors may have inhabited these lands many millennia ago. However, a number of distinct tribes that differ linguistically and anthropologically from each other now populate this region, with these differences probably reflecting their heterogeneous origins and ethnic histories. To ascertain the degree of biological relatedness of these groups, and determine the extent of their genetic contribution to the peopling of Eurasia and the Americas, we collected samples from several ethnic groups from the Altai Republic and analyzed sequence variation in their mtDNAs. These included 350 individuals from the northern Chelkans, Kumandinians, and Tubalars, and 275 individuals from the southern Altay-kizhi. For all mtDNAs, we sequenced the entire control region and screened each sample for diagnostic RFLP markers of West and East Eurasian haplogroups, while, for a subset of them, we also performed whole genome sequencing. Our initial results indicate that about 75% of Southern Altaian mtDNA haplotypes belong to East Eurasian maternal lineages, namely, haplogroups CZ, D, F, G, M8a, and M9a, while the remainder belong to West Eurasian haplogroups H, TJ, XI, and UK. Relatively similar frequencies of these haplogroups also occur in northern Altaians, who exhibit less diversity of West Eurasian haplogroups than southern Altaians. When contextualized with genealogical information, such data will allow us to reconstruct the genetic histories of Northern and Southern Altaian populations, as well as delineate the relationships between Altaian and other native Siberian populations, particularly other Turkic speaking groups such as Tunisiens, Tofalars and Yakuts, with whom they may share certain biological similarities.

**MALARIAL SELECTION AND THE DOGON: PATTERNS OF DNA SEQUENCE VARIATION AT THE -GLOBIN LOCUS.** *E.T. Wood<sup>1</sup>, D.A. Stover<sup>1</sup>, B.I. Strassman<sup>2</sup>, M.W. Nachman<sup>1</sup>, M.F. Hammer<sup>1</sup>*. 1) Ecol & Evol Biol, Univ Arizona, Tucson; 2) Anthropology, Univ Michigan, Ann Arbor.

Infectious diseases have affected humans throughout our evolutionary history yet the nature and magnitude of this selective pressure in shaping patterns of genetic variation remain elusive. To better understand the genetics of resistance to infectious diseases, we examine patterns of sequence variation at the -globin locus in the Dogon who reside in an endemic malarial environment in Mali, West Africa. The malarial resistance HbC allele is virtually restricted to West Africa and is found at a frequency of ~11% in the Dogon. We evaluated sequence variation in a number of contexts. First, we compare patterns of variation at -globin for 48 Dogon individuals to 3 other loci which are not likely to be under selection. Second, we compare patterns of variation at -globin in the Dogon with 5 other worldwide populations. Third, we resolve linkage phase across 1-kb located within the region of increased recombination for 38 HbAA, HbAC, and HbCC Dogon individuals. Fourth, we determine chromosomal linkage phase for 3-kb in the same region for 20 HbAC and HbCC individuals from Ghana, the Ivory Coast, and the Dogon. Neither levels of diversity (as measured by the HKA test) nor the skew in the frequency spectrum (as measured by Tajima's D) at -globin in the Dogon reject a model of neutral evolution. We also examine linkage disequilibrium patterns, which provides a more powerful approach for identifying selection on a new allele. The degree of linkage disequilibrium is compared between HbC (n=10) and HbA (n=66) chromosomes. We find that across a 1-kb region, only one HbC haplotype is represented; whereas, at least 6 haplotypes are found associated with the HbA chromosomes. An extended analysis of 3-kb also reveals fewer haplotypes associated with the HbC mutation than the HbA chromosomes. These results are consistent with a model of selection acting on the HbC alleles at the -globin locus in the Dogon. To further support this inference and to clarify the model of selection acting at -globin, we are extending the analysis to include more HbC chromosomes across a larger sequenced region.

**Family history, SELP and ITGB3 polymorphisms and their association with premature MI.** *J. Wessel*<sup>1,2</sup>, *J.J. McCarthy*<sup>2</sup>, *E.J. Topol*<sup>3</sup>. 1) University of California, San Diego, CA; 2) San Diego State University, San Diego, CA; 3) Cleveland Clinic, Cleveland, OH.

Premature MI has been considered to have a stronger genetic basis than late-onset MI. Family history serves as a proxy for the contribution of genetic factors and shared environment. The purpose of the present study is to assess the contribution of family history, clinical covariates and polymorphisms in 19 candidate genes and their association with premature MI. A case series of 469 men and women with MI were dichotomized by age of onset to define premature disease (<55 years men, <65 years women). Different definitions of family history were used to determine which is the strongest predictor of premature MI. One polymorphism each from 19 candidate genes was selected based on their frequency, functionality and missing data. Each polymorphism and clinical covariate was evaluated for their association with premature MI and age of onset of MI. In our series of 223 premature MI cases and 188 late-onset cases, we found parental history of premature MI to be the strongest predictor of premature MI of all of the definitions considered, even after adjustment for other risk factors (odds ratio 1.42,  $p=0.006$ ). High cholesterol ( $p=0.011$ ) and gender ( $p<.0001$ ) were also significantly associated with premature MI. The four most significant polymorphisms ( $p$ 's<.25) (Q534R F5, R478K FGB, 511(G/A) ITGB3 and S290N SELP) were entered into a multivariate model and their contribution reassessed. Only the ITGB3 polymorphism was significantly associated with premature MI (odds ratio 0.43,  $p=0.042$ ), after adjustment for parental history, gender, high cholesterol, FGB and SELP polymorphisms. The SELP polymorphism approached significance ( $p=0.081$ ). When considering their association with age of onset of MI as the outcome, the SELP N allele was associated with a later age of onset (59.92.6 vs. 53.10.9,  $p=0.009$ ). This suggests the ITGB3 and the SELP polymorphisms may be associated with later onset of MI. Family history is still an independent risk factor for premature MI even when accounting for some of the genetic variation that exists.

**Testing for Population Stratification in Case-Control Studies of Asthma Among Latinos.** *N. Coyle<sup>1</sup>, D. Lind<sup>1</sup>, H. Tang<sup>2</sup>, K. Salari<sup>1</sup>, S. Choudry<sup>1</sup>, S. Clark<sup>1</sup>, N. Ung<sup>1</sup>, H. Matellena<sup>1</sup>, P. Avila<sup>1</sup>, J. Casal<sup>3</sup>, A. Torres<sup>3</sup>, S. Nazario<sup>3</sup>, M. Toscano<sup>1</sup>, W. Rodriguez-Cintron<sup>3</sup>, P. Kwok<sup>1</sup>, D. Sheppard<sup>1</sup>, M. Shriver<sup>4</sup>, N. Risch<sup>5,6</sup>, E. Ziv<sup>1</sup>, E. Burchard<sup>1</sup>.* 1) Univ California, San Francisco, San Francisco, CA; 2) Fred Hutchinson Cancer Center, Seattle WA; 3) University of Puerto Rico, San Juan PR; 4) Penn State Univ, Alleghany PA; 5) Stanford Univ, Palo Alto CA; 6) Kaiser Division of Research, Oakland CA.

**Purpose:** Case-control studies are a powerful approach to detect common low to moderate susceptibility alleles for complex diseases. However, such studies may be confounded in populations with substructure and/or recent admixture such as Latinos. We tested whether population stratification may affect the results of case-control studies in Puerto Ricans and Mexican Americans. **Methods:** We compared 93 Puerto Rican asthmatics with 93 healthy Puerto Ricans and 93 Mexican American asthmatics with 93 healthy Mexican Americans. Cases and controls were recruited from the same clinics. We typed 44 markers selected for their high allele frequency differences between West Africans, Europeans and Native Americans. For each population we tested whether the degree of association between pairs of markers on different chromosomes was greater than expected using a permutation test. Population stratification was assessed by comparing the global differences in allele frequencies between cases and controls. **Results:** Among Puerto Ricans, the association between markers on different chromosomes was significantly greater than expected ( $p < 0.0001$ ). Among Mexicans, there was a non-significant trend towards association between markers on different chromosomes ( $p = 0.07$ ). Among Puerto Ricans, 6 of 44 markers were significantly associated with asthma, and there was a significant difference between cases and controls ( $p = 0.019$ ). Among Mexican Americans 2 of 44 markers were associated with asthma and there was no significant difference between cases and controls ( $p = 0.64$ ). **Conclusion:** Asthma case-control studies may be confounded in some admixed populations. Empirical assessment of the effects of stratification will be important to appropriately interpret the results of case-control studies.

**Genetic structure inferred from surnames for all rural localities in Sao Miguel Island (Azores).** *S. Costa, C.C. Branco, R. Cabral, T. Cymbron, P.R. Pacheco, L. Mota-Vieira.* Genetics & Molec Pathol Unit, Hosp Divino Espirito Santo, Azores Islands, Portugal.

Sao Miguel is the biggest (747 Km<sup>2</sup>) and most populated (131,609 inhabitants) island of the Azores, a Portuguese archipelago located in the north Atlantic Ocean. The island includes 2 urban, 8 semi-urban and 44 rural localities (where 50% of the population lives). The mean number of inhabitants and families by rural locality are 1,510 (309-7,407) and 410 (101-1,711), respectively. In the present study, we infer the genetic structure of rural population, using the 2001 telephone directory. In a total of 12,625 subscribers we found 812 different surnames, of which only 92 subscribers have foreign surnames. The highest value of surname diversity was found in Capelas (socio-economically more developed) and Rabo-de-Peixe (the most populated); and the lowest value was found in Lomba de S. Pedro (the least populated). In order to characterize surname diversity, we estimated the coefficient of relationship between localities ( $R_{ij}$ ), the random component of inbreeding ( $F_{st}$ ) for each locality and Nei's genetic distance. The analysis of rural population relationships reveals that Povoacao and Nordeste are the two localities with highest value of  $R_{ij}$  (0.217), whereas Capelas and Nordeste have the lowest value (0.0042). The rural locality displaying the greatest homogeneity is Salga ( $F_{st}=0.0145$ ). The genetic similarity between localities was obtained by a dendrogram based on Nei's distance matrix. We identified two main clusters, one includes Nordeste and Achada, both located in the most eastern part of S. Miguel, and the other includes the remaining 42 localities grouped in three major subclusters. The subcluster that stands out groups all the localities of the western part of the island. These data are consistent with the spatial distribution of surnames obtained by Principal Component (PC) analysis. In fact, the first two PC account for 59% of the total variance and shows a cluster at the upper left corner of the plot with 8 western localities. These findings are valuable for an ongoing project based on DNA sampling of S. Miguel's population. Funded by DRCT-Azores. (lmotavieira@hdes.pt).

**Spatial analysis of the Azorean population based on surname diversity.** *R. Cabral<sup>1</sup>, C.C. Branco<sup>1</sup>, S. Costa<sup>1</sup>, G.U. Caravello<sup>2</sup>, M. Tasso<sup>2</sup>, L. Mota-Vieira<sup>1</sup>.* 1) Genetics & Molec Pathol Unit, Hosp Divino Espirito Santo, Azores Islands, Portugal; 2) Dipartimento di Medicina Ambientale e Sanità Pubblica - sede di Igiene, Università di Padova, Padova, Italy.

Azores is a Portuguese archipelago located in the middle of the Atlantic Ocean. The islands are dispersed over 3 geographic groups: oriental (Sao Miguel and Santa Maria), central (Terceira, Faial, Pico, Graciosa and Sao Jorge) and occidental (Flores and Corvo). Here, we outline the structure of the Azorean population based on surname specificity and distribution. Using the telephone directory (2001), we identified 2,455 different surnames in a total of 55,530 subscribers. In order to characterize the influence of geographic discontinuity on surname diversity, we performed a surname specificity analysis. Our results reveal that each island has surnames 50% more frequent than in the rest of the archipelago (specific surnames). This is particularly evident in the islands of S. Miguel (14 specific surnames with frequency 75%), Santa Maria (2 specific surnames with frequency 80%) and Terceira (2 specific surnames with frequency 90%). Corvo is the only island where a single surname has a value of 100%. To evaluate the genetic similarity between the islands's populations, we then analyzed surname distribution by spatial autocorrelation (Moran's *I*). In a total of 161 surnames, we identified 24 (15%) surnames with statistically significant patterns for 4 distance classes. These patterns were classified as: isolation by distance and depression (37.5%), cline (12.5%), intrusion (12.5%) and long-distance differentiation (8.3%). The remaining 29.2% had no defined pattern. The overall spatial correlogram plot of the 24 surname frequencies shows that the highest Moran's *I* coefficient (0.69) was present in the first distance class (105 Km). Moreover, autocorrelation change from positive to negative for distances greater than 105-250 Km, indicating that mobility is higher between islands of the same geographic group. In population genetic terms, the data show that geographic distance shapes surname diversity among Azores Islands. Funded by DRCT, Azores. (lmotavieira@hdes.pt).

**False positive rates in association studies as a function of marker allele frequency difference between subgroups.**

*D.L. Koller<sup>1</sup>, M. Peacock<sup>2</sup>, T. Foroud<sup>1</sup>, M.J. Econs<sup>1,2</sup>.* 1) Dept of Medical & Molecular Genetics, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Dept of Medicine, Indiana Univ Sch Medicine, Indianapolis, IN.

Uncorrected, racial stratification can result in spurious association findings. This is particularly important for phenotypes with known racial differences such as bone mineral density (BMD), where African American women have significantly higher values as compared with Caucasian women of the same age. We have utilized femoral neck BMD data from a sample of Caucasian (n=381) and African-American (n=126) premenopausal women to examine the effect on association results when the proportion of African American admixture was increased (0%, 1%, 2%, 5%, 10%, 15%, and 20% African-American subjects in the total sample). A genome screen with 373 markers was completed in this sample. Each microsatellite was reduced to a bi-allelic marker, using the most common allele as one allele and binning all other alleles as the second. An ANOVA test of association of BMD was performed in each admixed sample for each marker. We examined the degree to which inflation in the false positive rate (FPR) due to admixture was affected by ethnic differences in the marker allele frequencies, as measured by delta (allele frequency difference/2). We computed the FPR when limiting the biallelic marker set to only those markers with a delta value above the median, and then performed the same analysis for markers with delta values in the lower half of the distribution. For the latter marker set, the inflation was minimal, with FPRs ranging from 0.055 to 0.064 as admixture increased from 1% to 20%. However, for markers in the upper half of the delta distribution, the effect on FPR was quite severe, with a value of 0.122 (compared to the nominal  $\alpha=0.05$ ) for the sample with 20% admixture. The mean delta of the reduced markers in the upper half of the delta distribution is much less (0.12) than the mean delta of all 373 microsatellites before reduction (0.23). This suggests that when multiallelic markers are employed for association tests, the effect of admixture on the FPR would be more severe than the results presented here.

**Determination of Population Structure in the Alzheimers Disease Patient Registry.** *S. Melquist<sup>1</sup>, R. Crook<sup>1</sup>, M. Baker<sup>1</sup>, J. Adamson<sup>1</sup>, R. Mueller<sup>2</sup>, R. Petersen<sup>2</sup>, M. Hutton<sup>1</sup>.* 1) Department of Neurogenetics, Mayo Clinic, Jacksonville, FL; 2) Alzheimer Disease Research Center, Mayo Clinic, Rochester, MN.

The Alzheimers Disease Patient Registry (ADPR), consisting of 300 case and 600 control subjects residing in Olmstead County, Minnesota is potentially a rich resource in genome-wide linkage disequilibrium (LD) mapping of genes involved in Alzheimers Disease (AD). Prior reports of gene variants associated with Alzheimers disease have not been replicated in subsequent studies using other populations (reviewed in 1,2). One explanation for this lack of replication may be that underlying population structure difference between case and control subjects is a confounding factor in the original studies. We hypothesized that population structure may exist in the ADPR samples and underlying structure would be a confounding factor in future AD linkage-disequilibrium studies. Therefore, we examined the extent of population structure in the ADPR series by genotyping a number of unlinked single nucleotide polymorphism and short tandem repeat markers and analyzing the genotype data using the structure program developed by Pritchard and colleagues (3). The results of the population structure analysis of the ADPR series are crucial to future linkage disequilibrium, gene association and epidemiologic studies using this case-control population.

**Time depth of population subdivision within Africa inferred from linked autosomal marker systems (SNPSTRs).**

*M.J. Jobin, U. Ramakrishnan, J.L. Mountain.* Anthropological Sciences, Stanford University, Stanford, CA.

The population history of Africa prior to the movement of anatomically and behaviorally modern humans out of Africa 50,000-75,000 years ago has had a major impact on the genetic relationships of living populations. Different classes of genetic markers are inconsistent regarding levels of population genetic substructure within Africa. The highly polymorphic mitochondrial and Y chromosomal regions have indicated extensive substructure, while microsatellites and SNPs have not. SNPSTRs are tightly-linked autosomal or X-chromosomal marker systems consisting of one Short Tandem Repeat (STR) polymorphism and at least one Single Nucleotide Polymorphism (SNP). The markedly different mutation rates of the two types of markers decrease homoplasy and increase power to distinguish between hypotheses. These systems therefore provide more detailed information regarding population history than either SNPs or STRs alone. We typed two SNPSTR systems in a set of over 1000 individuals from Africa and other regions of the world. Statistics including  $F_{ST}$  and  $D_{SW}$  along with linkage disequilibrium indicate that subdivision within Africa arose prior to the movement of anatomically and behaviorally modern humans out of Africa 50,000-75,000 years ago. These data are most consistent with mtDNA and Y-chromosomal data and contribute to a growing body of evidence for subdivision within Africa prior to that early migration.

**Use of isolated inbred human populations in genetic epidemiology of complex traits: the Carlantino project.** C. Specchia<sup>1</sup>, P. D'Adamo<sup>2</sup>, M. Carella<sup>5</sup>, L. Zelante<sup>5</sup>, F. Bertoldo<sup>4</sup>, A. D'Eustacchio<sup>2</sup>, A. Ferrara<sup>3</sup>, A. Molinari<sup>3</sup>, P. Gasparini<sup>2</sup>. 1) University of Brescia, Italy; 2) TIGEM, Napoli, Italy; 3) SUN, University of Napoli, Italy; 4) University of Verona, Italy; 5) IRCCS, CSS, San Giovanni Rotondo, Italy.

The use of isolated inbred populations to reduce disease heterogeneity of complex disorders is a valid instrument to study genetic basis of complex diseases. The main objective of this project is the epidemiological description and the genetic analysis of a geographic isolate located in Southern Italy in order to construct linkage disequilibrium maps. Carlantino, a small village settled 5 centuries ago by few founders, was identified. The endogamy rate during last century has been calculated to be 99.5% and three different surnames account for the majority of the living people. In addition birth registers are available from 17th century. A screening of the whole population was performed by a full clinical examination of all individuals including anamnesis, blood pressure measurements, electrocardiogram and bone mineral density evaluation, a clinical chemistry evaluation (blood count plus 20 different biochemical parameters), a development of DNAs and sera banks. Information collection was characterized by a high acceptance rate (94%) from the entire population. Data refer to 1417 Carlantino inhabitants, 615 males and 802 females. Haplotypes study of chromosome Y and of mitochondrial DNA confirmed the presence of 6 couples of founders. Epidemiological data suggest an increased frequency of osteoporosis, hypercholesterolemia, hypertension, heart stroke and diabetes compared to the same region standardized rates. Few preliminary polymorphisms of candidate genes (TGFB, Leptin, AIB1) for bone mass, bone turnover and obesity were studied in the whole sample without any result of genetic association to bone mass. Some families with low bone mass as well as one large pedigree characterized from extremely high bone mass values were identified and will be further investigated. Pedigrees showing the presence of many risk factors for coronary artery disease with and without clinical coronary events will also be studied.

**Influence of past migratory events on Croatian female and male gene pool.** *M. Pericic<sup>1</sup>, L. Barac<sup>1</sup>, H.V. Tolk<sup>2</sup>, I. Martinovic Klaric<sup>1</sup>, S. Rootsi<sup>2</sup>, B. Janicijevic<sup>1</sup>, T. Kivisild<sup>2</sup>, J. Parik<sup>2</sup>, R. Villems<sup>2</sup>, P. Rudan<sup>1</sup>.* 1) Institute for Anthropological Research, Zagreb, Croatia; 2) Department of Evolutionary Biology, Institute for Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

Numerous studies of mitochondrial and Y chromosomal biallelic markers have resolved major prehistoric routes of the settling of Europe and proved that the majority of European gene pool has Paleolithic genes. In order to determine the extent of Paleolithic vs. Neolithic impact among Croatian maternal and paternal lineages, we analyzed biallelic markers diagnostic for main Eurasian haplogroups in 457 Croatian Y chromosomes and 721 mitochondrial DNA of inhabitants from various Croatian regions (mainland and four eastern Adriatic islands: north-Krk; south-Brac, Hvar and Korcula). If Y chromosomal haplogroups: J-12f2, G-201, E-SRY4064 and mitochondrial J and T1 are considered as major Neolithic markers, the majority of females and males in the investigated population are carrying Paleolithic haplogroups. Overall, frequency of mitochondrial Neolithic markers is 11.5%; whereas Y chromosomal Neolithic impact is 13.1%. When investigated populations are analyzed separately, the highest mitochondrial Neolithic impact is noticed in mainland population whereas the lowest is on the island of Korcula. For Y chromosomal markers, the lowest Neolithic impact is noticed in mainland population and the highest on the islands of Krk and Korcula. We will discuss the differentiation between mainland and insular populations in the context of random genetic drift as a predominant stochastic process at the islands. Finally, the obtained results will be reviewed with respect to archeological data relevant to material evidence of Paleolithic and Neolithic legacy in the investigated area, both mainland and islands.

**Study of the stratification of Japanese founding lineages.** *K. Tounai<sup>1</sup>, S. Mano<sup>1</sup>, T. Katoh<sup>1</sup>, B. Munkhbat<sup>1, 2</sup>, H. Ando<sup>1</sup>, G. Oyungere<sup>2</sup>, H. Han<sup>3</sup>, N. Saitou<sup>4</sup>, K. Tokunaga<sup>5</sup>, N. Munkhtuvshin<sup>2</sup>, H. Inoko<sup>1</sup>, G. Tamiya<sup>1</sup>.* 1) Dept. of Molecular Life Science, School of Medicine, Tokai University, Isehara, Japan; 2) Central Scientific Research Laboratory, National Institute of Medicine, Mongolia; 3) Dept. of Microbiology, College of Medicine, The Catholic University of Korea, Seoul; 4) Div. of Population Genetics, National Institute of Genetics, Mishima, Japan; 5) Dept. of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan.

Population stratification may cause a spurious association in a case-control study for complex traits. Generally, the Japanese population is considered to be homogeneous. However, for its origins, a dual structure model is more reasonable on the basis of archaeological and morphological findings. Interestingly, the results of Hammer and Horai (1995) suggest that the presence/absence of a specific Alu insertion on Y-chromosome (YAP) corresponds to descendants of two ancestral populations. Here, we have reexamined the dual structure model using 16 biallelic markers on Y-chromosome and then, using 26 Y-STR markers, assess the levels of differentiation between the two major lineages observed in Japan. Subsequently, we have employed 24 unlinked markers (selected from each autosome) to test for stratification between the Japanese subgroups classified by Y-chromosome haplogroups. We confirmed the existence of two major Y-haplogroups (defined by YAP+ and M175, respectively) in the Japanese population, and found a distinctive differentiation between them for 26 Y-STR markers. On the other hand, the Japanese subgroups classified by Y-chromosomal haplogroups showed no significant differentiation or stratification in the test for 24 unlinked STR loci. Furthermore, we performed a simulation study on the basis of genetic distance,  $R_{st}$ , to verify the decay of stratification suggested by the above results. In conclusion, the dual structure model was supported by our analysis of Japanese Y-chromosomes, but no stratification between two Japanese founding lineages was observed broadly over unlinked loci.

**Mexican American ancestry-informative markers: Examination of population structure and marker characteristics in European Americans, Mexican Americans, Amerindians and Asians.** *M.F. Seldin<sup>1</sup>, H.E. Collins-Schramm<sup>1</sup>, B. Chima<sup>1</sup>, T. Morii<sup>1</sup>, K. Wah<sup>1</sup>, Y. Figueroa<sup>1</sup>, L.A. Criswell<sup>2</sup>, R.L. Hanson<sup>3</sup>, W.C. Knowler<sup>3</sup>, G. Silva<sup>4</sup>, J.W. Belmont<sup>5</sup>*. 1) Rowe Program, Univ California, Davis, CA; 2) Ctr for Arthritis, Univ California, San Francisco, CA; 3) National Institutes of Health, Phoenix, AZ; 4) Obras Sociales del Hermano Pedro, Antigua, Guatemala; 5) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Markers with large differences in allele frequencies between ethnicities provide ancestry information that can be applied to genetic studies. These markers also provide an opportunity to examine population structure and relationships between populations. We identified over 100 biallelic Ancestry Informative Markers (AIMs) with large allele frequency differences between European Americans (EA) and Pima Amerindians from laboratory and database screens. For 35 of these markers, Mayan, Yavapai and Quechuan Amerindians were genotyped and compared with EA and Pima allele frequencies. Markers with large allele frequency differences between EA and one Amerindian tribe showed only small differences between the Amerindian tribes (e.g. the mean standard variance ( $f$ ) for EA/Pima = 0.36, while Pima/Mayan = 0.02). Examination of structure in individuals demonstrated a clear separation of subjects of European from those of Amerindian ancestry, and a remarkable similarity between individuals from disparate Amerindian populations. The AIMs demonstrated the variation in ancestral composition of individual Mexican Americans, providing evidence of applicability in admixture mapping and in controlling for structure in association tests. In addition, a high percentage of SNPs selected on the basis of large frequency differences between EA and Asian populations had large allele frequency differences between EA and Amerindians (e.g. 13/30 markers with EA/Japanese  $f > 0.3$  had EA/Pima  $f > 0.30$ ), suggesting an efficient method for greatly expanding AIMs for use in admixture mapping/structure analysis in Mexican Americans. Together, these data provide additional support for the practical application of admixture mapping in the Mexican American population.

**Caste, geography and genetic structure in Hindu populations.** *D.J. Witherspoon<sup>1</sup>, T.N. Srinivasan<sup>3</sup>, R. Thara<sup>3</sup>, D.J. Nancarrow<sup>4</sup>, W.S. Watkins<sup>1</sup>, M. Bamshad<sup>1</sup>, B.J. Mowry<sup>2</sup>, L.B. Jorde<sup>1</sup>.* 1) Dept. of Human Genetics, University of Utah, Salt Lake City, UT; 2) Dept. Psychiatry, University of Queensland, Brisbane, Australia; 3) Schizophrenia Research Foundation India, Chennai, Tamil Nadu, India; 4) Queensland Institute of Medical Research, Herston, Brisbane, Australia.

The effect of Hindu caste rank on genetic structure is controversial. Small genetic data sets lack statistical power, while geographical and caste effects can be confounded. In the largest data set yet collected, from upper, middle and lower caste populations in Andhra Pradesh, we found the largest genetic distance between upper and lower castes. In an attempt to replicate these findings in another location, we obtained mtDNA HVS1 sequence from 186 individuals from Tamil Nadu, 800 km to the south. Four groups were sampled in nearly equal numbers: Tamil- and non-Tamil-speaking Brahmins (upper caste), Mudaliar (middle) and Harijan (lower). In both data sets, the upper caste populations had the least genetic diversity, in accord with their presumed lower effective population sizes. By Nei's genetic distance, the non-Tamil-speaking Brahmin, Mudaliar, and Harijan are each most similar to the upper, middle and lower caste groups from AP, respectively. This suggests that caste divisions outweigh geographical effects at this range. The Tamil-speaking Brahmin are unusual in that they are most similar to the lower caste group from Andhra Pradesh and most different from the upper-caste group. (Support: NSF SBR-9514733, SBR-9512178, SBR-9818215)

**Nei's genetic distance (x100,000) between caste groups in Andhra Pradesh (rows) and Tamil Nadu**

	NonTamil	Brahmin	Mudaliar	Harijan	Tamil Brahmin
Upper	27	55	63	71	
Middle	37	44	45	60	
Lower	45	72	33	54	

**The gender effect in juvenile Huntington disease patients of Italian origin.** *M. Cannella<sup>1</sup>, C. Gellera<sup>2</sup>, V. Maglione<sup>1</sup>, P. Giallonardo<sup>1</sup>, G. Cislighi<sup>3</sup>, M. Muglia<sup>4</sup>, A. Quattrone<sup>4</sup>, F. Pierelli<sup>5</sup>, S. Di Donato<sup>2</sup>, F. Squitieri<sup>1</sup>.* 1) Neurogenetics Unit, IRCCS NEUROMED, POZZILLI, IS, Italy; 2) . Division of Biochemistry and Genetics, Neurological Institute IRCCS C. Besta, Milan, Italy; 3) Division of Neurology, Fornaroli Hospital, Magenta (MI), Italy; 4) . Institute of Experimental Medicine and Biotechnology, National Research Council (CNR), Piano Lago Mangone (CS), Italy; 5) Dept. of Neurological Sciences, University La Sapienza, Rome.

We analyzed a population of juvenile Huntington disease (HD) subjects of Italian origin (n = 57). The main aim of this study was to analyze the gender effect of the affected parent on age at onset and clinical presentation of offspring with juvenile HD. We also analyzed molecular features of the disease, including CAG mutation length and GluR6 gene polymorphism, according to the affected parents gender. The mutation length was longer in paternally than in maternally transmitted HD juvenile patients (p = 0.025), nevertheless a similar mean early onset in the two groups (p > 0.05). This data was even enforced by that obtained from the whole cohort of patients included in the databank (n = 600) where, in the presence of increased mean parent-child CAG repeat change in paternal vs maternal meiotic transmissions (+ 7.3 vs + 0.7 CAG, p = 0.0002), the mean parent-child year-of-onset change was similar in the two groups (-10.4 and 7.0 years, p > 0.05). A lower TAA-triplet in GluR6 was associated with an earlier age at onset in juvenile patients (p = 0.031, R<sup>2</sup> = 0.10). When we added the GluR6 effect on age at onset to the CAG expanded number effect (p = 0.0001, R<sup>2</sup> = 0.68) by multiple regression approach, the coefficient of determination R<sup>2</sup> increased to 0.81. This effect in addition to the expanded CAG repeat number, found in juvenile and not in adult patients, was slightly enforced by paternal compared to maternal transmissions (R<sup>2</sup> 0.82). Our findings suggest the occurrence of a weaker effect of the paternal mutation on juvenile age at onset in our population, possibly amplified by other genetic factors, such as the TAA-triplet length in the GluR6 gene.

**Segregation Analysis of Intraocular Pressure in the Beaver Dam Eye Study.** *P. Duggal<sup>1</sup>, A.P. Klein<sup>1</sup>, K.E. Lee<sup>2</sup>, R. Klein<sup>2</sup>, J.E. Bailey-Wilson<sup>1</sup>, B.K. Klein<sup>2</sup>.* 1) Statistical Genetics Section, IDRB/NHGRI/NIH, Baltimore, MD; 2) Dept of Ophthalmology and Visual Sciences, University of Wisconsin-Madison Medical School.

Primary open-angle glaucoma is a leading cause of blindness in the world. In the US, it is estimated that 3 to 6 million people have elevated intraocular pressure (IOP) and are at an increased risk for developing glaucoma. To investigate a potential genetic contribution to IOP, we performed a complex segregation analysis on 2,337 individuals in 620 extended pedigrees ascertained through a population-based cohort, the Beaver Dam Eye Study in Beaver Dam, Wisconsin. Detailed medical histories and eye examinations were performed on all participants. Intraocular pressure was measured with a Goldmann applanation tonometer in each eye. The higher IOP measurement between the eyes was used as a continuous trait, and treatment with drops and age were covariates. Analyses were conducted using regressive class D models in REGC in S.A.G.E 3.1. This segregation analysis does not support a single major Mendelian locus for IOP since these models were rejected. The most parsimonious model was an environmental mixed model with the transmission probabilities ( $\tau$ ) equal to the allele frequency. This model was not rejected ( $p=0.39$ ) when compared to a totally unrestricted (general) model. Another version of the general model (semi-general) commonly used to test for the presence of a major locus effect in a mixed model is one in which the  $\tau$  of the A allele for AA and BB genotypes are fixed to 1.0 and 0, and the remaining parameters are unrestricted. This model was not rejected ( $p=0.13$ ) and yielded an estimate of the  $\tau_{AB}$  genotype of 0.66, close to its Mendelian value of 0.5. Since we could not reject the environmental mixed model with equal  $\tau$ s it is plausible that there are non-transmitted or environmental factors that influence IOP. When the Mendelian dominant mixed model was compared to the semi-general model, the dominant model was marginally non-significant ( $p=0.056$ ). This is consistent with a multifactorial model that may include multiple genes and environmental factors that contribute to IOP.

**Molecular testing of buccal cell DNA is the method of choice for Tay Sachs Disease screening in Ashkenazi Jewish high schools.** *A. Bankier*<sup>1, 2, 3</sup>, *A. Gason*<sup>1</sup>, *E. Sheffield*<sup>2</sup>, *V. Petrou*<sup>2</sup>, *M.B. Delatycki*<sup>1, 2, 3</sup>. 1) Genetic Health Services Victoria, RCH, Victoria, Australia; 2) Bruce Lefroy Centre for Genetic Health Research, RCH, Victoria, Australia; 3) Murdoch Childrens Research Institute, RCH, Victoria, Australia.

Tay Sachs disease is an autosomal recessive neurodegenerative condition that is more common in the Ashkenazi Jewish community and generally results in those affected dying before five years. Carrier screening programs have been very successful in reducing the incidence of this disease. Carrier screening has traditionally been done by measuring levels of hexosaminidase A in blood. Molecular testing for three common mutations allows over 98% of Ashkenazi Jewish carriers to be identified. Some have argued that enzyme analysis should nevertheless be used, as ancestry is sometimes uncertain. We have conducted a screening program in Jewish day schools since 1997. Screening has been by enzyme analysis until this year where we have changed to buccal swab molecular DNA testing. From 1998 to 2003 the education and testing process has been identical apart from the testing method in 2003. Students receive education and 2-10 days later are offered screening after one to one counselling. Testing is free of charge. We surveyed students who chose not to be tested in 2002 as to whether they would have done so had testing been by buccal swab rather than venesection. 16/24 (66.7%) indicated that they would have done so. From 1999-2002, 780/965 (81%) of students had testing by blood enzyme analysis. In 2003, 222/229 (97%) of students had testing by buccal swab and molecular analysis. This is a significant increase in uptake ( $\chi^2=35.6$ ;  $p<10^{-4}$ ). Therefore, more students who wish to have testing do so where it is offered by buccal swab rather than venesection.

**Adult genetic services generate revenue for a university medical center.** *R.L. Bennett<sup>1</sup>, D.L. Olson<sup>1</sup>, P.H. Byers<sup>1,2</sup>.*  
1) Division of Medical Genetics, University of Washington, Seattle, WA; 2) Department of Pathology.

Services provided to 834 patients seen at the Adult Medical Genetics Clinic (AMGC) at the University of Washington Medical Center (UWMC) were tracked from July 2001 through June 2002. Patients were seen with 150 different diagnoses. There were 1093 visits, a 376% increase from 1996. Fifty-seven percent of patients were new to the UWMC at the time of referral to the AMGC. Thirty-six percent of patients had procedures or laboratory studies ordered at their AMGC visit--44% of these laboratory studies were performed at UWMC, and 90% of the procedures ordered were performed at UWMC. AMGC providers made 80 patient referrals to other UWMC clinics. The vast majority of patients seen during the study period were referred by an outside provider; only 18% of patients were referred to AMGC by a UWMC provider. In addition to the fees generated for AMGC visits, the revenue generated for laboratory tests performed at UWMC was \$35,000-\$36,000, \$77,000-94,000 for procedures done at UWMC, and \$38,000-43,000 for new consultations with other UWMC providers. These data indicate that an adult genetics clinic is an entry to medical care for patients with complicated medical diseases, many of whom will continue their care with other health care providers at the medical center. The services coordinated through a medical genetics clinic generate substantial revenue and bring prestige to the medical center.

**Recurrent *de novo* mitochondrial DNA mutations in respiratory chain deficiency.** *S. Lebon<sup>1</sup>, M. Chol<sup>1</sup>, P. Bénit<sup>1</sup>, C. Mugnier<sup>1</sup>, D. Chretien<sup>1</sup>, I. Giurgea<sup>1</sup>, I. Kern<sup>3</sup>, E. Girardin<sup>3</sup>, L. Hertz-Pannier<sup>2</sup>, P. de Lonlay<sup>1</sup>, A. Rötig<sup>1</sup>, P. Rustin<sup>1</sup>, A. Munnich<sup>1</sup>.* 1) INSERM U393 and Department of Genetics, Hôpital Necker, Paris, France; 2) Department of Pediatric Radiology, Hôpital Necker, Paris, France; 3) Department of Pediatrics, Hôpitaux Universitaires de Genève, Genève, Switzerland.

Starting from a cohort of 50 NADH-oxidoreductase (complex I) deficient patients, we carried out the systematic sequence analysis of all mitochondrially-encoded complex I subunits (ND1 to ND6 and ND4L) in affected tissues. This approach yielded the unexpectedly high rate of 20% of mutation identification in our series. Heteroplasmic recurrent mutations included two hitherto unreported (T10158C and T14487C) and three previously reported mutations (T10191C, T12706C and A13514G) in children with Leigh or Leigh-like encephalopathy. Surprisingly, the recurrent mutations consistently involved T-C transitions (p10-4). Why specific mitochondrial (mt) DNA residues (thymine and guanine) were recurrently targeted in respiratory chain deficiency remains unexplained. One can hypothesize that the thymine and guanine residues were more vulnerable to ROS-induced oxidative damages into the mitochondria. Whatever the mechanism, this study supports the view that an efficient molecular screening should be based on an accurate identification of respiratory chain enzyme deficiency.

**Folate Metabolizing gene polymorphisms and Head and Neck cancer.** *H. Chen<sup>1</sup>, K. Yanamandra<sup>1</sup>, J. Rodriguez-Paris<sup>2</sup>, M. Smith<sup>2</sup>, D. Napper<sup>1</sup>, T.F. Thurmon<sup>1</sup>, S.A. Ursin<sup>1</sup>, R. Dhanireddy<sup>1</sup>, J.A. Bocchini Jr.<sup>1</sup>, G.M. Mills<sup>2</sup>, J. Glass<sup>2</sup>.*

We have a long-standing interest in the relationship of Methylene tetrahydrofolate reductase (MTHFR) genotypes and birth defects. We found a significant association of maternal MTHFR genotypes with Trisomy 18 but not with Down syndrome pregnancies. Then, we extended our studies to the associations of folate and cobalamin metabolizing gene polymorphisms with orofacial clefts, vascular conditions such as retinal vascular occlusions, and recently, to cancer etiology. We found significant associations between maternal MTHFR genotypes and cleft palate, and between patient MTHFR genotype and retinal vascular occlusions. In studies in West Africa, we found a much lower frequency of MTHFR mutant genotypes and the correlation with orofacial clefts was less significant. This implied an ethnocentric mechanism for the association. In the present research project we studied over 300 non-Hispanic white patients with various forms of cancer including over 80 patients with Head and Neck cancer to investigate the relationship of MTHFR genotypes and the cancer etiology, using allele specific multiplex PCR genotyping method. Our pilot data showed 11% 677TT mutant homozygotes, 52% 677CT Heterozygotes, and 36% 677CC normal homozygotes in Head and Neck cancer patients compared to control frequencies of 13%, 45%, and 42%, suggesting similar frequencies of MTHFR mutant genotypes between Head and Neck cancer and controls. This is the first study of this type. If our data are verified by other centers, there is neither association of MTHFR mutant genotype with this cancer (odds ratio 1.1) nor protection by normal genotype. Data on various cancer types, genotypes, and statistics will be presented.

**The Manitoba Experience with *GJB2* & *GJB6* Genetic Testing.** *T.L. Dyck*<sup>1</sup>, *S.L. Marles*<sup>2,3</sup>, *J. Gorin*<sup>2</sup>, *E. Grudeski*<sup>1</sup>, *E.L. Spriggs*<sup>1,2,3</sup>. 1) Molecular Diagnostic Lab, Health Sciences Centre, Winnipeg, Canada; 2) Section of Genetics & Metabolism, Health Sciences Centre, Winnipeg, Canada; 3) Depts. of Pediatrics & Child Health and Biochemistry & Medical Genetics, Univ. of Manitoba, Winnipeg, Canada.

Non-syndromic hearing loss (NSHL) accounts for 70% of hereditary deafness. Mutations in the *GJB2* gene are the predominant cause of the autosomal recessive form of NSHL. The most common mutation, 35delG, accounts for half of all *GJB2* mutations. Ethnic-specific mutations, including 235delC in the Asian population, and 167delT in the Ashkenazi Jewish, have also been identified. Manitoba, a Canadian province, has a unique population with a number of different ethnic groups. The objective of this study was to determine the prevalence of *GJB2* and *GJB6* mutations in Manitobans with autosomal recessive NSHL. Fifteen unrelated patients with bilateral hearing loss and no evidence of syndromic or environmental involvement were accepted into the study. All patients were tested for the 35delG and 167delT mutations. If no mutation or only one was found, the entire gene was sequenced. One third of the patients had two *GJB2* mutations. Four were homozygous for the 35delG mutation. One child of part Japanese ethnicity was determined to be a compound heterozygote with the Asian 235delC mutation and a rare E120 mutation. Another patient was heterozygous for the M34T mutation; the significance of this mutation is unclear as it has been reported in the literature as an autosomal dominant, an autosomal recessive, as well as a non-disease causing change. Given the recent finding regarding the contribution of *GJB6* to NSHL, all patients were also analyzed for the common 342 Kb deletion in the *GJB6* gene. To date, no patients were found to harbour this deletion or any other *GJB6* mutation. From our results it can be concluded that 35delG is the most common mutation in our population. Due to the diversity of ethnic groups in Manitoba, sequence analysis of the *GJB2* gene should be performed on all patients as the compound heterozygote (235delC/E120) would not have been identified if analysis had stopped when no 35delG mutations were detected. Furthermore, *GJB6* does not appear to be a common cause of NSHL in Manitoba.

**Genetic diagnosis in congenital deafness: molecular analysis of Connexin 26, Connexin 30 and Pendrin. R.**

*BERNARD<sup>1</sup>, S. SIGAUDY<sup>1</sup>, S. ROMAN<sup>2</sup>, D. TAULIER<sup>1</sup>, JM. TRIGLIA<sup>2</sup>, N. LEVY<sup>1, 3</sup>.* 1) Departement de Genetique Medicale, Hopital d'enfants de la Timone, Marseille, France; 2) Service d'Oto-Rhino-Laryngologie pediatrique, Hopital d'enfants de la Timone, Marseille, France; 3) Inserm U491 Genetique Medicale et Developpement, Faculte de Medecine de la Timone, Marseille France.

Despite the fact that hereditary hearing loss is a frequent and heterogeneous disorder, high prevalence of connexin 26 (GJB2) mutations in congenital isolated deafness has been demonstrated. More recently the implication of connexin 30 (GJB6), located also on chromosomal region 13q12, has been reported in some deaf families in association with Cx26 mutations, suggesting a possible complexity of the mechanisms responsible for some congenital cases of deafness, such as digenism. In addition, the Pendrin (PDS) gene is known to be responsible for the Pendred syndrome, which is an autosomal recessive form of deafness associated with developmental abnormalities of the cochlea and goiter. However, the PDS gene could be also involved in non syndromic hearing loss, though its frequency in this case remains to be determined. Here we present the study of a serie of 52 unrelated deaf patients, clinically evaluated and explored by molecular analysis of Cx26, Cx30, and PDS. We report an original method for rapid detection of the most frequent mutation of Cx26, the 35delG, based on fluorescent PCR. Our study allowed the identification of Cx26 mutations in 30% of the cases ; deletion of Cx30 was observed in 2 patients, and PDS analysis identified genomic variations in six patients. Our results include genotype-phenotype correlations and tend to raise up again the difficult questions of molecular strategy and genetic counselling in heterogeneous non lethal disorders, such as neurosensory disorders.

**Connexin-26 mutations associated with the most common form of non-syndromic neurosensory autosomal recessive deafness (DFNB1) in the Iranian Population.** *M. Mohseni*<sup>1</sup>, *S. Arzhangi*<sup>1</sup>, *R.A. Cucchi*<sup>2</sup>, *Y. Riazalhosseini*<sup>1</sup>, *M. Malekpour*<sup>1</sup>, *A. Daneshi*<sup>3</sup>, *M. Farhadi*<sup>3</sup>, *K. Kahrizi*<sup>1</sup>, *Y. Shafeghati*<sup>1</sup>, *R.J.H. Smith*<sup>2</sup>, *H. Najmabadi*<sup>1</sup>. 1) Genetics Research Center, The Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA; 3) Department of Otolaryngology, Rasoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran.

The incidence of congenital hearing loss is approximately 1 per 1000-2000 infants. In many populations of European descent, mutations in *GJB2* (chromosomal locus 13q11-q12) encoding the gap-junction protein connexin-26 (Cx26) are the most common known cause of severe-to-profound deafness that is inherited in an autosomal recessive fashion (DFNB1). One mutation in *GJB2* (35delG) accounts for approximately two-thirds of all Cx26 mutations in DFNB1 patients. We also established the efficacy of Denaturing High Performance Liquid Chromatography (DHPLC) as a screening assay for detecting mutations in the coding region of *GJB2* in 220 patients with hereditary hearing impairment. Sequence confirmation was 100% concordant with DHPLC and identified allele variants in 21 patients. These mutations included: 167delT, R184P, R32H, - 3170GA, delE120, V153I, V27I, 329delA, I69I, W24X, R127H. V153I (in 9 patients) and V27I are common polymorphisms. 329delA and I69I are novel allele variants. We screened patients heterozygous for only one *GJB2* allele variant (12 probands), as well as 103 patients with wild-type alleles, for (*GJB6-D13S1830*). No deletion was detected in any patient. These data suggest that other loci may make major contributors to the ARNSHL genetic load in the Iranian population.

**Assessing *GJB2/GJB6* testing and counseling as adjunct to newborn hearing screening.** C. Palmer<sup>1</sup>, A. Martinez<sup>1</sup>, M. Fox<sup>1</sup>, B. Crandall<sup>1</sup>, N. Shapiro<sup>1</sup>, M. Telatar<sup>1</sup>, Y. Sininger<sup>1</sup>, W. Grody<sup>1</sup>, L. Schimmenti<sup>2</sup>. 1) UCLA, Los Angeles, CA; 2) U Minn, Minneapolis, MN.

Introducing genetic information into the early hearing detection and intervention (EHDI) process may streamline diagnosis and treatment of infants with hearing loss. Here we describe our early experience in a 4y, prospective, longitudinal study in an ethnically diverse population to assess the timing and impact of *GJB2/GJB6* testing and counseling in the EHDI process. Testing is offered at 2 different points: 1) after failure of newborn screening but before final diagnosis (prediagnosis) and 2) after diagnosis of hearing loss (postdiagnosis). Families are eligible if the child with (potential) hearing loss has no other medical conditions and is <2y. Following informed consent through parental genetic counseling, the child's genomic DNA is subject to mutation analysis (*GJB2*: 35delG, 235delC, 167delT; *GJB6*: 342kb del) and *GJB2* sequencing as needed. Family history and demographic data are collected. Questionnaires assessing parental anxiety, perceived personal control, risk perception, attitudes toward genetic testing, and understanding are completed at enrollment, 1m-and 6m-post genetic counseling of results. Genetic evaluation is performed, medical and audiology records are obtained for up to 4y. To date, 9 ethnically diverse families, with no other history of congenital hearing loss, are enrolled in the postdiagnosis group. At enrollment, all parents (n=12) felt that genetic testing could help them understand why their child has hearing loss, and the majority felt that it was somewhat likely that their child had *GJB2/GJB6*-related hearing loss. 5 babies were found to have *GJB2*-related hearing loss; 1m after disclosure, these parents responded that their child definitely had *GJB2*-related hearing loss. Hearing loss of 4 babies was not explained by genetic testing; 1m after disclosure, these parents responded that it was not at all likely that their child had *GJB2/GJB6*-related hearing loss, and that testing did not help them understand the cause of the hearing loss. This early experience indicates parental interest in, and reasonable understanding of, genetic testing and results.

**(GJB6-D13S1830) is not a frequent DFNB1-causing allele in the Iranian population.** *Y. Riazalhosseini*<sup>1, 2</sup>, *Kh. Jalalvand*<sup>1</sup>, *S. Arzhangi*<sup>1</sup>, *M. Mohseni*<sup>1</sup>, *C. Nishimura*<sup>3</sup>, *N. Mahdieh*<sup>1</sup>, *A. Ebrahimi*<sup>1</sup>, *H. Najmabadi*<sup>1</sup>, *R.J.H. Smith*<sup>3</sup>. 1) Genetics Research Center, The Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 2) Khatam University, Tehran, Iran; 3) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA.

Mutations in the gene that encodes the gap-junction protein connexin 26 (*GJB2*) at the DFNB1 locus on chromosome 13q12 are the major cause of autosomal recessive non-syndromic sensorineural deafness (ARNSD) in many different populations. A fraction of patients with *GJB2* mutations have only one mutant allele, and in some familial cases with linkage to the DFNB1 locus no mutations in *GJB2* are reported. Recently, a large deletion involving the *GJB6* gene encoding connexin 30 which is also located at the DFNB1 locus ((*GJB6-D13S1830*)) has been reported to cause ARNSD in homozygotes for this mutation and in compound heterozygotes carrying deafness-causing allele variants of *GJB2* on the opposite allele. To evaluate the importance of (*GJB6-D13S1830*) in the Iranian population, we screened 115 deaf probands with ARNSD from various regions of the country. One hundred three of them were deaf probands with normal *GJB2* alleles, the remaining 12 were heterozygote for only one *GJB2* mutation. Screening for (*GJB6-D13S1830*) was completed using PCR primers that amplify the breakpoint junction of this deletion (NEJM 2002; 346:243-9). (*GJB6-D13S1830*) was not detected in our subjects. We conclude that (*GJB6-D13S1830*) is not a frequent DFNB1-causing allele in the Iranian population.

**Mutation screening of the calcium-sensing receptor (CASR) gene by denaturing HPLC (dHPLC) in the diagnosis of inherited disorders of parathyroid hormone metabolism.** *R.A. Booth<sup>1</sup>, B.Y.L. Wong<sup>2</sup>, A. Scillitani<sup>3</sup>, A. Shuen<sup>1</sup>, L. Fu<sup>2</sup>, C. Wei<sup>4</sup>, G.N. Hendy<sup>5</sup>, D.E.C. Cole<sup>1,2</sup>.* 1) Dept. of Laboratory Medicine & Pathobiology, Univ. of Toronto, Toronto, Canada; 2) Dept. of Clinical Pathology, Sunnybrook & Womens College Health Sciences Centre, Toronto, Canada; 3) Dept. of Endocrinology, Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; 4) Toronto Medical Laboratories, University Health Network, Toronto, Canada; 5) Dept. of Medicine, Physiology & Human Genetics, McGill Univ., Montreal, Canada.

Activating mutations of the CASR gene cause autosomal dominant hypoparathyroidism with hypercalciuria. When they arise de novo, the clinical picture is one of idiopathic hypoparathyroidism, but germline mosaicism may alter recurrence risks. Inactivating mutations are associated with hypercalcemia and the phenotype is usually benign, although homozygosity manifests as neonatal severe hyperparathyroidism. Recently, however, mutations have also been identified in some kindreds with familial isolated hyperparathyroidism. To address the question of whether CASR mutations underlie some cases of sporadic primary hyperparathyroidism (PHPT) as well, we developed a high-throughput mutation screening protocol using dHPLC. Genomic DNA from 137 cases of PHPT, in which other genetic causes of hyperparathyroidism (MEN1, HPT with jaw tumors) had been rigorously excluded, were PCR-amplified to produce a series of amplicons covering exons 2 to 7 of CASR, as well as their exon-intron boundaries. Screening exon 4, we identified heterozygosity for a novel T263M mutation that disrupts an N-glycosylation consensus sequence (Asn-X-Ser/Thr) and is predicted (by NetNGlyc1.0) to knock out N-glycosylation at Asn261. Glycosylation of the calcium-sensing receptor appears to be required for a full response to extracellular calcium. Otherwise, known polymorphisms are readily distinguished by our dHPLC protocol, but novel heterozygosity has been observed in exon 4 and exon 7 in two additional PHPT samples, respectively, and mutational analysis is underway. Full screening of all exons will provide a clearer idea of the minimal mutation yield that can be expected of dHPLC screening in this parathyroid disorder.

**Is there a gender difference in the population prevalence of Factor II gene G20210A polymorphism?** *D. Napper, K. Yanamandra, S.A. Ursin, H. Chen, R. Dhanireddy, J.A. Bocchini Jr., T.F. Thurmon.* Dept Pediatrics, Louisiana State Univ Med Ctr, Shreveport, LA.

Venous thrombosis is caused by genetic and non-genetic factors. Several polymorphic gene factors are implicated in thrombophilia including Factor II G20210A, Factor V Leiden, and Methylenetetrahydrofolate reductase (MTHFR) C677T. The Factor II gene is 21 kb in size and is localized on chromosome 11p11-q12. The gene has 14 exons with a 5'-upstream and a 3'-untranslated regions. Poort et al in 1996 from Leiden, the Netherlands, identified a polymorphic marker, G20210A in the 3'-UT region of the gene and found the polymorphism was associated with increased risk for venous thrombosis. The population frequency of G20210A polymorphism varies with ethnicity. Many of the reports showed a very rare to none 20210AA homozygotes in the general population. The Leiden thrombophilia study revealed a 2.3% (11 out of 474) 20210GA heterozygosity among the Dutch Caucasians. According to the Centers of Diseases Control (CDC) Atlanta, Georgia study the heterozygote frequency was 1 in 318 African-Americans (0.3%). A Brazilian study revealed 1.6% (2 in 120) heterozygosity in whites, none in 112 Blacks, none in 148 Amerindians, or 40 Japanese. So far there was no mention of population prevalence figures stratified by gender for the Factor II G20210A polymorphism. In the course of our present investigation of Factor II polymorphism studies in the etiology of cancer we found a nonsignificant but more than doubling (3% vs 1.3%) of the heterozygous 20210GA frequency in our NW Louisiana female healthy infants compared to male infants (Chi Sq 0.5,  $p=0.5$ , odds ratio  $>2.3$ ). If our data are verified by other centers, then any association studies involving Factor II gene polymorphism must not only stratify the genotypes by ethnicity but also by the gender to get a meaningful relationship. Data on genotypes by race and by gender, and statistics will be presented.

**Methylenetetrahydrofolate reductase (MTHFR)C677T polymorphism and Lung cancer.** *T. Thurmon<sup>1</sup>, K. Yanamandra<sup>1</sup>, S.A. Ursin<sup>1</sup>, H. Chen<sup>1</sup>, D. Napper<sup>1</sup>, R. Dhanireddy<sup>1</sup>, J.A. Bocchini Jr.<sup>1</sup>, J. Rodriquez-Paris<sup>2</sup>, M. Smith<sup>2</sup>, G.M. Mills<sup>2</sup>, J. Glass<sup>2</sup>.* 1) Dept Pediatrics-Genetics, Louisiana State Univ, Shreveport, LA; 2) Feist-Weiller Cancer Center, LSU Health Sciences Center, Shreveport, LA.

Folate deficiency has been implicated in the etiology of birth defects, cardiovascular anomalies, stroke, and recently, tumorigenesis of solid tumors such as breast, cervix, colon, pancreas, and liver. There has been very little study of enzyme gene polymorphisms in the shared folate and cobalamin (vitamin B12, another B vitamin) metabolic pathway in the etiology of cancer. Since Folate and Cobalamin metabolizing enzymes share the C1 metabolic pathway, we are studying the methylenetetrahydrofolate reductase (MTHFR) C677T, methionine synthase reductase (MTRR) A66G, and methionine synthase (MS) A2756G polymorphisms. This report concerns MTHFR. Over 200 non-Hispanic white cancer patients have been investigated to study the relationship of MTHFR genotypes with various forms of cancer, using allele specific multiplex PCR genotyping method. Overall, there were 14% 677TT homozygotes, 46% 677CT heterozygotes, and 40% 677CC homozygotes compared to control frequencies of 13%, 45%, and 42%. Previous studies have shown that low folic acid or mutant MTHFR genotypes could be risk factors in lung cancer. However, our data suggests similar frequencies of MTHFR mutant genotypes between lung cancer and controls showing neither association of MTHFR mutant genotype with lung cancer (odds ratio 1.1) nor protection by the normal genotype, in contrast to reports in the literature. Data on various cancers, genotypes, and statistics will be presented.

**Factor II G20210A polymorphism and Breast Cancer.** *S.A. Ursin<sup>1</sup>, K. Yanamandra<sup>1</sup>, J. Rodriquez-Paris<sup>2</sup>, M. Smith<sup>2</sup>, D. Napper<sup>1</sup>, T.F. Thurmon<sup>1</sup>, H. Chen<sup>1</sup>, R. Dhanireddy<sup>1</sup>, J.A. Bocchini Jr.<sup>1</sup>, G.M. Mills<sup>2</sup>, J. Glass<sup>2</sup>.* 1) Pediatrics, Perinatal Gen Sec, LSUHSC, Shreveport, LA; 2) Feist-Weiller Cancer Center, LSU Health Sciences Center, Shreveport, LA.

Venous thrombosis is caused by genetic and non-genetic factors. Several polymorphic gene factors are implicated in thrombophilia including Factor II G20210A, Factor V Leiden, and Methylene tetrahydrofolate reductase (MTHFR) C677T. The Factor II gene is 21 kb in size and is localized on chromosome 11p11-q12. The gene has 14 exons with a 5'-upstream and a 3'-untranslated regions. Poort et al in 1996 from Leiden, the Netherlands, identified a polymorphic marker, G20210A in the 3'-UT region of the gene and found the polymorphism was associated with increased risk for venous thrombosis. The polymorphic frequency of 20210GA genotype has been found to be 1-2% in Caucasians and less than 0.2-0.3% in African-Americans. Although Factor II polymorphism was found to be a risk factor for vascular diseases, its association with cancer etiology was not studied. In the present investigation we studied the association of thrombophilic polymorphic gene markers in the etiology of cancer. We genotyped over 200 cancer patients and over 2300 controls. Previous studies in the literature showed negligible number of 20210AA homozygotes in the population. Similarly, we have not found any mutant 20210AA homozygotes. When we stratified the data by ethnicity and gender we found a significant increase of mutant 20210GA genotypes in Caucasian breast cancer patients over Caucasian controls 9.7% vs 2.1% (Chi Sq 3.7,  $p < 0.05$ , odds ratio 4.9). When combined with our data on lung cancer, the results were 6.4% compared to 1.9% in controls (Chi sq 5.5,  $p < 0.02$ , odds ratio 3.6). Our data showed that 20210GA genotype is a significant risk factor in the etiology of breast cancer. This is the first report in the literature. Genotypes and cancer data among different ethnicities will be presented.

Program Nr: 1362 from 2003 ASHG Annual Meeting

**Five years experience of a diagnostic service for craniofacial syndromes.** *R.L. Jones, E.M. Craig, C.J. McMahon, G.M. Monaghan, M. Boxer, R.M. Winter, C.G. Norbury.* Regional Genetics Service, Great Ormond Street Hospital, London, UK.

The NSCAG-funded craniofacial genetics service was established at Great Ormond Street Hospital in October 1997. Since then we have tested around 900 patient samples for a variety of craniosynostosis syndromes associated with the FGFR and TWIST genes. Mutation screening cascades have been developed for the various disorders, in order to maximise the efficiency of screening for future samples. Mutation detection rates vary widely by condition, for example mutations were found in only 3.5% of referrals requesting only the common FGFR3 P250R mutation, associated with Muenke syndrome (non-syndromic craniosynostosis), compared to 60% of Saethre-Chotzen syndrome cases, over 70% of patients with a definite clinical diagnosis of Crouzon or Pfeiffer syndrome, and 100% of confirmed cases of Apert syndrome. Genotype-phenotype correlations will be discussed. Testing for familial mutations and prenatal diagnosis is offered when a mutation has been identified, and prenatal diagnosis is also offered for abnormal ultrasound findings. So far around 20 cases of prenatal diagnosis have been performed as part of the service. The service continues to expand, and new and future developments (e.g. CE SSCP) will also be discussed.

**Test error tolerance and physician-offspring concordance in attitudes toward Alzheimers Disease (AD) genetic susceptibility testing.** *G. Chase<sup>1</sup>, M.D. Fallin<sup>3</sup>, S.S. Bassett<sup>2</sup>*. 1) Dept of Health Evaluation, Penn St Univ College of Med , Hershey, PA; 2) Dept of Psychiatry, Johns Hopkins School of Medicine, Baltimore, MD; 3) Dept of Epidemiology, Johns Hopkins School of Publi Health.

We studied 107 adult offspring of AD cases ascertained in a genetic linkage study and also administered parallel questionnaires regarding various aspects of genetic susceptibility testing to the physicians who treated their affected parents. This report is concentrated on the question of whether attitudes and opinions about such testing were concordant between offspring and medical care providers as well as with determinants of test error tolerance among adult offspring. Tolerance for tests with high error rate was predicted by male gender, low education and concern with financial planning. Concern with financial planning as a reason for taking an AD susceptibility test was not associated with male gender among offspring of AD patients. The predictive importance of male gender for high test error tolerance is not attributable to greater financial concerns among male offspring; both factors predict this outcome independently. There is a marked discrepancy between the physicians' report on importance of discussing genetic factors in AD with offspring and the offspring reporting that such discussion actually took place. Although there was no greater than a chance association between offspring and physicians on the issue of preference for the latest tests and treatments, there was substantial agreement between offspring and physicians on reasons for taking an AD susceptibility test.

**Alpha synuclein gene dosage in familial and sporadic Parkinson's disease.** *J.O.M. Johnson<sup>1</sup>, M.J. Hanson<sup>3</sup>, S. Hague<sup>1</sup>, A. Singleton<sup>2</sup>, A. Crawley<sup>2</sup>, B. Ravina<sup>2</sup>, J. Hardy<sup>3</sup>, K. Gwinn-Hardy<sup>2</sup>, A. Singleton<sup>1</sup>.* 1) National Institute on Aging, National Institutes of Health, Bethesda, MD; 2) Neurogenetics Branch, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD; 3) Laboratory of Neurogenetics, National Institutes of Health, Bethesda, MD.

The first reported linkage for Parkinsons disease (PD) was PARK-1 a locus on chromosome 4q. This region contains the -synuclein gene in which two mutations (A30P and A53T) were shown to cause autosomal dominant PD. This protein was subsequently demonstrated to be a major component of Lewy bodies. We have been following a large family, the Iowan kindred with autosomal dominant disease ranging clinically from Dementia with Lewy bodies at one end of the spectrum to typical Parkinsons disease at the other. Recently, using the technique of quantitative PCR and in situ hybridization we have characterized a whole gene triplication event of the alpha synuclein gene. Furthermore, western blot analysis shows that this mutation results in overexpression of wild-type alpha synuclein protein in blood confirming the triplication event is responsible for the disease in this large kindred. We hereby report our results assaying for the gene triplication in a collection of 118 familial, 152 sporadic Parkinsons disease patients, and 92 controls using quantitative real time duplex PCR.

**A new quantitative PCR assay for rapid detection of aloid deletion of exon 7 in SMA health carriers.** A. Patitucci<sup>1</sup>, R. Mazzei<sup>1</sup>, FL. Conforti<sup>1</sup>, A. Magariello<sup>1</sup>, T. Sprovieri<sup>1</sup>, C. Rodolico<sup>2</sup>, AL. Gabriele<sup>1</sup>, G. Peluso<sup>1</sup>, G. Di Palma<sup>1</sup>, A. Toscano<sup>2</sup>, M. Muglia<sup>1</sup>. 1) ISN-CNR, Mangone, Cosenza, Italy; 2) Department of Neuroscience, Psychiatry and Anesthesiology Science, University of Messina, Italy.

The routine molecular test for diagnosis of SMA is based on the detection of a homozygous deletion of exons 7 and 8 of the telomeric copy of SMN gene. This does not allow the detection of the hemizygous absence of SMN1 gene which characterizes the carriers of the disease. The demand of SMN1 quantitative test is permanently growing because there is a high incidence of carrier frequency. Here we present a new non-radioactive quantitative PCR assay based on real time quantitative PCR. We analyzed 8 SMA patients, 14 related SMA patients and 50 normal control individuals by real time quantitative reaction using FAM labeled TaqMan MGB probe derived from SMN1 exon 7, and FAM labeled TaqMan probe with TAMRA quencher from RNase P gene as internal reference. SMN copy number was determined by the comparative threshold cycle method (Ct). The starting copy number of the unknown samples was determined comparing to the copy number of the calibrator sample applying the following formula:  $Ct = Ct_{RnaseP}(\text{calibrator sample}) - Ct_{SMN1-7}(\text{calibrator sample}) - [Ct_{RnaseP}(\text{unknown sample}) - Ct_{SMN1-7}(\text{unknown sample})]$ . The advantages of the real time quantitative PCR are two: first the possibility to calculate the gene copy number based on a Ct value, rather than using endpoint measurement; second it avoids the use of a standard curve with relative errors of dilution. The relative gene copy number was calculated by the expression  $2^{-Ct}$ . At first we determined genotype of SMA patients with traditional method of amplification and digestion with DraI for exon 7; then we analyzed all samples with this new quantitative method. The results confirmed the deletion in all homozygous patients and permitted to evaluate the number of alleles in the health carriers. This method is fast, reproducible, and makes us able to discriminate health subjects from health carriers, until now impossible with normal techniques like amplification and digestion.

**Diagnosis of haploid and triploid based on measurement of gene copy number in CMT and HNPP.** *T. Sprovieri, A. Patitucci, A. Magariello, FL. Conforti, R. Mazzei, AL. Gabriele, G. Peluso, G. Di Palma, M. Muglia.* ISN, CNR, Mangone, Cosenza, Italy.

A 1.5-Mb tandem duplication, including the gene for peripheral myelin protein 22 (PMP22) in chromosome 17p11.2-12 is responsible for 70% of the cases of Charcot-Marie-Tooth disease or hereditary motor and sensory neuropathy I (CMT1A/HMSN I). A reciprocal deletion of this CMT1A region causes the hereditary neuropathy with liability to pressure palsies (HNPP). We report a method for diagnosis of heterozygous deletions or duplications in HNPP and CMT based on measurement of gene copy number. This method involves amplifications of a test locus with unknown copy number and a reference locus with known copy number using real time PCR (ABI Prism 7900). The CMT1A duplication increases the PMP22 gene dosage from two to three, the HNPP deletion reduces the gene dosage from two to one. Our method is fast, reproducible and needs only a little quantity of DNA. We analyzed 41 CMT patients, 25 HNPP patients and 50 normal individuals by real time PCR using FAM labeled TaqMan MGB probe derived from PMP22 exon 4, and FAM labeled TaqMan probe with TAMRA quencher from RNase P gene as internal reference. Both reactions were run in parallel in the same time. The effective gene copy number was determined by the comparative threshold cycle method (Ct). The starting copy number of the unknown samples was determined comparing to the copy number of the calibrator sample applying the following formula:  $Ct = [Ct_{RnaseP}(\text{calibrator sample}) - Ct_{PMP4}(\text{calibrator sample})] - [Ct_{RnaseP}(\text{unknown sample}) - Ct_{PMP4}(\text{unknown sample})]$ . The relative gene copy number was calculated by the expression  $2^{-Ct}$ . The patients were previously examined by microsatellite analysis: most of patients showed the presence of three alleles, while a little number had two alleles with different dosage. The duplication in these last patients has been revealed by PFGE. The quantitative PCR confirmed the duplications in all examined patients. Thus, this method shows superior sensitivity to microsatellite analysis and has the additional advantage of being a fast and uniform assay for quantitative analysis of both CMT1A and HNPP.

**Comparison of a novel quantitative PCR assay with other methods of PMP22 gene dosage detection in HMSNI/HNPP.** *C. Thiel, C. Kraus, A. Rauch, A. Ekici, B. Rautenstrauss, A. Reis.* Institute of Human Genetics, University of Erlangen-Nuremberg, Germany.

A 1.4-Mb duplication including the gene for peripheral myelin protein 22 (PMP22) is responsible for 70 % of Charcot-Marie-Tooth disease 1A (HMSNI) while a deletion causes hereditary neuropathy with liability to pressure palsies (HNPP). Diagnosis is mainly performed with polymorphic markers (MS), fluorescence in situ hybridisation (FISH) and Southern hybridisation (SB). We have developed a novel single tube real-time PCR assay (qPCR) for determination of PMP22 gene dosage (Thiel et al. *Eur J Hum Genet* 2002) and now sought to evaluate the accuracy of this method through a retrospective analysis of 409 previously diagnosed patients (252MS, 157SB). Concurrent calling of the gene dosage was seen in 250/252 MS samples. One sample suspected of a deletion, gave normal results in qPCR and FISH analysis. One sample previously suggested unaffected by MS showed a duplication of the PMP22 gene in qPCR and FISH analysis. SB analysis in this sample using a PMP22 specific probe revealed a novel junction fragment due to an atypical, smaller duplication including PMP22. This confirms that MS analysis is a reliable method, but is prone to error in rare uninformative or atypical cases. Analysis of 157 patients previously diagnosed by SB revealed 12 inconsistencies (7,6%). In 8 cases a normal result was obtained with SB while qPCR diagnosed 5 duplications and 3 deletions. In 3 samples a difference in gene dosage was suspected but qPCR gave a normal result. MS analysis of all cases was concordant with qPCR results. In addition, one sample with a 7.8 kb junction fragment in SB showed normal gene dosage in qPCR, indicating the presence of a previously reported rare polymorphism. These findings confirm the lack of diagnostic precision of the absence/presence of junction fragments in SB. Our results show, that SB methods made 7% false callings while MS analysis was more reliable with a 1% false calling rate when compared to our new qPCR assay. We conclude that gene dosage detection in routine analysis of HMSNI and HNPP is most reliable when performed with this novel multiplex qPCR assay.

**FMR1 and FMR2 analysis in autistic population.** *T. Yamagata, K. Suwa, M. Mori, M. Nakamura, M.Y. Momoi.* Dept Pediatrics, Jichi Medical School, Tochigi, Japan.

FMR1 and FMR2 are genes responsible for fragile X syndrome (FRAXA) and FRAXE mental retardation (FRAXE), respectively. Both diseases are caused by the large CGG/CCG repeat expansion in 5'UTR of each gene that induce gene inactivation. Main symptoms of FRAXA are mental retardation (MR), typical facial appearance and macroorchidism. Some patients with FRAXA showed autistic symptom and about 0.75% (0-6%) of autistic population were reported to have CGG repeat expansion of FMR1. There is a report that no disease related base change was detected in FMR1 gene in autism patients. Most patients with FRAXE show mild MR or learning difficulty, but not facial abnormalities, and some patients were reported to have autistic phenotype. Thus far, there is no report about the repeat expansion or mutation screening of FMR2 gene in autistic population. Therefore, we screened FMR1 and FMR2 as candidate genes for repeat expansion and base substitution in Japanese autism population. We extracted DNA from patients with autism or pervasive developmental disorder not otherwise specified after obtaining informed consent from their parents. Repeat expansion of each gene was screened by PCR or Southern analysis. For mutation screening, each exon of the genes was amplified by PCR and mutations were screened by DHPLC method and sequencing. In FMR1 screening, one female autism patient had repeat expansion in 70 autistic patients. She was typical autism with mental retardation. In FMR2, no repeat expansion was detected. No base substitution that would relate to autism was detected in both FMR1 and FMR2, and several polymorphisms were detected. Our result on FMR1 analysis was same with previous report that FMR1 repeat expansion was the cause of autism in minor population. FMR2 repeat expansion was detected in only few patients in MR population and it might be same in autism population because we could not detect the mutation in autistic patients. Our sample was small and it should be analyzed further. However, most of the patients were caused by another genes mutations.

Program Nr: 1369 from 2003 ASHG Annual Meeting

**Translational Genetics in Cardiovascular Disease and Cancer; bridging the gap between basic research and clinical practice.** *J.C. Taylor.* Genetics Knowledge Park, Wellcome Trust Genetic Centre, Oxford, Oxfordshire, England.

The Oxford Genetics Knowledge Park (OxGKP) is part of a UK government-funded programme of translational clinical genetics. The major aim of the OxGKP is to ensure that advances in basic human genetics research are applied rapidly, efficiently and ethically in a health service framework. The OxGKP programme will focus on a few diseases which represent the spectrum of genetic complexity and can be used as paradigms for future studies. We are studying disorders such as sudden cardiac death (SCD), which result from multiple Mendelian variants, through to more complex diseases such as cardiovascular disease and cancer, where multiple DNA variants and environmental factors contribute to the end phenotype. For SCD we will use Wave DHPLC to identify mutations in the proband and sequencing to identify other family members at risk. For cardiovascular disease (CVD), mass spectrometry will be used to genotype polymorphisms in candidate genes in large cohorts. Variants associated with susceptibility to CVD or response to statins may be identified using these cohorts. Microarray-based comparative genomic hybridisation (CGH) will be developed for detection of somatic mutations in colorectal cancer tissues and identification of variants which correlate with response to chemotherapy. This technique will potentially provide an efficient and cost-effective alternative to classical cytogenetics for detecting chromosomal deletions and duplications in many other disorders. In addition to addressing the scientific and technical issues which must be resolved before such genetic tests can be offered, the OxGKP programme will assess the ethical, legal and sociological implications of providing such tests. Finally, we will calculate whether the introduction of expanded genetic testing services would be a cost-effective initiative for health services. Like other aspects of biomedicine, there is a gap between new discoveries and their implementation in clinical practice that is often difficult to bridge. This programme should considerably facilitate this transition in the area of human genetics.

**Cost-effectiveness of DNA based screening for Familial Medullary Thyroid Carcinoma.** *J.L. Brown<sup>1</sup>, P.J. Bridge<sup>2</sup>, D.W. Morrish<sup>3</sup>, D.M. Gilchrist<sup>3</sup>*. 1) Medical Genetics Clinic, University of Alberta Hospital, Edmonton, AB, Canada; 2) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada; 3) Department of Medicine, University of Alberta, Edmonton, AB, Canada.

**Objective:** One of the goals of genetic testing is to reduce morbidity and mortality. A secondary goal is reduction in health care costs. This can be demonstrated most effectively in large families with mutations in dominantly acting genes. **Methods:** A point mutation (Cys620Arg) in exon 10 of the RET proto-oncogene was first identified in two individuals in a large French Canadian family. The proband had medullary thyroid carcinoma (MTC), as did her deceased mother. One son has MTC and Hirshsprung. The proband's mother had nine siblings; the proband has three siblings, another son, and 69 maternal first cousins. Genetic testing has commenced with closest relatives. **Results:** Five out of six living siblings of the proband's mother have tested negative for the mutation. This has eliminated the need for genetic testing in 36 cousins. One of the proband's sisters tested positive and both her children tested negative. Four nieces and nephews did not require genetic testing because of negative parental status. This has saved \$4,800 in genetic testing (\$120 per test). Clinical screening for individuals at risk for familial MTC involves annual pentagastrin screening (\$279 yearly). Clinical savings in one year for the 49 excluded family members are \$13,671. The savings for MEN2 screening would be even more significant. **Conclusion:** Economic costs of genetic diagnostics should take into account potential saved monies in tests, both molecular and clinical, for relatives. Note: 1 Canadian Dollar = 0.74873 US Dollar.

Program Nr: 1371 from 2003 ASHG Annual Meeting

**Development and use of risk assessment criteria to evaluate cancer family histories.** *H. Hampel, K. Sweet, J.A. Westman, C. Eng.* Clinical Cancer Genetics Program, Division of Human Genetics, The Ohio State University, Columbus, OH.

Assessing a cancer family history is a powerful public health tool for stratifying patients according to their risk of developing cancer so that they can be managed appropriately. A standard set of risk assessment criteria is needed to ensure consistency when different individuals or institutions are assessing risk. The objective of this study was to develop criteria to assist in comprehensive and consistent risk assessment of cancer family histories. The criteria are based on comprehensive literature review of publications describing diagnostic criteria for hereditary cancer syndromes and risk to first-degree relatives of cancer patients, with priority given to consensus statements. These criteria were used to assess 2828 cancer family histories obtained from an ambulatory patient area at a comprehensive cancer center (CCC). These criteria categorized 339 (12%) families into the High Risk level leading to referral for cancer genetics consultation and a recommendation to discuss increased cancer surveillance with their primary care physicians. Another 450 (15.9%) fulfilled at least one Moderate Risk criterion, a risk level that does not require referral for cancer genetics consultation but does suggest discussion of increased cancer surveillance with their physicians. Most families (69.5%) were categorized as Low Risk, i.e., a similar cancer risk to the general population, as expected. The remaining 85 (3%) users did not meet High or Moderate Risk criteria, but were offered cancer genetic consultation because of a concerning family history. This set of cancer risk assessment criteria successfully stratifies the expected proportion of patients into the various risk categories, and are easy to apply to large-scale family history screening.

**Breast cancer genetic susceptibility: does testing first an affected family member impose an undue burden?** *P. Rowley, C. Shields, S. Loader.* Univ Rochester Medical Ctr, Rochester, NY.

In cancer genetic risk counseling, the standard practice is to test an affected family member first. Typically the person seeking testing is unaffected and must therefore recruit a relative with cancer to be tested. Does this practice impose an undue burden on the recruited relative?

We have previously reported a clinical trial in which any woman in a defined geographic region who had a qualifying family history and who was referred by her physician was offered free genetic counseling and DNA testing. (Loader et al. 1998). The index family member could have breast or ovarian cancer (affected) or not (unaffected or at risk), but had to recruit another family member willing to be tested so that each family was represented by one affected and one unaffected person. Additional patients were recruited from a cancer registry. Of 140 women qualifying, 112 came for pretest education. After pretest education, 98 chose to be tested; of 87 families actually tested, thirteen had deleterious mutations.

To assess the impact of the counseling and testing process, we recontacted the individuals at one month and at one year and those with abnormal test results at four years following the communication of the test result. We found that index subjects differed significantly from relatives. Before coming for counseling, index subjects, whether having had cancer or not, perceived both their general health and emotional health as worse than did relatives. After counseling and testing, index subjects continued to worry more about breast cancer than did relatives.

In summary, the group most prone to distress by cancer risk genetic counseling and testing is, not the recruited relatives, nor even those affected with cancer, but rather the index patients themselves. Thus relatives do not appear to be unduly burdened by the process. The index patients, i.e. the ones who want the risk information most, appear to undergo the most stress in obtaining it.

**Meeting a Need: Genetic Cancer Risk Assessment Protocol for an Underserved Population.** *C. Ricker<sup>1</sup>, V. Lago<sup>1</sup>, S. Fuentes<sup>2</sup>, S. Hiyama<sup>3</sup>, V. Kumar<sup>2</sup>, N. Feldman<sup>3</sup>, G. Uman<sup>4</sup>, K. Blazer<sup>1</sup>, J. Weitzel<sup>1</sup>.* 1) Clinical Cancer Genetics, City of Hope Natl Medical Ctr, Duarte, CA; 2) QueensCare Foundation (QC), LA CA; 3) OliveView Medical Center (OV), Sylmar CA; 4) Vital Research, LA CA.

Outreach clinics were established at OliveView Medical Center (OV), a county indigent care hospital, and QueensCare (QC), a foundation-funded clinic for individuals at < 200% of poverty level, to provide genetic cancer risk assessment (GCRA) to underserved (predominately Latino) patients. A needs assessment survey on knowledge and perceptions about cancer and screening, administered in QC and OV general medicine and oncology waiting rooms, documented gaps in knowledge and interest in prevention, indicating a need for and receptivity to GCRA. Thirty-five percent of respondents had a personal and/or family history of cancer and 80% voluntarily included an address to receive more information. Clinicians at both sites participated in CME lectures on cancer genetic and referral guidelines were disseminated and posted. A marked increase in clinician knowledge (66-72%) was demonstrated and their understanding was reflected by the quality of referrals, of which 85% were appropriate. Patients participated in language appropriate GCRA. Each of the 14 families found to carry deleterious mutations had on average 23 at-risk family members (range 10-32). This extension of GCRA impact to other family members is referred to as the Family Amplification Factor (FAF). Feasibility and acceptability of the program was demonstrated by the high rate of clinic attendance (88% of patients scheduled kept appointments), supporting our hypothesis that GCRA would be well received. Future impact was foreshadowed by 4 mutation carriers with bilateral breast cancer, who would have been candidates for genetic testing at the time of their first diagnoses. Had GCRA services been accessible, their second diagnosis might have been avoided or detected at an earlier, more treatable stage. Preliminary findings indicate that investigation of follow-up care uptake is necessary to judge the efficacy of GCRA with respect to cancer risk reduction. However, indigent patients are motivated and as likely to benefit, as insured patients.

**Novel Mutation L187P in KCNQ1 Causes Autosomal Dominant Long QT Syndrome.** *M. Liu*<sup>1,2</sup>, *L. Zhang*<sup>3</sup>, *L. Wang*<sup>2</sup>, *S. Chen*<sup>2</sup>, *G.M. Vincent*<sup>3</sup>, *Q. Wang*<sup>2</sup>. 1) Institute of Genetics, Fudan University, Shanghai, Shanghai, P. R. China; 2) Center for Molecular Genetics, Department of Molecular Cardiology, Lerner Research Institute, and Center for Cardiovascular Genetics, The Cleveland Clinic Foundation, Cleveland, OH 44195; 3) Department of Internal Medicine, LDS Hospital and University of Utah Health Sciences Center, Salt Lake City, UT, 84103.

Congenital long QT syndrome (LQTS) is characterized by a prolonged QT interval and polymorphic ventricular arrhythmias (torsade de pointes) and sudden death. Here we report a novel potassium channel KCNQ1 mutation in a large autosomal dominant family. Methods: A 7-generation family pedigree was established to search affected members by electrocardiogram (ECG) screening. Forty-two family members agreed to participate in the genetic study. Five markers (D11S4046, D7S798, D3S1277, D4S402, and D21S266) were used for linkage analysis. Results: The disease gene of this family is linked to D11S4046 with a lod score of 6.11 ( $q=0.10$ ). SSCP and sequence analysis in the coding region of KCNQ1 gene (including exon-intron boundaries) identified SNP T-C transversion at codon 187 (between transmembrane domains S2 and S3), which is predicted to result in a substitution of proline for leucine (L187P). SSCP and RFLP analysis showed that mutation L187P co-segregated with the disease. Thirty-one family members were identified as mutation carriers (age 3321 yrs, 13F) with mean QTc 0.460.03 sec and 12 non-carriers (age 3022 yrs, 4F) with mean QTc 0.430.02 sec. Typical LQT1 T wave pattern were present in 84% of gene carriers. 16% were symptomatic. There was one sudden death before LQTS diagnosis. 58% (18/31) of carriers had normal to borderline QTc (0.450.04 sec) in the initial ECGs. RFLP analysis was performed in 200 normal controls, but none of them carry the mutation. Conclusions: L187P causes low QTc penetrance in this LQT1 family, highlighting the importance of genetic testing.

**High-throughput genotyping of recurrent mutations in hypertrophic cardiomyopathy by MALDI-TOF mass**

**spectrometry.** *C. Wei*<sup>1</sup>, *A. Romaschin*<sup>1</sup>, *W. Newman*<sup>2</sup>, *D.E.C. Cole*<sup>3</sup>, *K. Siminovitch*<sup>2</sup>, *M. Yazdanpanah*<sup>2</sup>. 1) Molecular Genetics Laboratory, Toronto Medical Laboratories, Toronto, ON, M5T 1V4, Canada; 2) Analytical Genetics Technology Center, Department of Medicine, Princess Margaret Hospital/University Health Network, Toronto, ON, M5G 2L7, Canada; 3) Departments of Laboratory Medicine & Pathology, Medicine, Paediatrics/Genetics, University of Toronto, Toronto, ON, M5G 1L5, Canada.

Familial hypertrophic cardiomyopathy (HCM) is an autosomal dominant myocardial disorder with incomplete penetrance and variable clinical expression. Clinical findings include left ventricular hypertrophy, dysrhythmias, heart failure and sudden death. More than 200 mutations in 10 genes encoding mainly sarcomeric proteins have been reported. Molecular diagnosis may lead to better understanding of genotype-phenotype correlations and better clinical management. However, it is technically challenging to screen for recurrent mutations that represent a minority of the total number of potential mutations. The University Health Network provides clinical care for one of the worlds largest cohorts of HCM, with more than 600 families. To facilitate mutation detection in this group, we have initiated a highthroughput protocol for known mutations using the Sequenom Matrix Assisted Laser Desorption Ionization Time of Flight (MALDI-TOF) Mass Spectrometer. Automated genotype call efficiency was 95% and assays precision and accuracy were 99.9%. Based on this technology, we developed a multiplex PCR for six mutations including P211L, R403Q, R403L, and L908V in the MYH7 gene, and P76L, and IVS15+1G A in the TNNT2 gene. While the great majority of samples were negative for all 6 mutations, MYH7 L908V was correctly identified in two samples from the same pedigree and MYH7 R403Q in a third sample. The two positives for the L908V mutation were confirmed by PCR and RFLP analysis. Based on this experience, MALDI-TOF has considerable promise as a high-throughput means of screening for HCM mutations with a prevalence of no more than 1-2%. We are currently setting up three more multiplex PCR reactions for a total of fourteen known mutations in MYH7, TNNT2, TNNI3, MYL2 and MYL3 genes.

**Presymptomatic Diagnosis of Inherited Disorders: Classification of Medical Interventions.** C. Dolan<sup>1,2</sup>, K. Marymee<sup>3</sup>, A. Amemiya<sup>2</sup>, J. Edwards<sup>1</sup>, I. Saphire-Bernstein<sup>4</sup>, P. Tarczy-Hornoch<sup>1</sup>, R. Pagon<sup>1,2</sup>. 1) University of Washington, Seattle; 2) Children's Hospital and Regional Medical Center, Seattle; 3) Inland Northwest Genetics Clinic, Spokane; 4) Blue Cross Blue Shield Association, Chicago.

**SIGNIFICANCE:** Presymptomatic diagnosis of inherited disorders in at-risk individuals has clinical utility when early diagnosis permits interventions that reduce morbidity and/or mortality.

**BACKGROUND:** While creating "GeneNotes," one-page summaries of genetic counseling and testing basics based on *GeneReview* entries ([www.genetests.org](http://www.genetests.org)), we recognized the need to classify the types of medical interventions made possible by early diagnosis of at-risk individuals.

**METHODS:** GeneTests staff reviewed medical interventions for the 72 diseases in *GeneReviews* for which early diagnosis of an at-risk asymptomatic individual alters medical management.

**RESULTS:** The four classes of medical interventions and examples include: 1) Treatment to prevent primary disease manifestations (23 diseases): e.g., PKU (dietary restriction), Wilson disease (copper chelation); 2) Treatment to prevent secondary complications (15 diseases): e.g., sickle cell disease (penicillin administration), hearing loss/deafness (hearing aids/communication skills); 3) Surveillance (30 diseases): e.g., hereditary cancer syndromes, Stickler syndrome (retinal detachment); 4) Avoidance (22 diseases): e.g., Romano-Ward syndrome (medications that prolong QT interval, hypohidrotic ectodermal dysplasia (fever).

**CONCLUSIONS:** Clarification of the medical benefits of early diagnosis of at-risk individuals through presymptomatic genetic testing may help establish clinical utility and improve reimbursement of clinically appropriate testing costs by third-party payers, thereby increasing patient access to testing. Discussions initiated with the Blue Cross and Blue Shield Association will explore the usefulness of this classification system.

**Detection of the 22q11.2 deletion within a population containing Specific Language Impairment (SLI) subjects.**

*D.R. Collins*<sup>1, 2</sup>, *J.C. Murray*<sup>2</sup>, *J.B. Tomblin*<sup>1</sup>, *S.A. Bullard*<sup>3</sup>. 1) Department of Speech Pathology and Audiology, University of Iowa; 2) Department of Pediatrics, University of Iowa; 3) Dows Institute of Dental Research, University of Iowa.

The purpose of this investigation was to screen for the 22q11.2 deletion associated with Velocardiofacial Syndrome (VCFS) in a population of subjects containing 121 normal controls, 56 individuals with Specific Language Impairment (SLI), 62 individuals with low nonverbal intelligence quotients but normal language abilities, and 38 subjects with below normal language abilities and low nonverbal intelligence quotients. Subjects were tested for type of language disorder by using components from the following diagnostic battery of tests; CELF-3, WISC-3, PPVT-3, and Woodcock Johnson. A diagnosis of SLI required a nonverbal IQ above 85 and failure on two or more language composite tests with a z score of 1.25 or less. In total, 277 subjects were successfully screened for the 22q11.2 deletion using a real time polymerase chain reaction protocol adapted from Kariyazono et al (2001). The results of this investigation indicated that one of the SLI subjects was identified as potentially having the 22q11.2 deletion. Additionally, after a review of the subjects medical records, it was also noted that this individual had been seen in cleft palate clinic for persistent hypernasality and language delay. The discovery of the 22q11.2 deletion within the SLI population has important clinical implications in regard to the potential genetic source of SLI and the incidence of VCFS within this population. The SLI population is considered to be a very heterogeneous and the genetic cause of SLI is considered to be multifactorial. According to the results of this study, it is possible that individuals with VCFS may display the language phenotype of SLI and that the incidence of VCFS may be higher within SLI population as compared to the normal population. However, the identification of an individual diagnosed with both VCFS and SLI remains a rare finding.

**Immunoblotting of ATM Protein and Kinase Activity for Diagnosing A-T.** S.A. Nahas, H.H. Chun, R.A. Gatti.  
Department of Pathology, UCLA School of Medicine, Los Angeles, CA 90095.

The laboratory diagnosis of ataxia-telangiectasia (A-T) currently relies upon measurement of serum alphafetoprotein (AFP) and cellular sensitivity to ionizing radiation. A previous report suggests that immunoblotting of whole cell lysates from lymphoblastoid cell lines (LCLs) might be informative for diagnosis. To further evaluate this possibility, and improve sensitivity, we performed immunoblotting for ATM protein on nuclear lysates of 71 consecutive radiosensitive LCLs that were established from patients with clinical features suggestive of A-T. Fifty-two LCLs (73%) contained no detectable ATM protein, with a representative sample (n=25) testing negative for ATM kinase activity, having at least one ATM mutation, and having elevated AFP levels; these results confirmed the diagnosis. Seventeen LCLs (24%) expressed intermediate or normal levels of ATM protein and exhibited normal ATM kinase activity; follow-up studies failed to detect ATM mutations and AFP levels were normal in all but three. Of the remaining two radiosensitive LCLs, one had 35% of normal protein with normal kinase activity and no ATM mutations (AFP was borderline). The other LCL had 9% of normal protein, with intermediate levels of kinase activity, homozygous missense ATM mutations and an elevated AFP. Our data suggest that it is very uncommon to encounter bonafide A-T patients with more than trace amounts of ATM protein in nuclear lysates. We conclude that immunoblotting for ATM protein and kinase activity is of higher specificity for diagnosing A-T than radiosensitivity testing. In addition, we have documented *in vitro* radiosensitivity in other patients who share some clinical features with A-T but must have some other disorder(s).

**Diagnostic strategy for Prader-Willi syndrome and Angelman syndrome in Korea.** *S.M. Ahn<sup>1</sup>, G.H. Kim<sup>1</sup>, E.Y. Choi<sup>1</sup>, S.H. Heo<sup>1</sup>, J.Y. Lee<sup>1</sup>, J.S. Kim<sup>1</sup>, H.W. Yoo<sup>1,3</sup>, E.J. Seo<sup>1,2</sup>.* 1) Medical Genetics & Lab., Asan Medical Center, Seoul, Korea; 2) Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Prader-Willi syndrome(PWS) and Angelman syndrome(AS) are clinically different neurobehavioral disorders resulting from molecular defects of 15 chromosome originated from father or mother. These disorders can result from microdeletion, uniparental disomy(UPD), or imprinting center defect in specific region 15q11-13 of chromosome. We had studied G-banding, FISH and methylation-specific PCR (MS-PCR ) for 96 patients with clinical features suggestive of PWS and AS. Microsatellite analysis was done in doubtful patients of UPD and mutation of UBE3A gene was analyzed in patients referred to AS. Of 85 patients referred for PWS, 24 patients had only maternal pattern by MS-PCR and were confirmed to PWS. In 21 of 24 confirmed PWS patients were found to show deletions by G-banding and FISH and 3 patients detected to deletion only by FISH. The remaining 3 patients has maternal UPD. In AS cases, 5 patients were suspected of having AS after detection of deletions by G-banding, and then confirmed by FISH and MS-PCR. Of 6 patients referred to AS tests by physician, 2 patients had deletion and one patient had single base deletion in exon 9 of UBE3A. Twelve patients of 64 patients with normal methylation pattern have shown abnormal karyotyping results exception with chromosome 15. These results show that PWS and AS are disposed to be misdiagnosed or underdiagnosed because many features are nonspecific or subtle. Therefore we recommend a effective strategy for diagnostic testing of PWS and AS. First of all, G-banding should be performed for all patients suspected of PWS and AS. In Korea, cost of cytogenetic analysis is from one-third to a half of one of FISH or MS-PCR. Simultaneously, MS-PCR must be analysed to diagnose accurately PWS and AS, followed by FISH or microsatellite analysis. In cases with normal methylation pattern and strongly suspected of PWS and AS, tests for imprinted genes can be performed lastly.

**Detecting chromosomal aberrations within 6-8 hours using MLPA.** *S.J. White, M. Kriek, M.E. Kalf, G-J.B. van Ommen, M.H. Breuning, J.T. den Dunnen.* Human and Clinical Genetics, Leiden University Medical Center, The Netherlands.

Genomic deletions and duplications play an important role in the etiology of human disease. It is therefore essential that the tests necessary to detect such rearrangements are available and readily applicable in diagnostic laboratories. Multiplex Ligation-dependent Probe Amplification (MLPA) is a technique that allows the rapid and precise quantitation of multiple (>40) sequences within a nucleic acid sample. It is based upon the hybridization, ligation and PCR amplification of 2 oligonucleotides. Common ends on the oligonucleotides mean that amplification can be performed with one primer pair. We are currently examining several different applications of this technique within a clinical setting. One use is for aneusomy screening of new borns. In cases where a diagnosis is uncertain it is often necessary to quickly rule out specific chromosomal abnormalities e.g. trisomy chromosome 13 or 18. The confirmation of a specific microdeletion/duplication syndrome may also be of benefit. To facilitate this we have performed the MLPA reaction on blood spotted onto an FTA card (Whatman). This virtually eliminates preprocessing, meaning that it is possible to go from blood sample to result within 6-8 hours. Using this method we have detected whole chromosome trisomies, as well as cytogenetically invisible rearrangements. The high resolution potential has prompted us to explore the possibility of using this as an alternative to FISH. The resultant PCR products have been successfully analyzed in several different ways, including on a capillary sequencer, the Lab-on-a-chip (Agilent) or by hybridization to a microarray. We are currently testing the possibility of simultaneous analysis of several hundred probes using arrays, providing a resolution far greater than that obtainable with FISH or array CGH. The fact that any combination of probes can be easily combined in a single reaction, coupled with the speed and flexibility of analysis afforded by the different platforms means that this technique has an important role to play in molecular cytogenetics within a diagnostic setting.

**Validation studies for Noonan syndrome molecular diagnostic testing.** *J. Wiszniewska<sup>1</sup>, M. Maheshwari<sup>1</sup>, S. Fernbach<sup>1</sup>, J. Belmont<sup>1, 2</sup>, B.B. Roa<sup>1</sup>.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Noonan syndrome is an autosomal dominant, genetically heterogeneous disorder with an estimated prevalence of approximately 1 in 1,000-2,500. Characteristic features include hypertelorism, downslanted eyes, posteriorly rotated low set ears, short stature, short webbed neck, cardiac anomalies, motor delay, and a bleeding diathesis. Approximately 50% of Noonan syndrome cases are associated with mutations in the PTPN11 gene, which maps to 12q24.1 and encodes the non receptor protein tyrosine phosphatase SHP-2. Patients with PTPN11 gene mutations are considered to have a higher prevalence of pulmonic stenosis as a cardiac manifestation. To date, mutations identified in the PTPN11 gene are missense alleles that are mostly clustered in N terminal SH2 and PTP domains. We developed an assay for routine molecular diagnostics of Noonan syndrome that involves bi-directional sequencing analysis of 15 coding exons of the PTPN11 gene. Validation studies were completed on 12 blinded DNA samples, including mutation-positive patients who were previously diagnosed with Noonan syndrome at our institution. DNA samples from seven Noonan syndrome patients were correctly identified to have the following documented PTPN11 missense mutations: Y62D, Y63C, F285L, S502T, and M504V. Additionally, sequence polymorphisms in intron 7 were also identified. Diagnostic sequencing analysis of PTPN11 gene is currently being offered for Noonan syndrome at the Baylor DNA Diagnostic laboratory. Data on molecular testing will be collected prospectively to determine the mutation detection rate in a clinical diagnostic setting, and hopefully to refine genotype-phenotype correlations for PTPN11 mutations in Noonan syndrome.

**An automated platform for the identification of fetal cells in maternal circulation.** *F. Tafas<sup>1</sup>, M.W. Kilpatrick<sup>1</sup>, I. Ichetovkin<sup>1</sup>, P. Rompolas<sup>1</sup>, A. Seppo<sup>1</sup>, Y. Agarwal<sup>1</sup>, Y. Kim<sup>1</sup>, J. Recht<sup>1</sup>, L. Strinkovsky<sup>1</sup>, A. Antsaklis<sup>2</sup>, B. Brambati<sup>3</sup>, P. Tsipouras<sup>1</sup>.* 1) Ikonisys Inc, New Haven, CT; 2) University of Athens, Greece; 3) University of Milan, Italy.

The presence of rare fetal cells in the maternal circulation is generally accepted, but their number, timing of appearance, and the best approach for their enrichment remain unclear. Fetal cells can be indisputably identified through detection of paternal genetic material, but over a million cells per maternal sample must be analyzed for detection of a handful of cells containing Y FISH signals. We developed an automated system to scan for cells bearing X and Y FISH signals. Target cells are screened at 20X magnification then verified at 100X. 20X images of all signals in each of 4,000 optical fields per slide and 100X images of target cells are displayed. We initially used single X and Y FISH probes but identified cells bearing single X and Y signals in all 12 maternal samples scanned. XY cells were indistinguishable, at both 20X and 100X, regardless of fetal sex, suggesting that FISH can cause a significant level of false positive signals affecting the specificity of automated chromosome counting. We therefore incorporated two independent Y-chromosome probes; one centromeric and one telomeric. Putative fetal cells are identified at 20X magnification based on the presence of the X and telomeric-Y signals, and fetal cells verified at 100X magnification based on the presence of a single X-chromosome signal, and single signals for each of the centromeric and telomeric Y-probes. Implementation of this approach reduced the false positive rate for detection of XY nuclei below 0.00005%. In 7 samples from pregnancies with male fetuses the automated system identified 1 - 7 XY cells per ml maternal blood; no XY cells were found in 5 samples from female fetus pregnancies. Ikonisys has developed a high fidelity automated system for the quantitation of fetal cells in the maternal circulation. It is capable of highly accurate detection and quantitation of FISH signals and has potential applications in a variety of areas where the reliability and speed offered by an automated system would be of benefit.

**Novel Approach to Improved Access to Cancer Genetics Services: the Columbus, Ohio Solution.** *M. Goulet<sup>1</sup>, L. Ahonen<sup>2</sup>, H. Hampel<sup>3</sup>, R. Nagy<sup>3</sup>, K. Sweet<sup>3</sup>, L. Vassy<sup>1</sup>, B. Sickel-Santanello<sup>2</sup>, C. Eng<sup>3</sup>.* 1) Cancer Risk Program, Mount Carmel Health, Columbus, OH; 2) Cancer Genetics Program, OhioHealth, Columbus, OH; 3) Human Cancer Genetics Program, Ohio State Univ.(OSU),Columbus, OH.

By developing strategic partnerships with a 6 year old cancer genetics program, patients have increased access to cancer risk assessment and genetic counseling services. Mount Carmel (in August 2001) and OhioHealth (in August 2002), both community hospital systems, entered into a collaborative relationship with OSU's academic medical center. This model allows patients to remain within their own healthcare systems and under their referring physicians' continued care while utilizing the geneticist and genetic counseling expertise already in place at OSU. Cancer genetics services are provided without the economic disadvantage of duplicating existing services within the community. This city-wide partnership has increased the number and diversity of referring physicians while decreasing the number of patients receiving genetic testing without appropriate counseling. Of the 97 physicians who referred patients to the community hospitals' cancer genetics programs, 78 physicians had not previously referred to OSU's cancer genetics program. Twelve area physicians had ordered BRCA gene testing directly from their office without genetic counseling prior to the partnerships; only 1 physician has since continued that practice. The collaboration has also afforded patients the opportunity to participate in numerous research studies available throughout the country. This solution demonstrates that the efficiency and effectiveness of a program is sometimes best achieved when competitors become collaborators and place more emphasis on patient, physician, and staff needs.

**Insight into genetic testing for non-disease traits: a qualitative assessment.** *E.S. Gordon<sup>1</sup>, H.A. Gordish-Dressman<sup>1</sup>, J.M. Devaney<sup>1</sup>, P.M. Clarkson<sup>2</sup>, M.J. Hubal<sup>2</sup>, P.M. Gordon<sup>3</sup>, E.E. Pistilli<sup>3</sup>, L.S. Pescatello<sup>4</sup>, B. Kelsey<sup>4</sup>, G. Gianetti<sup>4</sup>, E.P. Hoffman<sup>1</sup>.* 1) Res Ctr Gen Medicine, Children's National Med Ctr, Washington, DC; 2) Dept of Exercise Science, Univ of Massachusetts, Amherst, MA; 3) Div of Exercise Physiology, West Virginia Univ, Morgantown, WV; 4) Health Promotion and Allied Health Sciences Dept, Univ of Connecticut, Storrs, CT.

As the field of genetics evolves from its focus on single gene disorders to complex disorders and normal traits, we must consider the psychological impact of this evolution. Here we present data from a qualitative assessment of 105 participants insights into non-disease genetic testing. All participants were part of a larger four year study (Factors affecting muscle size and strength; FAMuSS). The long-term goal of this study is to assess the impact of non-disease genetic information on participants, including their views on non-disease genetic testing for themselves, their children, concerns about insurance and job discrimination and the direct impact that non-disease genetic testing may have on their lives. At the time of enrollment (T1), assessment tools including a series of qualitative, open-ended questions as well as standardized assessments of self-concept (Tennessee Self-Concept Scale; Health Orientation Scale) were administered to the participant. Each participant donated a blood sample for genotyping of 4 SNPs previously shown to influence muscle performance: ACE, CNTF, gamma sarcoglycan and UPC-2 genes. After completing a 12 week exercise program, participants were told which SNPs they possess and were given information about the traits associated with each SNP. Both qualitative and standardized assessments were then repeated (T2). In a comparison of responses prior to and after receiving results related to the ability to gain muscle strength and/or muscle mass, only 2% of participants felt that the information changed their self-concept. However, 34% of participants reported that the information they received would change their behavior. This is a clear indication of the impact of non-disease genetic testing and the realization that caution must be taken when providing this information.

**The contribution of polymorphisms of the TNF gene to disease severity, susceptibility to amyloidosis and response to treatment in patients with familial Mediterranean fever.** *R. Gershoni-Baruch<sup>1</sup>, R. Brik<sup>1</sup>, N. Zaks<sup>2</sup>, M. Lidar<sup>2</sup>, M. Shinawi<sup>1</sup>, A. Livneh<sup>2</sup>.* 1) Dept Human Genetics and pediatrics, Rambam Medical Ctr, Haifa, Israel; 2) Heller Institute of Medical Research, Sheba Medical Center, Tel-Hashomer, Israel.

Familial Mediterranean fever (FMF) is an autosomal recessive disease characterized by attacks of fever and serositis, and a predisposition to the development of amyloidosis. The disease is noted for its wide clinical variability, which is mainly, yet not solely, attributed to MEFV allelic heterogeneity. Modifiers contributing to the phenotypic profile in FMF remain to be defined. In this study we investigated the effect of TNF-alpha promoter polymorphisms, which seem to be related to an individual's production of TNF-alpha, on disease severity, susceptibility to amyloidosis, and response to treatment, in 150 FMF patients, who were all homozygous for the M694V mutation. A detailed chart review and physical examination were undertaken to determine demographic characteristics, history, clinical manifestations, treatment, and calculate the severity score from the Tel-Hashomer key. Using sequence-specific primers to the TNF-alpha gene and polymerase chain reaction, we examined three single nucleotide polymorphisms (SNPs) of the TNF-alpha gene, TNF (-376G/A, 308 G/A and -238 G/A). An association was sought between the presence of high-producing (A homozygotes, GA heterozygotes) or low-producing (G homozygotes) TNF-alpha genotype with disease severity, the development of amyloidosis and response to treatment. This results of this study suggest that the TNF promoter polymorphisms do not significantly influence the patients' outcome and are not positively associated with amyloidosis or response to treatment. The presence, however, of the high-producing TNF-alpha alleles led to an earlier age of onset, yet the difference was not significant. Further investigation is required to determine if these polymorphisms or others (in the TNF-receptor genes) play a key role in the pathogenesis of FMF.

Program Nr: 1386 from 2003 ASHG Annual Meeting

**Medical challenges of practicing medicine through the approach of principles of genomic science of systems biology.** *R. Chakraborty*. Dept. of Environmental Health, Univ. Cincinnati, Cincinnati, OH.

The emerging field of systems biology as a discipline of studying complexity of biological systems and its biomedical applications has a direct relevance on using the tools of functional genomics from laboratory to the patients. Advocates of this *-omics* platform of practicing medicine claim that this approach would be evidence-based, through which patients should be able to receive personalized attention for treatment, control, as well as prevention. It is true that the systems-based approach of understanding diseases may circumvent some of the reductionism-related drawbacks of contemporary medicine. However, new medical challenges that would arise from such post-genomic approaches of practicing medicine are not trivial, and policies to combat such challenges are not exactly in place. This presentation raises some of these issues, and offers suggestions for development of guidelines for meeting these challenges, based on models of other post-genomic translational research. Need for international enforcement of such guidelines is also important in this regard. Apart from the privacy and safety issues in relation to the information gathered, which can be raised by the patients, providers of post-genomic medicine will have to make patients aware of uncertainties of risk estimation, predictions about range of outcomes of treatment modalities, and side effects, based upon which the patients are to be counseled with regard to options open to them and their cost-benefit analyses. Since the providers of post-genomic medicine will consist of teams with contributions from academia, industry, venture capitalists, health care providers, as well as governmental and legal agencies, guidelines for meeting such challenges and protocols for enforcing them are not so trivial. Patent laws and rules of accessibility of databases may also need to be revisited in this context. But it is not too early to formulate an integrative set of guidelines to institutionalize individualized medicine based on the advances of being made in this field of translational research. (Supported by US Public Health Service Research grants from the National Institutes of Health).

**Impact of Genetic Cancer Risk Assessment (GCRA) in an Underserved Setting: Outcomes and Adherence to Cancer Risk Management Recommendations.** *V. Lagos<sup>1</sup>, C. Ricker<sup>1</sup>, S. Fuentes<sup>2</sup>, S. Hiyama<sup>3</sup>, V. Kumar<sup>2</sup>, N. Feldman<sup>3</sup>, J. Weitzel<sup>1</sup>.* 1) Clinical Cancer Genetics, City of Hope, Natl Medical Ctr, Duarte, CA; 2) QueensCare Foundation, Los Angeles, CA; 3) OliveView Medical Center, Sylmar, CA.

Outreach clinics were established with community collaborators to address populations that are underserved by virtue of socioeconomic status as well as by lack of access to genetic cancer risk assessment (GCRA). The objective is to determine impact of GCRA on access, adherence and barriers to cancer screening and prevention recommendations. Patients referred for GCRA were consented and enrolled in a hereditary cancer registry. A knowledge test covering genetic principles, hereditary risks, and risk reducing intervention was administered immediately post-GCRA to assess initial learning and at 12 months to assess knowledge retention. Adherence to risk management recommendations was assessed by structured interviews at six months and one year post-GCRA. The study population (n=50) was predominantly Hispanic (75%). Fifty-eight percent had a current or past diagnosis of cancer and the average gene mutation probability was 28%. Thirty percent of patients proceeded with testing and 14 families were found to be carriers of a deleterious mutation. Follow-up has been conducted on 37 patients. The mean score on the post-GCRA knowledge survey was 78%. Behavioral impact was exemplified by the fact that all patients interviewed six months post-GCRA were performing monthly breast self-exams and all have been able to obtain a clinical breast exam. Seventy one percent of the women whose recommendations included a mammogram within the follow-up period have had one. Every patient interviewed has expressed her satisfaction with the GCRA experience. Other outcomes include expressions of reduced anxiety, increased understanding of cancer and personal risk, and better grasp of care options. Based on preliminary data GCRA had a positive impact on these patients and they appear motivated to adhere to cancer risk management recommendations. Longer term follow-up on a larger sample is necessary to determine the uptake of risk reduction surgery and to characterize personal and healthcare system barriers to follow-up care.

**Establishment of a human DNA bank in a small and geographically isolated island: The case of Sao Miguel (Azores).** *L. Mota-Vieira<sup>1</sup>, P.R. Pacheco<sup>1</sup>, M.L. Almeida<sup>2</sup>, R. Cabral<sup>1</sup>, J. Carvalho<sup>2</sup>, S. Costa<sup>1</sup>, C. Matos<sup>2</sup>, C.C. Branco<sup>1</sup>, M. Loura<sup>2</sup>, B.R. Peixoto<sup>1</sup>, A.L. Araujo<sup>2</sup>, P. Mendonça<sup>2</sup>.* 1) Genetics & Molec Pathol Unit; 2) Hematology Dept, Hosp Divino Espirito Santo, Azores Islands, Portugal.

Azores is a Portuguese archipelago located in north Atlantic Ocean, corresponding to the western extreme of Europe. Here, we describe the strategy used to build a DNA bank of the population living in the Azorean island of Sao Miguel (131,609 inhabitants) and the analyses of the distribution and geographic origin of the first 350 samples (Dec. 2002 through May 2003). This DNA bank is based on a population sampling of 1,000 healthy unrelated individuals (about 0.8% of the current population), obtained through a collaboration with the Hematology Dept. of the Hospital of Divino Espirito Santo, the only hospital located in S. Miguel island. This DNA bank follows the international ethical guidelines and has been approved by the Hospital's ethical committee. Blood samples (7.5 mL) were collected with appropriate Informed Consent, which includes (1) the distribution of free informative leaflet explaining the goals of proposed studies, the confidentiality of the personal data, and the methods of identification and storage of DNA samples; and (2) an interview with a health professional for additional information. All samples in the repository are anonymous and have self-reported data concerning sex, age, birth and current living places (locality and municipality in the island), and parental birthplaces. To date, we collected 350 blood samples, of which 309 (88%) are male. The mean age of all participants is 36.5y (20-62y). All the six municipalities of the island are represented. The analysis of birthplaces shows that 295 (84%) of all participants have both parents born in S. Miguel island. Moreover, 172 (58%) of these participants have both parents born in the same locality. This data corroborates the high rate of marriages within the rural localities. Thus, the DNA bank of S. Miguel island represents a important resource for population and biomedical genetic research and provides opportunities for us to participate in international collaborative projects. Funded by DRCT, Azores. (lmotavieira@hdes.pt).

**Technology or talk? Equally effective: computer program and an oral presentation in a Tay Sachs disease carrier screening program for secondary school students.** *M.A. Aitken<sup>1,2,3</sup>, A.A. Gason<sup>1,2,3</sup>, S.A. Metcalfe<sup>1,2,3</sup>, E. Sheffield<sup>4</sup>, M.B. Delatycki<sup>5</sup>.* 1) Genetics Education Unit, Murdoch Childrens Res Inst, Parkville, Australia; 2) Dept Paediatrics, The University of Melbourne, Australia; 3) Cooperative Research Centre for the Discovery of Genes for Common Human Diseases, Australia; 4) Genetic Health Services Victoria, Royal Children's Hospital, Parkville, Australia; 5) The Bruce Lefroy Centre for Genetic Health Research, Genetic Health Services Victoria and Murdoch Childrens Research Institute Parkville, Australia.

Tay Sachs disease (TSD) is an inherited neurodegenerative disorder, fatal in children usually by the age of five. Identification of the enzyme deficient in TSD, hexosaminidase A, allowed the implementation of carrier screening programs within the high risk Ashkenazi Jewish community. The Melbourne TSD carrier screening program includes secondary school students and may be used as a model for future screening programs. Therefore, an efficient and flexible educational approach is important. This study compares the effectiveness of a recently developed computer based educational resource with an oral presentation for delivering information to enable informed decision making for testing. Over two years, 348 students completed a pre and post education questionnaire relating to their knowledge, interest, attitudes and anxiety. There was an overall increase in students knowledge following education (1.670.2 points,  $p < 0.0001$ ). The computer program (1.590.21 points) was just as effective for increasing students' knowledge score as the oral presentation (1.600.19 points). Computer based education is widely integrated into school curricula offering a number of advantages such as allowing individuals to be educated at a time that is convenient to them without the necessity of a consistent and experienced educator. Genetic screening programs can use computer based educational approaches as an alternative to face-to-face education without undermining their educational outcomes both in the school setting as well as in the community at large.

**Haemscreen: a Workplace Hemochromatosis Screening Program.** *M.B. Delatycki<sup>1, 2</sup>, A. Nisselle<sup>1, 2</sup>, K.J. Allen<sup>2</sup>, Haemscreen Group.* 1) Bruce Lefroy Centre, MCRI, Royal Children's Hosp, Parkville, Australia; 2) MCRI, Royal Children's Hosp, Parkville, Australia.

Hereditary hemochromatosis (HH) is a common preventable iron overload disease, most often due to homozygosity for the C282Y mutation in HFE. We are piloting a workplace-screening program for C282Y and aim to assess test acceptability and understanding of genetic information for HH.

Employees were invited to an education session and offered screening for C282Y by cheek brush DNA sampling. Questionnaires were administered prior to testing and to C282Y homozygotes and controls four weeks after receiving results. A cohort of non-attenders was surveyed to determine the reasons for non-attendance.

6495 people eligible for testing attended education sessions. 98.0% had testing. The attendance rate was 6.5%. C282Y results are available for 5626 and there have been 22 homozygotes (1:256) and 638 heterozygotes (1:9).

The education resulted in a good understanding of the cause of HH (84% correct) and how it can be prevented (90%) but poorer understanding of penetrance (50%) and genetic and allelic heterogeneity (65%).

Of the 22 homozygotes (age range 18-59), 8 were male. 3/22 were already aware of their genetic status. Of 17 previously unaware whose iron status is known, 6 had markedly abnormal iron studies and have commenced treatment.

The main reason for non-attendance (n= 262) was related to practical constraints in 62% (eg: didnt know about the program), low iron or being a blood donor (9%), HH unimportant or hadnt heard of it (4%), concerns about anxiety related to being found to be C282Y homozygous (1%) and insurance and confidentiality concerns (2%).

In conclusion, of people attending the education session almost all have testing. People understand the cause and prevention of disease but understand the genetic aspects of HH less well. 35% of those unaware of their homozygous state had markedly abnormal iron studies and are undergoing venesection.

**Cooperation in medical genetics in Latin America.** *V.B. Penchaszadeh<sup>1</sup>, A. Giraldo<sup>2</sup>, R. Giugliani<sup>3</sup>, S. Kofman<sup>4</sup>.* 1) Beth Israel Med Ctr, W.H.O. Collab Center for Community Genetics, New York, NY; 2) Genetics Institute, Medical School, National University, Bogota, Colombia; 3) Dept Medical Genetics, Federal University RGS, Porto Alegre, Brazil; 4) Dept Genetics, General Hospital, Mexico City, Mexico.

Latin America is the region of the third world with the longest history and development of human and medical genetics. Current epidemiological transition determines rising proportion of morbidity and mortality due to birth defects and genetic disorders. However, medical genetic services are incipient and fragmented, with coverage reduced to the well off. A meeting of medical genetics experts from Argentina, Brazil, Chile, Colombia, Costa Rica, Ecuador, Mexico, Paraguay and Peru was convened by the World Health Organization in Porto Alegre, Brazil, in June 19, 2003. The group reviewed the status of medical genetics services and research in those countries and designed an agenda for collaboration in specific projects aiming at improving services, education and research for the prevention and management of genetic disorders and birth defects in the region. Task forces were created on specific subjects: clinical genetics services and genetic counseling, genetic testing laboratories, newborn screening, undergraduate and postgraduate education in medical genetics, collaborative research, and ethical, social and legal issues. These groups will work within the recently created Latin American Network of Human Genetics ([www.relagh.ufrgs.br](http://www.relagh.ufrgs.br)) and start concerted actions to further the stated goals. A coordination committee constituted by three of the authors (VBP, AG and RG) will serve as liaison with the different working groups and with non-genetic health professionals, parent/patient organizations, public health officials and legislators. Expected products of this work include prioritization of preventive actions and organization of genetic services according to health status and other factors in each country, model curricula for the teaching of genetics in schools of health sciences, and education modules in genetics for primary health care workers, general public and policymakers.

**Development of a PCR- and minisequencing-based assay for congenital adrenal hyperplasia (21-hydroxylase deficiency).** *D. Keen-Kim, M. Eachus, J. Nakamoto, R. Fenwick.* Dept. Molecular Endocrinology, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder caused by defects in adrenal steroid biosynthesis, resulting in reduced corticoid and increased androgen production. Approximately 90% of CAH cases are caused by mutations in the 21-hydroxylase gene (*CYP21A2*). Genomic rearrangements between *CYP21A2* and *CYP21A*, a nearby and highly homologous pseudogene, are responsible for the majority of mutations. Both deletions and gene conversion occur. Mutation detection is useful for carrier screening and prenatal diagnosis as well as for neonatal and adult diagnosis in selected cases. Southern hybridization detection of *CYP21* rearrangements, followed by intragenic mutation detection based on nine allele-specific PCR reactions, is typically used. These methods are both laborious and time-consuming. We have designed an allele-specific PCR assay to detect rearrangement at the *CYP21* locus, followed by minisequencing, to detect *CYP21A2* mutations. **Methods:** *CYP21A2*, *CYP21A*, and each of the *CYP21A2/A* and *CYP21A/A2* fusion products produced by genomic rearrangement are amplified using PCR. The nine common intragenic mutations (P30L, In2G, Delta 8bp, I172N, exon 6 cluster, V281L, F306+t, Q318X, R356W) and P453S are subsequently detected by primer extension with fluorescently-labeled dideoxynucleotides and electrophoretic separation on an ABI PRISM 310 Genetic Analyzer (Applied Biosystems, Foster City, CA). Data from the ABI 310 are then analyzed with GeneScan and Genotyper software (Applied Biosystems). To validate our method, we assayed, in a blind manner, 13 samples collected from CAH-affected individuals and 10 samples from normal controls. **Results:** The resultant genotypes were 100% concordant (23/23) with the known phenotypes. Turnaround time was 2 days, relative to more than 5 days for Southern hybridization methods. **Conclusions:** We have developed an accurate PCR-based method suitable for CAH (21-hydroxylase deficiency) diagnosis and carrier screening. Moreover, the method has reduced turnaround time compared with other currently used methods.

**Recruitment of Hispanics in Texas and New Mexico into the Cancer Genetics Network using culturally appropriate educational materials.** *L.L. Ballinger<sup>1</sup>, K.J. Gallion<sup>2</sup>, A.R. Miller<sup>4</sup>, G.P. Mineau<sup>3</sup>, A.G. Ramirez<sup>2</sup>.* 1) Cancer Research and Treatment Ctr, Univ. New Mexico, Albuquerque, NM; 2) Chronic Disease Prevention and Control Research Ctr, Baylor College of Medicine, San Antonio, TX; 3) Huntsman Cancer Inst., Univ. Utah, Salt Lake City, UT; 4) Cancer Therapy & Research Ctr, San Antonio, TX.

To increase the participation of Hispanics in cancer genetics research, the Texas Cancer Genetics Network (TCGN) and the Rocky Mountain Cancer Genetics Coalition (RMCGC) are collaborating in a study to test culturally appropriate recruitment materials. This study will evaluate the effectiveness of a magazine, developed by the TCGN, as a recruitment device for the Cancer Genetics Network (CGN) registry. The 24 page, 4-color, English/Spanish, culturally and literacy appropriate magazine is aimed at increasing interest in cancer research. In Texas, Hispanic registrants from tumor registries in San Antonio will be recruited to participate in this CGN recruitment study. This group consists of English and Spanish speaking persons at an increased cancer risk (having had some form of cancer or having family history of cancer). Individuals will be randomly selected into three different conditions: those who receive standard materials via mail; those who receive standard materials plus the magazine; and those who receive standard materials plus the magazine, as well as phone contact. In New Mexico, subjects will be recruited from clinic sources and the general community through advertisements and flyers. Subjects are randomized into receiving standard study recruitment materials with and without the magazine. All subjects receive phone contact if they do not respond to the mailing. The outcome of this study for both sites will be the completion of the standard CGN registry materials and enrollment into the CGN. Participants and those who refuse enrollment will complete questionnaires regarding the effectiveness these recruitment strategies.

Program Nr: 1394 from 2003 ASHG Annual Meeting

**Parental Satisfaction with Active Informed Consent for Expanded Newborn Metabolic Screening.** *S.M. Au<sup>1</sup>, L.E. Hasegawa<sup>2</sup>, C.A. Matsumoto<sup>1</sup>*. 1) Genetics Program, Hawaii Department of Health, Honolulu, HI; 2) Research Corporation of the University of Hawaii, Honolulu, HI.

The first major overhaul of newborn metabolic screening (NBMS) in the past thirty years brings to the forefront the question of whether informed consent should be required before the screening test is performed. Expanded NBMS using tandem mass spectrometry (MS/MS) may detect some disorders which may not have available treatment(s) to date. The State of Hawai'i has been conducting a pilot study examining expanded NBMS with informed consent actively obtained by project assistants trained in providing information about the expanded screening. The project assistants spent approximately 15-20 minutes per new mother providing information and answering questions. Over the past year, 78.0% (5,606/7,186) of the parents opted to have the expanded NBMS after the informed consent process. Parents were asked to complete a satisfaction survey after accepting or declining to participate in the expanded NBMS project. Of the parents who answered the survey question, 98.8% (4,565/4,621) indicated that they understood the information provided. However, 31.2% of the parents still had questions after the project assistants explained the project information. The majority of parents who still had questions (87.9%) also indicated that their additional questions were answered satisfactorily by the project assistants.

**The impact of gene patents on the conduct of research.** *M.R. Henry<sup>1</sup>, J.F. Merz<sup>1</sup>, M.A. Weaver<sup>2</sup>, M.K. Cho<sup>2</sup>.* 1) Center for Bioethics, Univ. of Pennsylvania, Philadelphia, PA; 2) Center for Biomed. Ethics, Stanford Univ., Palo Alto, CA.

**Introduction:** We interviewed researchers who study one of seven specific human genetic conditions to examine if gene patents affect their ability to conduct research. We provide new data on the extent to which patenting and licensing of disease genes is affecting basic research and the development of DNA-based diagnostics and therapeutics. We describe the role of patents in research topic choice, collaboration, competition, material and information sharing, funding, and product commercialization. **Methods:** We conducted semi-structured telephone interviews averaging 35 minutes each with 121 researchers from both non-profit and commercial institutions involved in gene discovery, basic mechanism research, or diagnostic and therapeutic development. Researchers involved in Canavan disease, Chronic Myelogenous Leukemia, Colon Cancers, Cystic Fibrosis, Factor V Leiden, Hereditary Hemochromatosis, or Spinal Muscular Atrophy were identified through patient advocacy websites, the MEDLINE and US Patent and Trademark Office databases, and referral by other study participants. **Results:** Researchers have begun to formalize opinions about the impact of gene patenting on their work. Trends that emerged from our interviews include: academic researchers see patents as a necessary tool to attract industry partners for the development and commercialization of diagnostic tests and therapeutics as well as direct research sponsorship; patents are seen as a reward for discovery rather than a motivation to pursue particular avenues of research; while publication may be delayed due to patent issues, patents are not perceived as placing roadblocks or barriers to research as many researchers believe that non-profit research is exempt from patent infringement; and patents have had little effect on collaborative behaviors. The biggest problem pertaining to patents is that negotiating rights to transfer materials, whether a license or a material transfer agreement, is resource-consuming and may delay or even block research. **Conclusion:** Patents are a secondary thought for the majority of researchers, and neither drive nor substantially hinder research.

**A surveillance of parental informed consent on newborn screening in southern Taiwan.** *C.K. Lee<sup>1</sup>, M.C. Huang<sup>1</sup>, I.C. Lu<sup>2</sup>*. 1) Department of Nursing, National Cheng Kung University, Tainan, Taiwan; 2) Department of Nursing, Chung Hwa College of Medical Technology, Tainan, Taiwan.

**Purpose:** The purpose of this study is to explore the parental consent on newborn screening (NBS) today. **Methods:** Twenty-three obstetric clinics/hospitals executed NBS in southern Taiwan were interviewed. Using content analysis, the transcriptions from interview and relevant document were analyzed to develop the framework of informed consent process in current practices. **Results:** The informed consent processes in current practices of NBS vary widely, and the quality of information provision before obtaining consent is unstable. Most informed consent model is similar to "informed dissent". In few clinics/hospitals, NBS was incorporate into routine pediatric practices. **Conclusions:** The government needs to establish specific legislation to regulate the informed consent process of the new NBS items, and advocates the information about NBS through mass media to educate public. It is crucial to establish the ethical basis of its informed consent model in Taiwan. Further study investigate parental responses to NBS is necessary.

**When genetic research findings progress to clinical application: the ethics of duty to warn.** *D. Pullman<sup>1</sup>, K. Hodgkinson<sup>2</sup>, S. Connors<sup>2</sup>, A. Latus<sup>1</sup>, B. Barrowman<sup>1</sup>, L. Thierfelder<sup>3</sup>, A. Bassett<sup>4</sup>, P. Parfrey<sup>2</sup>, J. Dean<sup>5</sup>.* 1) Medical Ethics, Memorial University, St. John's, NL, Canada; 2) Patient Research Centre, Health Sciences Centre, St. John's, NL, Canada; 3) Max-Delbrück Centre, Berlin, Germany; 4) Clinical Genetic Research, University of Toronto, Ontario; 5) Department of Medical Genetics, Aberdeen, Scotland.

The collection of DNA for linkage studies may provide useful clinical information prior to the determination of a causative mutation, especially for diseases which are difficult to diagnose clinically, have a significant recurrence risk, a high morbidity and mortality, and for which an effective treatment is available. In eleven large families with autosomal dominant arrhythmogenic right ventricular cardiomyopathy (ARVC) in Newfoundland, a founder haplotype defines risk status. ARVC is sex-limited, and severe: 50% of high-risk (HR) males (based on clinical, DNA and pedigree data) are deceased by 40y in the absence of treatment compared with 5% HR females. Implantable cardioverter defibrillator therapy is effective at preventing early sudden death. The use of research haplotype information for clinical management introduces ethical dilemmas between subjects rights and researchers duty of care. Two ARVC subjects with the HR haplotype declined to hear their genetic result. One had several adult offspring, now at 50% risk, the other had employment where sudden death would place many individuals at risk. The ethical principles of beneficence and non-maleficence may imply a duty to warn the at 50% risk adult offspring and to reduce the risk to the public, but this would violate subject confidentiality. The use of anonymous research samples is possible, but this would restrict follow-up research e.g. genotype-phenotype correlations or linkage confirmation. Further, many researchers want to provide predictive genetic information to subjects for serious conditions with effective therapy. We suggest that a desire not to be informed of a possible future genetic result should be an exclusion criterion in research using identifiable samples. In this way, a balance between duty to warn and subject autonomy can be struck.

**Automated Haplotyping in *BRCA1* and Localization of Polymorphisms on Alleles.** *T. Judkins*<sup>1</sup>, *C. Schwensen*<sup>1</sup>, *B.C. Hendrickson*<sup>1</sup>, *H. Harpending*<sup>2</sup>, *J. Barrus*<sup>1</sup>, *T. Scholl*<sup>1</sup>. 1) Myriad Genetic Laboratories, Salt Lake City, UT; 2) Department of Anthropology, University of Utah, Salt Lake City, UT.

Ten canonical haplotypes, defined by 14 common, biallelic polymorphisms detected by DNA sequencing during clinical genetic testing of *BRCA1* describe approximately 99% of chromosomes. An algorithm was developed that defines patient haplotypes from these SNPs using only existing, completely anonymized data. This method successfully assigned haplotypes to 99% of 25,000 individuals and the prevalence of these haplotypes concurred with published data. Previous sequencing had identified 1048 different genetic variants of *BRCA1* in these individuals. Of these, 453 were detected more than once, 411 (over 90%) of which could be assigned to one or more haplotypes.

A phylogenetic tree was created for these *BRCA1* alleles. This tree depicts *BRCA1* bifurcating into two distinct clades. The prevalence of haplotypes within this data set indicates divergence from ancestral alleles in both clades. An analysis of intragenetic variability reveals a paucity of polymorphisms in one of these clades and suggests that it has arisen recently. Conversely, two of the least prevalent alleles, which lie between the two clades, contain disproportionate numbers of genetic variants. Therefore, these oldest (ancestral) alleles appear to be selected against. Correlation with ethnicity data indicated that these haplotypes were 20 times more prevalent in patients that indicated African ancestry.

This model demonstrates accurate and comprehensive assignment of haplotypes in patients undergoing clinical genetic testing for breast/ovarian cancer predisposition. This method increases the clinical utility of patient data by facilitating projects that identify genetic rearrangement mutations and that determine the clinical significance of intronic variants on RNA splicing. This method may also permit highly automated laboratories to achieve these benefits in a number of genetic analyses.

**Extended Mutation Panel for Population-Based CF Carrier Screening.** *G. Tsukerman*<sup>1, 2</sup>, *N. Mosse*<sup>2</sup>, *K. Mosse*<sup>2</sup>. 1) Genetic Screening Program, Reproductive Genetics Institute, Chicago, IL, USA; 2) Institute for Hereditary Diseases, Minsk, Belarus.

More than 1,000 CFTR alleles have been identified to date. The frequency of most CFTR mutations is highly variable and often depends on the ethnic origin of the patients. In October 2001, ACMG/ACOG jointly recommended CF carrier screening using a panel of 25 mutations. The panel of selected mutations was primarily based on mutation frequency in the Northern European and Ashkenazi Jewish population. In 2000, a large genomic deletion, spanning introns 1-3 of the CFTR gene, was detected in CF patients from Central and Eastern Europe. The mutation, termed CFTRdele2,3(21kb), was particularly common, 1.1-6.4%, in Czech, Russian, Austrian, German, Polish, Ukrainian, Slovenian and Slovak CF patients. It was suggested that the CFTRdele2,3(21kb) deletion could have originated in a common Slavic ancestral population (Dork T. et. al., 2000). Analysis of 244 CF alleles from Belarus patients has shown that the delta F-508 mutation covered 63% of CF chromosomes, R334W 0.8%, R347P 0.4%, G542X 1.3%, S549N 0.4%, R553X 0.4%, W1282X 0.9%, N1303K 3.7%, 2184delA 3.7%. The CFTRdele2,3(21kb) deletion accounted for 6.7% of all CF chromosomes and became the second most common CF mutation in Belarus after delta F-508. This observation can be additional evidence of Slavic ancestry of that deletion. Currently, in the USA, (ACMG 25, Quest 32, Genzyme Genetics 87) no CF mutation panel includes the CFTRdele2,3(21kb) deletion. Taking into consideration the fact (US Census Bureau, 2000) that more than 10 million US residents have Slavic Central and Eastern European origin it seems justified to add the CFTRdele2,3(21kb) deletion to the mutation panel for CF carrier screening. CF carrier screening for the CFTRdele2,3(21kb) deletion should substantially improve the detection rate of the mutations in European American couples of Slavic descent.

**Analysis of dystrophin mRNA show nonsense, splice and cryptic splice site mutations cause Becker muscular dystrophy.** *S.C. Yau, Z. Hatton, V. Nihalani, R.G. Roberts, S.J. Abbs.* Genetics Centre, Guy's Hospital, London, UK.

We have applied the protein truncation test to screen muscle RNA from 9 BMD patients with no gross rearrangements of the dystrophin gene. Four cryptic splice site mutations were identified. An A to G change 2 kb into intron 25 of BMD1 creates a cryptic acceptor site, resulting in two mutant cDNAs with 95bp and 207bp of intronic sequence inserted between exons 25 and 26. The effect on RNA splicing is similar to the donor site mutation reported by Ikezawa et al., despite the mutations being 206bp apart. This same acceptor site mutation has also been reported by Tuffery-Giraud et al. but only results in the 95bp insertion.

In BMD2 an A to T change 636 bp 3 of exon 32 creates a cryptic acceptor site adding 43bp of intronic sequence between exons 32 and 33. An A to T change 9kb 5 of exon 45 creates a cryptic donor site in BMD3 and results in an extra 71bp incorporated between exons 44 and 45 in the cDNA. In BMD4 an A insertion more than 55kb 5 of exon 45 produces a cryptic donor site causing an extra 74bp insertion in the cDNA. In all cases despite premature stop codons, alternative splicing produces full-length protein, accounting for the milder phenotypes.

Nonsense mutations in exons 25 and 49 (BMD5 & 6) and donor site mutations in exons 4 and 64 (BMD7 & 8) were found to cause alternative splicing of inframe exons in the mRNA. The 1bp deletion at the donor site of exon 64 also resulted in an additional methionine residue in BMD8s dystrophin. Although BMD9 has an out-of-frame 5bp deletion in exon 71, it is thought that failure of nonsense mediated decay means that some mutant mRNA is not completely degraded but is translated into near full-length dystrophin that can rescue the predicted severe phenotype.

Four of these mutations would not have been detectable with DNA-based mutation screening strategies. In order to offer comprehensive mutation screening in genes with large introns such as dystrophin, an RNA-based approach is likely to be required for the foreseeable future.

**Diagnostic testing for Cystic Fibrosis by MALDI-TOF mass spectrometry: Identification of a CF patient with a G542X/3199del6 genotype.** *I.M. Buysse<sup>1</sup>, S.E. McCarthy<sup>1</sup>, R.P. Pace<sup>1</sup>, E.S. Schmitt<sup>1</sup>, P. Ward<sup>1</sup>, C. Oermann<sup>2</sup>, C.M. Eng<sup>1</sup>, B.B. Roa<sup>1</sup>.* 1) Medical Genetics Laboratory, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Cystic fibrosis diagnostic testing is currently performed in our laboratory using the MALDI-TOF mass spectrometry platform (Sequenom). This PCR-based assay employs oligonucleotide primer-extension, followed by discrimination of specific extension products by mass spectrometry. This high-throughput system was successfully validated against our previous allele-specific oligonucleotide (ASO) hybridization assay by parallel testing on >1000 patient samples. Since implementation, we have tested >2000 patient samples using the expanded MALDI-TOF assay. Our current CF panel contains the 25 core mutations recommended by ACMG, plus additional CF alleles including the 3199del6 allele. This was previously reported as a potential modifier for the I148T allele, wherein classic CF patients have a complex I148T/3199del6/9T genotype on one chromosome, paired with a CF mutation on the other chromosome (1). The clinical significance of the 3199del6 allele without I148T is unclear given the current limited data. In the course of our CF clinical testing, we studied a 2 year old Hispanic male with an atypical CF presentation consisting of meconium ileus, positive sweat test, malabsorption that resolved following pancreatic enzyme supplementation, and absence of respiratory symptoms at this time. He tested positive for the G542X mutation and the 3199del6 allele, but negative for I148T; he was compound heterozygous for the 7T/9T alleles. Additional studies are being pursued, including parental analysis to determine haplotypes, and *CFTR* gene sequence analysis to assess for a possibly unidentified mutation. These studies could help elucidate the clinical significance of the 3199del6 and I148T alleles, and could potentially illustrate the value of including the 3199del6 allele in routine CF testing.

1. Rohlfs et al. *Genet. Med.* (2002), 4: 319-323.

**Genotype-phenotype correlation between the complex allele I148T-3199del6 and Cystic Fibrosis.** *A.F. Ruchon, S.R. Ryan, R. Rozen, P. Scott.* Molecular Genetics Laboratory, McGill University Health Center, Montreal, Quebec, Canada.

Over the past decade, mutation analysis of the CFTR gene in Cystic Fibrosis patients has identified more than 1000 mutations. Only a small number of these mutations result in a predictable disease phenotype and are classified as severe or mild, based on their effect on protein function and/or the resulting phenotype. The I148T mutation is considered a severe mutation and is included in the ACMG/ACOG recommended CF mutation screening panel. Recently, it has been suggested that I148T by itself is not responsible for the severe phenotype. Rather the severity appears to be due to an association in cis of I148T and 3199del6. The 3199del6 mutation is an in-frame deletion in exon 17 that removes two conserved amino acids from the second membrane-spanning domain of the CFTR protein, likely resulting in the absence of functional protein. We have studied 24 CF patients, originally identified as carrying the I148T mutation and a second severe CFTR mutation, for the presence of 3199del6. All our patients have the deletion and are of French Canadian descent. Genotype-phenotype correlation for this complex allele has been established based on the characterization of the clinical status at the time of diagnosis and thereafter. To date, available clinical information confirms the previous observation of a classical CF phenotype based on pancreatic status, sweat test and pulmonary function associated with this complex allele.

Program Nr: 1403 from 2003 ASHG Annual Meeting

**Extensive survey of *ABCA4* mutations with a commercial gene chip in a cohort of patients with Stargardt Disease or retinitis pigmentosa.** *A.N. Yatsenko*<sup>1</sup>, *R.A. Lewis*<sup>1,2,3,4</sup>, *W. Wiszniewski*<sup>1</sup>, *J.R. Lupski*<sup>1,2</sup>. 1) Molecular & Human Genetics; 2) Pediatrics; 3) Medicine; 4) Ophthalmology, Baylor College of Medicine, Houston, TX.

Mutations of *ABCA4* (*ABCR*) have been associated with several retinal disorders including Stargardt Disease (STGD) and recessive retinitis pigmentosa (arRP). However, the large size of the gene and heterogeneity of *ABCA4* variants (to date ~400 alteration variants) have confounded genetic analyses and diagnoses. To resolve these problems, a fast and affordable test, an *ABCA4* genotyping microarray screening of known *ABCA4* alterations, has been developed recently by ASPER (Tartu, Estonia). The test uses an ABCR-400 DNA chip created with allele-specific primer extension (APEX) technology. To validate efficiency and to estimate mutation detection rates for this novel technology, we screened 162 independent STGD, 30 arRP, and control samples with known *ABCA4* mutations. We confirmed the presence of identified mutations by both sequence and segregation analyses. Our preliminary data indicate that this microarray technology identifies reported disease-associated *ABCA4* alleles with ~98-99% accuracy. We estimate a mutation detection rate near 60%. This is perhaps the first extensive study of *ABCA4* mutations in patients with recessive RP. Additional studies with an ethnically diverse cohort of STGD patients will validate this technology. We suggest that microarray screening with subsequent sequence analysis confirmation will be sufficient to confirm the clinical diagnosis of classic Stargardt disease and other *ABCA4*-associated retinopathies.

**Novel contributions to the Asian CFTR mutation spectrum: genotype and phenotype in Thai patients with cystic fibrosis.** *S. Ramalingam*<sup>1</sup>, *R. Sankaran*<sup>1</sup>, *W. Karnsakul*<sup>2</sup>, *P. Gardner*<sup>1</sup>, *I. Schrijver*<sup>3</sup>. 1) Medicine, Stanford University Medical Center, Stanford, CA, USA; 2) Pediatrics, Siriraj Hospital, Mahidol University, Bangkok, Thailand; 3) Pathology, Stanford University Medical Center, Stanford, CA, USA.

Cystic fibrosis (CF) is an autosomal recessive disorder caused by CFTR mutations. Due to the prevalent F508 mutation, CF is common in Caucasians and the mutation spectrum in this group is well characterized. Other ethnic groups, however, have not been analyzed in depth. As yet, only one mutation has been reported from Thailand. We studied three Thai CF patients, who presented with hyponatremic hypochloremic metabolic alkalosis in the first months of life. The CFTR coding region and intervening sequences flanking the 27 exons were amplified by PCR, followed by direct DNA sequencing. Five mutations were identified, three of which are novel. Patient 1, a child of parents with Chinese ancestry, is thus far free of lung disease and pancreatic insufficiency. One of his mutations (4330delTG in exon 23) is associated with a mild phenotype in another patient. The second mutation (3206 C>A in exon 17a) leads to A1025D and has not yet been described. Patient 2 has classic CF. He carries a splice site mutation in IVS 3 (405+1G>A) and the novel 1001+3A>T in IVS 6b. This mutation is expected to also result in alternative splicing and mRNA studies will be performed. Patient 3, a child of non-consanguineous parents, presented with pancreatic insufficiency and pneumonia at four months of age and expired of respiratory failure and sepsis. One of her siblings had an identical clinical course. DNA analysis revealed homozygosity for a novel nonsense mutation in exon 6a (738G>A, W202X). A larger study is ongoing to determine prevalence of these mutations in the Thai population. Our results support the notion that CFTR mutations in non-Caucasians are under-studied, and that Asian individuals may carry specific mutations that remain undetected by limited mutation panels. Further analysis of this mutation spectrum will allow population-specific genetic analysis in Thailand, and improve diagnostic sensitivity in the multi-ethnic US population.

**Newborn screening for  $\alpha$ -thalassemia: molecular genetic confirmatory testing by multiplex-ARMS.** *U. Bhardwaj*<sup>1</sup>, *Y.-H. Zhang*<sup>1</sup>, *F. Lorey*<sup>2</sup>, *L.L. McCabe*<sup>1,3</sup>, *E.R.B. McCabe*<sup>1,3,4</sup>. 1) Dept Pediatrics, David Geffen Sch of Med at UCLA, LA, CA; 2) Genetic Disease Branch, CA Dept of Health Services, Berkeley, CA; 3) Dept of Human Genetics, David Geffen Sch of Med at UCLA, LA, CA; 4) Mattel Children's Hosp at UCLA, LA, CA.

$\alpha$ -Thalassemia ( $\alpha$ -thal) is an increasing health problem in the US due to changing demography. Many US neonatal screening laboratories use high performance liquid chromatography or isoelectric focusing, which may result in diagnostic confusion due to interaction of various hemoglobinopathies with  $\alpha$ -thal. We developed single-tube multiplexed PCR assays using original neonatal screening specimens to identify the mutations responsible for  $\alpha$ -thal to expedite diagnostic confirmation. Primers were designed for 2-6 common ethnic-specific mutations using the amplification refractory mutation system (ARMS) and were standardized on positive control samples. The multiplex-ARMS approach was validated using DNA samples with known  $\alpha$ -thal mutations. Specimens from African-American neonates were tested for two mutations (-88 and -29); Asian Indians for five mutations (IVSI-1, IVSI-5, Cd 41/42, Cd 8/9 and 619 bp del); Chinese for five mutations (Cd 41/42, Cd 17, -28, Cd 71/72 and IVSII-654); and Southeast Asians for six mutations (Cd 41/42, Cd17, -28, IVSII-654, IVSI-5 and IVSI-1). We identified  $\alpha$ -thal mutations by multiplex-ARMS from positive control samples, confirming successful development and application of the assay. We tested 25 anonymized dried blood specimens from neonates belonging to these ethnic groups who had  $\alpha$ -thal. We detected a mutation using the ARMS approach in nearly all specimens: four Asian Indian mutations in five samples; two Chinese mutations in seven samples; two Southeast Asian mutations in 12 samples; and one African-American mutations in one sample. Results were confirmed by sequencing. Multiplex-ARMS for ethnic-specific  $\alpha$ -thal mutations using original newborn screening dried blood specimens is a rapid and efficient approach for diagnostic confirmation. Implementation of DNA confirmatory testing for  $\alpha$ -thal will not only improve early diagnosis, but also will facilitate genetic counseling in these families.

**Frequency of the single deletional alpha-thalassemia allele ( $-^{3.7}$ ) in the different racial groups in Malaysia - A molecular study.** *Y.C. Wee<sup>1</sup>, J.A.M.A. Tan<sup>1</sup>, K.L. Tan<sup>1</sup>, W.P. Chow<sup>2</sup>, S.F. Yap<sup>3</sup>, E. George<sup>4</sup>.* 1) Department of Molecular Medicine, University of Malaya, Kuala Lumpur, Malaysia; 2) Department of Obstetrics and Gynecology, University of Malaya, Kuala Lumpur, Malaysia; 3) Department of Pathology, University of Malaya, Kuala Lumpur, Malaysia; 4) Department of Clinical Laboratory Sciences, Faculty of Medicine and Health Sciences, University Putra Malaysia, Selangor, Malaysia.

Alpha-thalassemia is one of the most common genetic Hb disorders in Malaysia and it is a public health problem. The disorder can result from deletional or non-deletional (mutations) of the  $\alpha$ -thalassemia genes. In Malaysia,  $\alpha$ -thalassemia is most often caused by gene deletions resulting in  $\alpha$ -thalassemia 1 ( $^0$ ) and  $\alpha$ -thalassemia 2 ( $^+$ ). Individuals with  $^0$ -thalassemia ( $--/$ ) possess a molecular defect where both  $\alpha$ -globin genes in cis are deleted, and this defect has been reported to be more commonly present in the Malaysian Chinese. Individuals with  $^+$ -thalassemia have one  $\alpha$ -gene deleted ( $-/$ ) and this was reported to be more common in the Malays. In this study of  $^+$ -thalassemia, the frequency of the single deletional alpha-thalassemia allele ( $-^{3.7}$ ) was characterized in 670 blood samples: 402 from the Malays, 148 from Indians, 100 from Chinese and 20 from other ethnic groups. The defect was studied using DNA amplification to detect the  $-^{3.7}$  rightward deletion and the normal 2-gene sequence in two separate reactions. Specific primers were used to amplify the 2 and 1 genes. One reaction amplifies the 2-1 genes flanking the  $-^{3.7}$  deletion region to detect the presence of  $-^{3.7}$  rightward deletion while the second reaction amplifies a comparable segment of the normal 2 gene. Both DNA amplification protocols produce a molecular weight product of 1.8 kb. The  $-^{3.7}$  deletional defect was confirmed in 11 % of Malays, 10 % of Chinese and 6.1 % of the Indians studied. The defect was also detected in a patient with Thai nationality and in an Orang Asli (Aborigine) patient belonging to the Bidayuh tribe. In conclusion, the  $^+$ -thalassemia ( $-/$ ) defect was found in similar frequencies in the Malays and Chinese and at a lower frequency in the Indians in Malaysia.

**Extensive Sequencing of the  $\beta$ -Globin Gene for the Detection of  $\beta$ -thalassemia Mutations.** *F. Quan<sup>1</sup>, S. Wang<sup>1</sup>, C.M. Strom<sup>1</sup>, M.V. Gallican<sup>2</sup>, W. Sun<sup>1</sup>.* 1) Molecular Genetics, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA; 2) Hematology, Quest Diagnostics Nichols Institute, Chantilly, VA.

$\beta$ -thalassemia is characterized by the reduced or absent synthesis of  $\beta$ -globin chains. Most common causes of the  $\beta$ -thalassemia are point mutations in the  $\beta$ -globin gene. To date, over 200  $\beta$ -globin mutations have been reported. The individuals homozygous for a  $\beta$ -thalassemia mutation, or compound heterozygous for 2 different mutations, may manifest with  $\beta$ -thalassemia major or intermedia that is characterized by severe anemia, skeletal deformities, and hepatosplenomegaly. Carriers of one  $\beta$ -thalassemia allele can be normal, or have mild anemia. Traditional hematological tests (red blood cell indices, peripheral blood smears, and hemoglobin analysis) can diagnose patients with typical  $\beta$ -thalassemia. However, it remains a challenge for these hematological tests to accurately detect all carriers or make prenatal diagnosis. Here we report the development and validation of a comprehensive  $\beta$ -globin sequencing assay for the detection of  $\beta$ -thalassemia mutations. In this assay, the three exons of the  $\beta$ -globin gene, including the promoter region and their neighboring intronic regions, and part of intron 2 are independently amplified by polymerase chain reaction (PCR) and sequenced in both directions by dye-terminator cycle sequencing. This extensive  $\beta$ -globin sequencing assay can detect all reported point mutations in  $\beta$ -globin gene. This assay has been validated with a panel of 10 DNA samples, including 4  $\beta$ -thalassemia patients with known mutations (total of 7 distinct mutant alleles). All DNA samples were genotyped correctly. We further analyzed DNA samples from 23 patients diagnosed or suspected, by hemoglobin analysis, as carrying  $\beta$ -globin mutation(s). A total of 27  $\beta$ -globin mutant alleles (15 distinct mutations) were detected in 19 of these patients. These studies demonstrated the validity, and clinical utility of the comprehensive  $\beta$ -globin sequencing assay we developed.

**Genetic Basis of Korean Patients with Prader-Willi Syndrome.** *H.J. Jo, C.S. Ki, J.W. Kim.* Dept Laboratory Medicine, Samsung Medical Ctr, Seoul, Korea.

Prader-Willi syndrome (PWS) is clinically distinct complex disorder mapped to chromosome 15q11-q13. PWS can result from microdeletion, uniparental disomy (UPD), or imprinting center defect (ID) in 15q11-q13. Although PWS is not uncommon in Korean population, there is no data on the frequency of each genetic mechanism of Korean patients with PWS. Therefore, we tried to analyze the genetic basis of Korean PWS. A total of 88 cases were analyzed. Chromosome analysis, interphase fluorescent in situ hybridization (FISH) with *SNRPN* probe, and methylation sensitive polymerase chain reaction (m-PCR) were performed with peripheral blood specimens. Clinical findings were scored according to the consensus diagnostic criteria for PWS. Sixteen cases tested with both FISH and m-PCR were confirmed as having PWS either by a deletion of PWS critical region (n=10) or by an abnormal methylation pattern (n=6). Among sixty-seven cases tested with FISH but not with the m-PCR, 15 cases were consistent with a deletion pattern. In addition, five m-PCR positive cases lack FISH data. Taken together, 6 out of 31 (19.4%) confirmed PWS patients showed a PWS-specific m-PCR pattern with normal FISH signal, which could be due to either UPD or ID mechanism. The above results suggest that about 80.6% of Korean patients with PWS may be due to microdeletion of PWS critical region in 15q11-q13. Considering these results, the frequency of UPD or ID seems to be a little lower than those of previously reported data in other populations (~30%). However, if we take into account of 57 cases in which either FISH or m-PCR was done, the proportion of UPD or ID might be greater than it is.

**Ethnicity-specific differences in second-trimester maternal serum screening.** *F. Alvarez Nava, M. Soto-Quintana, T. Padrón, A. Morales-Machín, M.C. Martínez, A. Rojas-Atencio, K. Urdaneta.* Unidad de Genética Médica, Universidad del Zulia, Maracaibo, Venezuela.

Background: Second-trimester maternal serum screening is associated with fetal and perinatal disorders. Effective and accurate screening is based on the establishment of the population-derived median values of AFP, -hCG, and uE<sub>3</sub> in pregnant women. Race-ethnicity-specific differences have been observed. Objective: To identify any race-ethnicity-specific variations between Venezuelan pregnant women and other populations in second-trimester maternal serum screening. Study Design: Maternal serum levels AFP, -hCG and uE<sub>3</sub> were measured in 2,000 unaffected singleton, nondiabetic pregnancies from 14 to 21 weeks in our laboratory, Maracaibo, Venezuela. Patients with chromosome abnormalities or fetal anomalies were excluded. All results were expressed as multiple of the median (MoM) gestation specific values. Data from many studies in Hispanic (born in USA), Caucasian and Afroamerican women were compared with our data. Results: There were variations across gestational ages between different groups. All three analytes in our women appeared to be higher than data from Caucasian women but they are lower than data from Afroamerican women. Differences were seen even when data were compared with Hispanics born in USA. These patterns are considered statistically significant when are compared at advanced gestational ages (p 0.05). Weight correction did not compensate for ethnic variations. Conclusions: Adjustment of medians for Hispanic ethnicity may have a small but significant effect, especially with regard to low values and at advanced gestational age. Use of separate data bases should result in more accurate screening.

Program Nr: 1410 from 2003 ASHG Annual Meeting

**Quality assurance of markers in integrated prenatal screening for Down syndrome.** *C. Meier, T. Huang, A.M. Summers.* Dept Genetics, North York General Hosp, Toronto, ON, Canada.

Maternal serum screening (MSS) for Down syndrome has been offered in the province of Ontario as a funded service since 1993. Quality assurance (QA) of MSS relies on both internal and external analyses of the biochemical markers used (AFP, uE3 and hCG) including periodic review of median MoM values, weight correction and positive rates. In 1999, our laboratory was the first in Canada to offer integrated prenatal screening (IPS), which incorporates the results of first trimester ultrasound (NT) and biochemical (PAPP-A) markers with the standard MSS markers to provide a single, more accurate, risk estimate. We have reported over 16,000 IPS results since introduction and integrated screening currently makes up 29% of the total provincial volume. We have found the methodology of using and monitoring the MoM values of integrated screening markers is effective in assuring the quality of screening results. While QA of biochemical markers is relatively straightforward, the ultrasound marker, nuchal translucency (NT), demands specialized methods to ensure that performance is acceptable. The NT measurements received from 133 sonographers enrolled to date in our screening program are subject to initial assessment and ongoing review. Using sonographer-specific NT medians provides the comparable improvement of risk estimates as does the use of laboratory-specific biochemistry medians, namely, the correction of variance attributed to the instrument and operator. Given that our actual screening performance, with respect to false-positive rates and detection rates, closely approximates the theoretical performance predicted by published sources, we can confirm that MoM-based quality assurance of integrated screening markers is effective.

**Weight Correction and Ethnic Differences for First Trimester Down Syndrome Biochemical Markers.** *D. Krantz, T. Hallahan, J. Macri.* NTD Labs, Huntington Stat, NY.

First Trimester Down syndrome screening using Free Beta hCG, PAPP-A and nuchal translucency is steadily replacing second trimester screening in routine prenatal care. As part of second trimester multiple marker screening weight and ethnic variation have been observed for all of the screening markers. We conducted a study to determine the effect of these factors on first trimester biochemistry. We reviewed the results of 36,635 patients, including, 1872 African Americans, 576 As. Indians, 1412 Asians, 1881 Hispanics, 68 Native Am, 30263 Caucasian and 563 Others. Maternal weight correction factors for free Beta hCG and PAPP-A were developed based on the white ethnic groups. Median MoM results were then compared before and after adjustment. The maternal weight correction formulas were:  $\ln(\text{FB hCG}) = \text{EXP}(3.7087 - .7449 * \ln(\text{wt}))$ ,  $110 \leq \text{wt} \leq 225$  lbs and  $\ln(\text{PA}) = \text{EXP}(6.7495 - 1.3556 * \ln(\text{wt}))$ ,  $115 \leq \text{wt} \leq 275$  lbs  
The Median MoMs for each ethnic group are shown below:

	Afr. Amer	As. Indian	Asian	Hispanic	Native Am	Caucasian	Other
Unadj FB	1.03	1.06	1.15	0.89	0.88	1.00	1.05
Wt.Adj. FB	1.15*	1.00	1.06*	0.89*	0.95	1.01	1.03
Unadj PA	1.09	1.12	1.19	0.98	1.01	1.00	1.01
Wt.Adj. PA	1.30*	0.99	1.03	0.98	1.01	1.01	1.01

\* Indicates significant difference vs. Caucasian group using Bonferroni criteria (overall  $P < 0.05$ ). As with second trimester screening, first trimester Down syndrome biochemical screening markers should be adjusted for maternal weight and ethnicity.

**Quality of human DNA from buccal cytobrushes depends on storage conditions.** P.A. Krakowiak, Y. Guan, J.J. Greenhaw, W.A. Freeman, J. Kimbrough, R. Lyle, W. Zhao, M.A. Cleves, C.A. Hobbs. Pediatrics, UAMS, Little Rock, AR.

**Background:** Obtaining DNA from participants enrolled in large epidemiologic studies is critical to unraveling genetic causes and susceptibilities to complex diseases. Buccal epithelial cell collection is a quick, safe, inexpensive, and noninvasive process of obtaining DNA that can be self-administered and returned via mail. However, the obtained DNA has two major problems: low concentration and bacterial contamination, that can lead to degradation of the human DNA. Our data from 1119 mailed buccal samples indicate that genotyping success rates are significantly better (86%) when cytobrushes are transported during colder months (average monthly high < 68F), compared to months when temperatures are above 68F (57%,  $p < 0.001$ ). Although bacterial contamination has been recognized, the storage conditions that may affect the extent of contamination have not been studied systematically. **Methods:** Using volunteer samples, we conducted experiments to determine the effects of storage time, humidity, temperature, and duration of sample collection on DNA quality and quantity. We calculated microsatellite genotyping success rate, specific gene (*NKX2.5*) PCR amplification success, and DNA quantity using real-time PCR. **Results:** Increased temperature and humidity were the most important elements that reduced the quality of DNA. Genotyping success rates were significantly lower for cytobrushes stored at 37C in air-tight (*humid*) compared to open-to-air (*arid*) containers (48 vs 88%,  $p = 0.003$ ) and when *humid* samples were stored for 5 days vs 1 day (60 vs 85%,  $p = 0.01$ ). *NKX2.5* PCR success scores were also lower for humid vs arid samples (0.45 vs 1.38,  $p < 0.001$ ). When cytobrushes were processed immediately, success rates were not different between a volunteers 1st and 10th brush ( $p < 0.001$ ), and for brushes collected 1 and 2 weeks later ( $p < 0.001$ ). **Conclusion:** When it is impractical to collect DNA by other means, buccal cell samples are a useful alternative. However, storage conditions of cytobrushes may significantly alter the quality of obtained DNA; therefore, they should be transported in containers permeable to air or in a buffer containing a lysis reagent to diminish bacterial growth.

**A new quantitative test to simultaneously screen for galactose uridylyltransferase and biotinidase deficiency in newborns using a single blood spot.** *S.J. Mihalik, J.G. Suzow, D.E. Freer, E.W. Naylor.* Neo Gen Screening Inc., Bridgeville, PA.

Newborn screening relies on the use of small quantities of dried whole blood on filter paper for testing. The large quantities of hemoglobin in whole blood frequently quench both colorimetric and fluorometric assays, and as such its role must be considered in assay design. The purpose of this study was to develop a routine newborn screening protocol in which one eluted blood spot could be used to screen for at least two disorders that are commonly included in newborn screening programs. Uridylyltransferase (classical galactosemia) and biotinidase assays meet the criteria and both utilize enzyme assays. Blood spots (3.2mm) were eluted in water and aliquoted to individual plates using a Packard Multiprobe. Both enzymes were then assayed using modifications of standard protocols, except that the interference from hemoglobin was addressed. For the uridylyltransferase, samples were diluted after the reaction, resulting in the avoidance of quenching of the NADH fluorescence. In the colorimetric biotinidase assay using the biotinyl-*p*-aminobenzoic acid substrate, proteins were precipitated with trichloroacetic acid and the interfering precipitate was removed by filtration before colorimetric quantitation. The assays were found to be both precise and accurate and were found to have a coefficient of variation that was comparable to that of the assays performed using an established continuous flow method. Future plans include the extension of this concept of multiple assays from one extraction to include at least one other enzyme assay. This miniaturization approach to assays continues to ensure that newborn screening is affordable and minimally invasive.

**Molecular Diagnosis of Beckwith-Wiedemann Syndrome: Quantitative Analysis of Methylation in the KvDMR**

**Region.** *B. Baskin*<sup>1</sup>, *R. Weksberg*<sup>2, 3</sup>, *P.N. Ray*<sup>1, 3</sup>, *T.L. Stockley*<sup>1, 4</sup>. 1) Molecular Genetics Laboratory, Department of Paediatric Laboratory Medicine; 2) Department of Clinical and Medical Genetics, The Hospital for Sick Children; 3) Department of Molecular and Medical Genetics; 4) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Ontario, Canada.

Beckwith-Wiedemann syndrome (BWS) is a genetic overgrowth syndrome characterized by a number of features such as somatic overgrowth, abdominal wall defects, macroglossia and embryonal tumours. BWS is associated with genetic or epigenetic abnormalities of several imprinted genes on human chromosome 11p15. These genes usually show differential DNA methylation. A differentially methylated region (DMR) is a DNA sequence that bears a CpG-methylation mark that is specific to the chromosomal parent-of-origin. Such DMRs may be maternally or paternally methylated. One important DMR in BWS is KvDMR1, which is located within intron 10 of the potassium channel coding gene *KCNQ1*. The paternal allele is non-methylated, permitting the paternal expression of a transcript called *KCNQ1OT1* whereas the maternal allele is methylated, keeping the maternal expression of *KCNQ1OT1* silenced. For diagnosis we currently provide UPD analysis which detects mutations in ~15% of BWS patients. The majority of BWS patients, ~60%, show loss of methylation at a certain degree in KvDMR1 on the maternal allele. However there is currently no clinical quantitative molecular test to analyze the methylation status in this region. We are developing a new diagnostic assay, which detects the methylation status in KvDMR1. The technology we are using is Pyrosequencing, a real-time mini-sequencing method, to quantify the amounts of incorporated C/Ts and thereby determine the methylation status at certain specific CpGs in KvDMR1. Using this technology we have been able to develop a new quantitative assay to identify maternal loss of methylation at CpG sites in BWS patients. This test will be validated in the Molecular Genetics Laboratory for diagnosis of BWS patients, as well as for potential use for other DMRs.

Program Nr: 1415 from 2003 ASHG Annual Meeting

**Comprehensive screening of the dystrophin gene.** *T.W. Prior, J.W. Heinz, J. Fang.* Pathology, Ohio State University, Columbus, OH.

Approximately 2/3 of the DMD/BMD population have been shown to have large deletions of the dystrophin gene. We have performed an extensive screen on our nondeletion patients for duplications by Southern blotting the entire gene and for point mutations by DHPLC and sequencing. Unlike the deletion distribution, duplications were found in only about 5-8% of the patients and were located primarily at the 5' end of the gene. 82 nondeletion/nonduplication patients were screened for point mutations by DHPLC and sequencing. Several novel point mutations were identified and were randomly distributed throughout the gene. Nonsense, frameshift and splice mutations all resulting in protein truncation were found. Analysis of intron 1 revealed a splice site mutation in an X-linked dilated cardiomyopathy patient. Several base changes causing significant amino acid substitutions were found, however, these were most likely polymorphic changes. Missense mutations in the dystrophin gene are rare events. The identification of duplications and point mutations is important for the confirmation of the diagnosis and for accurate carrier studies. In the future, molecular therapies (such as antisense oligonucleotides, antibiotics or chimeric RNA/DNA) will be applied according to the specific dystrophin mutation. This will require a complete mutation analysis and identification of all types of dystrophin mutations. (This research has been generously supported by the Muscular Dystrophy Association).

**A Blood Based Diagnostic Test for LGMD 2B and Miyoshi Myopathy.** *A. Hennigan<sup>1</sup>, L. Hayes<sup>1</sup>, M. Tatis<sup>1</sup>, J. Sisson<sup>1</sup>, K. Greenough<sup>1</sup>, L. Kertiles<sup>1</sup>, E. Gallardo<sup>2</sup>, I. Illa<sup>2</sup>, R.H. Brown, Jr<sup>3</sup>, S.D. Batish<sup>1</sup>, W.K. Seltzer<sup>1</sup>.* 1) Athena Diagnostics, Inc., Worcester, MA 01605; 2) Department of Neurology, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 3) Department of Neurology, Massachusetts General Hospital, Charlestown, MA 02129.

Limb Girdle Muscular Dystrophy 2B (LGMD 2B) and Miyoshi Myopathy (MM) are allelic autosomal recessive disorders that arise from defects in the dysferlin (DYSF) gene. The disease, which begins in young adults, is progressive with muscle degeneration resulting from dysferlin protein deficiency. In LGMD 2B, weakness starts in the proximal muscles of the pelvic girdle, while in MM, weakness affects the gastrocnemius muscles and subsequently the proximal muscles. It is estimated that loss of dysferlin accounts for 5% to 10% of all incidences of muscular dystrophy. Associated phenotypes include HyperCKemia and distal anterior phenotype. We describe the development of a diagnostic test for LGMD 2B/MM based on the method of Ho et. al. that screens for dysferlin expression in whole blood. Dysferlin-expressing monocytes are purified, extracts prepared and specific protein detected in Western blotting by using a commercially available monoclonal antibody. Monocyte purification coupled with the use of highly sensitive immunoblotting technique ensures detection of dysferlin protein, if present. This is a critical feature of our test since, by definition, individuals with LGMD 2B/MM have no detectable dysferlin protein. Data obtained during test development demonstrates dysferlin to be a stable protein, detectable in whole blood of normal control individuals up to two days after blood draw. The primary benefit of this technology is the ability it gives clinicians to confirm dysferlinopathy by using a simple blood test. The need to perform a muscle biopsy is therefore eliminated. This poster will present an overview of the testing service and its value in the diagnosis of individuals affected with LGMD 2B/MM.

**Mutational Analysis of ATM Gene in Iranian Patients with Ataxia Telangiectasia.** *H. Atashi Shirazi*<sup>1</sup>, *B. Bayat*<sup>2</sup>, *S. Ahmad. Aleyasin*<sup>2</sup>, *A. Farhoodi*<sup>3</sup>, *M. Moin*<sup>3</sup>, *M. Hosse Sanati*<sup>3</sup>. 1) Tehran Khatam University Tehran, Iran; 2) National Research Center for Genetic Engineering and Biotechnology (NRCGEB), Tehran, Iran; 3) Children Medical Center, Tehran, Iran.

Ataxia telangiectasia is an autosomal recessive disease. More than 100 mutations in ATM gene have been reported which cause ataxia telangiectasia. Identifying common mutations in each population provides information for genetic counseling, prenatal testing and carrier detection. This study is to permit detection of ATM mutations in Iranian patients. We screened some Hotpoint exons and introns of five A-T patients and their families. Genomic DNA was extracted from their blood samples and the specific regions of the gene were amplified using PCR. Single strand conformation polymorphism (SSCP) was used for mutational analysis of amplified fragments from genomic DNA. We screened 11 terminus exons in which some were overlapped with introns. We identified polymorphic bands on SSCP gels after staining them with silver stain. Among 14 blood samples we studied, 5 were homozygotes for the polymorphism, 5 were heterozygotes, and 4 showed no polymorphism compared to negative control bands. In this study, polymorphism has been identified in exons 40, 41, 58, and 62. Homoallelic mutations would be expected to occur in consanguineous population, whereas heteroallelic (compound) mutation should be frequent among unrelated individuals.

**THE SPECTRUM OF ALPHA-THALASSEMIA MUTATIONS IN IRAN.** *M. Garshasbi Safi Abadi*<sup>1,2</sup>, *H.Y. Law*<sup>3</sup>, *M. Neishabury*<sup>2</sup>, *C. Oberkanins*<sup>4</sup>, *K. Kahrizi*<sup>2</sup>, *E. Keyhani*<sup>2</sup>, *Sh. Dadgar*<sup>2</sup>, *R. Kariminejad*<sup>1</sup>, *N. Al Madani*<sup>1</sup>, *F. Afrozani*<sup>1</sup>, *W. Krugluger*<sup>5</sup>, *H. Najmabadi*<sup>1,2</sup>. 1) Kariminejad/Najmabadi Genetic and Pathology Center, Tehran, Iran; 2) Genetics Research Center, The Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 3) Genetics Service, KK Womens and Childrens Hospital, Singapore; 4) ViennaLab Labordiagnostika GmbH, Vienna, Austria; 5) Institute of Clinical Chemistry, Rudolfstiftung Hospital, Vienna, Austria.

Alpha-thalassemia (-thal) is one of the most common single-gene diseases in the world. It is caused by a variety of deletional and non-deletional -globin mutations, leading to a reduction or complete absence of gene expression. In this study we have tested 87 Iranian individuals, randomly chosen from a pool of patients with low MCV, low MCH, normal or slightly reduced Hb levels, normal HbA<sub>2</sub>, and negative results in -thalassemia genotyping, for the presence of common -thal mutations. Two single-gene deletions (-<sup>3.7</sup>, -<sup>4.2</sup>), five double gene deletions (--SEA, --MED, --THAI, --FIL, -<sup>20.5</sup>), and five point mutations (Hb Constant Spring, Hb Quong Sze, Hb Pakse, Hb Adana, cd 30 delGAG,) were analyzed by PCR and reverse dot-blot methods, and -thal mutations were identified in 50 cases (57%). The following genotypes were observed: -<sup>3.7</sup>/(25 subjects), -<sup>3.7</sup>/<sub>-<sup>3.7</sup></sub> (10) --MED/ (3), -<sup>3.7</sup>/<sub>-<sup>4.2</sup></sub> (2), -<sup>3.7</sup>/<sub>--MED</sub> (1), -<sup>4.2</sup>/<sub>--MED</sub> (1), -<sup>20.5</sup>/<sub>-<sup>20.5</sup></sub> (2), CS/ (4) and CS/CS (1). In 37 individuals none of these mutations was found. Our study shows that the -<sup>3.7</sup> single gene deletion is a very frequent cause of microcytic, hypochromic anemia in Iran, whereas other globin deletions and point mutations seem to be rather uncommon.

**Mutations of the steroid 21-Hydroxylase Gene among Filipino Patients with Congenital Adrenal Hyperplasia.** *E. Cutiongco*<sup>1,2</sup>, *C.E. Abaya*<sup>1</sup>, *C. Padilla*<sup>1,2</sup>, *B.C. Cavan*<sup>2</sup>, *C.L. Silao*<sup>1,2</sup>, *P. Barut*<sup>1</sup>. 1) Inst Human Genetics, Manila, Philippines; 2) Department of Pediatrics, College of Medicine Philippine General Hospital, University of the Philippines Manila.

Congenital Adrenal Hyperplasia (CAH), an autosomal recessive disorder, is due to defective enzymes involved in adrenal steroidogenesis. Phenotypic manifestations are variable depending on the effects produced by the deficient hormones and by the excess production of steroids unaffected by the enzymatic block. CAH, with ethnic and racial variability, has a worldwide incidence of 1 in 15,000. The incidence in France, Italy, Scotland, New Zealand and Japan ranges from 1 in 10,000 to 1 in 23,000. The Philippine CAH crude incidence of 1 in 6,747 (Philippine Newborn Screening Update, 2002) is higher than what is reported in most populations. More than 90% of all cases result from a 21 hydroxylase (cytochrome P450c21) deficiency involving two 21 hydroxylase genes CYP21, the active gene and CYP21P, a pseudogene. Studies have shown that mutations result from unequal crossover during meiosis leading to complete gene deletions, gene conversion events or to point mutations and have demonstrated differences in the frequency of several gene mutations. Using a previously reported combined differential Polymerase Chain Reaction (PCR) and Amplification Created Restriction Site (ACRS) approach (Lee et al, 1996), direct probing of known mutations in exons 1, 3, 4, 6, 7, 8 and intron 2 of the CYP21 and CYP21P genes among Filipino CAH patients was performed. Of the 12 unrelated CAH patients examined, one (8%) demonstrated two different mutations in her CYP21 gene. Ten of the twelve cases (83%) had only one type of mutation detected. Majority of these cases had a premature splicing error involving nucleotide 656 of intron 2. The determination of the most frequent alleles in our population will facilitate rapid screening for 21 hydroxylase gene mutations. Establishment of a definitive diagnosis, essential in the management and counseling of Filipino CAH cases, can also be made available.

**Towards harmonization of external quality assessment (EQA) schemes.** *E. Dequeker, J.J. Cassiman.* Human Gen/Gasthuisberg O&N 6, Univ Leuven, Leuven, Belgium.

Efforts to assess and improve the quality of the output of molecular genetic diagnostic laboratories have been initiated over the last years. Among these are organizations of EQA schemes, also named proficiency testing. Here we provide an overview of the variety of EQA schemes for molecular genetic testing that are being organized in Europe. Several EU member state institutions and international organizations organize EQA schemes at a national, a regional / multinational, or a large-scale international level. Together, EQA schemes have been organized nowadays in Europe for 19 different genetic diseases. For some disorders, multiple initiatives are being undertaken at different levels. For example, for cystic fibrosis genetic testing is one national scheme, three regional or multi-national, and two international schemes, with a range of participation between 6 and 210 labs. For Duchenne and Becker Muscular Dystrophy, four initiatives are undertaken (involving all levels), with number of participants per scheme ranging between 19 and 27. As a logical consequence of this variation between EQA schemes, it becomes difficult for laboratories to distinguish between the designs, and to judge the added value of participation to one or more specific schemes. National or local schemes are important because samples with region-specific mutations can be selected, and reporting can be done in the local language. On the other hand, the organization of large international schemes is more cost-efficient, allows broad recruitment of participants, can provide a broader evaluation of the state-of-the art of routinely applied methodologies for a specific disease, and is more likely to pinpoint eventual shortcomings in commonly used methods. Given the contribution of EQA schemes to assure high-quality genetic service by diagnostic laboratories (education, monitoring of performance), it is encouraging that different organizations are willing to set-up such schemes. However, no guidelines or requirements have been defined yet for the design or organization of EQA schemes for molecular genetic testing, which could lead to a harmonization of different EQA schemes. Suggestions on how to harmonize the different EQA scheme will be further presented in the paper.

**Genetic testing for familial Mediterranean fever in Austria by means of reverse-hybridization teststrips. C.**

*Oberkanins<sup>1</sup>, A. Weinhaeusel<sup>2</sup>, G. Kriegshaeuser<sup>1</sup>, F. Kury<sup>1</sup>, O.A. Haas<sup>2</sup>.* 1) ViennaLab Labordiagnostika GmbH, A-1110 Vienna, Austria; 2) Children's Cancer Research Institute (CCRI), St. Anna Children's Hospital, Vienna, Austria.

Familial Mediterranean fever (FMF) is an autosomal-recessive, inflammatory disorder characterized by short, recurrent attacks of fever, accompanied by pain in the abdomen, chest or joints, and erysipelas-like erythema. Its most severe complication is progressive amyloidosis, leading to end-stage renal failure. FMF predominantly affects Turks, Arabs, Armenians and Sephardic Jews, with carrier rates reported as high as 1 in 5, but has been observed in lower frequencies throughout the Mediterranean area. It is caused by a number of mutations within the marenostin/pyrin-encoding gene MEFV on chromosome 16p13.3, which differently affect the severity of the disease phenotype and the risk to develop renal amyloidosis. Owing to the rather nonspecific clinical symptoms, molecular genetic analysis significantly improves early and correct diagnosis of FMF, and allows to commence lifelong prophylactic treatment of affected individuals with colchicine. We have developed a simple and convenient reverse-hybridization assay (FMF StripAssay) for the simultaneous detection of the following 12 MEFV mutations: E148Q, P369S, F479L, M680I (G/C), M680I (G/A), I692del, M694V, M694I, K695R, V726A, A744S, R761H. The test is based on multiplex DNA amplification and hybridization to a teststrip presenting a parallel array of allele-specific oligonucleotide probes for each mutation. The entire procedure from blood sampling to the identification of mutations requires less than 6 hours, and hybridization/detection may be carried out manually or essentially automated using existing instrumentation (e.g. TECAN profiBlot). After validation on DNAs of known genotype, the assay was used to investigate 199 Austrian individuals suspected to suffer from FMF. We identified MEFV mutations in 109 patient samples, 80 of which carried two, and the remaining 29 carried a single mutation. Ninety patients tested negative for any of the 12 MEFV mutations. (oberkanins@viennalab.co.at).

**Preconception and prenatal cystic fibrosis carrier screening of African Americans reveals a higher carrier frequency and unanticipated frequencies for specific mutations.** *K. Monaghan<sup>1</sup>, D. Bluhm<sup>1</sup>, M. Phillips<sup>2</sup>, G.L. Feldman<sup>2,3</sup>*. 1) Medical Genetics, Henry Ford Hosp, Detroit, MI; 2) University Laboratories, Detroit Medical Center, Detroit, MI; 3) Wayne State University, Detroit, MI.

It is recommended by ACOG/ACMG that cystic fibrosis (CF) carrier screening be made available to African Americans who are either pregnant or planning a pregnancy. One in 65 African Americans is a CF carrier and the current recommended mutation panel detects 69% of mutations in this race, therefore 1/94 African Americans is expected to have a positive carrier screen. F508 accounts for nearly 50% of CF mutations in this group, with 3120+1GA accounting for another 12%. Between April 2001 and June 2003, we performed carrier screening for 1791 African Americans, testing for at least the 25 recommended mutations. A total of 30 CF carriers were detected (1/60), which is greater than expected ( $p < 0.025$ ). Four mutations were detected which are not part of the recommended panel: G622D, F693L (TG), Q98R, and P140S. The F508 mutation was detected in 47% of carriers. We did not detect any 3120+1GA carriers, although we expected 3 carriers of this mutation. The next most common mutations detected were R117H/7T (13%), G622D (10%), F693L (TG) and G551D (7% each). Although F693L (TG) is classified as a CF mutation, its significance is unclear as F693L (TC), originally reported as a CF mutation, was later re-classified as a polymorphism. G622D is reported as a disease-causing mutation and this has been confirmed by others by functional studies. When considering only the 25 recommended CF mutations, 1/78 African Americans screened in our laboratories were carriers (within the expected range); however, the addition of 4 mutations increased the carrier frequency to 1/60, which is significantly higher than expected. The frequencies of several specific mutations detected were unanticipated, as was the absence of 3120+1GA carriers. The current CF mutation panel is likely to be modified as additional racial and ethnic-specific information regarding CF mutations becomes available. Further studies are needed on the incidence of CF mutations that are not part of the current panel, such as G622D.

**Diagnosis of haploinsufficiency of NSD1 in patients with Sotos syndrome using real-time PCR.** *S. Langlois<sup>1, 2</sup>, S. Young<sup>2</sup>, M. Van Allen<sup>1</sup>, S. Lewis<sup>1</sup>, B. McGillivray<sup>1</sup>, S.L. Yong<sup>1</sup>.* 1) Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada; 2) Department of Pathology and Laboratory Medicine, Children's and Children's and Women's Health Center of British Columbia.

Sotos syndrome is characterized by developmental delay, macrocephaly, a distinctive facial appearance, overgrowth, and advanced bone age. In 2002, intragenic mutations and deletion of the NSD1 gene were found to cause Sotos syndrome. Published reports of deletions in patients with Sotos syndrome have relied either on the analysis of polymorphic microsatellite markers or FISH analysis. We present the use of real-time quantitative PCR to rapidly assess the NSD1 gene copy number in patients with Sotos syndrome.

Patients with Sotos syndrome seen in our clinic were invited to participate in the study. Taqman primers and amplification probes corresponding to the first coding exon of NSD1 as well as exon 12 of the albumin gene were used to quantitatively co-amplify their respective genes using an ABI 7000 Sequence Detection System. Comparison of the resulting amplification curves to those obtained from normal controls allowed for the NSD1 gene copy number to be determined according to the Ct method. The analysis of 11 patients is complete. Two patients are siblings and 9, sporadic cases. Four patients including the siblings were found to have a deletion of the NSD1 gene. Patient 1 had significant expressive language delay, macrocephaly, overgrowth, advanced bone age, frontal bossing, bitemporal narrowing, and a downward slant to her palpebral fissures. Patient 2 presented with significant developmental delay and macrocephaly. She had a dolicocephalic head, bifid uvula, height (90th perc.), weight (50th perc.), and advanced bone age at age 5. CT scan showed agenesis of the corpus callosum. Patients 3, 4 (sibs) presented with significant developmental delay, macrocephaly, and dolicocephaly. Analysis of parental DNA is pending on all cases. Our results indicate that real-time PCR allows for a rapid DNA based approach to the identification of NSD1 gene deletions and consequent confirmation of a diagnosis of Sotos syndrome.

**Cystic fibrosis transmembrane regulator mutations in Hispanic Californians with cystic fibrosis.** *M. Kharrazi<sup>1</sup>, O. Alper<sup>2</sup>, S. Young<sup>3</sup>, M. Pearl<sup>4</sup>, S. Graham<sup>4</sup>, F. Lorey<sup>1</sup>, J. Sherwin<sup>1</sup>, L-J. Wong<sup>2</sup>.* 1) Genetic Disease Branch, CA Dept of Health Services, Richmond, CA; 2) The Institute for Molecular and Human Genetics, Georgetown University, Washington, DC; 3) Public Health Institute, Oakland, CA; 4) Sequoia Foundation, La Jolla, CA.

Genetic information is currently lacking to build solid population-based cystic fibrosis (CF) screening programs because a large proportion of CF mutations are still unknown, especially in Hispanics. The discovery of mutation 3876delA with 10% prevalence in a selected group in Los Angeles suggests that major CF mutations in Hispanics exist but have yet to be found. The purpose of this study is to describe the distribution of CFTR mutations found in the California Hispanic CF population using multiple mutation sources and stepped mutation analyses. CF cases were identified from California Medi-Cal claims records, death records, and CF Care Center data. Mutation information was abstracted from clinic records and if unknown, analyzed from stored newborn screening blood spots using a 31-mutation panel (Applied Biosystems) or an 87-mutation panel (Genzyme Genetics). If mutations were still unknown, patients were recruited and blood was analyzed using the 87-mutation panel and temporal temperature gel electrophoresis (TTGE). Mutation information is available on over 300 Hispanic CF patients. To date, 94% have both mutations identified and 6% have only 1 mutation identified. Over 55 different mutations have been identified in this population. F508 comprised 62% of the mutations and 3% remain unknown. The 4 most prevalent mutations are F508, G542X, 3876delA and 3120+1G>A. Eight novel mutations were identified through TTGE: 2289-2295 del7bp ins GT, 3960-3961 del A, 360-365 ins T, 379-381 ins T, 1285-1288 ins TA, 296+2T>A, 124-146 del 23bp, and F1016S. Mutation 1285-1288 ins TA was found on 6 chromosomes in 5 unrelated patients with Mexican backgrounds. Unidentified mutations will be further analyzed using DNA sequencing. These data will be used to determine which CF mutations should be included in screening panels in California where over 50% of births are to Hispanics.

**Artificially Constructed CFTR Mutation Samples for Use in Quality Control and Proficiency Surveys:**

**Development and Pilot Testing.** *M. Jarvis*<sup>1</sup>, *R.K. Iyer*<sup>1</sup>, *L.O. Williams*<sup>2</sup>, *W.W. Grody*<sup>1</sup>. 1) Pathology & Laboratory Medicine, UCLA, Los Angeles, CA; 2) Division of Laboratory Systems, Centers for Disease Control and Prevention, Atlanta, GA.

The paucity of patient-derived mutation-positive clinical samples for molecular genetic testing of many heterozygous or rare disorders could be surmounted if it were possible to construct artificial samples containing mutations of interest that would sufficiently resemble natural human samples to function as acceptable and realistic performance evaluation challenges and quality control reagents for recipient laboratories. Using the cystic fibrosis gene (CFTR) as a prototype, we have devised and executed proof-of-principle experiments designed to generate unique mutant cell lines that could be used for these purposes.

We are using site-directed mutagenesis and targeted homologous recombination techniques to introduce specific mutations into the cystic fibrosis (CFTR) gene of a lymphoblastoid cell line (RGA-1). CFTR mutations G85E and N1303K represent the most 5 and 3 mutations in the ACMG-recommended population-screening panel of 25 mutations, while 1078T represents a mutation that has not yet been isolated and stocked for laboratory community use. Molecular testing and characterization of these mutations has proceeded in several defined steps: analysis of spiked genomic DNA containing various concentrations of plasmids and BACs of interest; analysis of DNA isolated from transient transfections; and analysis of DNA isolated from homologous recombination events. Here, we present data for one product construction method that shows positive results when tested at nine pilot facilities using several assay methodologies. All the pilot labs correctly detected the artificial mutations in both heterozygous and homozygous states using platforms varying from reverse ASO hybridization to microarray technology to sequencing. Thus, this method, which is amenable to scale-up and incorporation of virtually any mutation of interest, shows promise as a practical means of obtaining rare positive mutation controls that resemble real human samples for use in quality assurance and proficiency testing.

**Deletion scanning approaches are needed for routine *RB1* analysis.** C. Houdayer<sup>1</sup>, M. Gauthier-Villars<sup>1</sup>, A. Laugé<sup>1</sup>, C. Dehainault<sup>1</sup>, S. Pagès-Berhouet<sup>1</sup>, V. Caux-Moncoutier<sup>1</sup>, F. Doz<sup>1</sup>, L. Desjardins<sup>1</sup>, J. Couturier<sup>1</sup>, M. Tosi<sup>2</sup>, D. Stoppa-Lyonnet<sup>1</sup>. 1) Institut Curie, Paris, France; 2) INSERM EMI 9006, Rouen, France.

Germ-line mutations of the *RB1* gene are associated with a predisposition to retinoblastoma. Twelve years ago, *RB1* deletions emerged as an important cause of retinoblastoma, but are still poorly documented on large series. Since 2001, we have implemented *RB1* testing on a routine basis using a DHPLC method for point mutation detection, combined with a deletion scanning approach that includes karyotypic and molecular investigations. We report the results of this comprehensive deletion screening of all exons and promoter of *RB1* in 192 unrelated patients (102 bilateral and/or familial cases and 90 unilateral, sporadic cases). We used standard cytogenetic evaluation, FISH analysis using a probe covering the whole gene and quantitative multiplex PCR of short fluorescent fragments (QMPSF) to screen for *RB1* rearrangements. In order to confirm exon deletions, long-range PCR was performed with primers flanking the suspected deleted region. Eighteen deletions were found among 88 mutations, ranging from complete gene deletions to single-exon deletions, which represented 20% of the mutations found in our sample i.e. the highest ratio reported to date. All but one were found in bilateral and/or familial cases. All deletions were found using the QMPSF approach and could be confirmed by FISH in 5 cases of complete *RB1* deletions. Among these cases, standard karyotypic examination identified a large del(13)(q14.2q21.2) found in a otherwise mentally-retarded patient. Our results clearly demonstrated the need for a deletion scanning approach in *RB1* analysis and also prompted us to use cytogenetic examinations as a second-line screening when no mutations were found or, alternatively, as a first-line test when a gross rearrangement was suspected from the patients phenotype. No genotype-phenotype correlation could be deduced since in-frame and out-of-frame deletions resulted in bilateral phenotypes. Moreover, the same deletion led to distinct phenotypes within families, thereby highlighting the role of modifier factors.

**Quality assurance of novel diagnostic technologies: a collaborative effort towards the generation of generic SOPs for DHPLC analysis.** *G. Matthijs<sup>1</sup>, E. Dequeker<sup>1</sup>, E. Schollen<sup>1</sup>, G. Michils<sup>1</sup>, B. Vankeirsbilck<sup>1</sup>, J. Harvey<sup>2</sup>, S. McQuaid<sup>3</sup>, R. van Schooten<sup>4</sup>, E. van den Akker<sup>4</sup>, O. Merle<sup>5</sup>, S. Schrooten<sup>5</sup>, Z. Clark<sup>5</sup>, for the Collaborative Group on Diagnostic DHPLC Quality Assurance (DDQA).* 1) Centre for Human Genetics, Leuven, Belgium; 2) National Genetic Reference Laboratory (NGRL), Salisbury, UK; 3) National Centre for Medical Genetics, Dublin, Ireland; 4) VUMC, Amsterdam, the Netherlands; 5) Transgenomic Ltd, UK.

Working in a clinical diagnostic environment, everybody is aware of the drive to ensure the best quality of service. Laboratory accreditation requirements include the availability of validated protocols and traceable quality control data. Obviously, all laboratories that head towards accreditation are faced with the same tasks. They have to generate and validate Standard Operating Procedures (SOPs) for all their methods. A few European clinical genetic laboratories, in close association with Transgenomic, have undertaken a collaborative project to produce SOPs for WAVE and WAVE MD System operation and maintenance, as well as validated protocols for the genes which are routinely being screened by the participating laboratories. Several aspects of the DHPLC method (e.g. PCR requirements, heteroduplex formation, column and oven calibration and stability, selection of temperatures, buffers and control samples, software) have been dealt with in 3 basic types of SOP: a machine or maintenance SOP, a general DHPLC SOP and several disease gene SOPs. These SOPs have been drafted as generic SOPs, which would be useful for all WAVE Users. We have chosen the analysis of MECP2 (Rett Syndrome) to demonstrate the feasibility of this approach. Eight primer sets, for use with Optimase, and the DHPLC conditions, required to effectively detect the most common mutations, have been validated. The primers and sequences were checked using MutationDiscovery.com. The generic SOPs and the validation protocols will be made freely available. The availability of the validated procedures will make the adoption of the technology and its quality management as simple as possible for others. Also, the general idea is applicable to other novel technologies, platforms, methods and kits.

Program Nr: 1428 from 2003 ASHG Annual Meeting

**Two High Throughput Genotyping Methods for Primary Newborn Screening.** *Z. Lin, J.G. Suzow, J.M. Fontaine, E.W. Naylor.* Neo Gen Screening, Inc., Bridgeville, PA.

Since the introduction of newborn screening for PKU in 1962 biochemical assays have been adapted for use with filter paper blood specimens to identify a number of additional metabolic disorders. The recent introduction of tandem mass spectrometry has expanded the scope of newborn screening through the use of multiple metabolite profiling. The recent development of high throughput molecular methods makes the possibility of primary DNA screening an attractive addition to existing newborn screening programs.

We developed a simple, inexpensive, automation friendly DNA extraction method using common reagents to extract DNA from filter paper blood specimens. This extraction method was adapted for use with a Beckman Coulter core robotic system in order to handle the number of samples in a newborn screening program and was used to set up PCR reactions. The first of the genotyping methods is a DNA microarray based platform for population-based screening. Amplified genomic fragments are immobilized onto the surface of a microarray slide such that each spot represents amplified DNA from one individual. Samples from up to 60,000 individuals can be spotted onto a single microarray. Allele-specific hybridization is used to detect mutant and wild type alleles within each spot. Overall costs for each genotyping are shared by the number of samples spotted on each microarray. The second genotyping method is a melting temperature analysis assay using the Roche LightTyper. Fluorescent labeled probes are added during PCR setup eliminating the need for any post-PCR sample handling step. Analysis is achieved by the difference in melting temperatures between matched and mismatched probe set and template. The system can identify the genotype of 384 samples in 10 minutes after completion of PCR. Both genotyping methods have been validated for the screening of sickle cell disease using a large number of newborn samples run in parallel with isoelectric focusing. Both methods have specificity greater than 99%. The LightTyper has advantages in both time and cost and we believe is the better method.

**Multiple Synthesized Control Mutations Optimize Clinical Test Quality.** *R. Lebo<sup>1,2</sup>, G. Dunphy<sup>1</sup>, M. Quicci<sup>1</sup>, D. Galehouse<sup>1,2</sup>.* 1) Dept Pathology & Lab Med, Children's Hospital Medical Center, Akron, Ohio; 2) Northeast Ohio Univ. Coll. Med., Ohio.

Maintaining highly reliable molecular genetic analyses requires simultaneously testing controls for all possible target sequences. Given total genomic template DNA from a single individual from the species to be tested and sequence-specific primers, PCR amplification can synthesize any characterized sequence. Synthesized control mutant sequences serve as standards to optimize and maintain quality control for any reported mutation or polymorphism no matter how rare or unavailable. First, selected short synthesized mutant or variant sequence primers are used to PCR amplify either adjacent upstream or adjacent downstream sequences from total genomic DNA. Then the synthesized upstream and downstream fragments are amplified together to produce a longer fragment with the mutation in the center. A modified strategy simultaneously synthesizes heterozygous controls. Included among the 31 homozygous mutations synthesized on 18 fragments each >400 bp in length are: (1) all 25 mutations in the core cystic fibrosis panel including four unavailable mutations (2184delA, 1078delT, 1898+1->G->A, and I148T), (2) four mutations on the same exon 11 fragment (G542X, G551D, R560T, and 1717-1G->A), (3) all four reflex test controls, and (4) four additional mutations on a commercial test strip. All 31 synthesized homozygous mutations verified on ASO test strips are tested on three test strips with each patient test run. These PCR synthesized controls demonstrate three principles: (1) placing multiple homozygous mutations on the same DNA sequence, (2) analyzing numerous independent homozygous controls from multiple gene regions simultaneously, and (3) using multiplex controls in multiplex tests optimize quality control while minimizing costly control assays. Addition of DNA from an unrelated organism to dilute PCR products will allow synthesized controls to be used throughout robust PCR assays. Splicing and cloning multiple control sequences will enhance long-term preparation and quality control.

**Simultaneous preconception/prenatal carrier screening for multiple genetic disorders by mass spectrometry (MALDI-TOF).** Z. Wang<sup>1</sup>, J.M. Milunsky<sup>1, 2, 3</sup>, V.A. Stevenson<sup>1</sup>, A. Milunsky<sup>1, 2</sup>. 1) Center for Human Genetics; 2) Dept. Pediatrics; 3) Dept. Genetics and Genomics, Boston Univ Sch Med, Boston, MA.

Preconception and early prenatal carrier screening for common mutations in selected genetic disorders is an increasingly desirable goal. For several genetic disorders, such screening is an already expected standard of care. Traditional analyses such as PCR-RFLP and ASO hybridization, are cumbersome, costly, and prone to false positive/negative results. The matrix-assisted laser desorption-ionization and time-of-flight mutation analysis by mass spectrometry has emerged as an efficacious technology offering increased accuracy and specificity, automation and high throughput. We have examined 2 groups of anonymized women in the preconception/early prenatal period studied in consecutive order of receipt of samples. Group I was constituted by 176 Ashkenazi Jewish women who were tested for a total of 19 mutations in the genes for Tay-Sachs disease, Canavan disease, Gaucher disease, Familial Dysautonomia, non-syndromic deafness (Connexin-26), Fanconi anemia, Niemann-Pick disease, and Bloom syndrome, as well as 41 mutations in the cystic fibrosis (CF) gene. 40 (23%) patients were found to carry at least one mutation, with 41 expected based on carrier frequencies for these genes. Group II was constituted by mostly Caucasian consecutive women undergoing routine CF carrier testing in the preconception/early prenatal period. In addition to CF, we assayed for 7 major mutations in 6 genes (Factor V Leiden, prothrombin, MCAD, Smith-Lemli-Opitz syndrome, and non-syndromic deafness (Connexin-26 and 12SrDNA). The mtA1555G mutation in the 12SrDNA gene was included to identify women at risk of having children susceptible to aminoglycoside-induced deafness. The other disorders have a 1% or greater carrier frequency in the patients studied. Carriers for at least one mutation were determined in 23 (11%) of the 209 women studied. Our purpose was to demonstrate the feasibility of preconception/early prenatal carrier testing simultaneously for 68 mutations in 14 common disorders using multiplex assays and MALDI-TOF. This approach appears to be accurate, practical, cost-effective, and informative.

Program Nr: 1431 from 2003 ASHG Annual Meeting

**Direct molecular haplotyping of R117H and intron 8 (IVS-8) thymidine track polymorphisms of the CFTR gene.**

*G. Pont-Kingdon<sup>1</sup>, C. Miller<sup>1</sup>, M. Jama<sup>1</sup>, A. Millson<sup>1</sup>, E. Lyon<sup>1, 2</sup>.* 1) ARUP Laboratories, Salt Lake City, UT; 2) Pathology Department, University of Utah.

Cystic Fibrosis (CF) is a common autosomal recessive genetic disease affecting 1:2500 Caucasian individuals. The disease is caused by mutation in the Cystic Fibrosis Transmembrane Regulatory (CFTR) gene. More than 1000 mutations in CFTR have been documented and the clinical significance of these mutations varies widely. The missense mutation R117H in exon 4 is considered mild if associated with polymorphisms consisting of 7 or 9 thymidines (7T or 9T) in the 3' region of intron 8. Conversely, if an individual carries the R117H mutation in cis with the IVS-8-5T polymorphism, this individual is a carrier of a severe CF mutation. Recently, following recommendations from the American College of Medical Genetics and the American College of Obstetrics and Gynecology, population screening covering a panel of 25 mutations is offered to expectant couples or those planning a pregnancy. The IVS-8-T track is tested only when the mutation R117H is found. If an individual is heterozygous for both the R117H mutation and the 5T variant, additional testing to establish the cis-trans status of both mutations is required to fully interpret the results. This is typically done by linkage analysis requiring DNA samples from parents or close relatives. To address these cases directly we have developed a molecular method to haplotype the mutations and bypass the need to obtain DNA from family members. The assay combines long range PCR (around 18kb) and allele specific PCR. Products are analyzed by melting analysis of hybridization probes or Oligonucleotide Ligation Assay (OLA). Sixteen R117H heterozygous samples were haplotyped. Five of the six possible haplotypes were found in 4 samples with a 5T allele. The accuracy of the PCR product was determined by the concordance of the result between the molecular method and traditional linkage analysis. Accuracy of the detection methods was established by comparison of results from hybridization probes and OLA.

**High Throughput Mutation Screening For Deafness By Denaturing High-Performance Liquid Chromatography.**

*S.D. Prasad, C.J. Nishimura, E.H. Chang, R.J.H. Smith.* Dept of Otolaryngology, University of Iowa, Iowa City, IA.

Genetic testing is playing an increasingly important role in the diagnosis of hereditary deafness. Although mutation screening can be accomplished in numerous ways, all techniques are not equally accurate, timely or cost effective. We use denaturing high-performance liquid chromatography (DHPLC) and offer complete mutation screening of GJB2 and SLC26A4 in persons with presumed autosomal recessive non-syndromic deafness (ARNSD), and of WFS1 and EYA1 in persons with DFNA6/14 or branchio-oto-renal syndrome, respectively. To determine the sensitivity of DHPLC to detect GJB2 allele variants, a panel of 55 individuals segregating 48 known mutations was analyzed by DHPLC, single stranded conformational polymorphism analysis (SSCP) and direct sequencing. The sensitivity of DHPLC to detect these allele variants was significantly greater than SSCP (98.1% vs 82.6%, respectively;  $p=0.0001$ ), with the detection rate of DHPLC nearly equal to that of direct sequencing. Using a panel of 55 individuals segregating 41 different SLC26A4 mutations as determined by direct sequencing of all exons, we found DHPLC sensitivity for detecting SLC26A4 allele variants to be 100%. Screening methodologies were also established for WFS1 and EYA1 on the DHPLC. To ensure high level accuracy and reliability, and to optimize cost effectiveness and turnaround time, we considered the following parameters, amplicon size, primer position, high-stringency PCR conditions, acetonitrile gradient, partially denaturing temperatures, clean durations, water quality testing, DNA-SEP column reliability testing, column maintenance etc. Although the accuracy of DHPLC nearly equals that of direct sequencing, we have not been able to correlate DHPLC chromatogram profile with mutation type. In our experience, wave profile for a given gene allele variant differs from column to column and even in the same column based on column life and buffer constitution. In total, we have now completed mutation screening on 3242 persons out of which 1022 were completed on the DHPLC. This study was supported in part by RO1-DC02842 (RJHS).

**Deleterious BRCA1/2 Mutations detected in a Portuguese Comprehensive Family Cancer Clinic.** *F. Vaz<sup>1,2</sup>, R. Brandao<sup>2</sup>, I. Povo<sup>2</sup>, P. Machao<sup>2</sup>, I. Duarte<sup>2</sup>, P. Rodrigues<sup>1</sup>, O. Costa<sup>1</sup>.* 1) Family Risk Cancer Department, Portuguese Cancer Ctr, Lisboa, PORTUGAL; 2) Molecular Patobiology Investigational CTR (CIPM), Portuguese Cancer CTR, Lisboa, Portugal.

Prevalence and characteristics of BRCA1/2 mutations is not known in portuguese breast and ovarian cancer families. Ours is a comprehensive program : risk characterisation of families and multidisciplinary approach of high risk women, that includes genetic screening of BRCA1/2 mutations. Criteria for BRCA1/2 screening is: at least 25 % of BRCA1/2 combined probability of mutation as calculated using the BRCAPRO or Myriad Models or male breast cancer in the family. Whole DNA was extracted from 25 affected probands from different families and screened with CSGE. 6 deleterious mutations have been found so far (4 in BRCA1 and 2 in BRCA2), and two of these (in BRCA1) are novel:1) del555A in exon 8 leads to a stop codon in exon 11 and a truncated BRCA1 protein; 2)another mutation occurs in a site of alternate splicing in the intronic region of exon 7 and may lead to deletion of a yet undetermined region between exons 8-10. Other BRCA1 mutations are:the 330 A>G and exon 13 duplication. The first is a missense mutation at the donor splice site of exon 5,considered to be a spanish founder mutation of galician origin (Vega A et al Hum Mutation 2001:17:520). Our family is the first without known spanish ancestors (at least for four generations). Exon 13 duplication,an important BRCA1 variant,was found in a family with high probability of BRCA1 mutation but CSGE negative, making it the second portuguese family described with this mutation.

Two BRCA2 mutations,6696del TC and D596H, were found in male breast cancer probands. These were already described in several families of western european origin.

Conclusions: genetic screening is ongoing and is likely that with our strict selection criteria we will obtain a high mutation detection rate.

**Novel Trp3985Arg mutation of the ryanodine receptor (RYR1) gene in a Taiwanese patient with malignant hyperthermia.** *S.I. Hung<sup>1</sup>, J.K. Cheng<sup>2</sup>, Y.L. Lin<sup>1</sup>, J.Y. Wu<sup>1</sup>, Y.T. Chen<sup>1</sup>*. 1) National Genotyping Center, Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Anaesthesiology, Mackay Memorial Hospital, Taipei, Taiwan.

Malignant hyperthermia (MH) is an autosomal dominant pharmacogenetic disorder that causes a life-threatening increase in body temperature after the susceptible individual exposures to certain anaesthetic agents. With a mortality rate of about 10%, MH is estimated to occur in 1 in every 50,000 adult anesthetics. Although the disease is genetically heterogeneous, genotyping analysis is the most effective way for diagnosis of malignant hyperthermia susceptibility. Here, we report the identification of a novel mutation of the intracellular calcium-ion-release channel (RYR1) associated with MH. A 47-years-old female was admitted to hospital for a surgical operation. After a general anesthesia with sevoflurane (concentrations of 2-4 percent), her body temperature rapidly increased to 41.5C. Biochemical exams showed elevated blood creatine kinase (28,485 IU/L). Under the impression of MH, she was supplied with Dantrolene sodium immediately and the clinical symptom subsided gradually. A muscle biopsy with the in vitro contracture test (IVCT) induced by caffeine halothane was performed and showed a positive result. As the skeletal muscle type 1 ryanodine receptor (RYR1) has been reported to be associated with the majority of reported MH cases, the 106 exons of RYR1 gene of the patient were screened by direct sequencing technique. Eleven nucleotide exchanges were found to lead to synonymous amino acid changes; six of them have been deposited in dbSNP database. A nucleotide substitution of T to C at position 11953 which causes a novel amino acid change from Trp3985 to Arg, composing the putative transmembrane domain, was identified at exon 87. Based on this genetic and diagnostic test data, this novel allele, Trp3985Arg, of RYR1 gene was evidenced to be associated with the MH phenotype. In view of the use of genetic method for the diagnosis of MH, the new identified allele should be taken into account.

Program Nr: 1435 from 2003 ASHG Annual Meeting

**Pharmacogenetics: ethical issues.** *S. Thomas.* Nuffield Council on Bioethics, London, United Kingdom.

Pharmacogenetics, the study of genetic variation that affects response to medicines, has the potential to play an important role in improving the safety and efficacy of treatments. However, both the research and its application raise ethical, legal, social and regulatory issues which it is important to consider now. In September 2003, the Nuffield Council on Bioethics will publish its Report on Pharmacogenetics: ethical issues. The talk will draw on the conclusions made in this Report, and present recommendations for future policy and practice. Issues discussed will include the application of pharmacogenetics to the research and development of medicines, the use and storage of genetic information, allocation of resources and the impact on clinical practice. The introduction of pharmacogenetics might lead to a further stratification of the drug market by redefining patient groups. There are concerns that some potentially valuable new medicines may not be developed if, as a result of genetic stratification, the number of patients who would benefit is too small to be profitable. If the potential benefits of pharmacogenetics are to be realised, consideration needs to be given to what incentives should be put in place to maximise possible benefits while also protecting the interests of patients and of society.

**Distribution of serum ferritin and transferrin saturation levels among Asians living in the U.S. and Canada: Hemochromatosis and Iron Overload Screening (HEIRS) Study.** *E.L. Harris<sup>1</sup>, C.E. McLaren<sup>2</sup>, P.C. Adams<sup>3</sup>, G.D. McLaren<sup>2</sup>, T.M. Vogt<sup>1</sup>, B.G. Mellen<sup>4</sup>, M. Speechley<sup>3</sup>, D.M. Reboussin<sup>4</sup>, R.T. Acton<sup>5</sup>.* 1) Kaiser Permanente Center for Health Research (KP), Portland, OR, Honolulu, HI; 2) University of California, Irvine (UCI), Irvine, CA; 3) London Health Sciences Centre (LHSC), London, Ontario; 4) Wake Forest University, Winston-Salem, NC; 5) University of Alabama at Birmingham, Birmingham, AL.

Little information is available about iron overload (IO) or hereditary hemochromatosis (HH) among individuals of Asian heritage. The *HFE* C282Y allele is rare. The HEIRS Study, a multi-site study of genotypic and phenotypic screening for HH and IO in primary-care populations, specifically recruited individuals of Asian heritage in 3 of its 5 Field Centers: KP, LHSC (London and Toronto), and UCI. Screening results from the first 50,000 participants confirm that *HFE* C282Y allele is rare among Asians. However, Asians have the highest prevalence of elevated serum ferritin (SF) and transferrin saturation (TS) levels (TS>50% and SF>300 g/L for men, TS>45% and SF>200 g/L for women). To better understand this finding, we compare TS and SF distributions for 5,086 Asian and 12,071 non-Hispanic Caucasian HEIRS Study participants who do not have *HFE* C282Y or H63D alleles.

Among Asians 7.0% of men and 3.0% of women have elevated TS and SF levels, compared with 1.6% and 0.6% of Caucasian men and women. Mean TS and SF levels for Asian men and women are significantly higher than in Caucasians, adjusted for age and Field Center. Plots of residuals (difference between observed and predicted values) from regression analyses suggest that there may be several underlying SF and TS distributions. Preliminary results from mixture modeling indicate that there are multiple underlying distributions of TS for each race/gender group, and that the means and frequencies of these underlying distributions differ by race and gender. The etiology and clinical significance of these differences is currently unknown. Future HEIRS Study analyses include further evaluation of participants with elevated SF and TS, and gene discovery for non-*HFE* iron overload.

**Genetic susceptibility for lung cancer: interactions with gender and smoking history and impact on early detection policies.** *O. Gorlova*<sup>1</sup>, *C. Amos*<sup>1</sup>, *C. Henschke*<sup>2</sup>, *L. Lei*<sup>1</sup>, *M. Spitz*<sup>1</sup>, *Q. Wei*<sup>1</sup>, *X. Wu*<sup>1</sup>, *M. Kimmel*<sup>3</sup>. 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) New York Presbyterian Hospital-Weill Cornell Medical Center, New York, NY; 3) Rice University, Houston, TX.

**Objectives:** To identify a genetically high-risk group to develop lung cancer, estimate the lifetime probability of the disease in high risk current, former, and never smokers (males and females), and assess a mortality reduction that can be achieved by screening the high-risk group. **Methods:** Case-control data (764 cases and 677 matched controls), on mutagen susceptibility and DNA repair capacity in different smoking categories were used to obtain the estimates of susceptibility using the formula of total probability. The estimates were inserted into a model of lung cancer natural history and detection by screening to assess mortality reduction due to screening of high-risk individuals. **Results:** The high-risk group included those 12.5% of the population who are above the third quartile for the bleomycin sensitivity and below the median for the DRC. High-risk male current, former, and never smokers have susceptibility to lung cancer of 38%, 21%, and 4%, respectively. Females have lower probabilities to develop lung cancer: 15%, 8%, and 1.5% for high-risk current, former, and never smokers, respectively. Screening of high-risk smokers (12.5% of all smokers) can reduce overall mortality by 7% compared to 30% reduction if all smokers are screened. Analogous results were obtained for former and never smokers. **Conclusions:** Genetic susceptibility constitutes an important factor in selection of high-risk group for early lung cancer detection.

Program Nr: 1438 from 2003 ASHG Annual Meeting

**Media Representations of Genetic Discoveries: What About Headlines?** *T. Caulfield, T. Bubela.* Health Law Inst, Univ Alberta, Edmonton, AB, Canada.

Science and medical stories have to compete with other news stories. Newspapers must therefore offer headlines that are interesting not only to the potential reader, which is the overriding objective of any journalist, but also to colleagues and to management that decides whether to publish a story and where to position it in the paper. However, sensationalism may have a number of effects. For example, in the case of hyped headlines of gene discoveries, one concern is that repeated exposure of the lay public to such headlines may lead to heightened genetic determinism (see Condit, 2001). However, there is, in fact, little data on the accuracy of headlines in relation to stories about human genetics. This poster will present data from an analysis of 590 headlines from 627 newspaper articles reporting on 111 papers in scientific journals. The newspaper stories were limited to those reporting a "genetic discoveries." We used a standard questionnaire and project nave coders. We compared the accuracy of the description of the scientific research and the claims and conclusions made in the primary research article with those made in the newspaper article and headlines. We found that the majority of headlines were categorized as having no exaggerated claims (64.2%) or slightly exaggerated claims (24.9%) when compared to the newspaper article. However 10.8% of headlines were moderately-highly exaggerated when compared to the newspaper article. Twice as many headlines (20.9%) had moderately-highly exaggerated claims when compared to the scientific journal article. By comparison, 11% of newspaper articles were categorized as having moderate-highly exaggerated claims and 26.3% had slightly exaggerated claims when compared to their scientific journal article sources (Bubela and Caulfield, submitted).

**The interaction between universities and industry in Genetics The Discovery of BRCA1 and BRCA2 Genes.** *R. Dalpe*<sup>1</sup>, *L. Bouchard*<sup>2</sup>. 1) Dept Political Sci, Univ Montreal, Montreal, PQ, Canada; 2) Dept Sociology, Univ Ottawa, Ottawa, ON, Canada.

**Objectives:** This paper addresses the new dynamics in genetics generated by industry's direct relations with university. (1) to understand the research dynamic occurring between university and industry, and its effect on university research. (2) (exploratory) to analyse the role of researchers and the medical community in the diffusion of new techniques emerging from commercialization. **Theoretical background:** (1) According to sociology of science, a new research system, from disciplinary and curiosity-driven to transdisciplinary and problem-driven research, is established which channels university culture (Gibbons et al, 1994). (2) For sociology of organizations, direct interactions fostered by new institutional arrangements, lead to a more rapid exploitation of new knowledge and the direct role of researchers and universities in commercialization (Powell and Owen-Smith, 1998). Industry may impose constraints, such as in information diffusion to secure property rights. **Methodology:** A case study of the discovery of two genes associated with breast and ovarian cancers was conducted. A bibliometric database of 800 publications has been built to trace the evolution of research between 1993 and 1998 (VanRaen, 1998). The analysis is also based on in-depth interviews of eleven researchers (from five countries) exemplifying the different profiles (Kvale, 1996). **Results:** The new research dynamic foreseen by sociology of science is only in its infancy and national differences remain important. Some actors in large networks are more important than anticipated, for instance the broad medical network was a key player in the diffusion of clinical applications. In scientific research per se, interaction with a clinic was also important. Intellectual property was a major issue and several organizations filed patents to protect and commercialize their discoveries. Our data suggests that scientific collaboration is more difficult when intellectual property is at stake. **Conclusion:** Sociology of networks offers a more accurate analysis of the research dynamic in genetics. The medical community tends to play an important role in the diffusion of the medical innovation.

**Obtaining informed consent from next-of-kin for research using genetic testing: Legal vs. biological relatives.** A. Fishbach<sup>1</sup>, M.A. Austin<sup>2,1</sup>, W. Burke<sup>2,1</sup>, D.J. Bowen<sup>1,2</sup>, T. Vu<sup>1</sup>. 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) University of Washington, Seattle, WA.

In an ongoing study of BRCA2 gene mutations among pancreatic cancer cases enrolled in the Northwest Cancer Genetics Network Registry, we identified a registry participant who had provided a DNA sample, but who had died before consent for this study could be obtained. The IRB approved protocol states that genetic testing can be performed on a deceased participants sample only after obtaining consent from the next-of-kin. The following hierarchical scale for next-of-kin contact, used by many research studies and established through legal precedent, was used: (1) Court appointed guardian, if one exists (2) Durable Power of Attorney, if it specifically includes this kind of authority (3) Legal spouse (one to which community property laws apply) (4) Children 18 & over, if unanimous agreement when >1 (5) Parent or parents, if unanimous agreement if both living (6) Adult siblings, if unanimous agreement when >1. Study staff contacted the legal spouse, who was estranged from the surviving biological relatives. After repeated contact attempts, the spouse refused permission to use the sample. After careful review and consideration given to the potential testing options and health benefits for the biological relatives if a positive genetic test result were obtained on the proband, the IRB granted an exception to the usual next-of-kin contact hierarchy. This decision allows use of the sample based on the biological relatives permission. As a result of this experience, we propose that the legal, hierarchical next-of-kin scale be revised for genetic research, in order to give priority to biological relatives who may benefit from genetic testing. Such proposed scale could use the following criteria: (1) Children 18 & over, if unanimous agreement when >1 (2) Parent or parents, if unanimous agreement if both living (3) Adult sibling, if unanimous agreement when >1 (4) Grandchildren 18 & over, if unanimous agreement when >1. The potential benefits to biological relatives that may result from a genetic testing protocol merit re-evaluation of the paradigm governing next-of-kin contact in genetic research.

**2003 Survey of medical geneticists: Demographics and professional activities.** *M. Blitzer<sup>1</sup>, J. Cooksey<sup>1</sup>, K. Kissam<sup>1</sup>, J. Benkendorf<sup>1</sup>, G. Forte<sup>2</sup>, M. Beaulieu<sup>2</sup>, E. Salsberg<sup>2</sup>.* 1) Univ Maryland Sch Medicine, Baltimore, MD; 2) New York Health Workforce Center, SUNY Albany, NY.

This study was part of a three-year national assessment of genetic services and the health workforce. It was designed to provide current data on the patient care and laboratory services provided by medical geneticists and to answer questions related to their supply and distribution, professional activities, and opinions on various aspects of genetic services. In early 2003, we conducted a mailed survey of all ABMG diplomates certified before 2002. The 67-question survey asked about demographics, education, professional parameters, job satisfaction, and opinions on genetic services. Separate sections asked patient care geneticists about their scope of practice, clinic staffing, and referrals. Laboratory geneticists were asked about laboratory type (molecular, cytogenetics, biochemical), scope of laboratory services, staffing, and referrals. Descriptive statistical analysis was conducted using SAS. The overall response rate was 56% (861/1524). Findings from 765 respondents professionally active in the US are described. Fifty percent were women; mean age was 52 years; and few respondents represented members of racial and ethnic minority groups (10% Asian American, 4% Hispanic, Black, or other). Primary work settings were: academic medical centers (62%), commercial labs (10%), hospitals (9%), medical practices (7%), and 12% other. Mean work levels were 52 hours per week and 48 weeks per year. Geneticists who provided patient care saw, on average, 8 new patients and 6 follow-up patients per week; however, patient care was only one aspect of their work week. Among laboratory geneticists, 16% worked in more than one lab. Analyses by primary laboratory type showed differences across labs. A comprehensive understanding of medical geneticists professional roles, referrals, and other perspectives will assist in broader workforce planning efforts that seek to prepare for growing genetic services demand.

**Transitions in Genetics Services Delivery Models (GSDM): Findings from Case Studies of Four Communities.** *J. Benkendorf<sup>1</sup>, J. Cooksey<sup>1,2</sup>, M. Blitzler<sup>1</sup>, D. Lea<sup>3</sup>, J. Mansour<sup>2</sup>, H. Travers<sup>1</sup>, P. Saunders<sup>4</sup>, C. Gordon<sup>1</sup>*. 1) Univ of Maryland Baltimore, Baltimore, MD; 2) University of Illinois at Chicago, Chicago, IL; 3) Foundation for Blood Research, Scarborough, ME; 4) Georgetown University, Washington D.C.

As part of a 3-year national assessment of genetics services and the health workforce we designed a study based on the premises that 1) genetic services are provided in the context of existing health care organization, and 2) changes in GSDM will reflect genetics-specific factors as well as overall changes in health care delivery. This research used a comprehensive approach and the research design follows a longitudinal study of health systems change ([www.hschange.org](http://www.hschange.org)). We conducted in-depth case studies of genetic services in four geographically diverse communities: Cleveland OH, Miami-Dade County FL, Orange County CA, and Boston MA. Our study used as core data telephone interviews with about 40 respondents in each community selected to cover specific service settings, categories, and types of personnel (geneticists, genetic counselors, physicians, laboratory directors, nurses, state health department representatives, and other health professionals). All relevant data were coded and analyzed using QSR N6 software for qualitative data analysis. Our preliminary analysis shows evidence of transitions in organized GSDM in most major service categories (prenatal, pediatric and adult genetics, laboratory services, state sponsored programs) due to market competition, funding changes, institutional reorganization, and other factors. As examples, AHCs lost market share of genetic testing services and prenatal diagnostic services to commercial laboratories and to free-standing diagnostic centers, respectively. Varied factors and trends affected specific professional roles such that pediatric geneticists are seeing larger numbers of adult patients and genetic counselors practice under a widening range of organizational models. Further analysis will allow us to compare findings from these case studies to our survey research of genetics professionals and to better characterize factors influencing changes in service organization.

**Carrier Screening Panels for Ashkenazi Jews: Is More Better?** *J.R. Leib<sup>1</sup>, S.E. Gollust<sup>2</sup>, S.C. Hull<sup>2</sup>, B.S. Wilfond<sup>2</sup>.*  
1) NGB/NINDS/NIH; 2) MGB/NHGRI/NIH.

Genetic carrier screening programs designed for the Ashkenazi Jewish (AJ) population were first implemented in the 1970s for Tay-Sachs disease (TSD). Testing targeted at this population has since expanded to include 10 autosomal recessive diseases, with panels of up to 9 diseases. The marketing of such panels to the AJ population is a valuable service but creates the potential for stigmatization. To determine the characteristics of AJ panels, we contacted 31 unique US laboratories listed on [www.genetests.org](http://www.genetests.org) that provide TSD testing. Four, in fact, did not provide TSD testing, and we identified one laboratory not listed on GeneTests. We collected data from 27 laboratories that provide AJ carrier screening. We determined the tests offered, panels offered, price and testing methodology used. The tests included 3 diseases associated with death in early childhood (Canavan disease, Niemann-Pick type A and TSD), 5 with a variably shortened life span (Bloom syndrome, cystic fibrosis, familial dysautonomia, Fanconi anemia type C, mucopolysaccharidosis type IV), and 2 diseases that do not routinely shorten the lifespan (Gaucher disease type I and hearing loss). Five diseases lead to progressive neurodegeneration, 2 instill a predisposition to malignancy, 2 result in reduced fertility, and 2 manifest with dysmorphic features. The carrier frequencies ranged from 1/13 to 1/127. All diseases occur more frequently in Ashkenazi Jews except for cystic fibrosis and hearing loss. Panels included from 2 to 9 diseases and ranged in price from \$200 to \$2082. Twenty-one laboratories provided panels. Of these, 18 panels cost less than if the tests were ordered individually, offering an incentive to purchase multiple tests. The defining feature of a disease as being Jewish and inclusion in a panel is the presence of a founder mutation, rather than absolute or relative frequency, or severity of the disease. Public policy guidance for establishing appropriate criteria for inclusion in panels may be useful to laboratories and to the AJ population. Pricing strategies that do not promote more tests should be considered. Developing culturally sensitive educational materials may limit the potential for stigmatization of carriers, affected individuals, and the community.

Program Nr: 1444 from 2003 ASHG Annual Meeting

**Factors affecting social and political legitimacy of rDNA research and embryo science in America and Britain.**

*M.A. Weed, M.R. Seashore, K.K. Kidd.* Dept. of Genetics, Yale U. School of Medicine, New Haven, CT.

Interviews with scientists, advocates and legislators have clarified aspects of policy making on "controversial research". Examples of the effect that different legislative and regulatory environments have on the legitimacy of controversial science are found in the 1970s rDNA research debate in the U.S. and recent action on embryo science in America and Britain. That 95% of private sector scientists complied with guidelines developed by the RAC for federally funded rDNA research demonstrates the regulatory legitimacy that it developed in America. Interviews with British scientists and transcripts of parliamentary debates on expansion of the purposes for which embryo research can be done indicate the development of strong regulatory legitimacy by the UK's Human Fertilisation and Embryology Authority (HFEA). The HFEA has become a guarantor that whatever embryo research is carried out is "necessary", much as the RAC assured Congress that rDNA research was "well regulated". The success of the RAC and HFEA suggests that outside regulation could be essential in the eventual legitimization of embryo research, gene transfer and genetic testing in America. Opponents to "controversial" research have been determined in their efforts to see it slowed or stopped. Interviews indicate that British opponents to embryo research feel that disorganization and limited resources have reduced their political effectiveness in comparison with that of their peers in America. For instance, Parliament and the HFEA have legitimized embryo research in the UK whereas Congress has been less supportive. Media reports suggest that American opponents of regenerative medicine have weakened their enemies by withdrawing financial support from groups with pro-research agendas like the American Heart Association. Proponents of embryo research claim that the Coalition for the Advancement of Medical Research (CAMNR) in America and Association of Medical Research Charities (AMRC) in Britain have been essential in achieving legislative goals like Parliament's passage of permissive regulations on embryo research in 2001 and the failure of the "Human Cloning Prohibition Act" in Congress last year.

**BRCA1 Polimorphisms in Portuguese Breast/Ovarian Cancer Families.** *R. Brandao<sup>1</sup>, P. Machao<sup>1</sup>, I. Pova<sup>1</sup>, I. Duarte<sup>1</sup>, O. Costa<sup>2</sup>, F. Vaz<sup>1,2</sup>.* 1) Molecular Pat. Invest., CIPM , Portuguese Cancer Inst, Lisboa, Portugal; 2) Family Cancer Risk Dep, Portuguese Cancer Institute, Lisboa, Portugal.

25 probands from high risk breast ovarian cancer families were selected for BRCA1/2 screening. So far 6 deleterious mutations have been found, 4 in BRCA1 (330 A>G, del55A, exon 13 duplication and a splicing mutation in the intronic region of exon 7) and 2 in BRCA2 (6696delTC and D596H). Although screening is not yet complete, several polimorphisms, mainly in BRCA1 were observed, some with striking frequency in these probands: IVS8-34 T/C (in 3 cases and one control); 2430T>C (3 cases and one control); the IVS 18+66 G>A (8 cases and 1 control) and IVS6+26invCA (2 cases and one control). Other polimorphisms were:IVS3-212T/C (2 cases) and IVS7+52T>C (2 cases); 1000 A>G and 3667 A>G (one case each). IVS18+66 G>A and 2430 T/C are known polimorphisms shared by several western populations. However IVS-34 T/C and and IVS6+26invCA (this one striking in the fact that was always observed as an homozigous mutation) are not yet described and their significance deserves further study. These findings also account for the sensitivity of our screening methodology (Conformational Sensitive Gel Electrophoresis).

**Prothrombin polymorphism and Lung Cancer.** *K. Yanamandra<sup>1</sup>, J. Rodriquez-Paris<sup>2</sup>, M. Smith<sup>2</sup>, D. Napper<sup>1</sup>, T.F. Thurmon<sup>1</sup>, S.A. Ursin<sup>1</sup>, H. Chen<sup>1</sup>, R. Dhanireddi<sup>1</sup>, J.A. Bocchini Jr.<sup>1</sup>, G.M. Mills<sup>2</sup>, J. Glass<sup>2</sup>.* 1) Dept Pediatrics, LSU Medical Ctr, Shreveport, LA; 2) Feist-Weiller Cancer Center, LSU Medical Center, Shreveport, LA.

Prothrombin is encoded by a 21 kb long gene localized on chromosome 11, at 11p11-q12. The gene is organized in 14 exons, with 5upstream and 3UT regions. Rogier Bertina group (Poort SR et al 1996) from Leiden, the Netherlands, has first identified a polymorphic marker, G20210A in the 3untranslated region of prothrombin gene. The 20210A allele was found to be a common variant and was associated with an increased risk of venous thrombosis. Later, several polymorphic gene factors such as Factor V Leiden, Prothrombin (FII) G20210A, and Methylene tetrahydrofolate reductase (MTHFR) C677T were implicated in hereditary thrombophilia. Prothrombin 20210GA genotype frequency was found to be 1-2% in non-Hispanic white Americans, negligible in Orientals, and less than 0.2-0.3% in African-Americans. This polymorphism was not studied in cancer etiology. In the present investigation we began to study the association of thrombophilic polymorphic gene markers in the etiology of cancer. We genotyped over 200 cancer patients and over 2300 controls. We have not found any mutant 20210AA homozygotes as expected from the literature. However, after stratification by ethnicity and gender we found a significant increase of mutant 20210GA genotypes in Caucasian lung cancer patients than in Caucasian controls 8.7% vs 1.3% (Chi Sq 3.8,  $p < 0.05$ , odds ratio 6.6) and 6.4% in breast and lung cancer patients, and 1.9% in controls (Chi sq 5.5,  $p < 0.02$ , odds ratio 3.6). Based on our pilot data we believe that prothrombin 20210GA genotype is a significant risk factor in the etiology of cancer especially lung cancer. This being the first report in the literature, experience from other centers would definitely strengthen our initial findings. Detailed data and statistics will be presented.

**Identification and detection of mutations causing Niemann-Pick type A Disease in Jewish Ashkenazi population by PCR-RFLP.** *V. Adir, E. Shahak, Z.U. Borochowitz.* The Simon Winter Institute for Human Genetics, Bnai-Zion Medical Center, Technion-Rappaport Faculty of Medicine, Haifa, Israel.

Type A Niemann-Pick disease (NPD) is an autosomal recessive fatal disorder, which is common among Ashkenazi Jews with an estimated frequency of 1:30,000. NPD is caused by a deficiency in the activity of a lysosomal hydrolase, acid sphingomyelinase (ASM) that leads to accumulation of sphingomyelin (SM). The accumulation of SM in ganglion cells leads to cell death.

In an effort to screen large populations of potential NPD carriers, we developed a simple, sensitive and non-radioactive assay. The method developed is based on the use of PCR mediated site directed mutagenesis (PSDM) followed by restriction enzyme digestion, for the detection of the three mutations (R496L, fsP330, L302P), which are responsible for 95% of the type A NPD among Ashkenazi Jews, and for the detection of type B NPD mutation delR608.

Screening of 1189 Israeli Ashkenazi Jews for the R496L, fsP330, L302P using this method revealed carriers at a frequency of 1:79.

Our results show higher carrier frequency and a slight difference in the mutations distributions in the Ashkenazi Jewish population screened at our center, from those described by Schuchman et al, 1997. Similar results were obtained for Tay-Sachs carrier frequency and mutation distribution (Bach 2001, Petersen et al., 1983). The reason for this distinction may be attributed to differences in the populations screened. While both populations come under the global heading of Ashkenazi Jews, the actual composition of the Israeli population may be significantly more homogeneously Ashkenazi Jewish than that of the North American population (Schuchman et al, 1997). This is compounded by the fact that relevant background information is obtained during screening solely by the declaration of the individual tested, which may lack information on non-Ashkenazi Jewish heritage.

**Confidential enquiry into pre-natal genetic care.** *I. Nippert*<sup>1</sup>, *C. Vogel*<sup>1</sup>, *J. Horst*<sup>2</sup>, *B. Eiben*<sup>3</sup>, *F. Louwen*<sup>4</sup>, *P. Miny*<sup>5</sup>, *H. Neitzel*<sup>6</sup>, *J. Schmidtke*<sup>7</sup>. 1) Women's Health Research, Universitaetsklinikum Muenster, Muenster, Germany; 2) Institut fuer Humangenetik, Universitaetsklinikum Muenster, Muenster, Germany; 3) Institut fuer Klinische Genetik und Zytologie Nordrhein, Oberhausen, Germany; 4) Klinik fuer Gynaekologie und Geburtshilfe, J.W. Goethe-Universitaet, Frankfurt, Germany; 5) Universitaets-Kinderspital beider Basel, Basel, Switzerland; 6) Institut fuer Humangenetik, Charité, Medizinische Fakultät der Humboldt-Universitaet zu Berlin, Berlin, Germany; 7) Institut fuer Humangenetik, Medizinische Hochschule Hannover, Hannover, Germany.

**Introduction:** Confidential enquiry is an accepted form of clinical audit that scrutinizes factors which may influence quality and outcome of care. Genetic prenatal diagnosis is part of routine ante-natal care for women with a known a priori risk for a genetic disorder or for those who are identified to be at increased risk by maternal serum screening and/or fetal ultrasound. This study was undertaken to assess how obstetricians manage the genetic aspect of care for these women. **Methods:** The study was designed to investigate the antecedents and sequelae of positive cytogenetic and molecular tests and of positive ultrasound findings. A total of 19.334 pregnancies were followed at different health care settings including university hospitals and private practice. **Results:** The majority (76%) of women with positive test results were offered qualified pre-test genetic counseling although major differences were observed at different settings ranging from 59%-92% of women who received counseling. However only 29% of all women received qualified post-test counseling; again significant differences (17%-100%) in different settings were observed. Termination of pregnancy took place at an average of 3.8 days after the information of the test result was provided (range: 0-13 days). 86% of all terminations took place until 24th week of gestation (overall range: 11+6 32+3 weeks). **Conclusions:** Whilst genetic testing is increasingly offered in pre-natal care, only a minority of women undergo qualified genetic counseling after a positive test result. (The study was funded by the German Human Genome Project.).

**Cost effectiveness of prenatal genetic and ultrasound screening for Van der Woude syndrome.** *G.L. Wehby<sup>1</sup>, R.L. Ohsfeldt<sup>1</sup>, J.C. Murray<sup>2</sup>.* 1) Health Management and Policy, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA.

**OBJECTIVE:** To evaluate the cost effectiveness of genetic screening (GS) and ultrasonography (US), US alone, and no screening (NS), as strategies for prenatal detection and prevention of Van der Woude Syndrome (VWS). **METHODS:** A decision analysis model was used with a time horizon of one generation of gene inheritance and assuming a payers perspective. Three risk groups of parents, differentiated by the probability of having a VWS mutation, were included in the analysis: first-degree relatives of VWS patients, parents diagnosed with nonsyndromic cleft lip and/or palate (NSCL/P), and parents diagnosed with VWS. Effectiveness was defined as having a normal birth outcome. Future costs were discounted to reflect time of their occurrence. Sensitivity analysis was conducted to test the robustness of the results according to the values of parameters used and assumptions made. **RESULTS:** Under reference case assumptions, GS and US had an incremental cost effectiveness ratio (ICER) of \$4667 per additional normal birth versus NS in the group of parents who are at a first-degree relative risk of having a VWS mutation. For parents diagnosed with NSCL/P, GS and US had an ICER of \$12382 per additional normal birth versus US alone. For parents diagnosed with VWS, the strategy of GS and US dominated both NS and US alone. **CONCLUSION:** For parents who are first-degree relatives of VWS patients, GS and US strategy dominates US alone and has a reasonable ICER over NS for most model scenarios. For parents diagnosed with NSCL/P, GS and US strategy has a reasonable ICER over US alone. For parents diagnosed with VWS, GS and US strategy dominates both NS and US alone for most model scenarios. Adoption of Quality Adjusted Life Years (QALYs) gained as another measure of effectiveness allows comparing the ICER of the intervention to those of other health interventions to provide better guidance for resource allocation decisions. A further step of the project will involve eliciting preferences over the health states of VWS patients to calculate the QALYs associated with the model outcomes.

**Genetic screening for Hemochromatosis is no less acceptable than biochemical screening.** *C. Patch*<sup>1</sup>, *P. Roderick*<sup>1</sup>, *W. Rosenberg*<sup>2</sup>, *Southampton Liver Epidemiology Unit.* 1) Health Care Research Unit, University of Southampton, Southampton, Hampshire, United Kingdom; 2) Division of Inflammation, Infection and Repair, University of Southampton.

Hemochromatosis, a treatable adult-onset condition of progressive iron overload is amenable to population screening for early case identification. Screening is possible using a biochemical test for iron overload or a genetic test for the common mutations. The possibility that genetic tests may be less acceptable and have greater adverse psychological consequences than other medical tests has been raised in the literature. We sought to compare the acceptability, feasibility and uptake of genetic and biochemical screening strategies for hemochromatosis. *Methods:* We conducted a randomised controlled trial of equivalence comparing biochemical and genetic screening. The sample was 3000 individuals aged 30 to 70 randomly selected from primary care age/sex registers, stratified for age and gender, randomised to screening arm and invited for screening. Psychological assessments of self-rated health, anxiety and depression were made at four time points. *Results:* Uptake of screening was no lower in the genetic arm than in the biochemical arm. There were no statistically significant differences between the two screening arms in the psychological assessments apart from at testing. Participants in the biochemical arm had lower anxiety and depression scores and higher health profiles. The factors that affected the probability of accepting screening were age, gender and social deprivation. Uptake was higher in women, in older age groups and in less deprived areas. *Discussion:* There appeared to be no difference in the acceptability of screening between a genetic and a biochemical test. The widely held assumption that a genetic test will necessarily cause more anxiety or be unacceptable should be investigated further. Uptake of screening was low overall, but highest amongst older women. Males aged between 30 and 50 years, the key target population have the lowest uptake. This will affect numbers of subjects needed to detect significant clinical differences in future screening and prognostic studies.

**Genetic screening for hereditary haemochromatosis in secondary schools: attitudes of the school community in Victoria, Australia.** *A.A. Gason<sup>1,2,3</sup>, S.A. Metcalfe<sup>1,2,3</sup>, M.A. Aitken<sup>1,2,3</sup>, K. Allen<sup>1,4</sup>, M.B. Delatycki<sup>1,5</sup>*. 1) Murdoch Childrens Research Institute, Parkville, Australia; 2) Dept Paediatrics, The University of Melbourne, Australia; 3) Cooperative Research Centre for Discovery of Genes for Common Human Diseases, Australia; 4) Dept Gastroenterology and Clinical Nutrition, Royal Children's Hospital, Australia; 5) The Bruce LeFroy Centre for Genetic Health Research, Genetic Health Services Victoria, Australia.

Community genetic screening programs can be offered in a variety of settings. Genetic screening for hereditary haemochromatosis (HHC) is the subject of significant debate in the literature. Nevertheless it is the best example of a preventable disease for which genetic predisposition testing is available. In Victoria, Australia, genetic screening for HHC is currently available to adults through a pilot program called HaemScreen. However, secondary schools are an alternative to offer genetic susceptibility screening, as carrier testing for Tay Sachs disease and cystic fibrosis are currently successfully offered in this setting. Screening within schools could vastly increase numbers of individuals exposed to both education and opportunities to be tested. Thus, we aimed to determine the attitudes of the secondary school community towards an HHC genetic susceptibility screening program without offering testing. Students, parents and teachers from secondary schools participated in focus group discussions. These data informed the development of a questionnaire to assess attitudes in students aged 16-17, both before and after an educational session in the school. Parents and teachers received written educational material and a questionnaire. Initial results from focus groups stressed the need for comprehensive education of all participants; concerns were raised regarding privacy of genetic information, paternity, employment and insurance. In conclusion, thorough education is essential to inform the school community of all relevant information in a genetic screening program for HHC. Results obtained from this study of community attitudes could be applied to other genetic screening programs and inform future implementation and policy development.

Program Nr: 1452 from 2003 ASHG Annual Meeting

**Exploring the information provision and in-service training on newborn screening in southern Taiwan.** *M.C. Huang<sup>1</sup>, I.C. Lu<sup>2</sup>, C.K. Lee<sup>1</sup>*. 1) Department of Nursing, National Cheng Kung University, Tainan, Taiwan; 2) Department of Nursing, Chung Hwa College of Medical Technology, Tainan, Taiwan.

**Objective:**To explore the information provision and in-service training for the providers on newborn screening (NBS). **Materials and Methods:**Of fifteen obstetric clinics/hospitals in southern Taiwan, twenty-two information providers were interviewed. Using content analysis method, the transcriptions of interviewed data were analyzed to demonstrate the process of information provision on NBS and the types of in-service training for information providers. **Results:**Although most of clinics/hospitals provided the NBS pamphlet to parents after delivery, they did not provide verbal explanation particularly. The information providers were not trained systematically. They often searched relevant information from NBS pamphlets or through their senior colleagues. **Conclusions:**It is crucial to establish a systematic education program for information providers to promote the quality of information provision on NBS. A further study to investigate the information needs of newborns parents is necessary.

Program Nr: 1453 from 2003 ASHG Annual Meeting

**Craniofacial Brazil Project: preliminary results of a long term health program.** *I.L. Monlleó<sup>1,2</sup>, V.L.G.S. Lopes<sup>1</sup>*. 1) Departamento de Genética Médica, Unicamp, Campinas, São Paulo, Brasil; 2) Departamento de Pediatria, Uncisal, Maceió, Alagoas, Brasil.

In order to recognize the localization of centers involved on attendance of craniofacial individuals and to make the access easier for genetic counseling for these individuals and their families, our team is performing a national study about geographic distribution of specialized hospitals, parents associations and clinical genetics services. This is the first phase of a project untitled Craniofacial Brazil Project, that is pioneer in this area in our country. After an extensive research, we detected 836 services, among 385 specialized hospitals, 79 parents association and 372 health professional faculties on treatment and (or) support for these conditions. A structured form was mailed for them, inviting for voluntary adhesion to the project, asking about characteristics of each service and where and how genetic evaluation and counseling are performed. After 1 month, 2,39 % of the correspondence was mailed back for address problems and 9,33 % of the services were favorable to the proposal. From specialized hospitals, 7,79 % were interested on this project, as well as 12,65% parents association, and health professional faculties 10,21%. Until now, no refused were detectable. This first phase of this project is still in course (conclusion deadline will be in August, 2003) and a diary update is performed, which makes premature any divulgation about genetic evaluation and counseling data. We considered this an important step for national health planning.

**Population studies of three X-linked Immunodeficiency Diseases and Genotype-phenotype correlations of PRF1 mutations in Familial Hemophagocytic Lymphohistiocytosis.** *K. Zhang<sup>1</sup>, S. Lee<sup>2</sup>, J. Villanueva<sup>2</sup>, K. Kogawa<sup>3</sup>, J. Sumegi<sup>2</sup>, R.J. Wenstrup<sup>1</sup>, A.H. Filipovich<sup>2</sup>.* 1) Human Genetics, Children's Hospital, Cincinnati, OH; 2) Hematology/Oncology, children's Hospital, Cincinnati, OH; 3) Department of Pediatrics, National Defense Medical College, Tokorozawa, Japan.

Primary immunodeficiencies are a group of diseases that have been increasingly recognized in both children and adults. Learning the molecular etiology of these diseases will improve understanding of the molecular basis of human immune function. Recently, mutation detection has been chosen as the definitive diagnostic criterion for these life-threatening diseases by the Pan-American Group for Immunodeficiency and the European Society for Immunodeficiency, which otherwise can be difficult to define clinically. We have developed four clinical molecular tests for 1) X-linked Severe Combined Immunodeficiency (IL2RG), 2) X-linked Hyper IgM Immunodeficiency (CD40LG), 3) X-linked Lymphoproliferative Disease (SH2D1A), and 4) Hemophagocytic Lymphohistiocytosis (PRF1). Because the SNPs in these genes are largely unknown, we screened 50 normal female (100 X-chromosomes) of the southern Ohio population for variants. The results have helped us to separate benign polymorphisms from the disease-causing mutations. Perforin mutations have been previously reported in approximately 30% of patients with primary Hemophagocytic Lymphohistiocytosis (HLH). We conducted comprehensive investigation of the genotype/phenotype correlations using perforin mutation analysis by direct DNA-sequencing, perforin expression analysis by flow-cytometry, and NK cell cytotoxicity assay of 50 Northern American families with children diagnosed with HLH. Twenty-five out of 50 had bi-allelic mutations in the PRF1 coding region; most of them were confirmed by genotyping of their parents. Thirteen novel PRF1 mutations were identified. Perforin expression in peripheral blood cytotoxic cells was dramatically decreased or absent regardless of the type of PRF1 mutations. Since approximately half of the cases of HLH in Northern American are caused by PRF1 mutations, DNA based screening for HLH affected families is recommended, even if the proband is unavailable.

**Surveying genomic deletions and duplications through the generation of oligonucleotide fingerprints using primer-free amplification.** *M. Dean*<sup>1</sup>, *B. Gold*<sup>1</sup>, *J. Van Ness*<sup>2</sup>, *D.J. Galas*<sup>2</sup>. 1) Lab Genomic Diversity, NCI-FCRDC, Frederick, MD; 2) Keck Graduate Institute of Applied Life Science, Claremont, CA 91711.

The near complete description of human genomic segmental duplications has been achieved through the application of an exact match algorithm on the April 2003 assembly of the human genome. This permits 1) verification of segmental duplications implicated in causing local genomic instabilities and 2) identification of genomic regions that may be susceptible to genomic rearrangement. To document genomic instabilities, we have devised a method in which a set of oligonucleotides are created and linearly amplified from template structures pre-existing in genomic DNA without the use of pre-synthesized probes or primers. The molecular signatures are composed of 6-16mer oligonucleotides that trigger their own exponential amplification. Through the synthesis of probes with adjoining nicking enzyme sites in combination with naturally occurring restriction endonuclease sites, amplification-templates are generated through incubation with a nicking enzyme (N.BstNBI) and a polymerase in an isothermal reaction at 60C. The triggers formed from the linear amplification are then coupled to an isothermal method for exponentially amplifying the triggering sequences in true chain reactions. Triggering and amplification provide a homogenous assay in which  $10^6$ - $10^9$  fold amplification can be achieved in as little as 3 minutes. Read-out is accomplished by mass spectrometry (LC-TOF or MALDI), real-time fluorimetry, or self-amplifying arrays. Because advance knowledge of the sequence of interest is not required to generate fragments de novo from genomic DNA, the method provides a way to create molecular signatures of genomic changes proximal to restriction endonuclease sites. Further, the method does not require the denaturation of the genomic DNA thus dramatically reducing the complexity of single strand DNA that has to be surveyed during the assay. These panels of diagnostic oligonucleotides can also be used to measure gene expression, and create useful biomarkers. The application of this method to deletions on the X chromosome will be discussed.

**Hidden Complexities of the Human Genome Revealed by Unbiased Mapping of Transcriptome.** *P. Kapranov<sup>1</sup>, S. Cawley<sup>1</sup>, S. Bekiranov<sup>1</sup>, H.H. Ng<sup>2</sup>, E.A. Sekinger<sup>2</sup>, D. Kampa<sup>1</sup>, A. Piccolboni<sup>1</sup>, V. Sementchenko<sup>1</sup>, J. Cheng<sup>1</sup>, J. Drenkow<sup>1</sup>, M. Yamanaka<sup>1</sup>, S. Patel<sup>1</sup>, S. Brubaker<sup>1</sup>, H. Tammana<sup>1</sup>, B. Narayanan<sup>1</sup>, G. Helt<sup>1</sup>, K. Struhl<sup>2</sup>, T.R. Gingeras<sup>1</sup>.*  
1) Affymetrix Inc, 3380 Central Expressway, Santa Clara, CA 95051; 2) Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MA 02115.

Recent completion of key genomic sequences, hallmarked by those of human and mouse, has provided unprecedented opportunities for the use of high density oligonucleotide arrays to discover novel transcripts, to map functionally important genomic regions and to integrate all this information in order to provide a genome-wide view of the transcriptional regulatory networks in the cell. We have recently reported unexpectedly high levels of transcriptional activity in human chromosomes 21 and 22 (Kapranov et al., 2002). It was shown that up to an order of magnitude more genomic sequence can be transcribed and transported into cytosolic mRNA than previously anticipated based on annotations of known exons in the human genome. This work has led to other ongoing studies involving the use of high density oligonucleotide array technology to empirically detect and map hitherto unknown transcriptional units and functional elements in the human genome. These observations have the potential to alter our current views of a genome's structure, regulation and function.

Program Nr: 1457 from 2003 ASHG Annual Meeting

**In silico prediction of novel neuronal-specific composite regulatory elements.** *S. Keryanov, K. Gardner.* Dept Neurology, Univ Pittsburgh, Pittsburgh, PA.

**Aim:** Composite cis-regulatory elements (CRE) in promoter and enhancer regions via binding with respective transcription factors essential for transcription control of gene expression. Here, our focus was to identify additional modules comprised of CREs for known transcription factors that predict neuronal-specific expression patterns. **Methods:** The approach was illustrated by comparative in silico search and characterization of two promoter regions cloned by our lab for the human KCN10 gene. Double Gn boxes combined with NF-Y and NFAT binding sites (REL factors) were identified exclusively in the distal promoter region which regulates the neuronal-specific isoform but not in the proximal promoter region which regulates the ubiquitously expressed isoform. Secondly, promoter regions of human Na, K-ATPase alpha 1,2,3 (ATP1A1,2,3) genes with known tissue-specific patterns and the putative 5 flank of the ATP1A4 gene were characterized. Multiple GC boxes (binding sites for Sp1/Sp5 proteins) in combination with other factors were typically found in 5 flanks of ubiquitously expressed genes such as ATP1A1. However, the promoter region of the neuronal-expressed ATP1A3 gene contained a double Gn box and NFY/REL factor. **Results:** Promoter and intron 1 in silico analysis of 47 abundantly neuronal expressed genes revealed that ~48.5% sequences contain a combination of Brn-2 / Brn-4 sites and mainly REL factors. Approximately 37.4% contain a double Gn box with only REL factors. The double Gn box is likely to be a target for the neuronal-specific transcription repressor Necdin. This in silico approach might provide a real alternative to predict key elements of neuronal-specific gene expression.

**Genomic structure of segmental duplications on human chromosome 8p23: implications for a modifying risk factor in hearing impairment due to the mitochondrial mutation A1555G.** *E. Ballana*<sup>1</sup>, *N. Bosch*<sup>1</sup>, *N. Fischel-Ghodsian*<sup>2</sup>, *X. Estivill*<sup>1</sup>. 1) Genes and Disease Program, Genomics Regulation Center, Barcelona, Catalonia, Spain; 2) Department of Pediatrics, UCLA School of Medicine, Cedars-Sinai Medical Center, Los Angeles, CA.

A five-Mb region of human chromosome 8p23 is inverted in a significant proportion (about 25%) of individuals of the general population. In addition to this common inversion, chromosome 8p23 hemizyosity and duplication are involved in several disorders. Linkage analysis has identified a putative modifier locus on 8p23 (around marker D8S277) for the hearing impairment phenotype due to the mitochondrial A1555G mutation. A1555G, affecting the mitochondrial 12S rRNA gene, has been associated with non-syndromic deafness with a variety of clinical phenotypes, yielding from mild to severe hearing impairment. The nuclear background is thought to modulate the phenotypic expression of this mtDNA mutation. We have characterized this genomic region and have found that flanking the inversion there are two pairs of segmental duplications with a complex organization. Although the sequence corresponding to the segmental duplications still contains 3 gaps, it is organized in 16 distinct subgroups of segmental duplications. Each subgroup comprises between 2 and 5 duplicons, ranging from 5 to 200 kb and a sequence identity between 93% and 99%, resulting in a mirror image defined by the duplicons that enables the 8p23 region to undergo different rearrangements. Several clusters of genes encoding defensins are located within these segmental duplications. In order to analyse the role of 8p23 genomic architecture as a modifying target for the A1555G phenotype, distinct microsatellite markers and defensin gene promoters located in the region have been screened in families carrying the A1555G change. By combining DHPLC, subcloning and sequencing we have found that both the defensin cluster and microsatellite markers of the region are polymorphic in copy number and sequence orientation. We suggest that this high level of polymorphism may have a role in the age of onset and severity of hearing impairment in patients carrying A1555G.

**Evidence of a founder effect for the 235delC mutation of *GJB2* (connexin 26) in East Asians.** D. Yan<sup>1</sup>, H.J. Park<sup>2</sup>, X.M. Ouyang<sup>1</sup>, A. Pandya<sup>3</sup>, K. Doi<sup>4</sup>, R. Erdenetungalag<sup>5</sup>, L.L. Du<sup>1</sup>, W.E. Nance<sup>3</sup>, A.J. Griffith<sup>2</sup>, X.Z. Liu<sup>1</sup>. 1) Dept Otolaryngology, Univ Miami, Miami, FL; 2) NIDCD, NIH, Rockville, MD; 3) Medical College of Virginia at VCU, Richmond, VA; 4) Dept of Otolaryngology and Sensory Organ Surgery, Osaka, Japan; 5) Dept of Human Genetics, Maternal and Child Health Research Center, Ulaanbaatar, Mongolia.

Mutations in the *GJB2* gene encoding connexin 26 (Cx26) are a major cause of autosomal recessive and sporadic cases of congenital deafness in most populations. The 235delC mutation of *GJB2* is the most frequent known mutation in some East Asian populations, with a carrier frequency of approximately 1%. The 235delC has never been reported in Caucasians. In order to explore whether the high frequency of the 235delC mutation of *GJB2* in East Asian populations is the result of a founder effect or a mutational hot spot, we searched for evidence of a shared common haplotype of 235delC with flanking polymorphisms. We analyzed three non-synonymous polymorphisms within the coding region of *GJB2* (V27, E114G, I203T) and four flanking SNPs in a total of 26 homozygous and 19 heterozygous 235delC chromosomes from Mongolia, China, Korea, and Japan and compared them to panels of 362 controls. In each population, the 235delC mutation was in significant disequilibrium with 5 linked polymorphic markers. In 235delC homozygotes, 235delC was associated with one core SNP2-V27I-E114G-SNP1 haplotype, A-G-A-C. In contrast, four major haplotypes were observed in the normal controls: G-G-A-C and A-G-A-C were the most common with frequencies of 30% and 21%, respectively. The detection of 235delC only in East Asians but not in Caucasians, and the small chromosomal interval of the shared haplotype, suggests that 235delC is an ancient mutation that arose after the divergence of Mongoloids and Caucasians. Similarly, the fact that the 235delC mutation appears on a single haplotype provides no support for the possibility that recurrent mutation is the explanation for the high frequency of the allele.

***In vivo* Characterization of the Transcriptional Response of Kidneys from *Aprt* Knockout Mice to Crystals of 2,8-Dihydroxyadenine.** *J. Chen*<sup>1</sup>, *Y. Chen*<sup>1</sup>, *D. Glass*<sup>1</sup>, *S.B. Bledsoe*<sup>2</sup>, *A.P. Even*<sup>2</sup>, *A. Sahota*<sup>1</sup>, *J.A. Tischfield*<sup>1</sup>. 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Department of Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN.

Adenine phosphoribosyltransferase-deficient (*Aprt*<sup>-/-</sup>) mice develop 2,8-dihydroxyadenine (DHA) nephrolithiasis, initially in collecting ducts, but how crystals form in this site is not clear. In this study, we used the Murine Genome Array to identify genes showing altered expression in kidneys from *Aprt*<sup>-/-</sup> mice at 1, 4, and 12 weeks postnatally. From over 12,000 genes, we identified 96, 88, and 85 genes, respectively, which were differentially expressed in these mice. Eight of these genes were common to all three age groups. Of 73 genes up-regulated in 12-weeks-old *Aprt*<sup>-/-</sup> mice, 44 were annotated as immunoglobulins or proteins related to inflammation/fibrosis, which is in full agreement with our previous histopathological observations. Interestingly, there were significant alterations in the expression of several genes previously not known to be associated with kidney stone disease. These included small proline-rich protein 2f (*Sprr2f*), cytokeratin 19, cytochrome P450, cell death activator A, and lysozymes. Real Time RT-PCR was used to confirm the microarray results. These findings demonstrate that DHA crystals modulate the expression of genes involved in several important kidney functions, including barrier fortification, apoptosis, cell injury, and proliferation. Because of its potential role in membrane functions, *Sprr2f* was chosen for further study. *Sprr2f* is a cross linker of cell envelope proteins that is not expressed in normal kidneys; however, it is expressed at high level in 1-week-old *Aprt*<sup>-/-</sup> mice, but not at later stages. Immunohistochemistry analysis showed that this protein is expressed in collecting ducts, the same location where DHA crystal deposition and mitosis are first observed. Water re-absorption at this site may account for DHA precipitation and crystallization. These results imply that *Sprr2f*-induced barrier fortification and proliferation of the collecting duct cells may play important roles in the formation of intratubular DHA crystals and subsequently stones.

Program Nr: 1461 from 2003 ASHG Annual Meeting

**Multiple Objective Linear Programming for Metabolic Networks.** *M. Sun*<sup>1</sup>, *MM. Xiong*<sup>2</sup>. 1) Dept Business, Univ Texas, San Antonio, San Antonio, TX; 2) Human genetics Center, University of Texas Health Science Center at Houston, Houston, TX 77030.

Living organisms have evolved by maximizing their surviving probability or fitness function. In the past several years, maximization fitness function subject to flux balance equations is reduced to a linear programming (LP) problem. However, metabolic networks evolve to accomplish multiple objectives: maximizing biomass production and ATP generations or optimizing consumers of available substrates. Multiple objectives will be fitness functions. The driving forces governing cellular metabolism are to compromise between ATP, redox, and biomass production. Therefore, a single LP is not sufficient to model operations of metabolic networks. To overcome this limitation, we propose a multiple objective LP model for metabolic networks. We will use duality theory to develop algorithms for identifying all efficient solutions to multiple objective LP. We will also perform sensitivity analysis to investigate the impact of addition or removal of biochemical reaction on the performance of metabolic networks and adaptation of metabolic networks in response to changes of various environments. Finally, we will investigate how multiple objectives are compromised to seek adaptive operation or evolution of metabolic networks.

**Nucleotide Intelligence Pattern Statistics in Bioinformatics--- Loci Expression on A Chromosome in Genetics &**

**Application.** *K. Chen*<sup>1, 2</sup>. 1) Visiting Professor Biostatistics and Bioinformatics Unit, Medical Statistics Section, Division of Hematology/Oncology, Department of Medicine, School of Medicine, The University of Alabama at Birmingham; 2) Professor, Department of Laboratory Medicine, NTU School of Medicine; Department of Biostatistics Institute of Epidemiology, NTU School of public Health; National Taiwan University, Taipei, 100 Taiwan.

Nucleotide information of a genome study in bioinformatics is transformed as nucleotide intelligence in the 3 levels of realization: chromosome, locus and gene. A chromosome is identified as an open interval on a real line; a locus on the chromosome is embedded on the open interval as a point to which the coordinate is decided; the gene of the locus on the chromosome of a certain subject is the value for a certain function of the coordinate for the point representing the locus. This 3-level realization takes care of the physical relationship for loci on the same chromosome, the linkage in genetics. The pattern recognition of the functions identifies the pattern of the intelligence. The study employs the established results of representation of a curve-hypersurface or image (CHOI) for data analysis and CHOI pattern recognition in biostatistics. The establishment is from the modeling that integrates the disciplines of bioinformatics, qualitative investigation (QI), biomathematics and biostatistics to define the statistics on CHOIs and to infer the likelihood for hypothesis testing. The study concentrates on employing QI on massive genome information to express as intelligence in terms of a set of CHOIs that are characterized by a limited number of continuous valued parameters. The number of the parameters is so limited that biostatistical inference on the parameters is manageable. The study moves on employing the parameters to characterize, with maximized likelihood estimators, the pattern of the embedded intelligence. A nucleotide information-profile in genetics for a clinic study in medicine stimulates the modeling for various issues in bioinformatics on analyzing DNA data. The functional relationship of loci on different chromosomes is not included here, and will be in the coming study of epistasis.

**Quantitatively prioritizing candidate disease gene sequences using annotation.** *T. Braun*<sup>1,2,5</sup>, *T. Scheetz*<sup>2,4</sup>, *H. Abdulkawy*<sup>5</sup>, *B. Brown*<sup>5</sup>, *S. Davis*<sup>5</sup>, *B. O'Leary*<sup>5</sup>, *J. Ritchison*<sup>5</sup>, *R. Sutphin*<sup>2</sup>, *S. Shankar*<sup>2</sup>, *V. Sheffield*<sup>3</sup>, *E. Stone*<sup>2</sup>, *T. Casavant*<sup>1,4,5</sup>. 1) Dept Biomedical Engineering; 2) Dept Ophthalmology/Visual Sciences; 3) Dept Pediatrics; 4) Center for Bioinformatics and Computational Biology; 5) Coordinated Laboratory for Computational Genomics, University of Iowa, Iowa City, IA.

A common method for mutation identification is to screen each successive candidate gene to completion. This approach is generally favored, and even considered practical, due to the overhead of identifying and acquiring the gene structure and annotation, selecting primers, and managing multiple assay results spanning the transcript and genomic sequence - the results of multiple PCR reactions, SSCP assays, and sequencing results. TrAPSS (Transcript Annotation Prioritization and Screening System) is an integrated system that utilizes sequence annotation features to accelerate the mutation screening process by predicting the potential of gene sub-sequences to contain disease-causing mutations. Evolutionarily conserved functional domains and motifs across species may contribute valuable information for determining the functional significance of gene sequences. This research explores the contributions of several types of annotation. These include: functional domains, secondary structure prediction, similarity to model organism sequences, SNPs, and conserved intronic and regulatory elements. A component of the system is a parallel amplicon prioritization algorithm PAR (Prioritization of Annotated Regions). This parallel amplicon prioritization algorithm is based on the assumptions that mutations are not uniformly distributed and that particular sequence features will be more sensitive to sequence changes. TrAPSS utilizes annotation to prioritize candidate genes and sub-regions of genes. It also distributes screening resources across multiple genes in parallel, while still covering entire genes when mutations are detected. A retrospective study examined 710 genes from OMIM that collectively contained 4,115 published mutations. The PAR algorithm increases the rate of mutation detection with a reduction of screening resources by more than 91%.

**Characterization of LINE 1 sequences on the human chromosome 21 short arm.** *H.D Beris<sup>1</sup>, M.R. Cummings<sup>2</sup>, J.L. Doering<sup>1</sup>*. 1) Dept. of Biology, Loyola University Chicago; 2) Dept. of Biological Sciences, University of Illinois at Chicago.

LINE-1 (L1) sequences are retrotransposons distributed throughout the human genome. There are about  $5 \times 10^5$  copies of L1 constituting 17% of the genome. The majority of these copies are 5' truncated and inactive. The organization of L1s in heterochromatic regions, like that found on the HC21p arm, is not well characterized. Our work using an HC21 hybrid cell mapping panel indicates that most 21p L1 elements are full length (FL), polymorphic in number and organization, with substantially more FL L1s on 21p than 21q. Since most FL L1s are in 21p heterochromatin, this suggests preferential integration sites, or lack of selection against such L1s in this region, resulting in their preferential accumulation on 21p. A number of FL and truncated L1 elements in the HC21 heterochromatic region have been subcloned from a yeast artificial chromosome contig containing portions of the centromere and p arm of HC21. Three subclones, one containing a FL L1 and two containing truncated L1s, have been sequenced and compared to the L1s on 21q with respect to target site duplication (TSD) region, integration site, and 3' transductions. The FL L1 belongs to the L1PA7 subfamily and contains an 8 nt TSD, which is shorter than the TSDs found on most 21q FL L1s. It is not integrated into the consensus AT rich integration site, suggesting integration via an endonuclease independent mechanism. This FL L1 also has two transductions of 81 nt and 16 nt. The truncated L1s belong to the L1PA2 and L1PA4 subfamilies. The finding of an L1PA2 suggests that evolutionarily young L1s can integrate into heterochromatic regions without negative selection and may account for some of the polymorphism seen in the structure of 21p. The concentration of FL L1s on 21p may facilitate p arm interactions among acrocentric chromosomes, increasing the risk of translocations and non-disjunction and may increase the rate of genome evolution.

**A dual role of segmental duplications in evolutionary rearrangements and human genomic disorders. L.**

*Armengol<sup>1</sup>, M.A. Pujana<sup>1</sup>, J. Cheung<sup>2</sup>, S.W. Scherer<sup>2</sup>, X. Estivill<sup>1</sup>.* 1) Genes and Disease Program, Genomics Regulation Center, Barcelona, Catalonia, Spain; 2) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada.

An initial comparison between the genomes of human and mouse has identified over 300 segments of synteny, but the nature of rearrangements leading to breaks of synteny (BOS) has not yet been elucidated. While the different segment sizes agree with a random breakage model of genome evolution, a tendency for chromosomal breaks to reoccur at certain genome regions has been suggested. The identification of sequences that are involved in evolutionary rearrangements should provide important insights into the understanding of genome plasticity, and should pinpoint regions that might be associated with disorders that undergo mutations at the genomic level. We have compared the human and mouse genome sequences and demonstrate here that recent segmental duplications correlate with BOS between these two species. By comparing observed and simulated data (390,000 simulations of human chromosome breaks), we found that the co-occurrence of segmental duplications at regions of BOS is significantly different from what one would expect by chance. Thus, 53% of all evolutionary rearrangement breakpoints between these species associate with segmental duplications, as compared to 18% expected in a random location of breaks along the chromosome ( $p < 0.0001$ ). We also observed that nine primary regions involved in human genomic disorders show changes in the order or the orientation of mouse/human synteny segments, and are often flanked by segmental duplications in the human sequence. These findings establish a strong relationship between human genomic disorders and evolutionary rearrangements with the mouse genome, being segmental duplications a common feature of both. Thus, the data presented here could help to the identification of candidate regions to be analyzed for new genomic mutations. Our data suggest that segmental duplications have participated in the recent evolution of the human genome, as driving forces for evolutionary rearrangements, chromosome structure variations, and genomic disorders.

Program Nr: 1466 from 2003 ASHG Annual Meeting

**Enterprise Genealogy: Managing the Life of a Sample.** *J. Ganjei, S. Alavi.* LabVantage Solutions, Inc. Bridgewater, NJ.

The evolution of high throughput technologies to identify and characterize genomic and proteomic data has been a major challenge to information management and bioinformatics. As information is nowadays more web-centric, the problems related to organizing and indexing large amounts of previously unrelated data is moving to the forefront. Thus, LIMS software must evolve to enable high volume processing of such heterogeneous data, irrespective of location and form. A framework for providing definitions, toolkits, and linking of multidimensional data, to facilitate data analysis, is essential, and is discussed below. Central to the overall operation of the laboratory is the integration of experimental protocols and workflow processes. Sapphire, an Enterprise LIMS software solution provided by LabVantage, has been used in many types of laboratory settings to manage samples, experiments, and results, in a systematic and organized fashion. This presentation explores Sapphire's utility to meet the demands of high throughput genomic and proteomic information management, specifically discussing the importance of project study management and hierarchy, experimental management, and integration of analytical and 3rd party tools, to provide a complete genealogy of the data. The core capabilities of Sapphire range from the ability to integrate information from analytical instruments and robotics devices, to reporting tools.

**Use of motif scanning to identify Phosphopantetheinyl transferases in yeast and man.** *M.T. Geraghty<sup>1</sup>, N. Braverman<sup>2</sup>*. 1) Dept Genetics, Children's Hosp Eastern Ontario, Univ Ottawa, ON, Canada; 2) McKusick-Nathans Inst Genetic Medicine, Johns Hopkins University, Baltimore, MD, USA.

Phosphopantetheinyl transferases (PPTs) activate enzymes by transferring the prosthetic group 4'-phosphopantetheine onto a specific target binding site. PPTs are characterized by an amino acid motif **G-X-D-X(2,100)-[FW]-X-X-K-E-[SAC]-X-X-K**. Using this sequence as a probe and the ScanProsite algorithm (<http://us.expasy.org/tools/scanprosite/>), we identified 4 putative PPTs in the proteome of *S cerevisiae*. These include Lys5p which activates -aminoadipate reductase (Lys2p); PPT2p which activates the mitochondrial Acyl Carrier Protein (ACP); cytoplasmic Fatty Acid Synthase (FAS2p) which auto-activates itself and a novel putative PPT, encoded by YDR520C. A similar scan of the human proteome identified 4 candidates; -aminoadipate semialdehyde dehydrogenase-phosphopantetheinyl transferase (AASD-PPT), the alpha and gamma sub-units of an Alcohol Dehydrogenase (P07327 and P00326) and the Emilin-2 precursor (Q9BXX0). Conversely target proteins for the PPTs have a highly conserved amino acid motif which acts as the binding site for 4'-phosphopantetheine, **L-G-[LAYG]-[DH]-S[LI]**. A motif scan of the yeast proteome identified 9 proteins including previously reported target proteins (ACP and Lys2p) and in addition the ADP-ribosylation factors 1 and 2. In the human proteome we identified a small subset of proteins including those orthologous to that found in the yeast search *i.e.* the Acyl Carrier Protein subunit of the NADH-ubiquinone oxidoreductase (NDUFAB1), the human Fatty Acid Synthase and the ADP-ribosylation factors 1 and 3 (ARF1 and ARF3). We have previously shown that the human AASD-PPT gene can complement the yeast *lys5* knockout and correct the lysine biosynthetic defect in this strain. However, man lacks a lysine biosynthetic pathway and it is unclear that AASD-PPT plays a role in the oxidation of -aminoadipate semialdehyde or that there is in fact a human equivalent of LYS2. This study shows that AASD-PPT may not be the only phosphopantetheinyl transferase in the human proteome and that FAS, NDUFAB1, ARF1 and ARF3 proteins are targets for the human PPTs identified here.

Program Nr: 1468 from 2003 ASHG Annual Meeting

**LAG-1 and LD78- chemokine genes are located in a segmental duplication at chromosome 17q12.** *W.S. Modi.*  
SAIC, National Cancer Institute-Frederick, Frederick, MD 21701 USA.

Sixteen CC chemokine genes form three clusters in an interval approximately 1.8 Mb in size at 17q12-21, and 14 of the genes are located on genomic contig NT\_010799. The two genes not on the contig (LAG-1 and LD78-) are 95% similar to two that are on the contig (MIP-1 and MIP-1). LAG-1 and LD78- are about 12 kb apart on clone AC036181, while MIP-1 and MIP-1 are similarly 12 kb apart on clone AC003976. Dot matrix analysis of the two clones reveals 90% similarity between the 40-kb intervals containing these genes and their flanks, suggesting segmental duplication is responsible for the origin for one of the two gene pairs. Additionally, other loci from AC036181 map to 150 different positions in the human genome revealing a very complex pattern of duplication. Recent UCSC, NCBI, and Celera assemblies delete or misrepresent genomic clones containing these two genes, indicating that substantial hand-editing may be necessary to complete the assembly of the human genome sequence in regions such as this containing duplicate genes. This project has been funded in whole or in part with Federal funds from the National Cancer Institute, National Institutes of Health, under Contract No. NO1-CO-124000.

**Gene expression profiling of bronchoalveolar lavage cells in acute lung rejection.** *J. Lande, V. Gimino, T. Berryman, M.I. Hertz, R.A. King.* Medicine/Inst Human Genetics, Univ Minnesota, Minneapolis, MN.

**Background:** Lung and heart-lung transplantation are effective treatments for many diseases unresponsive to other therapy. However, long term survival of recipients is limited by the development of bronchiolitis obliterans syndrome (BOS). Acute lung rejection (AR) is common and is the leading risk factor for the development of BOS. Despite many investigations there are no reliable biomarkers of AR. We used microarray analysis to investigate the gene expression of bronchoalveolar lavage (BAL) cells to identify biomarkers for AR. **Methods:** Gene expression microarrays were performed using RNA from BAL cells of lung transplant recipients with AR (n=7) or with no rejection (n=27). BAL cell and differential counts were done. Statistical Analysis of Microarrays (SAM) was used to compare signal values between groups. The relationships of transcripts found differentially expressed between the groups were visualized with 2D hierarchical clustering (Cluster, Treeview), and relationships of significant genes across biologic pathways (GenMAPP) were investigated. **Results:** The BAL cell counts were similar between both rejection groups and differentials indicated no significant difference in cell composition between groups. Both groups consisted primarily of macrophages, but with a small percentage of lymphocytes. 135 genes were upregulated in the AR samples as compared to the no rejection samples with a false discovery rate less than 1%. These included AR response genes, immune-response genes with unknown roles in AR, and genes of unknown function. Clustering grouped all AR samples, and separated them from the majority of the no rejection samples. The genes that were differentially expressed in AR samples displayed 6 GenMAPP pathways with significant changes when an expanded list of 885 genes were found using SAM with a false discovery rate less than 5%. **Conclusions:** Microarray analysis is a powerful tool to identify candidate genes involved in acute rejection of the lung allograft. The individual genes, distinct patterns of gene expression, or biologic pathways identified may represent novel biomarkers for AR or for the development of BOS.

**SNP Information Mining Pipeline (SIMP) for Complex Disease Studies.** *C. Liu<sup>1, 2</sup>, T. Nguyen<sup>1</sup>, R. Zhang<sup>2</sup>, F. Yao<sup>2</sup>, Z. Zhu<sup>2</sup>, E.S. Gershon<sup>1</sup>.* 1) Dept Psychiatry, Univ of Chicago, Chicago, IL; 2) National Lab of Medical Genetics of China, Central South University, Changsha, China.

SNPs are the major genetic markers commonly used for association studies, in the hunt for genes responsible for complex/common diseases. A region-wide (~ 10 Mb size genomic region) association study require utilization of hundreds or more SNPs. More than 4 million SNPs were deposited into dbSNP. ~ 6% of them have allele frequency data. ~ 80% of them are mapped by NCBI. There are more than 10,000 SNPs in a region of ~ 10 Mb in public SNP databases. To fulfill the task of collecting SNP-related data, prioritizing them, and designing genotyping experiments for hundreds or thousands of SNPs, heavy reliance on bioinformatics tools is required. Unfortunately, allele frequency data are dispersed in several different databases. Also, 31% of the 5 or 3 flanking sequence of the reference SNPs in dbSNP are less than 200 bp. Batch query for SNP sequence and allele frequency data is not intuitively simple with existing tools. SNP sequences mostly are not in the format required by primer design software. Most SNP genotyping methods do not provide primer design software in batch mode. Not all SNPs have map information. And so on. All these problems slow down the progress of SNP-based region-wide association study. A SNP Information Mining Pipeline (SIMP) is under development to provide real-time SNP-related data to serve the purpose of data mining and experimental design. So far, we have implemented these tools: "DNannotator" for mapping SNPs; "Frequency Finder" for collecting SNP allele frequency data; "SNPSequer" for fetching SNP flanking sequence of length sufficient for primer design; "SNP cutter" for PCR-RFLP experiment design; "PrimerNerd" for FP primer design. All these tools are web-based applications, supporting batch process, accepting uniformed inputs and producing both user and database-friendly outputs. They are accessible at <http://sky.bsd.uchicago.edu>. More components of this pipeline will be implemented in the coming year. SIMP aims to provide a one stop shopping site for informatics needs of SNP data mining for region-wide association study.

Program Nr: 1471 from 2003 ASHG Annual Meeting

**Shrinkage and Likelihood Estimates of Differential Gene Expression in Oligonucleotide Arrays.** *J. Hu, F. Wright.*  
Biostatistics, UNC-CHAPEL HILL, CHAPEL HILL, NC.

The identification of the genes that are most differentially expressed in two-sample microarray experiments remains a difficult problem when the number of arrays is very small. We discuss the implications of using ordinary t statistics and examine other commonly used variants. For multi-probe oligonucleotide arrays, we introduce a simple model relating the mean and variance of expression, possibly with random gene-specific effects. The model is used to obtain maximum likelihood estimates for the degree of differential expression. Like related approaches developed for cDNA arrays, the estimates have natural shrinkage properties that dispense with the need for ad hoc approaches to guard against inappropriately small variance estimates. The likelihood approach enables a comparison to the Cramer-Rao lower bound, and it is shown that the estimates are highly efficient, even for small sample sizes. We demonstrate that our approach performs well compared to other proposed approaches in terms of the false discovery rate. We also show that it performs well in terms of a new criterion based on the area under the receiver-operator characteristic function, in which the degree of differential expression is compared among rejected genes vs. non-rejected genes. The likelihood framework suggests straightforward extensions to comparisons of multiple groups, and perhaps further shrinkage steps applied to the likelihood estimates.

**Identification of active ID element loci in the rodent genome.** *G.L. Odom, J. Robicheaux, P.L. Deininger.* Tulane Cancer Center, Tulane University, New Orleans, LA.

Throughout evolution, the eukaryotic genome has been bombarded by mobile elements. These elements constitute approximately 45% of the human genome. SINEs (short insertional nuclear elements) are the most abundant mammalian mobile elements. SINEs are also considered to be non-autonomous, in that they do not have a coding capacity, and therefore are thought to parasitize the retrotransposition machinery from other elements (namely L1) or cellular functions. SINEs are recognized as a familiar agent of human disease, and must also have had a significant influence in shaping the eukaryotic genome. In humans, Alu elements make up about 11% of the mass of the genome. We estimate conservatively that there is about one Alu insertion in every 200 humans born. These insertions cause ~0.1% of all human germ-line disease and could possibly contribute to somatic cell damage as well. Our lab has reported that recent (disease causing) Alu insertions consistently possess a homopolymeric adenine region (HAR) of >40 residues in length. We hypothesize that the length of the HAR is critical to amplification events of SINEs. Thus identification of SINEs with the longest A-tails would allow the identification of the currently most active SINEs. We have conducted searches of the rodent genome for HARs of 50 adenine residues followed by analysis by Repeatmasker. Following the establishment of Genbank-derived copy numbers of individual ID elements, we discovered two unique subfamilies contributing ~500 copies in the genome, both of which are located on Chromosome 7 of the Rat. We have also demonstrated experimentally by PCR that these copies are recently inserted in the majority of samples tested in *R. norvegicus* compared to that of *R. rattus*. This suggests that these elements have amplified within the past 1 million years, since the divergence of these two rat species. This approach can be used on any sequenced genome to identify the SINE subfamilies most likely to contribute to disease, or to provide population-specific markers.

**Improved Quantitation of Affymetrix GeneChip Microarray Data.** *B. Merriman, Z. Chen, S. Nelson.* Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

The Affymetrix GeneChip is a commercially available DNA microarray system for large scale gene expression analysis in human and other organisms. The platform is based on synthesizing short oligo DNA probes (25-mers) at high density (500,000 distinct probes on 1 cm. square glass substrate). In this system, each gene is monitored by a set of 25-mer oligo probes---typically 22 probes per gene, with 11 sequences matching the transcript, and the other 11 obtained by introducing a single base change into these sequences. Their analysis software reduces these 11 hybridization signals per gene into a single measurement of gene expression level, which they call the "Signal". There is little published data that validates this approach to producing a single gene expression number from the 22 measurements available. Moreover, in typical mammalian experiments, it can be seen that the oligo probes within an expressed gene are highly variable in how well they "work", i.e. in their binding affinities and specificities. It is not unusual to see the match probe intensities vary by a factor of 10 within a gene, or to see a mismatch probe give more signal than the corresponding match probe. This suggests that there may be more accurate ways of extracting gene expression information from the underlying oligo hybridization signals provided by the Affymetrix System. We investigate this possibility in detail, based on the analysis of over 2000 human GeneChip experiments. We show a variety of performance statistics for the oligo probes, and present several ways of obtaining more consistent and accurate expression measurements. We compare our alternative quantitation methods with others available, and perform over 100 RT-PCR measurements to resolve discrepancies between methods. Overall, our results suggest that by restricting to a well-behaved subset of the probes on the array, approximately 25% more genes can be detected, and the overall sensitivity and accuracy can be significantly improved. A simple "mask" file is available that can be used to implement our approach within other quantitation schemes.

**Genetic and Transcriptional Analysis of Metabolic Networks.** *M.M. Xiong, J.Y. Zhao.* Human Gen Ctr/Houston HSC, Univ Texas, Houston, TX.

Modern molecular biology is a mainly descriptive and qualitative science. It focuses on studying individual components such as genes and proteins and on the individual interactions between these molecules. It is now recognized that cells phenotypes are determined by complex biological systems, which consist of various networks such as metabolic networks, genetic networks and protein networks, and their different level of organization. Understanding processes of translation of genetic information into gene transcription and protein production, which in turn regulate metabolic networks, is essential for unraveling principle underlying biological processes. Developing hierarchical mathematical models for joint genetic, proteomic and metabolic analysis of cell function, and integrating various types of biological data such as DNA sequences, gene and protein expressions, and metabolic profiles, is a useful tool for achieving this goal. In this report, we first develop a linear model for prediction of concentrations of enzymes and regulatory proteins from DNA sequences. Then, we express the rate of biochemical reaction as a function of concentrations of enzymes, substrates, products and regulatory proteins. We formulate cellular metabolism as a linear programming in which metabolic flux will be constrained by flux balance equations and the largest possible rates of biochemical reactions. Subgradient and sensitive analysis of linear programming will be used to define price directive and resource directive, which will be used to measure the effect of DNA variation on the metabolic activity at the systems level. Nonsmooth analysis will be used to discover the pattern of control of metabolic networks by DNA, enzymes and substrates and to identify core biochemical reactions for cell function. Finally, examples will be provided to illustrate the proposed models and algorithms for joint genetic, transcriptional and proteomic analysis of metabolic networks.

**Haplotype Block Partitioning and Tag SNP Selection Using Genotype Data.** *K. Zhang<sup>1</sup>, Z.S. Qin<sup>2</sup>, J.S. Liu<sup>2</sup>, T. Chen<sup>1</sup>, M.S. Waterman<sup>1</sup>, F. Sun<sup>1</sup>.* 1) Molecular and Computational Biology Program, Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089; 2) Department of Statistics, Harvard University, Cambridge, MA 02138.

Recent studies have revealed that the human genome can be divided into discrete blocks of limited haplotype diversity. A small fraction of SNPs (tag SNPs) are sufficient to capture most of the haplotype structure of the human genome. Several methods have been developed to identify the boundary of blocks and corresponding tag SNPs based on known haplotypes. Unfortunately, phase information could be difficult to obtain from diploid samples. In this paper, we develop a method to partition haplotypes into blocks and to identify tag SNPs based on genotype data by combining the dynamic programming algorithms for haplotype block partition and tag SNP selection based on haplotype data with a variation of expectation maximization (EM) algorithm for haplotype inference. The program is successfully tested on a real data set. We assess the effect of both haplotype and genotype data in haplotype block identification and tag SNP selection as a function of a number of factors, including sample size, density or number of SNPs studied, allele frequencies, fraction of missing data and genotyping error rate, using extensive simulations. We find that a modest number of haplotype or genotype samples will result in consistent block partitions. This study provides practical guidelines for designing experiments to identify haplotype block structure and corresponding tag SNPs.

**Neocentromeres in 15q24-26 map to duplicons which flanked an ancestral centromere in 15q25.** *M. Ventura<sup>1</sup>, J.M. Mudge<sup>2</sup>, V. Palumbo<sup>1</sup>, S. Burn<sup>2</sup>, E. Blennow<sup>3</sup>, M. Pierluigi<sup>4</sup>, R. Giorda<sup>5</sup>, O. Zuffardi<sup>6</sup>, N. Archidiacono<sup>1</sup>, M.S. Jackson<sup>2</sup>, M. Rocchi<sup>1</sup>.* 1) Dept DAPEG Sez. Genetica, University of Bari, Bari, Italy; 2) The institute of Human genetics, University of Newcastle, Newcastle upon Tyne, United Kingdom; 3) Dept of Clinical genetics, Karolinska Hospital, Stockholm, Sweden; 4) Centro di Genetica, Ospedale Galliera, Genova, Italy; 5) Istituto di Ricovero e Cura a Carattere Scientifico Eugenio Medea, Lecco, Italy; 6) Dept. Patolg. Umana ed Ereditaria, Sezione di Biologia Generale, Pavia, Italy.

The existence of latent centromeres has been proposed as a possible explanation for the ectopic emergence of neocentromeres in man. This hypothesis predicts an association between the position of neocentromeres and the position of ancient centromeres inactivated during karyotypic evolution. Human chromosomal region 15q24-26 is one of several hotspots and harbours a high density of chromosome specific duplicons, rearrangements of which have been implicated as a susceptibility factor for panic and phobic disorders with joint laxity. We have investigated the evolutionary history of this region in primates and found that it contains the site of an ancestral centromere which became inactivated about 25 million year ago. This inactivation has followed a noncentromeric chromosomal fission of an ancestral chromosome which gave rise to phylogenetic chromosomes XIV and XV in human and great apes. Detailed mapping of the ancient centromere and two neocentromeres in 15q24-26 has established that the neocentromere domains map approximately 8 Mb proximal and 1.5Mb distal of the ancestral centromeric region, but that all three map within 500kb of duplicons, copies of which flank the centromere in Old World Monkey species. This suggests that the association between neocentromere and ancestral centromere position on this chromosome may be due to the persistence of recombinogenic duplications accrued within the ancient pericentromere, rather than the retention of centromere competent sequences per se. The high frequency of neocentromere emergence in the 15q24-26 region and the high density of clinically important duplicons are understandable in the light of the evolutionary history of this region.

Program Nr: 1477 from 2003 ASHG Annual Meeting

**Development and validation of a predictive model for robust primer design.** *J. Sorenson, S. Glanowski, N. Edwards, Y. Wang, C. Fosler, A. Parker, L. Johnston-Dow, R. Fang, M. Furtado, L.-Z. Pham.* Applied Biosystems, 850 Lincoln Centre Dr, Foster City, CA 94404.

The proper design of PCR primers which will consistently amplify well with high specificity under a desired set of PCR conditions is a challenging task and one which often results in much duplicated effort across laboratories. As part of the Applied Biosystems Genome Initiative, scientists at Celera Genomics resequenced the coding and regulatory regions of 23,000 genes in 40 DNA samples. More than 200,000 primers were designed and 18 million sequence reads were generated. From this unprecedented large-scale resequencing project and with this enormous data set, we have learned a great deal about primer design. To address the complexity of primer design, we have developed a predictive model of amplicon quality which takes into account features known to influence successful amplification and sequencing and predicts an *in silico* probability of amplicon success. This model has been formulated and verified using amplification and sequencing results from the Applied Biosystems resequencing project and the Applied Biosystems Resequencing Primer Sets project. The model allows the successful *in silico* discrimination of amplicons which are likely to succeed under the chosen PCR and sequencing conditions versus amplicons which would likely be more successful under alternative chemistry protocols or amplicons which are highly unlikely to succeed under any conditions. The availability of such a model facilitates the robust design of resequencing primers for genes and regions of interest in human and many other genomes.

Program Nr: 1478 from 2003 ASHG Annual Meeting

**An HMM model for scoring peptides against tandem mass spectrometry data.** *Y. Wan, T. Chen.* Dept of Math, University of Southern California, Los Angeles, CA.

Accurate scoring functions are crucial to database search methods for peptide identification via tandem mass spectrometry. Many mathematical models have been proposed to score peptides against mass spectra, but most scoring functions such as Sequest and Mascot do not consider the continuous and complementary information for b and y ions and intensity information of mass peaks in the data. Here we propose a validation method to compare different scoring functions. We obtain 4070 spectra and peptides with significant p-values, and use these as training data. We build an HMM model to capture the continuous and complementary information of ions, and to combine the mass peak intensities and machine errors into emission probabilities. The result of our method is better than previously existing methods.

**Gene expression profiles define mitochondrial pathology in yeast mutants and human disease.** *H. Smeets<sup>1</sup>, L. Eijssen<sup>1</sup>, R. Mineri<sup>2</sup>, R. van Eijsden<sup>1</sup>, C. van den Burg<sup>1,3</sup>, R. Peeters<sup>4</sup>, I. De Coo<sup>5</sup>, H. Scholte<sup>5</sup>, E. Rubio<sup>3</sup>, M. Zeviani<sup>2</sup>, R. Vlietinck<sup>1</sup>, V. Tiranti<sup>2</sup>.* 1) Dept Genetics & Cell Biol, Univ Maastricht, Maastricht, Netherlands; 2) Div Molec Neurogen, Nat Neurolog Inst "C.Besta", Milano, Italy; 3) Dept Pediatr, Academ Hosp Maastricht, Maastricht, Netherlands; 4) Dept Mathematics, Univ Maastricht, Maastricht, The Netherlands; 5) Depts Neurol & Biochem, Erasmus Medical Centre, Rotterdam, Netherlands.

The applicability of mathematical techniques for microarray data analysis and the incorporation of background knowledge into this analysis was tested for the mitochondrial system in yeast and human mutants. Mathematical techniques were derived from basic statistics, clustering, discriminant analysis and principal component analysis (PCA). Background knowledge was incorporated for the yeast data by downloading website ontology annotations automatically. As test data we used the set from Hughes et al. (Cell 102: 109-126 (2000) or [www.rii.com](http://www.rii.com)) containing whole genome (6,000 genes) expression profiles of 300 (mostly) gene knockout experiments in yeast. PCA reduced the dimension of the data set significantly without losing much of the information and reduced noise as well. By subsequent discriminant analysis, we could distinguish mitochondrial gene knockouts from non-mitochondrial gene knockouts (cytoskeleton, cell membrane, cell wall, cytoplasm, lysosome/vacuole/ peroxisome). As a next step, we applied the same approach on Affymetrix GeneCHIP data (U133A) of a group of 18 fibroblast cell lines of patients with Leigh disease, caused by a Surf1-mutation and 11 controls. The Surf1-patients could be reliably distinguished from the controls by a group of 13 mainly cell structure and ribosomal genes. Untested samples, which were analysed next, were correctly classified by this system. It is not clear at this point if these classifiers reflect Surf1-specific pathology or are characteristic for mitochondrial pathology in general. Gene expression studies in patients with mtDNA caused Leigh (8 fibroblast lines with the T8993G/C or T9176C mutation) or other syndromes and patients with secondary mitochondrial pathology are currently being performed to solve this question.

**Common chromosomal inversions and functional genomic variability.** *M. Riel-Mehan*<sup>1</sup>, *M. Almonte*<sup>1</sup>, *N.P. Rao*<sup>2</sup>, *N.B. Freimer*<sup>1,3</sup>, *R.A. Ophoff*<sup>1,3</sup>. 1) Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 2) Department of Pathology, UCLA, Los Angeles, CA; 3) Department of Human Genetics, UCLA, Los Angeles, CA.

Recent studies have revealed large blocks of almost identical sequences in particular chromosomal regions, comprising about 5% of the human genome. Non-allelic homologous recombination between these paralogous sequences results in changes of genomic structure, *e.g.* inversions and duplications. Variation in chromosomal architecture is more widespread in the human genome than previously thought. Examples of common inversion polymorphisms are identified on chromosome 8p23 and 4p16 (Giglio 2001; 2002). Duplicated segments spanning up to 300 Kb in length flank both of these regions. The paralogous sequences on chromosome 8p23 are 200 Kb and 300 Kb in length, 4.5 Mb apart, and are 99% identical. The other known pair of segmental duplications on chromosome 4p16 is each 200 kb, spaced 5 Mb apart, and are 94% identical. Each of the segmental duplications of these pairs is in opposite orientation to one another, which is an integral characteristic to their predisposition to inversions. Intra- chromosomal comparison of these sequences revealed that they are 92% identical to each other. This led us to design a probe to see if any other segmental duplications of similar structure existed in the human genome. A BLAST of the human genome with this probe exposed two more occurrences of paired segmental duplications sharing the same sequence and structure as those on chromosomes 8 and 4, as well as a number of lone instances. We are currently performing FISH tests in different ethnic groups to examine these regions for the presence of common inversions. Based on these results, we have developed an algorithm to expand this approach to the entire genome to discover more sets of paired segmental duplications that could predispose to paracentric inversions, and classify them by family. For our study we focus on inverted pairs of segmental duplications between 500 Kb and 10 Mb apart, with a minimum identity of 90%. Identification of these regions will lead to a better understanding of the architecture of the human genome and a possible functional role in human genetic variation.

**Advancement of Electronic PCR.** *P.S. White*<sup>1,2</sup>, *K. Murphy*<sup>1</sup>, *T. Raj*<sup>1</sup>, *R.S. Winters*<sup>1</sup>. 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA.

We have adapted the originally described electronic PCR algorithm (Schuler, 1997) to perform string searches more accurately and much more rapidly than previously possible. Our implementation (e-PCR2) runs sufficiently fast to allow even desktop machines to quickly query large genomes with very large genomic element sets. In addition, e-PCR2 is multithreaded, interprets all IUPAC nucleotide symbols, allows searches with elements specified by long sequences (such as SNPs), accepts ranges in the expected PCR size input field, requires substantially less memory for analysis of large sequences, and corrects a number of minor flaws causing misreporting of hits in exceptional cases. In comparison tests using a variety of platforms and parameter settings, e-PCR2 consistently performed several hundred times faster than e-PCR under identical conditions for large genomic sequences. Analysis of word size parameter changes determined that a word size of 11 (currently possible only with e-PCR2) was optimal, and running e-PCR2 under these conditions yielded an additional 3-fold increase in speed. Using a search margin of 1,000 bases and a word size of 11, e-PCR2 running on a single 750 Mhz RS64 IV CPU (IBM p660) was able to identify sequence positions for 130,650 STSs in the entire human genome in 53.1 minutes. A similar single-processor-based search for 3.5 million STSs, which approximates the number of non-redundant human SNPs currently in dbSNP, took 277.2 minutes. Using a margin of 50 increased performance 263% at the cost of 2.4% fewer localizations, and using 8 threads further increased elapsed (but not actual) performance 320%. Thus, e-PCR2 provides increased annotation capabilities for complex genomes to non-expert laboratories. e-PCR2 has been compiled for Linux, Solaris, AIX, Windows, and Macintosh platforms. Source and executable code is freely available to the research community at <http://genome.chop.edu/mePCR/>.

Program Nr: 1482 from 2003 ASHG Annual Meeting

**DNA Banking Study in an Ethnically Diverse Urban University Hospital.** *W.A. Wolf, M.J. Doyle, S.A. Aufox, T.M. Frezzo, M.E. Smith, W.A. Kibbe, R.L. Chisholm.* Center for Genetic Medicine, Northwestern University Chicago, IL.

The Northwestern University gene bank (NUgene) is a genetic banking project with a centralized genomic DNA sample collection and storage system that anonymizes DNA samples and regularly updates phenotypic data from electronic medical records (eMR). The purpose of NUgene is to provide an ethnically and medically diverse population of samples that will allow association of specific genetic variants with disease and therapeutic outcomes. NUgene's DNA samples and associated phenotypic information are available to internal and external researchers with Northwestern University IRB approved studies. We plan to enroll 100,000 participants over 6 years. Eligibility criteria includes the ability to provide informed consent, persons who are 18 years or older and who receive medical care through Northwestern Memorial Hospital or one of its affiliates. Participants are recruited through a variety of clinical settings and physician groups. Consenting individuals complete a self-administered family and medical history questionnaire, a consent form and a HIPAA authorization form in a single encounter. Phenotypic and genotypic data are housed in a separate database from participant identifiers and enrollment data to enhance security. Phenotypic information is updated biannually from eMR. To make gene-disease associations, we will use the Disease Ontology to link known human disease information to our genotype/phenotype repository. Recruitment began in November 2002 and over 400 participants are currently enrolled. Across venues, enrollment uptake is 10% of those approached to participate. The majority (77%) of participants come from a general internal medicine clinic. Participants represent the diverse nature of the Chicago community, with representation from 9 major ethnic groups. Females are slightly overrepresented in our sample at 62% and ages range between 19 and 85. 70% of our participants have a college or graduate degree. The NUgene project is jointly supported by Northwestern University, Northwestern Memorial Hospital and Evanston Northwestern Healthcare.

**Phenotype in locus-specific databases: contents and directions.** *S.A. Teebi<sup>1</sup>, R.G.H. Cotton<sup>2</sup>*. 1) Centre for Computational Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Genomic Disorders Research Centre, St. Vincent's Hospital, Melbourne, Australia.

Discussions of phenotype content in locus-specific mutation databases (LSDBs) have until now been vague and under-informed. Specifically, these databases, which in turn largely dictate the contents of whole genome variation databases like HGVbase and dbSNP, have, by and large, been assumed to be vacant of significant clinical and phenotype-related information. Here we present the results of a study conducted with the aim of ameliorating the extant knowledge on this field and using the new knowledge to outline possible directions to be taken in the development of phenotype-conscious databases in the future. 134 LSDBs listed by the HGVS (<http://www.hgvs.org>) and MutRes (<http://srs.ebi.ac.uk/srs6bin/cgi-bin/wgetz?-page+LibInfo+-newId+-lib+MUTRES>) resources were polled, covering 282 genes. 82% of LSDBs were found to record some or any phenotype information. 377 total phenotype-related fields were found in all the databases, an average of 3.53 fields per database. A significant percentage of fields contained just one phenotype field (30%). A low percentage of LSDBs had in excess of 10 phenotype fields (3%). In general, phenotype parameters in LSDBs exhibited a great deal of heterogeneity (i.e. different data were recorded for different loci) and sparseness (i.e. phenotype data were not often present in every mutation entry in a given database). Other findings indicated a great level of willingness among LSDB curators to record phenotype, as well as an understanding of what needs recording. Despite this, a naivety in regards to classifying and tabulating the difficult parameter of phenotype was evinced. To tackle this "phenotype problem", especially as it pertains to whole-genome databases and their interoperability with LSDBs, we propose a method for the recording of such data that is based on the Entity-Attribute-Value (EAV) model. Basic aspects of this model will be discussed.

Program Nr: 1484 from 2003 ASHG Annual Meeting

**A tool for "Genomic Convergence": Annotating the Ensembl human genome browser with disease-specific graphical representations of linkage analysis data.** *J.E. Stenger, H. Xu, C. Haynes, R. Cornwell, E. Hauser.* Center for Human Genetics, Institute for Genome Science and Policy, Duke University, Durham, NC.

"Genomic Convergence" is a multi-step data reduction strategy that merges the resulting potential candidate gene lists obtained by different laboratory and statistical approaches to prioritize candidate disease susceptibility genes that may be contributing to complex human diseases [Hauser et al., 2003] We are using this approach at the Duke Center for Human Genetics to identify candidate susceptibility genes that warrant subsequent association analysis by identifying the subset of genes that are within regions with high LOD scores greater than one and are also identified by either serial analysis of gene expression (SAGE) analysis or gene chip technology as having a significant alteration in the levels of mRNA expression. For this purpose we have exploited the Ensembl open source genome annotation system and database ([www.ensembl.org](http://www.ensembl.org)) which we maintain an instance of on our local servers in conjunction with the Distributed Annotation System (DAS) [Dowell, Eddy & Stein] to store our laboratory-specific data on our local secure server and to visually display this data in the context of the Ensembl genomes browser We also have previously developed high-throughput bioinformatics methods to map the location of SAGE tags and probes spotted on the Affymetrix gene chip sets (which we have contributed to Ensembl.org) on to the human genome working draft sequence builds. To facilitate genomic convergence, we have created a database on our DAS server to hold coordinates from both single point and multipoint linkage analysis pertaining to different research projects and have developed an algorithm that uses the stored coordinates to draw a graph, selected by the user from a pull down box, plotting LOD scores on the y-axis vs.the position in base pairs on the X-axis. This graph is displayed under the ideogram of the chromosome that is in view. This graph maps markers from the genetic position on Decode map to their position in base pairs and seamlessly integrates into the Ensembl display environment.

**Adding annotation to identify at-risk DNA motifs in unknown Genes Identify.** *T. Wang, J.E. Stenger.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Following a genomic scan, the research team identifies a region defined by two peak LOD scores. A bioinformatics savvy geneticist then brings up the human genome browser page at [ensembl.org](http://ensembl.org), and clicks on export data. From there she downloads all the candidate genes between the two markers denoted by the peaks. Of the list of 55 candidate genes, only 21 have the function associated with them. The geneticist, not knowing what to do with the genes without a function, focuses entirely on the genes with a function. This very real scenario drives home the message that without more annotation many important genes may be overlooked. The first thing we can do is analyze the human genome for sequence motifs that laboratory research has indicated are primed for instability. Our previous research has shown that closely-spaced, highly identical, inverted Alu pairs with homologous regions > 250 base pairs are likely to undergo homologous recombination in yeast model systems (Lobechev et al., 2000). Using computational methods we have been able to determine the Alu pairs in the human genome working draft sequence that meet this set of criteria (Stenger et al., 2001). By identifying such biases we have a clue as to what is not well-tolerated in the genome. This gives us the ability to predict which genes are likely to have their functions abrogated by undergoing a homologous recombination event. DNA repeats, be they microsatellites, or inverted, highly identical, short distant repeats (SINES) and long interspersed repeats (LINES) are ubiquitous in all genomes. These repeats, under certain mitigating circumstances, such as in the presence of the mutator phenotype (mismatch repair defective) or helicase defects, are length dependent fragile sites in yeast and higher eukaryotes. Collectively, these DNA motifs have been coined as at-risk factors for genomic alterations by Gordenin and Resnick (1998). Genes containing at-risk motifs have a high likelihood of contributing to disease. Annotating the genome with such at-risk motifs is therefore a reasonable thing to do to help identify genes associated with complex disease.

**Microarray gene expression analyses of multiple sclerosis plaque tissue.** *L.R. Griffiths<sup>1</sup>, L. Tajouri<sup>1</sup>, A.S. Mellick<sup>1</sup>, E.G. Tannenber<sup>2</sup>, W.W. Tourtellotte<sup>3</sup>.* 1) Genomics Research Centre, Griffith University, Parklands Drive, Southport QLD Australia 4215; 2) QLD Medical Laboratories, West End QLD Australia; 3) Human Brain & Spinal Fluid Resource Center, Wilshire Blvd, LA. Cal. USA.

Multiple sclerosis (MS) is an autoimmune disease of the central nervous system, characterized by zones of demyelination and inflammatory plaques. Symptoms include limb weakness, sensory loss, visual alterations and bladder dysfunction, and the appearance of lesions or plaques that are disseminated in time and space. In this study, we have employed array hybridisation and Q-PCR analysis to examine gene expression changes, that may differentiate inflammatory forms of MS plaques. RNA from MS chronic active and MS acute lesions was extracted, and compared with patient matched normal white matter using fluorescent cDNA microarray hybridisation analysis. This resulted in the identification of 139 genes that were differentially regulated in MS plaque tissue compared to normal tissue. Of these, 70 transcripts were uniquely differentially expressed (>1.5-fold) in either acute or chronic active tissues, while 69 genes showed a common pattern of expression in the chronic active and acute plaque tissues investigated ( $P < 0.0001$ ,  $r = 0.73$ , by Spearman's analysis). For these 69 genes, the mean fold level of gene expression difference was found to be significantly higher in acute plaques, suggesting that symptomatic variation in inflammatory lesions in MS may be the result of overall quantitative, rather than specific gross qualitative differences in gene activity. In this study, SYBR Green I, real time Q-PCR was also used to validate the differential expression of array selected clones and to examine the expression of transcripts that may be present below the level of sensitivity for array analysis. The determinations of fold regulation, obtained by Q-PCR analysis of 7 array-selected genes, were found to correlate significantly with determinations of fold obtained following fluorescent array analysis, of chronic active and acute plaque tissue ( $r = 0.75$ ,  $P < 0.01$ , by Pearson's bivariate correlation,  $n = 14$ ).

**Evidence for a hominoid specific splicing form of neuropsin, a gene involved in learning and memory.** *Y. Li<sup>1</sup>, B. Su<sup>1,2</sup>*. 1) Laboratory of Cellular and Molecular Evolution, Kunming Institute of Zoology, the Chinese Academy of Sciences, Kunming, Yunnan, China; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH.

Neuropsin is a secreted-type serine protease expressed in the brain and involved in learning and memory. We sequenced exon 3 and its flanking introns of neuropsin gene containing the alternative splicing site in humans and representative nonhuman primate species. We found that the Type-II splicing form of neuropsin is specific to hominoid species (humans and apes), indicating that this splicing form originated about 18 million years ago. The synonymous and nonsynonymous mutation analysis revealed the signature of adaptive evolution of Type II neuropsin due to Darwinian positive selection. Hence, this hominoid specific splicing form of neuropsin may contribute to the progressive changes of cognitive skills during primate evolution.

**Rapid evolution of microcephalin, the gene determining human brain size.** *YQ. Wang<sup>1</sup>, B. Su<sup>1,2</sup>*. 1) Laboratory of Cellular and Molecular Evolution, Kunming Institute of Zoology, the Chinese Academy of Sciences, Kunming, Yunnan, China; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH.

Microcephalin is a major player in human brain development. Truncated mutations in this gene can cause primary microcephaly in humans with a brain size comparable with that of early hominids. We sequenced two exons and flanking introns of the microcephalin gene in humans and seven nonhuman primate species including great apes, lesser apes and Old World monkeys. Our results showed that there are frequent amino acid substitutions with 23.6% of the sites being variable in humans and nonhuman primates. The nonsynonymous substitution rate ( $K_a$ ) between humans and rhesus monkeys is 0.05, which ranks microcephalin one of the fastest evolving proteins in primates. There are 5 fixed and 8 polymorphic amino acid substitutions in human populations, most of which are conserved in apes and Old World monkeys. The Fu's  $F_s$  neutrality test and individual codon substitution test in human populations are against the neutral expectations, suggesting the accelerated evolution of microcephalin gene in humans is likely the consequence of Darwinian positive selection during human evolution.

**Adaptive Evolution of ASPM During Human Origin.** XJ. Yu<sup>1</sup>, B. Su<sup>1,2</sup>. 1) Laboratory of Cellular and Molecular Evolution, Kunming Institute of Zoology, the Chinese Academy of Sciences, Kunming, Yunnan, China; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH.

ASPM (abnormal spindle-like microcephaly associated gene) is essential for normal mitotic spindle function in human embryonic neuroblasts. Mutations of ASPM can cause human autosomal recessive primary microcephaly (MCPH) with a brain size comparable with that of early hominids. Therefore, ASPM may play an important role in brain enlargement during primate evolution, especially human origin. We sequenced a 3700 bp fragment of exon 18 of ASPM in seven representative primate species, including humans, chimpanzees, gorillas, orangutans, gibbons and two Old World monkey species. Our result showed that there are nine fixed sequence substitutions within the coding region of exon 18 in humans, and eight of them are replacement mutations. The calculation of Ka (nonsynonymous mutation rate)/Ks (synonymous mutation rate) revealed an accelerated amino acid substitutions of exon 18 in the human lineage. The Ka/Ks ratios are 1.63 between humans and chimpanzees and 3.52 between the putative human ancestor and modern humans. The McDonald-Kreitmans neutrality test is significant ( $P = 0.047$ ), indicating adaptive evolution, i.e. Darwinian positive selection of ASPM during human origin.

**Analysis of APOE specific hippocampal gene expression in Alzheimers Disease (AD) using Serial Analysis of Gene Expression (SAGE).** *P. Xu<sup>1</sup>, C. Kroner<sup>1</sup>, C. Browning<sup>1</sup>, C. Hulette<sup>2</sup>, D.E. Schmechel<sup>2</sup>, J. Ervin<sup>2</sup>, M. Hauser<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>, J.R. Gilbert<sup>1</sup>.* 1) Center for Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Alzheimer Disease Research Center, Duke Univ Medical Ctr, Durham, NC.

Serial analysis of gene expression (SAGE) is a powerful technique for the generation of quantitative information about tissue specific gene expression. SAGE can detect small changes in expression level and transcripts from entirely novel genes. To identify new genes conferring susceptibility to Alzheimers disease (AD), and study the influence of APOE genotype on gene expression in AD, we have constructed four SAGE libraries: one each from APOE3/3, APOE3/4 and APOE4/4 Alzheimers patients, and one from APOE3/3 control samples, using total RNA isolated from the hippocampus of AD patients and normal controls. Initial analysis of APOE 3/3 AD and control SAGE libraries showed each contained more than 400,000+ tags (16,000 ~ 19,000 clones). Preliminary sequence results confirm that the PCR amplified DNA fragments contain concatemers composed of an average 26~28 bp ditags. We have picked, cultured and commenced sequencing using an ABI 3700 automated sequencer more than 3,000 clones from each APOE 3/3 library to generate initial data from a minimum of 60,000 tags. Sequence analysis of APOE 3/4 and 4/4 libraries will commence once this initial sequencing is finished. Sequence files are analyzed by means of the eSAGE software, which identifies the anchoring enzyme site with proper spacing and extract the two intervening tags and records them in a database. We will evaluate gene expression patterns in AD and normal control SAGE libraries by comparing the abundance of individual tags, and identifying the corresponding genes using the tag-to-gene mapping database generated from NCBI's UniGene sets. Through the combined use of both Affymetrix microarrays and SAGE, we will obtain a detailed and quantitative picture of known and novel genes expressed in the normal and AD hippocampus.

**Integration of CGH data and microarray gene expression data aids in the discovery of DNA-based diagnostic tumor markers.** *C.C. Harris*. Exagen Corporation, Albuquerque, NM.

The maturation of microarray technology has enabled the routine collection of genome-wide gene expression (RNA) data. In cancer diagnostics, several authors have shown that microarray data collected from tumors may be useful in differential diagnosis, tumor staging and prognosis. The data produced by these studies ideally represents a valuable resource for the development of new diagnostics. However, at present, the application of microarray technology requires steps in sample collection and sample preparation that inhibit routine clinical adoption.

In contrast, DNA-based markers are commonly used in cancer diagnostics. Diagnostic implementations utilizing FISH and RT-PCR technology are in widespread use. New diagnostic products based on such accepted technology will more quickly find clinical acceptance. A major obstacle to the development of new DNA-based diagnostics is the lack of genome-wide gene-scale DNA data. However low-resolution band scale DNA copy number information is available in the form of comparative genomic hybridization (CGH) data. While clinical application of the CGH process for diagnostic purposes is limited by the technical difficulties associated with the process, this does not preclude the use of existing CGH data in the identification of new diagnostic markers. We propose that the integration of band-scale CGH data and gene-scale microarray gene expression data is a viable path to the development of new clinically relevant and clinically useable DNA-based cancer diagnostics.

As a demonstration, we have analyzed publicly available microarray and CGH data collected from glioblastoma and anaplastic oligodendroglioma tissue samples. Notably, the analysis of each dataset independently did not result in the identification of statistically significant markers discriminative of phenotype. Concurrent analysis, by way of identifying gene-specific markers consistent across both datasets, resulted in statistically significant markers ( $p < .05$ ). Markers identified in such a manner can be easily implemented for validation studies and ultimately as diagnostic products.

**Gene Expression in Congenital Heart Disease.** *D. Bittel, N. Kibiryeve, G.K. Lofland, J.E. OBrien, M.G. Butler.*  
Childrens Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Congenital heart disease occurs in 0.5 to 1% of all newborns and represents a significant proportion of birth defects. Due to the high number of infants with conotruncal defects treated at Childrens Mercy Hospital compared with other pediatric centers, the Sections of Cardiovascular & Thoracic Surgery and Medical Genetics have established a program to elucidate the underlying epidemiological, physiological and molecular genetic mechanisms responsible. Most congenital heart disease is thought to be multifactorial in origin implying the involvement of anomalous gene expression and epigenetic factors. Recent advances in microarray technology, allowing for the simultaneous study of novel genome-wide expression of human genes, are aiding the search for the genetic causation of conotruncal defects. We have examined gene expression in dysplastic pulmonic valve from two nonsyndromic infants (a 7 month old female and a 6 month old male) with tetralogy of Fallot (TOF) and comparable tissue from a control infant (1 month old male) with no heart disease. We have examined in excess of 12,800 genes using the Agilent Technologies Human 1 cDNA microarray to identify genes involved in conotruncal defects. Initial comparisons in the affected infants were made between dysplastic pulmonic tissues and pericardium. In those comparisons, more than 450 genes were found to express differently ( $\pm 10X$ ) in the two tissues: Cell cycle or apoptosis factors, 18; Structural proteins, 18; Calcium binding, 2; Transcription, translation or processing factors, 40; Metabolic factors, 29; Growth factors or kinases, 28; Signaling proteins, 41; Homeostasis factors, 25 and Unclassified factors, 38. Subsequent gene expression comparisons with pulmonary artery from our control infant focused on known candidate genes for cardiac defects. JAG1 was detectable in the control infant but had no detectable expression in the affected infants by microarray analysis or quantitative RT-PCR. This was confirmed in three additional infants with TOF. JAG1 is a promising candidate gene for isolated TOF and is known to be causative for Alagille syndrome in which cardiac defects are described.

**Regulation of Metabolism Protein, HPRT in CD8+ Cells of Human Immunodeficiency Virus Type-1 Infected Subjects on Highly Active Antiretroviral Therapy.** *E.M. McGhee, L.S. Diaz, H.G. Foster.* University of California San Francisco, Department of Community Health Systems, UCSF Comprehensive Cancer Center, Medicine.

Previous studies have shown that genetic changes observed in human immunodeficiency virus type-1 (HIV-1) infected peripheral blood monocyctic cells in the era of highly active antiretroviral therapy (HAART) may be involved in abnormal purine metabolism-hyp oxanthine-guanine-phosphoribosyl transferase (HPRT) regulation, genetic polymorphisms, and increased mutation frequency. HPRT is an enzyme that catalyzes the transfer of the phosphoriboyl moiety of 5-phosphoribosyl-1-pyro-phosphate to the 9 position of hypoxanthine and guanine to form inosine monophosphate and guanosine monophosphate. Also, in instances of mutational damage in the HPRT gene, cells may commit to an increased sequence analysis of mutations indicating the formation of single-base, transversion (G -> T) and transition (G -> A) substitutions. Overall, this indicates that patients infected with HIV-1 and exposed to nucleoside analog and protease inhibitor drugs, may sustain significant genotoxic insults and should be therefore subjected to long-term surveillance. Given these evidences for genetic damage in these patients, consideration should be given to HAART, and HAART induced-long term genomic instability. We are currently investigating genomic damage at the HPRT locus in HIV-1 infected cells from subjects receiving HAART. We show that HPRT is down regulated in CD8+ cells from subjects receiving HAART. cDNA from CD8+ cells of HIV-1 infected subjects receiving HAART, those no longer on HAART, and uninfected people were analyzed by microarray analysis to determine gene expression of the HPRT gene. Microarray analysis for gene expression indicated that HPRT is down regulated in CD8+ cells from HIV-1 infected subjects on HAART when compared to people that are uninfected, and subjects infected but not on HAART. Down regulation of the HPRT gene in cells from HIV-1 infected subjects on HAART, may impose limitations for effective optimal treatment in HIV-1 patients. Therefore, in a population based study we are analyzing additional CD 8+ cells from subjects receiving HAART, and using RT-PCR to determine mRNA expression of other proteins that may be involved in abnormal purine metabolism. This information can be helpful in advancing our knowledge of protein function in biochemical metabolism in HIV-1 infect subjects in the era of HAART, and could lead to new strategies for better therapy.

**Dissecting the molecular bases of kidney stone disease by microarray analysis.** *L. Liang<sup>1</sup>, J. Chen<sup>1</sup>, R. Vittal<sup>2</sup>, L. Deng<sup>1</sup>, Z.E. Selvanayagam<sup>3</sup>, J.A. McAteer<sup>4</sup>, J.A. Tischfield<sup>1</sup>, K.V. Chin<sup>2</sup>, A. Sahota<sup>1</sup>.* 1) Dept of Genetics, Rutgers Univ, Piscataway, NJ; 2) Dept of Chemical Biology, Rutgers Univ, Piscataway, NJ; 3) Dept of Pediatrics, UMDNJ, New Brunswick, NJ; 4) Dept of Anatomy and Cell Biology, Indiana University, Indianapolis, IN.

Renal deposition of calcium oxalate monohydrate (COM), primarily due to idiopathic causes, accounts for the vast majority of cases of stone disease. Genetic causes of stone disease are rare, but over 30 disorders have been described including 2,8-dihydroxyadenine (DHA) nephrolithiasis due to adenine phosphoribosyltransferase (APRT) deficiency. The interaction of crystals with renal tubular epithelial cells may be a critical event in the initiation of the disease process. In an earlier cDNA microarray study using a small number (588) of genes, we showed that DHA and COM crystals induced qualitatively similar gene expression changes in primary cultures of human kidney epithelial cells. To verify whether DHA stone disease can be used as a model for the more common COM stone disease, we carried out a detailed microarray study involving over 10,000 transcripts and with cells exposed to crystals for up to 48 h. Expression changes for a selected number of genes were confirmed by Real Time RT-PCR. Both DHA and COM crystals induced time-dependent changes in gene expression, but very few genes were detected at the early exposure stages. Most of the expression changes occurred at the intermediate or late stages, which may reflect the time required for crystals to attach to or be internalized by the epithelial cells. As in our previous study, DHA and COM crystals induced similar patterns of gene expression, but a small number of crystal-specific expression changes were also observed. In particular, DHA crystals, but not COM crystals, induced a significant increase in the expression of a cluster of cytokines that may be involved in the inflammatory process. Inflammation of kidney tissue is rare in COM stone disease, but is common in APRT deficiency. These findings suggest that the cell culture system may be useful for identifying the common events underlying stone disease as well as for differentiating crystal-specific effects.

**Towards high-throughput *RAII* mutation screening by temperature gradient capillary electrophoresis.** *R.E. Slager*<sup>1</sup>, *T.L. Newton*<sup>2</sup>, *E.S. Wilch*<sup>1</sup>, *C.N. Barth*<sup>2</sup>, *A. Rohr*<sup>3</sup>, *B. Finucane*<sup>4</sup>, *P.I. Patel*<sup>3</sup>, *S.H. Elsea*<sup>1,2</sup>. 1) Genetics Program, Michigan State University, East Lansing, MI; 2) Department of Zoology, Michigan State University, East Lansing, MI; 3) Department of Neurology, Baylor College of Medicine, Houston, TX; 4) Elwyn Training and Research Institute, Elwyn, PA.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies and mental retardation syndrome associated with deletions involving chromosome 17p11.2. Through careful clinical and molecular evaluation, we recently reported the identification of three distinct frameshift mutations in the retinoic acid induced 1 (*RAII*) gene in three unrelated individuals who display the characteristic SMS behavioral and physical phenotype but who do not harbor a detectable deletion on 17p11.2. These mutations, a 29 base pair deletion in SMS129, and deletions of a single C in SMS159 and SMS156, were detected through PCR amplification and sequencing of the coding region and known splice variants of *RAII*. Our pilot sequencing experiments also encompassed three nondeletion patients who displayed several phenotypic aspects of the syndrome but displayed some features discordant with SMS. We did not find any deleterious *RAII* mutations in this sample group. Since *RAII* is a large and complex gene, our current studies have focused on developing an effective high-throughput mutation screening method. Using the SpectruMedix temperature gradient capillary electrophoresis (TGCE) system, we demonstrate that we are able to distinguish the three deletion mutations from known control samples. We also show that TGCE can identify known single nucleotide polymorphisms within *RAII*. The TGCE method is desirable for high-throughput mutation screening because the cost per sample is low, and we are able to use diluted, crude PCR product in the analysis without losing adequate signal. We report the *RAII* mutation screening results of 10 putative SMS nondeletion patients by analysis of PCR products by TGCE followed by sequence confirmation of any potential mutations. We believe that the TGCE method is a reliable and cost-effective method to determine the spectrum of *RAII* mutations in the SMS population.

***Drosophila* model of Down syndrome.** K.T. Chang, Y.J. Shi, K.T. Min. Neurogenetics Branch, NINDS, NIH, Bethesda, MD.

Down syndrome (DS), a disorder that affects 1 in 700 births, is the most common genetic cause of mental retardation and other abnormalities. Despite much effort, the underlying cause of mental retardation in DS remains elusive. Down Syndrome Critical Region 1 (DSCR1) gene, located within the DS critical region on chromosome 21, is overexpressed in the brain of Down syndrome fetus and encodes an inhibitor of calcineurin, but its physiological significance is unknown. An attractive system for studying the functions of DSCR1 is *Drosophila melanogaster*; it has a short generation time, and is easily amenable to genetics, biochemical, molecular, and behavioral analyses. We thus generated *Drosophila* loss-of-function and overexpression mutants of nebula, an ortholog of human DSCR1. Biochemical studies show that the nebula protein can bind to and inhibit calcineurin activity, as well as regulate cAMP-dependent protein kinase activity, CREB phosphorylation, and CREB-dependent gene transcription. Behavioral analyses revealed that the nebula mutant exhibits defective learning and long-term memory. Strikingly, transgenic flies overexpressing nebula also show severely impaired learning. Furthermore, we demonstrate that the same calcineurin-mediated signaling pathway is altered in human trisomy 21 fetal brain tissue overexpressing DSCR1. Together, these results suggest that DSCR1 mediates learning and long-term memory, and that alteration of DSCR1 expression could be one cause of mental retardation in Down syndrome.

**Dysregulation of Interferon inducible and Aquaporin 1 genes in the blood of patients with Sjogrens syndrome.**

*E.S. Emamian, M.E. Grandits, C.M. Meyer, A.N. Leiran, J. Ermer, E.C. Baechler, T.W. Behrens, N.L. Rhodus, K.L. Moser.* Medical School, University of Minnesota, Minneapolis, MN.

Sjogrens syndrome (SS) is an autoimmune disorder characterized by lymphocytic infiltration into lacrimal and salivary glands leading to symptomatic dry eyes and mouth. Disease mechanisms are not well defined but include production of autoantibodies, dysfunction of molecular water transport processes, dysregulation of apoptosis, and alterations in cytokine activity. To gain insight into the underlying etiology of this disease, we have used microarray technology to profile global gene expression of whole blood from SS patients and controls. Initial studies indicated that differential gene expression patterns were detectable in SS patients compared with healthy controls and suggested that numerous genes induced by interferons (IFNs) were overexpressed in patients. We have now enlarged the patient sample (n=33), evaluated a second independent matched control group (n=18), and increased the number of genes interrogated from approximately 12,600 to 22,000. All patients fulfilled the 2002 revised European criteria for classification of SS. Labeled cRNA was generated from the cDNA sample by an in vitro transcription (IVT) reaction and fragmented cRNA was hybridized to Affymetrix Human U133A Microarray Chips. After scanning and scaling gene expression values, the expression levels of transcripts from patients and controls were compared using unpaired students t-test. Over 330 genes were differentially expressed using nominal significance criteria of  $p < 0.001$ , and over 40 of these genes differed in mean expression levels by greater than 1.5 fold. The results confirmed a significant over-expression of genes involved in the control of interferon responses or that are inducible by IFN. Among the down-regulated genes, the most significant was aquaporin1 (AQP1,  $P=0.00058$ ). The down-regulation or dislocation of AQP1 has been considered to have role in dysfunction of the salivary gland in SS. These results implicate a role for IFN-related pathways in the pathophysiology of SS, and identify several candidate genes that may be useful as biomarkers in the diagnosis of this disease.

**The 9q subtelomeric microdeletion syndrome; Evidence for a genomic susceptibility.** A. Huang<sup>1</sup>, D.R. Stewart<sup>1</sup>, F. Faravelli<sup>2</sup>, B.M. Anderlid<sup>3</sup>, M. Kaur<sup>1</sup>, E. Rossi<sup>4</sup>, R. Tenconi<sup>4</sup>, M. Nordenskjöld<sup>3</sup>, K.W. Gripp<sup>5</sup>, W.S. Meschino<sup>6</sup>, O.W.J. Quarrell<sup>7</sup>, M. Irons<sup>8</sup>, C.A. Zaleski<sup>9</sup>, M. Budarf<sup>1</sup>, E.H. Zackai<sup>1</sup>, N.B. Spinner<sup>1</sup>, I.D. Krantz<sup>1</sup>. 1) Div of Hum Genet and Mol Biol, The Children's Hosp of Philadelphia, PA; 2) S.C. Genetica Umana, Ospedale Galliera, Genoa, Italy; 3) Dept of Mol Med, Karolinska Inst, Stockholm, Sweden; 4) Univ di Pavia/Univ di Padova, Italy; 5) AI duPont Hosp for Children, Wilmington, DE; 6) North York Gen Hosp, Dept of Genetics, Toronto, Canada; 7) Sheffield Childrens Hosp, Sheffield, UK; 8) Div of Genet and Metab, Boston Childrens Hosp, MA; 9) Marshfield Clinic, Marshfield, WI.

With the recent advent of clinical testing for subtelomeric rearrangements, several submicroscopic deletions of chromosome 9q have been reported. Cytogenetically visible deletions of this region are rare with only 2 reported cases (Ayyash et al, J Med Genet 34:610; Schimmenti et al, Am J Med Genet 51:140), likely indicating a decreased viability for affected fetuses. The 9q subtelomeric deletion syndrome has a recognizable pattern of malformations including hypertelorism, eyebrow and ear abnormalities, a high arched palate, a tented upper lip, hypotonia, mental retardation, and conotruncal heart defects. Cytogenetic and molecular mapping of the deletion breakpoints in 12 probands using a series of 8 FISH probes, 14 microsatellite markers, and 14 SNPs revealed an apparent common proximal breakpoint in 11/12 probands, similar to what has been seen in other microdeletion syndromes. This breakpoint maps between SNP C12020842 (rs13631) centromerically and SNP C80658 (CACNA1B gene) telomerically and falls within a gap in the published genomic sequence (~1 Mb). The gap falls between clones RP11-350O14 and CTD-2521H7 proximally and RP11-417A4 distally with the proximal clones terminating in the same region, suggesting that it may be unclonable in bacteria. Unclonable human sequences have been associated with regions of the genome that undergo chromosomal rearrangement. Molecular definition and analysis of this region using 10 additional SNPs mapped between the two proximal breakpoint flanking SNPs in these patients is underway.

**Expression atlas of the mouse orthologues of the Williams-Beuren syndrome critical region genes.** *A. Reymond<sup>1</sup>, M. Yaylaoglu<sup>2</sup>, G. Merla<sup>1</sup>, C. Thaller<sup>3</sup>, C. Caccioppoli<sup>4</sup>, C. Ucla<sup>1</sup>, D. Montanaro<sup>4</sup>, T.M. Chen<sup>3</sup>, N. Scamuffa<sup>1</sup>, A. Ballabio<sup>4</sup>, S.E. Antonarakis<sup>1</sup>, G. Eichele<sup>2</sup>, V. Marigo<sup>4</sup>.* 1) Division of Medical Genetics, University of Geneva Medical School; 2) Max Planck Institute, Hannover; 3) Baylor College of Medicine, Houston; 4) TIGEM, Naples.

The Williams-Beuren syndrome (WBS) is a neurodevelopmental disorder characterized by mental retardation with unique cognitive and personality profile, distinctive facial features, supraaortic stenosis, short stature, connective tissue anomalies, hypertension, infantile hypercalcemia, dental and kidney abnormalities and premature aging of the skin. Its incidence is estimated at 1/15,000 and sporadic de novo inheritance is usual. Molecular basis of the syndrome is a heterozygous ~1.5 Mb microdeletion or inversion at chromosome band 7q11.23. While our understanding of the etiology of WBS has improved greatly, we are still ignorant as to the molecular basis of all except the cardiovascular phenotype. To define where the 31 WBS critical region genes exert their function and identify their possible role in the WBS phenotypes we performed a systematic analysis of the expression profile of all their murine orthologues. To obtain an high resolution expression pattern several complementary methods were combined: RT-PCR on a mouse cDNA panel of 12 adult tissues and 4 developmental stages; wholemount in situ of E9.5 and E10.5 embryos, section in situ of E14.5 embryos, brain section in situ of E15.5 embryos, P7 and P56 mouse. These stages correspond to mid and late embryonic and fetal human periods, when the major organs and body regions are organized, while the brain sections allow to correlate expression with neuroanatomical changes described in WBS patients. The topographical catalogue of expression of the murine orthologues of WBS genes will be instrumental to the understanding of the pathogenesis of this contiguous gene syndrome. The entire data set will be comprehensively documented on a freely accessible web page, which will lists the WBS genes, their murine orthologs and the probes used for ISH and displays images as well as annotation tables.

**Comparative genomic hybridization using a proximal 17p BAC/PAC array detects rearrangements responsible for four genomic disorders.** *C.J. Shaw<sup>1</sup>, C.A. Shaw<sup>1</sup>, W. Yu<sup>1</sup>, P. Stankiewicz<sup>1</sup>, L.D. White<sup>1</sup>, A.L. Beaudet<sup>1</sup>, J.R. Lupski<sup>1,2</sup>.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX.

Proximal chromosome 17p is a region that is rich in low copy repeats (LCRs) and prone to chromosomal rearrangements. Four genomic disorders map within the interval 17p11-p12: Charcot-Marie-Tooth disease type 1A (CMT1A), hereditary neuropathy with liability to pressure palsies (HNPP), Smith-Magenis syndrome (SMS) and dup(17)(p11.2p11.2) syndrome. While 80-90% or greater of the rearrangements resulting in each disorder are recurrent, several non-recurrent deletions/duplications of varying sizes within proximal 17p also have been characterized using fluorescence in situ hybridization (FISH). Here we tested the ability of a BAC/PAC array-based comparative genomic hybridization (array-CGH) method to detect these genomic dosage differences and map breakpoints in 26 patients with recurrent and non-recurrent rearrangements. We found that array-CGH detected the dosage imbalances resulting from either deletion or duplication in all the samples examined. Furthermore, the array-CGH approach mapped 46/47 (97.9%) of the analyzed breakpoints to within one overlapping BAC/PAC clone compared to that determined independently by FISH. In addition, array-CGH was sensitive enough to readily identify a dosage gain for clones contained on a small marker chromosome 17 present in 72% of cells. Interestingly, while a handful of clones (some containing LCRs) within the array performed less well than the majority when patient to control fluorescence ratios were analyzed, several clones that contain large LCRs did not have an adverse effect on the interpretation of the array-CGH data. Our data demonstrate that array-CGH is an accurate and sensitive method for detecting genomic dosage differences and identifying rearrangement breakpoints, even in LCR-rich regions of the genome.

**Development of a full-coverage X-chromosomal BAC array for high-resolution screening of genomic alterations in patients with X-linked mental retardation.** *J. Veltman<sup>1</sup>, H. Yntema<sup>1</sup>, H. Arts<sup>1</sup>, D. Lugtenberg<sup>1</sup>, C. on Choy<sup>2</sup>, K. Osoegawa<sup>2</sup>, E. Huys<sup>1</sup>, W. van der Vliet<sup>1</sup>, H. Straatman<sup>1</sup>, B. Hamel<sup>1</sup>, P. de Jong<sup>2</sup>, H. Brunner<sup>1</sup>, A. Geurts van Kessel<sup>1</sup>, H. van Bokhoven<sup>1</sup>, E. Schoenmakers<sup>1</sup>.* 1) Human Genetics, UMC Nijmegen, Nijmegen, Netherlands; 2) BACPAC resources, Oakland, CA.

Approximately half of the mentally retarded patients have a genetic origin and a significant proportion thereof is due to defects on the X chromosome. The European XLMR consortium (Leuven, Paris, Tours, Berlin, Nijmegen) has established a cohort of 200 well-characterized families with nonspecific X-linked mental retardation (MRX) which are being studied by various approaches. This unique cohort has been instrumental for the isolation of 6 of the 9 MRX genes that are known to date. Since most of the cytogenetically visible X-chromosomal deletions have already been studied, novel methods are needed to efficiently identify small submicroscopic deletions and duplications in MRX patients. Identification of such aberrations will immediately result in novel candidate genes for MRX. The technology that we have focussed on is array-based comparative genomic hybridisation (arrayCGH). We have constructed a full-coverage X-chromosomal BAC array consisting of approximately 1600 clones. The sensitivity and specificity of the technology were tested in a series of normal versus normal control experiments and a series of patients with known chromosome X copy number changes (including an Xq26 duplication, several Xq21 deletions, an Xp and an Xpter deletion, two PLP duplications and an XXXY). The results show that our array allows the detection of copy number changes >50 kb on the human X chromosome.

This study clearly demonstrates the power of the arrayCGH technology. Deletion and amplification mapping can now be performed at the submicroscopic level and will allow high throughput identification of novel X-chromosomal regions harboring genes involved in X-linked mental retardation.

**Submicroscopic chromosomal abnormalities and large-scale polymorphisms in mental retardation patients detected by genome-wide microarray analysis.** *L.E.L.M. Vissers<sup>1</sup>, B.B.A. de Vries<sup>1</sup>, K. Osoegawa<sup>2</sup>, I.M. Janssen<sup>1</sup>, T. Feuth<sup>1</sup>, C. on Choy<sup>2</sup>, H. Straatman<sup>1</sup>, W. van der Vliet<sup>1</sup>, E.H.L.P.G. Huys<sup>1</sup>, A. van Rijk<sup>1</sup>, D. Smeets<sup>1</sup>, C.M.A. van Ravenswaaij-Arts<sup>1</sup>, N. Knoers<sup>1</sup>, I. van der Burgt<sup>1</sup>, P.J. de Jong<sup>2</sup>, H.G. Brunner<sup>1</sup>, A. Geurts van Kessel<sup>1</sup>, E.F.P.M. Schoenmakers<sup>1</sup>, J.A. Veltman<sup>1</sup>.* 1) Human Genetics, UMC Nijmegen, Nijmegen, Netherlands; 2) BACPAC resources, Oakland, CA.

Microdeletions and microduplications, not visible by routine chromosome analysis, are a major cause of human malformation and mental retardation. In order to detect these microdeletions, novel high resolution whole genome technologies are needed. Array-based comparative genomic hybridization allows such a high-resolution screening by hybridizing differentially labeled test and reference DNAs to arrays consisting of thousands of genomic clones. In this study we tested the diagnostic capacity of this technology using approximately 3500 FISH-verified clones selected to cover the genome with an average of one clone per megabase. The sensitivity and specificity of the technology were tested in normal versus normal control experiments and through the screening of patients with known microdeletion syndromes. Subsequently, a series of 20 mentally retarded and dysmorphic patients with normal karyotypes were analyzed and 3 microdeletions and 2 microduplications were identified and validated. Two of these genomic changes were identified also in one of the parents, indicating that these are large-scale genomic polymorphisms. Deletions and duplications as small as 1 Mb could reliably be detected by our approach. The percentage of false positive results was reduced to a minimum by using a dye-swap replicate analysis, all but eliminating the need for laborious validation experiments and facilitating implementation in routine diagnostics. This high-resolution assay will facilitate the identification of novel genes involved in human mental retardation and/or malformation syndromes and provide insight in the flexibility and plasticity of the human genome.

**Analysis of the D21Z1 alphoid junction regions in the centromere of human chromosome 21.** *M. Bozovsky<sup>1</sup>, S. Shukair<sup>1</sup>, M. Puckelwartz<sup>1</sup>, M. Cummings<sup>2</sup>, J. Doering<sup>1</sup>*. 1) Dept. of Biology, Loyola University Chicago; 2) Dept. of Biological Sciences, University of Illinois at Chicago.

The centromeric and other heterochromatic regions that constitute 10-15% of the human genome have not been included in the completed genome sequence. Sequences required for a functional centromere have not been fully defined, but alphoid repetitive sequences clearly play a role. D21Z1, the major alphoid cluster of HC21 is a 1.0Mb long homogenous array with a higher-order repeat structure and regular CENP-B boxes. A 0.3Mb long heterogeneous satellite-I cluster is located 0.25Mb from the p-arm end of D21Z1. Characterizing the ends of the alphoid array may clarify evolutionary events in centromere formation. We have identified YAC clones that contain the D21Z1 p-arm junction. The physical structure of the alphoid DNA present in this region suggests a gradual loss of alphoid sequence homogeneity as one moves closer to the end of the array. In contrast, the physical structure of the q-arm junction region suggests an abrupt alphoid/non-alphoid transition. Sequence analysis of the q-arm junction has been done using BAC clone 21B49A22, the last clone in the q-arm sequence, which contains 31.2kb of alphoid DNA adjacent to non-repetitive DNA. This alphoid DNA is highly heterogeneous, showing as little as 74% sequence similarity between monomers, and is devoid of both regular CENP-B boxes and higher-order repeat structure. The unequal crossing over model of tandem array evolution predicts a similar structure at both array ends, but our data on D21Z1 suggests that the two junction regions have very different organizations from one another.

The monomeric alphoid array at the D21Z1 q-arm junction seems to have been established and evolved independently of the D21Z1 array and may therefore have HC21 specific sequences. We have subcloned a region of the q-arm monomeric alphoid array that is polymorphic and which BLAST analysis indicates may be chromosome specific. An HC21 specific centromeric marker would be useful in diagnosing aneuploidy and permit more accurate scoring of parent of origin and stage of meiosis of a nondisjunction event.

**An estimate of telomere length for an acrocentric short arm.** *H. Dimitropoulos<sup>1</sup>, S.M. McCutcheon<sup>1</sup>, Y. Ahn<sup>1</sup>, J. Doering<sup>2</sup>, M.R. Cummings<sup>1</sup>.* 1) Department of Biological Sciences, University of Illinois, Chicago, Chicago, IL; 2) Department of Biology, Loyola University, Chicago, IL.

Telomeres protect the ends of human chromosomes in normal cells and are composed of the tandem hexameric repeat (TTAGGG)<sub>n</sub>. Each chromosome end contains a variable number of these repeats that contribute to a characteristic telomere length ranging from 2-12 kb. Shortening of telomeres has been linked to cellular events such as aging and genetic instability. Factors that contribute to the size of a particular telomere include chromosome size, proximity of the centromere, the subtelomeric region and telomerase activity within the cell. Acrocentric short arm telomeres and subtelomeric regions have not been included in mapping and sequencing projects. Our laboratories are creating a physical map of the distal tip of the human chromosome 21 short arm, spanning the region from the rDNA to the short arm telomere. This region can be separated into the telomere-containing region and a subtelomeric domain that contains over a dozen different types of repetitive sequences. We used two separate approaches to estimate telomere length of the distal tip: terminal restriction fragment (TRF) analysis and Bal31 exonuclease digestion of DNA from somatic cell hybrids carrying the p arm of chromosome 21. Our findings from both assays show that the p arm distal tip contains only about 1 kb of the (TTAGGG)<sub>n</sub> sequence and provide the first estimate of telomere length for an acrocentric short arm. Our findings are in agreement with studies in other mammals that show that the closer a telomere is to the centromere, the shorter the telomere is likely to be. Additionally, recent evidence shows that it is the shortest telomere in a cell that may be critical in controlling cell fate. Our data suggests that telomere length on the p arm of chromosome 21 and/or other acrocentric chromosomes may have a significant functional role in phenomena such as cellular aging and genetic instability.

Program Nr: 1505 from 2003 ASHG Annual Meeting

**Identifying matrix attachment regions in human genome using microarray-based approach.** *Z. Jiang<sup>1</sup>, Z. Yuan<sup>1</sup>, L. Jin<sup>1,2</sup>*. 1) Dept. Environmental Health, University of Cincinnati, Cincinnati, OH; 2) School of Life Sciences, Fudan University.

Identification of functional and structural DNA elements is important in annotating the sequence of the human genome. One of these elements, the matrix attachment region (MAR) is a basic component of chromosome loop structure and was reported to play an important role in DNA replication, gene transcription, recombination and DNA repair. We developed a microarray-based method which allows a reliable and highthroughput detection of all MARs in the human genome. The validation of the method was conducted by successfully identifying all four MARs that have been reported in a 200-kb region containing TOP1 gene.

**Extended haplotype block structure and evidence for selection in a 900 kb region of the ATM Gene in human and chimpanzee.** *Y.R. Thorstenson<sup>1</sup>, P. Shen<sup>1</sup>, D.P. Wall<sup>2</sup>, T.L. Wayne<sup>1</sup>, V. Chou<sup>1</sup>, R.W. Davis<sup>1</sup>, P.J. Oefner<sup>1</sup>.* 1) Stanford Genome Technology Ctr, Palo Alto, CA; 2) Harvard Medical School, Boston, MA.

The ATM gene product is an important regulator of cell cycle control and DNA repair in mammalian cells. Mutations in the gene are known to cause the cancer-prone, recessive genetic disease ataxia-telangiectasia. Previous haplotype analysis at ATM indicated it was part of an extended haplotype block. To delineate the boundaries of the ATM haplotype block, SNP markers were identified across a 900 kb region encompassing the genes ATM, NPAT, ACAT1, CUL5 and SLAC2\_B in both human and chimpanzee. The markers were then genotyped in 34 African and 154 non-African chromosomes, and in 24 chimpanzee chromosomes. Pairwise  $|D'|$  patterns were constructed and plotted using unphased genotype data. A strong LD covering both the ATM and NPAT genes was found both in African and non-African samples, defining an unusually large haplotype block of around 300kb. Analysis of the same region in chimpanzee revealed an LD block of around 180kb, which covered only the ATM gene region. This unusually large LD block in ATM region (vs. an average of 24kb across the genome) indicated the presence of either a recombination cold-spot, or selection forces acting on this gene. To test the hypothesis of selection, Yang's likelihood ratio test was performed to estimate the rates of synonymous and nonsynonymous substitutions in the primate lineages using the orthologous ATM coding sequences for human, chimp, gorilla, orangutan, macaque, patas monkey and mouse. A significantly lower rate of change of non-synonymous versus synonymous sites observed in ATM is consistent with purifying selection across all primate lineages.

**A New Method for Amplification and Labeling of RNA from Small Clinical Samples for Use with the Affymetrix GeneChip Platform.** *G. Deng, A. Dafforn, M. Wang, P. Chen, R. Purohit, S. Wang, S. Pillarisetty, D. Iglehart, S. Koritala, S. Lato, M. Herrler, J. Heath, J. Stanchfield, N. Kurn.* NuGEN Technologies, Inc., San Carlos, CA 94070.

Microarray analysis is a powerful technology for profiling the large-scale changes in gene expression that occur as part of both normal and disease state biological processes. However, the application of the technology has been limited by the need for relatively large amounts of RNA. Most clinical RNA samples are derived from minute amounts of tissue, such as obtained by fine needle aspiration or laser capture microdissection, and require RNA amplification. Most available RNA amplification methods are tedious and time-consuming. There is a need for simple amplification methods suitable for automation and high throughput analysis. The RNA amplification and labeling system developed by NuGEN is based on a novel linear, rapid and sensitive amplification method, Ribo-SPIA. This system generates micrograms of cDNA from nanogram amounts of starting total RNA in less than four hours. The Ribo-SPIA based amplification and labeling system for the generating labeled amplified cDNA for microarray analysis with dual channel detection was used successfully on a variety of microarray platforms (home-brew spotted oligonucleotide and cDNA arrays, Agilent printed arrays). We have recently developed methods of fragmenting and chemically coupling biotin to Ribo-SPIA products, as required for Affymetrix GeneChip and Amersham CodeLink arrays. The Ribo-SPIA based system generates highly reproducible array results on both platforms. GeneChip analysis revealed higher sensitivity afforded by Ribo-SPIA amplified cDNA (prepared from 20ng input total RNA) as compared to cRNA prepared by Affymetrix standard protocol (20ug input total RNA). Spike detection experiments demonstrate that Ribo-SPIA has a wide linear amplification range, which is critical for maintaining high fidelity of message representation. We have successfully applied this amplification technology to examine gene expression in a variety of clinical samples including tissue biopsies.

**Whole genome amplification for genotyping, sequencing, and methylation analysis-Applications in genomics, pharmacogenomics, diagnostics, biosurveillance, and forensics.** *J. Langmore.* Rubicon Genomics, Inc., Ann Arbor, MI.

Many genetic studies and diagnostic tests are limited by the amount of DNA or RNA that is available for study. Common factors that lead to inadequate amounts of nucleic acid are small initial sample size, degradation at the source or in handling/storage, cost, depletion of existing samples by unanticipated numbers of tests or collaborators, and difficulties of recontacting subjects. Cell transformation and growth is not a viable solution to these problems. We have developed a simple method for whole genome amplification, called OmniPlex WGA, that can accurately and robustly amplify sub-nanogram amounts of total human DNA using common reagents. The process is a random, non-enzymatic fragmentation of genomic DNA followed by addition of adaptor sequences to both ends to form an in vitro molecular library that is amplified using PCR. Library preparation and amplification takes less than three hours, is automatable, and can be repeated multiple times to produce milligram amounts of DNA. OmniPlex WGA data will be shown from whole blood, blood spots, buccal swabs, serum, fixed or frozen tissue, hair follicles, degraded archived DNA, single cells, and single sorted chromosomes. OmniPlex has been used in academic, government, and commercial projects for SNP and STR genotyping, for mutation discovery by sequencing and heteroduplex analysis, for chromosome painting and CGH, and for methylation and expression analysis. Genotype concordance between the gDNA and the WGA DNA is >99.7% on high throughput single base extension, ligation, and exonuclease assays. By enabling large-scale genotyping or resequencing studies to be done with blood spots, hair, or buccal swabs, WGA allows genetic resources for large-scale population studies to be collected, archived, and shared more rapidly and economically than by other methods. The very low background, insensitivity to DNA breakage, and high sequence accuracy of the amplification process make WGA an attractive method for more accurate and sensitive genetic and epigenetic diagnostics, and human and pathogen identification.

**Comparative genomic analysis of the HNF-4 transcription factor gene.** *A.M. Bagwell<sup>1</sup>, A. Bailly<sup>3</sup>, J.C. Mychaleckyj<sup>1</sup>, B.I. Freedman<sup>2</sup>, D.W. Bowden<sup>1</sup>.* 1) The Center for Human Genomics; 2) Department of Internal Medicine, Wake Forest Univ Sch of Med, Winston-Salem, NC; 3) Pasteur Institute, Paris, France.

A positional candidate gene in the type 2 diabetes mellitus (T2DM) linked region on chromosome 20q12-q13.1 is hepatocyte nuclear factor-4 alpha (HNF-4), the gene for the Maturity-Onset Diabetes of the Young type 1 (MODY1) sub-type of T2DM. Mutations in the coding region of HNF-4 are rare in T2DM individuals. We hypothesized that altered regulation of HNF-4 gene expression may contribute to susceptibility to T2DM. Comparative genomic analysis using PipMaker was performed with 13kb of 5' promoter sequences of human, mouse, and rat HNF-4. Three regions, located at -10.344kb (295bp in length), -6.476kb (421bp in length), and -5.472kb (263bp in length), were identified as having significant sequence identity between the 3 species with expect values of  $1e-37$ ,  $1e-84$ , and  $1e-79$ , respectively. Functional analysis of these regions using transient transfection assays revealed that the sequences have weak ability to activate gene expression in pancreatic cells or dedifferentiated hepatoma cells, with expression being 1.0-2.5-fold over control. In differentiated hepatoma cells, the 295bp region and the 263bp region exhibit weak, though statistically significant, activity over control ( $P=0.001$ ). The construct containing the 421bp sequence confers strong activity in the differentiated hepatoma cells, with a  $13.71 \pm 1.95$ -fold increase in reporter gene activity over control vector ( $P=0.006$ ), suggesting that the 421bp sequence is an enhancer of HNF-4 gene expression that acts in a tissue-specific manner. The DNA of 259 Caucasian T2DM subjects was screened by denaturing high performance liquid chromatography to identify sequence variants in the conserved regions. Only 2 SNPs were identified, both of which increased reporter gene activity 1.42-1.70-fold over wild type in the insulinoma cell lines ( $P=0.05$ ). These results suggest that functional regulatory elements of HNF-4, and likely other genes, can be identified by comparative genomic analysis. Furthermore, the limited sequence variation within these regions suggests that these elements are likely of functional importance in humans.

**An ENU mutagenesis program using mice for identifying genes controlling complex traits.** *P. Charmley<sup>1</sup>, M. Appleby<sup>1</sup>, K. Staehling-Hampton<sup>1</sup>, N. Wiegand<sup>1</sup>, J. Gilchrist<sup>2</sup>, F. Ramsdell<sup>1</sup>, J. Bouck<sup>1</sup>, T. Britschgi<sup>1</sup>, A. Snell<sup>1</sup>, T. Howard<sup>1</sup>, M. McEuen<sup>1</sup>, B. Paeper<sup>1</sup>, S. Proll<sup>1</sup>, P. Tittel<sup>1</sup>, G. Carlson<sup>2</sup>, R. Schatzman<sup>1</sup>, M. Brunkow<sup>1</sup>.* 1) Department of Genomics, Celltech R&D, Inc., Bothell, WA; 2) McLaughlin Research Institute, Great Falls, MT 59405.

ENU mutagenesis in mice is being used to dissect aspects of complex traits in clinically relevant areas such as lymphocyte biology, inflammation and autoimmunity. The particular approach we are using involves a three-generation recessive screen, focusing on phenotypes which mimic desired clinical responses (e.g., suppressed inflammatory response), thus improving our chances of directly identifying relevant therapeutic targets. We have implemented a number of in vitro screens including lymphocyte activation, as well as T-dependent and T-independent inflammatory responses. These are carried out on peripheral blood lymphocytes, and have the advantage of being relatively high throughput and requiring only small volumes of blood, thus affording us the opportunity to perform a number of manipulations on a single sample. The in vitro screens have been coupled with a complementary set of more complex in vivo screens based on classic pharmacologic models of inflammation and immune response (e.g. contact sensitivity). In instances where tissue samples can be collected (e.g. ear punches), we have also applied gene expression technologies to study inherited variation on a per-gene basis. In the past 3 years, over 100 phenodeviants have been identified and entered into our mapping process. We have developed an integrated laboratory / informatic pipeline which enables rapid identification of a candidate interval and the genes contained within, as well as efficient tracking of gene testing results, capturing both DNA sequence and gene expression data. The development and utilization of informatics tools has proven critical in the effective management of the program. Another important aspect of the program is the ongoing process of new screen development to ensure as broad an interrogation of the immune system as possible. Specific lessons learned from the mutations identified so far will be discussed in more detail.

**Autosomal localization of mouse X-linked genes in the rat.** *B.-Y. Liao*<sup>1</sup>, *S. Tyan*<sup>1</sup>, *M.-J. Hwang*<sup>1</sup>, *P. Yen*<sup>1,2</sup>. 1) Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Pediatrics, Harbor-UCLA Medical Center, Torrance, California, U.S.A.

Ohno's law of the conservation of the X chromosome in placental mammals predicts that genes on the X chromosome of one mammalian species will be X-linked in all mammals due to X-inactivation. Translocations between autosomes and the X chromosome during evolution would result in dosage imbalance and be detrimental to the species. So far this law has been observed on most X-linked genes, with the exceptions being genes located within or near the pseudoautosomal regions. In a recent blast of the rat draft genome sequence at NCBI, we unexpectedly found autosomal assignments of several mouse genes from different regions of the X chromosome. Orthologues of these mouse X-linked genes were located on the supercontigs of several rat chromosomes, including chromosomes 1, 4, 5, 6, 7, and 8. To investigate whether and when these X-autosomal translocations have occurred, we performed Southern hybridization/dosage analysis on several rodent species including lab mouse (*Mus musculus*), wood mouse (*Apodemus semotus*), rat (*Rattus norvegicus*), and Syrian hamster (*Mesocricetus auratus*). Comparison of the signal intensities between male and female animals provided unambiguous assignments of the genes to the X or the autosomes when known X-linked and autosomal genes were used as controls. We failed to confirm the autosomal localizations, as indicated in the rat draft genome sequence, for the few genes tested. Our results have uncovered significant errors in the assembly of the rat genome that used a hybrid of the whole genome shotgun approach and the hierarchical BAC clone approach. These errors are likely caused by the presence of highly homologous sequences on different chromosomes.

**Interactive Locus Specific DataBases for muscular dystrophies.** *C. Beroud*<sup>1</sup>, *J.A. Urtizbera*<sup>2</sup>, *J.C. Kaplan*<sup>3</sup>, *M. Claustres*<sup>1</sup>. 1) Laboratoire de Genetique, Hosp Arnaud de Villeneuve, Montpellier, France; 2) Hosp Raymond Poincare, 92380 Garches, France; 3) Department GDPM, Institut Cochin, 75014 Paris, France.

In addition to **general** mutation databases, **locus specific** mutation databases are needed to confront molecular and clinical data. The **UMD** (*Universal Mutation Database*) generic software (*Beroud et al, Human Mutation 2000*) was created to develop Internet accessible Locus Specific DataBases (LSDB). We are currently applying this concept to 9 muscular dystrophy genes: *DMD*, *LMNA*, *EMD*, *LAMA2*, *SGCA*, *SGCG*, *CAPN3*, *DYSF* and *FKRP*. The **UMD-DMD** database (dystrophinopathies) comprises the entire fully annotated genomic sequence encompassing the *DMD* gene. The software features *DMD*-specific packages such as automatic computation of the impact of the mutation upon: (i) the reading frame, (ii) the consensus value of splice sites, (iii) the theoretical size of transcripts and translational products, (iv) the loss of epitopes, polymorphic markers and critical protein domains. In addition it computes all possible exon-skipping patterns capable of restoring the frame and compatible with a functional dystrophin. It also provides graphical display of the various deletions and duplications. The **UMD-DMD** accommodates mutational events occurring deep in the huge introns (cryptic exon activating point mutations, deletion/duplication intronic breakpoints etc). The current version of the database contains 800 unrelated patients with fully documented mutations in the *DMD* gene. **UMD-LSDBs** are not inert repositories but interactive tools using the power of computer analysis to answer complex queries such as phenotypic heterogeneity and genotype/phenotype correlations. They will help to pinpoint discrepant cases in which the clinical tolerance differs from that expected. They should help elaborate allele-specific gene-based therapeutic strategies. One drawback of **LSDBs** is that one has to query various databases before knowing which gene is associated with a specific phenotype. To solve this problem, we are developing the **UMD-central system** which is able to query all **UMD-LSDBs** and give an overview of their data. For this, we have developed a standard clinical submission form for all **UMD** muscle dystrophy **LSDBs**.

**A Novel Method for Building Neuropsychiatric Candidate Gene Sets and SNP Maps for Association Studies.**

*K.J.L. Irizarry<sup>1</sup>, A. Day<sup>2</sup>, K. Mitsouras<sup>2</sup>, C.J. Lee<sup>3</sup>, J. Licinio<sup>1</sup>*. 1) NeuroPsychiatric Insititute, UCLA, Los Angeles, CA; 2) Department of Human Genetics, UCLA, Los Angeles, CA; 3) Department of Chemistry & Biochemistry, Laboratory of Bioinformatics & Structural Proteomics, UCLA, Los Angeles, CA.

We describe a novel method for producing candidate gene sets which rescues many false negatives and simultaneously reduces the addition of false positives. Such a gene set can be of considerable value for use in disease gene association studies. We applied this approach to the human genome to produce a neuropsychiatric candidate gene set with cSNPs enriched for protein functional impact. We successfully identified 906 neuronal signaling genes which together contain 1917 SNPS. We have assessed the impact of non conservative cSNPs on protein function by analyzing such SNPs when they occur with a functionally important domain. In addition we performed two independent verifications to assess, first the association of genes exhibiting non-conservative cSNPs with known disease genes. We searched for published disease annotation among 18 genes and identified 15 that have been implicated in one or more diseases. Secondly, we mapped our 906 candidate gene set to 61 schizophrenia associated loci from OMIM and identified 208 genes and with 497 SNPs. This candidate gene set, together with the identified SNPs and comprehensive schizophrenia map represent a valuable resource for genetic association studies of diseases affecting the human nervous system.

**INTEGRATING GENETICS WITH GENOMICS AS A TOOL TO UNRAVEL MOLECULAR PATHWAYS IN CELIAC DISEASE.** *C. Wijmenga, M. van Belzen, B. Diosdado, A. Zhernakova, A. Monsuur, A. Bardoel, L. Franke, M. Wapenaar.* Dept Biomedical Genetics, Univ Medical Ctr, Utrecht, Netherlands.

Celiac disease (CD) is a complex disease of the small intestine induced by gluten. CD is common with a prevalence of ~1:200 in Western populations. The causative molecular pathways underlying celiac disease pathogenesis are poorly understood. To unravel novel aspects of disease pathogenesis, we use both genetic linkage studies and microarray analysis of duodenal biopsies. A major known susceptibility locus for CD is the HLA DQ locus on chromosome 6p. Recently we identified two additional risk loci, on chromosomes 6q and 19p. The 19p region covers some 3Mb and contains 92 known genes and ETSs. The region on 6q is ~10 Mb and contains 101 transcript. In addition, cDNA microarrays were used to compare gene expression profiles of duodenal biopsies from celiac disease patients with villous atrophy and control individuals with normal biopsies. We identified 109 genes that differed significantly ( $p < 0.001$ ) in expression levels between patients and controls. A large number of these genes have functions in proliferation and differentiation pathways and might be important for proper development of crypt-villous units. Alterations in this pathway may lead to the characteristic hyperplasia and villous atrophy seen in celiac disease. In order to combine genetic linkage data and microarray gene expression results, we developed a Java based computer program. This program includes a viewer, capable of showing karyobands, genes, markers, linkage graphs, gene expression levels, SNPs and additional annotation data simultaneously. Additionally data management and filtering functionality was implemented and the databases Ensembl, LocusLink, Gene Ontology and Unigene were integrated. Interestingly, the linkage peaks on 6q and 19p contain 11 and five differentially expressed genes, respectively. These genes are currently being followed up with a high density of SNPs.

**Accentuate the negative: Uniqueness in proteome comparisons among model organisms.** *E. Bier, M. Fischer, N. Hong, L. Reiter.* Department of Biology, University of California, San Diego, La Jolla, CA.

With the completion of the genome sequences of model genetic organisms we enter a new era of bioinformatics. The majority of amino acid sequence comparisons of model organisms to the human proteome have been aimed at identifying similar proteins or related protein domains. What has largely been under-studied, however, is the nature of proteins that are either unique to particular proteomes or are shared by some but not all organisms. These proteins may be essential in defining organismal identity. To identify the proteins unique to a given proteome BLAST analysis was performed between proteomes using the most current sets of proteins from *H. sapiens*, *M. musculus*, *D. melanogaster*, *C. elegans*, *S. cerevisiae*, *E. coli* and *A. thaliana*. Comparisons were done at the low stringency e-value of 1 in order to identify proteins that unquestionably did not match in a given comparison. This BLAST data was compiled in a flexible MySQL database for cross species associations: the [Negative Proteome Database](http://superfly.ucsd.edu/negprot). We used this database to identify sets of proteins which are unique to a given model organism, and may represent evolutionary novelty, such as genes regulating flowering in *A. thaliana*, genes conferring sensitivity to BT toxins in *C. elegans*, or proteins involved in pheromone response in *D. melanogaster*. We find that genes encoding structural components of the organisms outer covering as well as innate defense genes are highly represented in all annotated organism-specific gene sets. With regards to studying human disease gene homologs, the database now allows us to select the most appropriate model system for a given gene. This database allows the user to find positive matches to proteins not found in a given comparison as well. For example, one can identify all of the proteins in insects that are not in plants or in humans. These proteins may prove excellent targets for pesticides or insecticides since they are not in either of the organisms one wishes to protect (plants and humans).

**Comparative analysis of ribosomal protein genes and evolution of introns.** *N. Kenmochi, M. Yoshihama, T. Uechi, A. Nakao.* Research Center for Frontier Bioscience, Miyazaki Medical College, Miyazaki, Japan.

The ribosome, as a catalyst for protein synthesis, is universal and essential for all organisms. Because of the fundamental role played by ribosomes, their structure and function have been significantly conserved during evolution. In higher eukaryotes, the ribosome is composed of 4 RNA molecules (rRNAs) and 79 distinct proteins (RPs). We have compared the intron/exon structures of these genes from humans, *Drosophila melanogaster*, *Caenorhabditis elegans*, and *Saccharomyces cerevisiae*. Because the size and sequence of the coding regions are very similar between the orthologs among these species (63% homology on average), it was easy to compare the intron positions in these genes.

In humans, we found 249 introns within the coding regions. Among them, the insertion sites of 137 (55%) were unique to the human genes; 77 (31%) were the same in humans and flies; and 60 (24%) were the same in humans and worms. Of these, 26 introns (10%) were common to all three species. By contrast, only 7 introns (3%) shared the same insertion sites in humans and yeast, and the position of only one, the second intron of *RPL14*, was conserved among all four species. About 80% of fruitfly introns were present in human RP genes, but only 30% of these introns appeared in worms.

Finally, we have constructed Ribosomal Protein Gene Database (RPG). It contains information about RP genes from above four species and *Methanococcus jannaschii* and *Escherichia coli*. Users can search the database by the gene name and organism. Each record includes various sequences (genomic, cDNA, and amino acid sequences), intron/exon structures, genomic locations, and information about orthologs. Also users can view gene structures from these organisms comparatively, and have multiple sequence alignments of amino acid sequences. RPG is available at <http://ribosome.miyazaki-med.ac.jp>.

Program Nr: 1517 from 2003 ASHG Annual Meeting

**ALFRED - the ALlele FREquency Database.** *H. Rajeevan<sup>1</sup>, M.V. Osier<sup>2</sup>, K. Cheung<sup>2</sup>, H. Deng<sup>1</sup>, L. Druskin<sup>2</sup>, J.R. Kidd<sup>1</sup>, S. Stein<sup>1</sup>, A.J. Pakstis<sup>1</sup>, N.P. Tosches<sup>2</sup>, P.L. Miller<sup>2</sup>, K.K. ALFRED (<http://alfred.med.yale.edu>) is an actively curated database designed to make allele frequency data on anthropologically defined human population samples readily available to the scientific community and to link these polymorphism data to the various molecular genetics-human genome databases. Users can search for frequency data through several search options including locus symbol, site name and a specific author's publications. Data may be viewed both as numeric tables and graphically. ALFRED is rapidly expanding and has doubled in size in the past year to 12,000 frequency tables (one population typed for one site or haplotype) involving 737 polymorphisms and 358 populations. All of the data in ALFRED are considered to be in the public domain and available for use in research and teaching. Researchers can download data useful for analysis in a variety of formats including a single compressed "data dump" file or separate files of relevant tables, in the declared XML format. The Data Type Definition (DTD) for validating the XML format is also available for download. The existing data are primarily those extracted from publications by curatorial staff or made available from a few laboratories. New data and new links to other databases are routinely being added to ALFRED. Presently addition of new data is focussed on popular and user-suggested polymorphic sites to help researchers to conduct comprehensive analyses. We now have systems in place to accept data directly from researchers. While XML data or a spreadsheet with the necessary descriptive information in specific columns are preferable, we can also accept data in most any electronic form if the descriptive information is submitted in parallel.

(Ongoing support of ALFRED is provided by NSF grant BCS-0096588).

**dbQSNP: a pipeline for SSCP based SNP-finding/quantification and publicizing allele frequency data of populations.** *T. Tahira*<sup>1</sup>, *S. Baba*<sup>1</sup>, *K. Higasa*<sup>1</sup>, *Y. Kukita*<sup>1,2</sup>, *Y. Suzuki*<sup>2</sup>, *S. Sugano*<sup>2</sup>, *K. Hayashi*<sup>1</sup>. 1) Res Ctr Genet Info, Med Inst Bioreg, Kyushu Univ, Fukuoka, Japan; 2) Human Genome Center, Inst Med Science, Univ. Tokyo, Tokyo, Japan.

We have developed a capillary-array-based single-strand conformation polymorphism (PLACE-SSCP) analysis, and shown that it is suitable for estimation of precise allele frequencies of SNPs using pooled DNA. In this method, allele frequencies of SNPs in the pool are determined from the peak heights of alleles separated by SSCP analysis. Here we present dbQSNP, a laboratory information management system that facilitates large scale SNP finding/allele frequency estimation by concerted analysis of SSCP and sequencing. dbQSNP is a relational database system, that uses PostgreSQL on the Unix server, and is managed through a WEB browser. Various newly developed as well as available algorithms are integrated. Data for each STS are summarized and publicized as a searchable record in a hypertext format, through which trace of SSCP and sequencing can be monitored. Using this system, we characterized SNPs in 1.2 kb genomic regions containing putative transcription start sites of various genes. SNPs are searched by examining 8 Japanese individuals, and allele frequencies of these SNPs are determined by quantifying peaks of pools (Japanese and Caucasian) after compensating for unequal peak heights in heterozygotes. We examined 4131 STSs (average size ca. 330 bp), found 1593 SNPs including 136 insertion/deletions, and half of the SNPs were new (not found in Build 115 dbSNP). Allele frequencies were successfully estimated for 86% of the STSs that contain single SNPs. Among 866 SNPs that showed more than 10% minor allele frequency in Japanese, 453 showed significantly different ( $p < 0.01$ ) allele frequency between Japanese and Caucasian. In addition, several of them showed high  $F_{st}$  values. Genetic differentiation in these particular sites after population subdivision is suspected.

Human Protein Reference Database (HPRD) is an object database that integrates a wealth of information relevant to the function of human proteins in health and disease. Data pertaining to protein-protein interactions, post-translational modifications, enzyme-substrate relationships, disease associations, tissue expression and subcellular localization were extracted from the literature for a non-redundant set of 2,750 human proteins. This includes all genes that encode proteins implicated in human diseases as annotated in the Online Mendelian Inheritance in Man (OMIM) database. Almost all the information was obtained manually by biologists who read and interpreted over 300,000 published articles during the annotation process. The database, which has an intuitive query interface allowing easy access to all the features of proteins, was built using open source technologies and is freely available at <http://www.hprd.org>. It documents over 10,000 protein-protein interactions and 1,900 post-translational modifications with over 25,000 links to PubMed. This unified bioinformatics platform will be useful in cataloging and mining the large number of proteomic interactions and alterations that will be discovered in the post-genomic era.

**A survey of housekeeping gene expression during germ cell development.** *A.L.Y. Pang<sup>1</sup>, W. Johnson<sup>1</sup>, N. Ravindranath<sup>2</sup>, M. Dym<sup>2</sup>, O.M. Rennert<sup>1</sup>, W.Y. Chan<sup>1,2,3</sup>.* 1) Laboratory of Clinical Genomics, NICHD, National Institutes of Health, Bethesda, MD; 2) Department of Cell Biology, Georgetown University, Washington, DC; 3) Department of Pediatrics, Georgetown University, Washington, DC.

With the advance of genomics technologies, studies attempting to identify the housekeeping (or maintenance) genes expressed in a variety of fetal and adult tissues have been performed recently. However, similar studies in specific cell lineages remain limited. Spermatogenesis is a tightly regulated developmental process of male germ cells; the intrinsic changes that occur during the transition from mitosis to meiosis as well as the rapid change in cell morphology underscore the existence of a sophisticated network of gene expression. In this study quantitative polymerase chain reaction (QPCR) was used to examine the expression of eighteen commonly known housekeeping genes at three distinct stages of mouse germ cell development (viz. type A spermatogonia, pachytene spermatocytes and round spermatids) along the spermatogenic pathway. Two of the genes (ubiquitin C and histone deacetylase 2) showed insignificant fluctuations in transcript levels among the three types of cells, while the other genes showed differences in the magnitude of their expression levels in the three stages. Besides these two genes, the 18S rRNA content was also found to display minimal changes between any types of germ cells examined. We concluded that the previously described two genes or 18S rRNA can be used as normalization markers for further gene expression studies during spermatogenesis in mouse germ cells. The constant expression of such genes along the spermatogenic pathway implies their indispensable role/activity in the germ cells.

**Mutational analysis of multiple developmentally important genes in the human condition Septo-Optic Dysplasia.**

*K.S Woods*<sup>1</sup>, *C. McCaffery*<sup>2</sup>, *J.P.G. Turton*<sup>1</sup>, *M.T. Dattani*<sup>1</sup>. 1) Biochem/Endoc/Metabolism Unit, Inst Child Health, London, United Kingdom; 2) London Genetics Knowledge Park, Institute of Child Health, UK.

Development of the anterior pituitary gland is a multigenic process regulated by complex signalling pathways which determine expression and interaction of a number of transcription factors. Fate map analysis reveals that the anterior neural ridge will give rise to the anterior pituitary whereas adjacent regions of the neural plate give rise to the posterior pituitary, optic vesicles and ventral forebrain. Previously, we described an association between septo-optic dysplasia (SOD), a human disease characterised by midline forebrain abnormalities, pituitary dysplasia and optic nerve hypoplasia and mutations in the homeobox gene *HESX1*<sup>1</sup>. However these mutations only account for a small number of cases of SOD (8/570). We have screened a large cohort (n=240) of SOD patients with variable phenotypes for candidate genes implicated in forebrain and pituitary development. The genes selected for this study (*EMX2*, *PAX6*, *NTNI*, *SIX3* and *SIX6*) were chosen on the basis of developmental expression pattern, information from mouse studies and previous association with genetic disorders affecting similar tissue types. Previously, we described a number of sequence variants, both exonic and intronic. None of the variations altered an amino acid residue and yet we were reluctant to dismiss any as non-pathogenic polymorphisms. To classify the importance of the sequence variations we identified, we utilised pyrosequencing technology. Using a panel of 94 Caucasian controls we were able to ascertain the frequency of each of these changes (*PAX6* IVS12 +42 t>g; +/+ 18%, +/- 54%, -/- 28%. *NTNI* IVS3 41c>t; +/+ 44%, +/- 44%, -/- 12% and *NTNI* IVS4 5 c>a; +/+ 42%, +/- 42%, -/- 16%). These results suggest that these sequence variants are indeed non-pathogenic polymorphisms. However non-pathogenic polymorphisms have been associated with functional consequence, e.g. an N125S polymorphism within *HESX1*<sup>2</sup>. Documentation of these polymorphisms will establish whether any, all or a combination of these variations may contribute to the SOD phenotype.

**Understanding the evolution of trypsinogen activation peptides through integration of functional characterization of disease-associated mutations with comparative genomic analysis.** *J.M. Chen<sup>1</sup>, Z. Kukor<sup>2</sup>, C. Le Maréchal<sup>1</sup>, M. Tóth<sup>3</sup>, L. Tsakiris<sup>4</sup>, O. Raguénès<sup>5</sup>, C. Férec<sup>1,5</sup>, M. Sahin-Tóth<sup>2</sup>.* 1) Institut National de la Santé et de la Recherche Médicale 01 15, Génétique Moléculaire et Génétique Epidémiologique, Université de Bretagne Occidentale, Etablissement Français du Sang-Bretagne, Brest 29220, France; 2) Department of Molecular and Cell Biology, Boston University Goldman School of Dental Medicine, Boston, Massachusetts 02118, USA; 3) Department of Medical Chemistry, Molecular Biology and Pathobiochemistry, Semmelweis University, Budapest, Hungary; 4) Centre Hospitalier Universitaire de Melun, Service de Gastroenterologie, Melun, France; 5) Centre Hospitalier Universitaire de Morvan, Brest, France.

The activation peptide of mammalian trypsinogens contains a highly conserved tetra-aspartate sequence (D19-D20-D21-D22) preceding the K23-I24 scissile peptide bond, which is hydrolyzed as the first step in the activation process. Here we examined the evolution and function of trypsinogen activation peptides through integrating functional characterization of disease-associated mutations with comparative genomic analysis. Activation properties of three pancreatitis-associated activation peptide mutants (D19A, D22G and K23R) were simultaneously analyzed, for the first time, in the context of recombinant human cationic trypsinogen. A dramatic increase in autoactivation of cationic trypsinogen was observed in all three mutants, with D22G and K23R exhibiting the most marked increases. The physiological activator enteropeptidase activated the D19A mutant normally; the D22G mutant was activated very poorly, while activation of the K23R mutant was stimulated. The biochemical and structural data, taken together with a comprehensive sequence comparison, indicates that the tetra-aspartate sequence in mammalian trypsinogen activation peptides has evolved not only for optimal enteropeptidase recognition in the duodenum, but also for efficient inhibition of trypsinogen autoactivation within the pancreas. Moreover, the use of Lys instead of Arg at the P1 position of activation peptides also has an advantageous effect against trypsinogen autoactivation.

**Concerted Evolution in Mammals of Talanin and Uricase Genes.** *F. Gianfrancesco*<sup>1,2</sup>, *T. Esposito*<sup>1,2</sup>, *G. Maninchedda*<sup>2</sup>, *G. Casu*<sup>1</sup>, *M. Rocchi*<sup>3</sup>, *M. Recently, we identified a susceptibility locus for human Uric Acid Nephrolithiasis (UAN) on 10q21-q22 and demonstrated that a novel gene (ZNF365) included in this region produces through alternative splicing, 4 different transcripts: A, B, C and D coding for different protein isoforms. Mutation analysis showed that one of them (Talanin) is associated with UAN. The comparative genomic approach can be instrumental for understanding the role of Talanin in uric acid metabolism. Searching for mouse homologs of ZNF365 transcripts, we identified a highly conserved mouse ortholog of ZNF365A transcript, expressed specifically in brain. We did not find a mouse homolog for ZNF365D transcript highly expressed in kidney, encoding the Talanin protein, even if we were able to identify the corresponding genomic region in mouse and rat not yet organized in canonical intron-exon structure suggesting that ZNF365D was originated after the branching of hominoid from rodent lineage. Mouse and most mammals have a functional uricase that degrades the uric acid to allantoin while in hominoid the uricase activity was lost during the Miocene epoch. Analyzing the presence of Talanin in Primates, we found in Old World and New World monkeys a canonical intron-exon structure but with so many mutations that protein production was in fact prevented. In nonhuman hominoids we detected expression at extremely low levels. In human we observed higher expression and evidence that ZNF365D transcript produces a functional protein. It seems therefore that ZNF365D transcript emerged during primate evolution from a noncoding genomic sequence that evolved in a standard gene structure and assumed its role in parallel with the disappearance of uricase, probably against a disadvantageous excessive hyperuricaemia. The interplay of these two processes, indicates a possible physiological role of Talanin in uric acid excretion as also suggested by its association to UAN. Our findings demonstrate that the analysis of gene evolutionary processes may help understand the functions of genes in physiological and metabolic pathways.

**Genome-wide comparative sequence analysis between human, mouse, and chimpanzee identifies human genes under positive selection.** *M. Cargill*<sup>1</sup>, *A. Clark*<sup>2</sup>, *S. Glanowski*<sup>3</sup>, *R. Nielsen*<sup>2</sup>, *D. Tanenbaum*<sup>4</sup>, *P. Thomas*<sup>5</sup>, *J. Duff*<sup>4</sup>, *H. Gire*<sup>3</sup>, *S. Ferreira*<sup>3</sup>, *D. Adams*<sup>4</sup>. 1) Celera Diagnostics, Alameda, CA; 2) Cornell University, Ithaca, NY; 3) Applied Biosystems, Rockville, MD; 4) Celera Genomics, Rockville, MD; 5) Celera Genomics, Foster City, CA.

Genome-wide sequence comparison of human and chimpanzee genes in the context of mouse can serve as a powerful filter to identify genes that show strongly divergent patterns of sequence change. Furthermore, the completion of the human genome sequence allows an opportunity for focused exploration of particular regions of the genome for human variation. Studies of human variation and sequence divergence from other species will provide markers for use in genetic studies and potentially provide insight into human phenotypes. Recently, we completed a project in which we designed over 200,000 PCR amplicons to 23,000 human genes and sequenced the amplified products in 39 human individuals and 1 chimpanzee. This large data set encompassing 18M sequence reads yielded 265,000 human polymorphisms and ~33Mb of human (~25Mb chimpanzee) genomic sequence. We performed an evolutionary sequence analysis on three data sets derived from this project: 7,645 human-mouse-chimp orthologous coding sequence trios; 20,000 human-chimp coding sequence alignments; and 5Mb human-chimp-mouse non-coding sequence alignments. Approximately 8% of genes in the human genome show evidence of adaptive evolution and this set of genes is enriched in genes causing Mendelian diseases. We will present specific human genes and classes of genes that show evidence of positive selection on the human lineage. Furthermore, the incorporation of human polymorphisms discovered from our re-sequencing effort will place into context the human-specific divergence present in the alignments. Finally, a genome-wide comparison of sequence divergence and polymorphism in putative transcription factor binding sites will be described.

**A mammalian chromosomal rearrangement involving a cis-regulatory element of the *Gdf6* gene: implications for duplication-mediated gene evolution and for gene regulatory boundaries.** *D.P. Mortlock*<sup>1</sup>, *R.L. Chandler*<sup>1</sup>, *K.J. McDermott*<sup>1</sup>, *M.E. Portnoy*<sup>2</sup>, *NIH Intramural Sequencing Center*<sup>2</sup>, *E.D. Green*<sup>2</sup>. 1) Vanderbilt University School of Medicine, Nashville, TN; 2) National Human Genome Research Institute, Bethesda, MD.

Duplicated stretches of mammalian genomic DNA, or duplicons, may catalyze evolution at both the gene and chromosomal levels. Here we provide evidence that a duplicon near the mammalian *Gdf6* gene led to a rodent-specific chromosomal rearrangement involving the *Uqcrb* gene and a *Gdf6* regulatory element. *Gdf6* is a BMP family gene required for development of multiple skeletal joints. Previously, we described BAC transgenes that revealed a regulatory region 5' to *Gdf6* which is required for *Gdf6* transcription in limb joints. To study *Gdf6* evolution, we sequenced *Gdf6* BACs from baboon, chimp, cat, dog, cow, opossum and platypus, then performed comparisons with mouse, rat and human *Gdf6* genomic sequences. MultiPipMaker comparisons showed *Gdf6* locus conservation across all non-rodent mammals, and *Uqcrb* as the closest 5' flanking gene. However in rodents a synteny break relative to other mammals was found 70 kb 5' to *Gdf6*. Analysis of genome browser data revealed that in mice, *Gdf6* and *Uqcrb* are unlinked and on chromosomes 4 and 13, respectively. However, adjacent to both genes are copies of a 10 kb duplicon. Each duplicon maps to the end of a human synteny block. Furthermore, the duplicon mobilized part of the *Uqcrb* gene and a *Gdf6* cis-regulatory sequence. Therefore, duplicons can spread not only genes to new genomic regions but also regulatory elements, which potentially could confer novel regulatory effects on other genes. We propose that the duplicons catalyzed a rodent-specific chromosomal rearrangement. Although previous transgenic evidence suggests more *Gdf6* enhancers lie in distant regions flanking the gene, the duplicon suggests a 5' boundary for *Gdf6* enhancers. Alternatively, the rearrangement may have separated rodent *Gdf6* from ancestral regulatory elements, or brought novel regulatory sequences into proximity with *Gdf6*, either of which may have had evolutionary consequences for rodent skeletal morphology.

**Evolution of the Alcohol Dehydrogenase Class I Gene Cluster in Human and Non-human Primates.** *H. Oota, W.C. Speed, J.R. Kidd, K.K. Kidd.* Dept Genetics, Yale Univ, New Haven, CT.

The human alcohol dehydrogenase (ADH) gene cluster on chromosome 4 includes seven genes subdivided into five classes based on kinetic properties and sequence similarities. Human Class I ADH genes (*ADH1A*, *ADH1B*, *ADH1C*), expressed in liver, are the main enzymes catalyzing alcohol oxidization to aldehyde in humans. The three Class I genes occur tandemly separated by ~ 15kb and show very high nucleotide similarity both in exons ( 90%) and introns ( 70%) suggesting recent duplication events, probably within the primate lineage since rodents have only one Class I gene. A previous comparative study of exons and 5 and 3 non-coding regions in humans and monkeys concluded that there were at least three gene conversion events in the evolution of Class I ADH genes. Our preliminary analysis of the complete human sequence shows complex similarities among the flanking regions of the genes but no clear indication of the order of gene duplication or of gene conversion. To provide better evolutionary histories, we have sequenced introns 2 and 3 of all three Class I genes (total 7.0 kb) for five non-human primates four apes (chimpanzee, bonobo, gorilla, and orangutan) and one monkey (baboon) and compared the sequences with those of human and mouse. The sequences within each gene cluster largely as expected with baboon as the outgroup, then orangutan, then gorilla, human, chimpanzee, and bonobo. All three genes show similar diversification for both introns. Assuming the baboon divergence at 25 My BP, the diversification between genes is at least another 30 My BP, placing the duplication close to and probably prior to the divergence of the prosimians in the primate lineage. There is little difference in the relative divergences of the three genes and no statistical support for order of duplication using mouse sequence. Thus, at least for these sequences there is no evidence of gene conversion and effective triplication is dated to near the origin of the primate order. [Supported in part by NIH grant AA09379].

**Analysis of Conserved Domain evolution: Conservation does not equal Constraint.** *G.J. Wyckoff<sup>1</sup>, C.M. Malcom<sup>2</sup>, J. Paschall<sup>1</sup>*. 1) Mol. Biol. Biochem., U. Missouri-Kansas City, Kansas City, MO. 64110; 2) Dept. of Anthropology, U. Chicago, Chicago, IL 60637.

Efforts such as the Conserved Domain Database (CDD; <http://www.ncbi.nlm.nih.gov/>), indicate that many structural and functional protein domains are conserved over evolutionary time. In this study, we examine patterns of molecular evolution between orthologous genes across species from the perspective of domain structure. The goal is to determine how sequence conservation within domains translates into functional constraint, and how variation and selective pressure within these otherwise conserved sequences may lead to adaptive protein function. We gathered a set of 6,921 orthologous genes between mice and humans. We aligned the coding regions of these genes in-frame and mapped conserved domain locations on to aligned protein sequences. Using a database we designed to mine sequence and evolutionary information, we generated data for a set of 16,728 Conserved Domain features within these genes. We calculated synonymous divergence rate (Ks), nonsynonymous divergence rate (Ka), and constraint (Ka/Ks) (Li 1993). Results show that, although conserved domains in general possess low enough variation to be detected as conserved, the pattern of variation among them reflects unique evolutionary pressures beyond simple constraint. We find that many conserved domains are the site of elevated Ka rates when scaled by synonymous mutation rate. A Ka/Ks > 1.0 normally implies positive, Darwinian selection. Although domains with a Ka/Ks > 1.0 were infrequent, many had Ka/Ks rates significantly greater than the those of the genes of which they are a part (7% of all domains). This result implies either a lack of functional constraint within these domains, which seems unlikely for a sequence conserved by evolution, or could indicate adaptation within these domains toward a new function. Specifically, we identify domains in genes implicated in human diseases for which the domain Ka/Ks is divergent from the rest of the gene it resides within or in comparison to the same domain type in other genes. We suggest ways to incorporate this type of information into disease gene analysis and mapping.

**Evolutionary analysis of metabolic genes and inborn errors of metabolism.** *J.E. Paschall, V.L. Nelson, G.J. Wyckoff.* Mol. Biol. Biochem., U. Missouri-Kansas City, Kansas City, MO. 64110.

Inborn errors of metabolism (IEMs) offer a unique opportunity to study patterns of evolutionary constraint for disease related genes. We examined orthologous genes between humans and mice that are responsible for IEMs to compare evolutionary constraint at these disease-linked loci to other sets of loci that are either metabolic or non-metabolic. Drawing from our database of 6,921 orthologous genes aligned in-frame between humans and mice, we identified 86 distinct genes responsible for 293 IEMs. We calculated synonymous divergence rate (Ks), nonsynonymous divergence rate (Ka), and functional constraint (Ka/Ks) for the entire set of orthologous genes (Li 1993). Genes causing IEMs were identified based on the SSIEM database (<http://www.ssiem.org.uk/>). This data was combined with our representation of metabolic pathway topology based on KEGG (<http://www.genome.ad.jp/kegg/>) and expression data from Unigene (<http://www.ncbi.nlm.nih.gov/Unigene>). Our hypothesis was that genes causing IEMs are less able to tolerate variation at either the nucleotide or chromosomal level than non-IEM genes; in short, we expected higher levels of constraint to correlate with disease status. Results show that genes involved in general metabolic functions have significantly lower levels of evolutionary constraint (Ka/Ks of approximately 7% lower on average) compared to non-metabolic genes ( $p < .001$  by either F-test or t-test). However, when a set of IEM genes and a set of general metabolic (non-IEM associated) genes are compared, no significant difference in evolutionary constraint is found. Additionally, there is no strong correlation between the number of different IEMs related to a given gene and Ka/Ks. We discuss the use of gene expression, metabolic relationships, and protein domain structure data to devise more sensitive tests of constraint and discuss a database schema used to perform these analyses. Further, we suggest ways in which these observations may be generalized for the examination of Mendelian and complex disease states.

**Compositional Constraints on X Chromosome and XY Gene Pairs Suggest Selection Pressure on Silent Sites. M.**

*Patel<sup>1</sup>, J.S. Sinsheimer<sup>2</sup>, E.R.B. McCabe<sup>3</sup>, A.P. Arnold<sup>4</sup>.* 1) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Canada; 2) Depts of Biomathematics and Human Genetics; 3) Dept of Pediatrics, David Geffen School of Medicine at UCLA, Dept of Human Genetics and Molecular Biology Institute; 4) Dept of Physiological Science and Laboratory of Neuroendocrinology of the Brain Research Institute, UCLA, Los Angeles CA USA.

We have previously shown that the X-linked gene, NR0B1, encoding the protein DAX1, is predisposed to amino acid-changing substitutions similarly to the Y-linked SRY and greater than the autosomal SOX9. Here, we compare NR0B1 (DAX1) sequence changes during evolution with other X-linked genes and X-Y gene pairs to determine if evolutionary profiles could be correlated with chromosomal location. Genes are thought to reflect the GC content of the isochore in which they reside, particularly in the GC content at the 3rd position of synonymous codons (GC3s). To address whether genes mapped to the same isochore show similar silent site evolution, we compared 573 X-linked genes, covering the entire human X. We found that genes mapped in close physical proximity ( 500 kb) in the same chromosomal band show differences in synonymous codon usage, overall GC and GC3s content; the differences in GC3s were significant enough to assign neighboring genes to different isochores. We then compared X-Y gene pairs (X-linked genes with active Y chromosome homologs). We found that the X copy resembles the Y linked copy more than its X-linked neighbors in GC3s content and synonymous codon usage. We then compared the nucleotide sequence of X-Y gene pairs in human and mouse. The number of non-synonymous substitutions per non-synonymous site (Ka) and synonymous substitutions per synonymous site (Ks) were calculated in pairwise comparisons for genes between species. X genes across species were more similar to each other than the X gene was to its Y copy in the same species. We conclude that gene specific influences preclude silent site homogenization with flanking sequences on the X chromosome, and that for X-Y gene pairs, X chromosome specific forces exert a dominant influence on X genes that results in sequence conservation across species.

**Identification of great ape and human lineage-specific genes using cDNA array-based CGH.** *J. Sikela<sup>1</sup>, K. Marshall<sup>1</sup>, Y. Kim<sup>4</sup>, E. MacLaren<sup>1</sup>, G. Hahn<sup>2</sup>, L. Meltesen<sup>2</sup>, R. Hink<sup>1</sup>, S. Burgers<sup>1</sup>, T. Hernandez-Boussard<sup>5</sup>, A. Karimpour-Fard<sup>3</sup>, D. Glueck<sup>3</sup>, L. Denver CO; 4) Department of Pathology; 5) Department of Genetics, Stanford University, Palo Alto CA.

Gene duplication is thought to be an important mechanism in hominoid evolution and speciation, and in the development of new biological processes and adaptations. While it has been estimated that approximately 5% of the human genome is comprised of segmental duplications, a genome-wide analysis of gene amplification (or loss) has not yet been reported for human or any other hominoid. To identify gene copy number changes unique to specific hominoid lineages, interspecies cDNA array-based comparative genomic hybridization (aCGH) was used to individually compare 39,711 cDNAs, representing 29,648 human genes, across five hominoid species: human, bonobo, chimpanzee, gorilla and orangutan. 1,026 genes were identified that produced hybridization signals unique to one or more of the hominoid lineages, including 135 that were human lineage-specific. Verification of the accuracy of the aCGH data was made by comparison to published estimates of hominoid gene copy numbers for two different genes. Additional confirmation was obtained by cross species FISH analysis using BAC probes containing genes predicted to be amplified only in the human lineage. Using software (Treeview) that allows genes to be visualized in the order in which they occur in the genome, genes showing lineage-specific copy number changes were identified that occurred either as single isolated genes or as clusters of contiguous or nearly contiguous genes. Of 23 lineage-specific gene clusters identified, the majority (17) were positionally biased in the genome, occurring more frequently in particularly dynamic genomic regions. Measured as a function of the evolutionary age of each lineage, gene copy number expansions (129) were most pronounced in human, and include a number of genes thought to be involved in the structure and function of the brain.

**Comparative transcriptome analysis of Hirschsprung versus normal human colon.** *M. Clement-Ziza<sup>1</sup>, J.P. Jaïs<sup>2</sup>, T. Attié-Bittach<sup>1</sup>, J. Augé<sup>1</sup>, F. Jaubert<sup>3</sup>, D. Jan<sup>4</sup>, A. Munnich<sup>1</sup>, S. Lyonnet<sup>1</sup>, G. Pitu<sup>5</sup>, L. Aggerbeck<sup>6</sup>, C. Besmond<sup>1</sup>.* 1) INSERM U393, Hôpital Necker-Enfants-Malades, Paris, France; 2) Biostatistique et Informatique Médicale, Hôpital Necker-Enfants-Malades, Paris, France; 3) Anatomopathologie, Hôpital Necker-Enfants-Malades, Paris, France; 4) Chirurgie pédiatrique, Hôpital Necker-Enfants-Malades, Paris, France; 5) CEA, Evry, France; 6) Centre de Génétique Moléculaire, CNRS, Gif-sur-Yvette, France.

Hirschsprung disease (HSCR), the most common hereditary cause of human intestinal obstruction, shows considerable variation and complex inheritance. HSCR is ascribed to an abnormal migration of the neural crest cells leading to the absence of enteric nervous system in the colon. RET is the major disease gene and accounts for about 50% of mutations. Mutations in other genes such as GDNF, EDNRB and SOX10 genes fail to explain the transmission of the disease. Recently, a large non-parametric study described HSCR as multigenic disease (Nat Genet. 2002; 31:89-93).

In order to tentatively identify genetic markers of the HSCR colon and other genes involved in the disease, we carried out microarray comparative transcriptome expression studies.

We analysed the transcriptome of HSCR versus normal colon, using cDNA microarrays containing about 4000 human genes. We identified differentially expressed genes in the HSCR context. This led to the determination of specific marker genes for the HSCR phenotype. These genes are also potential candidate genes for a possible involvement in HSCR.

In conclusion, this study helps us to identify candidate genes for HSCR, genetic markers for this disease and should lead to a better understanding of the physiopathology of the gut function. Further studies will include microdissection steps in order to investigate the transcriptome of the Meissner and Auerbach plexi.

**Time-Resolved fluorometric DNA hybridization assay for the determination of celiac disease associated HLA alleles.** *H. Grey, M. Sjoroos, H. Sahlberg.* Life and Analytical Sciences, PerkinElmer, Turku, Finland.

Genetic susceptibility to celiac disease is strongly associated with HLA-DQA1\*05 - DQB1\*02 (DQ2 heterodimer) and HLA-DQA1\*03 - DQB1\*0302 (DQ8). The primary importance of HLA-DQ alleles conferring the disease susceptibility and the rarity of patients carrying neither the DQ2 nor DQ8 heterodimers have been frequently emphasized. The HLA typing assay developed relies on the amplification of the exon 2 fragments of DQA1 and DQB1 genes as well as solution hybridization with lanthanide-labeled allele-specific oligonucleotides. Hybridization reactions are measured in microtitre plate format using time-resolved fluorometry detection. The temporal and spectral resolution in time-resolved fluorometry allows the measurement of three different labels (europium, samarium and terbium) in the same well. For the interpretation of the results, a MultiCalc program is used to calculate the signal-to-background ratios and normalize the difference in amplification levels of individual samples. Both inter- and intra-assay as well as total variation (% CV) was found to be < 20 (10 PCR products in 10 runs with 2 replicates per plate). To validate the specificity of the developed assay, selected samples were genotyped using sequencing as a reference method. A correct classification of the genotypes confirmed the accuracy of our HLA assay. The developed assay is fast, specific, easy-to-perform and ideally suited for HLA typing because of the possibility to use multiple lanthanide chelates to label the probes. In addition to exploiting isolated genomic DNA as PCR template, the assay also supports the direct use of dried whole blood spots without any sample pre-treatment steps.

**Characterisation of the gene expression profile of human fetal cartilage.** *R. Pogue<sup>1</sup>, E. Sebald<sup>1</sup>, L. King<sup>1</sup>, A. Day<sup>2</sup>, F.E. Castro<sup>2</sup>, E. Kronstadt<sup>1</sup>, S. Nelson<sup>2</sup>, D. Krakow<sup>1</sup>, D. Cohn<sup>1</sup>.* 1) Dept Pediatrics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles.

The transcriptional profile of human cartilage, and fetal cartilage in particular, remains poorly characterised in the databases of the human genome project. To address this discrepancy, and to identify genes whose expression is restricted to cartilage, we constructed a cartilage cDNA library derived from the humeri and femurs of two 18-20 week old human fetuses. Sequence data were obtained for 6,266 individual clones, and the genes represented by these were identified by BLAST analysis. Our analysis of the most frequently represented genes in the library indicated that 178 genes accounted for 47.1% of the transcripts in the tissue. Of these, 44 were not previously known to be expressed in cartilage. The majority of the genes had been previously characterised in terms of function, sub-cellular localisation and/or homology to known genes. These included a number of genes known to be crucial to cartilage function by virtue of the fact that mutations in them give rise to osteochondrodysplasias, diseases of skeletal development and growth. The library also contained approximately 600-700 uncharacterised genes, genes for which the sequence is known but the function is unknown. Fourteen of the 178 most highly expressed genes were uncharacterised. Affymetrix microarray analysis, with confirmation by real-time PCR, was used to determine the tissue expression profiles of the genes, showing that 29 of the top 178 genes, including 3 uncharacterised genes, are cartilage specific. We present here a complete summary of the transcriptional profile of 18-20 week human fetal cartilage, including expression data identifying those genes with a cartilage-specific profile. The genes in the library represent potential candidates for the roughly 170 forms of osteochondrodysplasia for which the causative gene has not yet been identified.

Program Nr: 1534 from 2003 ASHG Annual Meeting

**Polymorphism of A-G at canine mtDNA 2683 corresponding to human mtDNA A3243G mutation.** *F.Y. Li, I.D. Duncan.* Dept Medical Sci, Sch Vet Med, Univ Wisconsin, Madison, Madison, WI.

Many efforts have been made to generate animal models with mtDNA mutations but only a few have succeeded. We screened the canine mtDNA encoded tRNA<sup>Leu</sup>(UUR) gene in 26 domestic dogs and found 16 dogs have a G while 10 have an A at canine mtDNA 2683, corresponding to human mtDNA A3243G mutation. The result was further confirmed by Southern blot analysis digested with Apa I and by Apa I digestion of nest PCR products. This result provides direct evidence that pathogenic mtDNA mutation in humans could be non-pathogenic in animals, suggesting that caution should be taken before attempts are made to generate an animal model with mtDNA mutations.

Program Nr: 1535 from 2003 ASHG Annual Meeting

**Development of Resequencing Primer Sets for High Throughput DNA Sequence Variation Studies.** *B. Nutter, J. Sorenson, C. Gire, M. Rydland, P. Shen, S. Glanowski, N. Edwards, M. Furtado, K. Guegler, E. Spier, R. Fang, L-Z. Pham.* Applied Biosystems, Foster City, CA.

The completion of a reference sequence for the human genome and improvements in high-throughput sequencing technology, including the Applied Biosystems 3730xl DNA analyzer and the BigDye Terminators v3.1 Cycle Sequencing Kit, have motivated the development of easier solutions for quickly resequencing human genes. Designing primers for robust PCR amplification of specific regions of the genome continues to present a significant challenge to high throughput resequencing studies. We report here results of our development of a validated process for designing primers for high-throughput amplification and resequencing of the promoter regions, exon regions, and flanking intronic regions for genes implicated in cancer and other diseases. Primer design for large scale resequencing projects has been greatly improved by our ability to correlate both unsuccessful PCR amplification and poor quality sequencing results to the presence of local and global factors in the genome. Using very large datasets of PCR primer amplification results (>100,000 amplicons) and sequencing data (>1,000,000 sequence files) generated during the Applera Genome Initiative, we are developing a model that will be predictive of the success rate for a given amplicon. We will present the results of a comparison of the success of primer amplification and generation of high quality sequence data in the laboratory to the success predicted by our model. The validation of a model for highly successful PCR primer design will permit the resequencing of all genes from a number of genomes.

**Variation in gene expression in lymphoblastoid cell lines.** *T. Rosser, F. Zhang, S.T. Warren.* Dept Human Genetics, Emory Univ, Atlanta, GA.

Gene chip microarrays are a now routine way to identify changes in gene expression for a variety of diseases and disorders. Often the amount of information gained from these analyses is overwhelming and must be carefully examined to determine significant results. We have investigated the variation in gene expression in lymphoblastoid cell lines through the use of Affymetrix U133 A and B gene chip microarrays in order to reduce the number of false positives to more quickly identify relevant results. We evaluated RNA samples from control cell lines created from three separate blood draws from two individuals, F (female) and M (male), as well as RNA samples extracted from the same cell line, F, at different time points in culture. We were able to show that there is variation between normal cell lines as expected but that there is also variation among cell lines created from the same individual. When we compared all 3 cell lines for F we saw 149 probe sets changed on the A chip with 18 above 1 signal log ratio (SLR) and only 1 above a 2 SLR. For the B chip, we observed 55 probe sets changed with only 4 above a 1 SLR and 0 above a 2 SLR. When we compared all three of the M cell lines, we saw 230 probe sets changed for the A chip with 21 above a 1 SLR and 0 above a 2 SLR. A comparison of the 2 cell lines with a pool of 5 control male cell lines showed an average of 2098 probe sets changed for F U133A, 1268 for F U133B, 2745 for M U133A and 2088 for M U133B. Of these only 49 were shared changes between F and M. As expected, the expression of several Y linked genes was not detected in the F cell lines. When we compared the 3 RNA samples from the F cell line at different culture time points, we observed 48 probe sets changed for the A chip with only 1 above a 1 SLR and only 12 changed for the B chip with none above a SLR of 1. We were also able to compile a set of probe sets that are reproducibly variable between controls and can serve as a mask when attempting to identify true gene expression changes if using lymphoblastoid cell lines as your RNA source.

**An Integrated Haplotype Map of the Human Major Histocompatibility Complex.** *J.D. Rioux<sup>1</sup>, K. Mather<sup>2</sup>, S. Schaffner<sup>1</sup>, L. Farwell<sup>1</sup>, M. Daly<sup>1</sup>, N. Patterson<sup>1</sup>, M. Cullen<sup>3</sup>, M. Carrington<sup>3</sup>, T. Bugawan<sup>4</sup>, H. Erlich<sup>4</sup>, J. Campbell<sup>1</sup>, J. Barrett<sup>1</sup>, K. Miller<sup>1</sup>, G. Thomson<sup>2</sup>, E.S. Lander<sup>1</sup>, E.C. Walsh<sup>1</sup>.* 1) Center Genome Research, Whitehead Inst, MIT, Cambridge, MA; 2) Dept. of Integrative Biology, University of California, Berkeley, CA; 3) Basic Research Program, SAIC-Frederick, Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD; 4) Roche Molecular System, Department of Human Genetics, Alameda, CA.

Numerous studies have clearly indicated a role for the Major Histocompatibility Complex (MHC) in susceptibility to autoimmune diseases. Such studies have focused on the genetic variation of a small number of classical human leukocyte antigen (HLA) genes in the region. Although these genes represent good candidates given their immunological roles, linkage disequilibrium (LD) surrounding these genes has made it difficult to rule out neighboring genes, many with immune function, as influencing disease susceptibility. It is likely that a comprehensive analysis of the patterns of LD and variation using a high density of single nucleotide polymorphisms (SNPs) would enable a greater understanding of the nature of the observed associations as well as lead to the identification of causal variation. We present herein an initial analysis of this region using 201 SNPs, 9 classical HLA loci, 2 TAP genes, and 18 microsatellites. This analysis suggests that LD and variation in the MHC aside from the classical HLA loci are essentially no different than that in the rest of the genome. Furthermore, we also demonstrate that multi-block SNP haplotypes contain considerable predictive information for common HLA alleles. An additional implication of these results is that multi-block SNP haplotypes may be sufficient to identify low frequency variants throughout the genome. Such low frequency variants would likely be missed in single block-based common variant analysis, however their contribution to disease could be assayed by using multi-block haplotypes in analysis. Finally, even though this map is not yet complete, the data presented will show that multi-SNP haplotypes will likely be a valuable means for refining disease association signals in this region.

**Detailed annotation and search for disease causing genes on 8q22-qter.** *S. Asakawa<sup>1</sup>, A. Shimizu<sup>1</sup>, S. Yamazaki<sup>1</sup>, S.K. Ishikawa<sup>1</sup>, T. Sasaki<sup>1</sup>, J. Kudoh<sup>1</sup>, S. Minoshima<sup>1</sup>, I. Kondo<sup>2</sup>, N. Shimizu<sup>1</sup>.* 1) Dept Mol Biol, Keio Univ Sch Med, Tokyo, Japan; 2) Dept Hyg, Ehime Univ Sch Med, Ehime, Japan.

We have finished sequencing of 180 BAC clones covering 20 Mb of human chromosome 8q22-q24.1. Furthermore, we have made detailed annotation of more than 55 Mb of genomic sequence on 8q22-qter by homology search, exon prediction and calculation of GC/CpG content. The homology search by BLAST was performed against nr, est database and Fugu whole genome shotgun sequences. For exon prediction, several prediction programs such as GENSCAN, X-Grail and MZEF were employed. All of the data obtained by these computational analyses were integrated using spreadsheet software, and then visualized graphically by a macro-program developed on a CAD program. More than 250 protein-coding genes were identified in the 8q22-qter. Computer-predicted proteins from many of those genes possessed no obvious domains and motifs, and hence we designated those proteins as Kao-nashi. We also calculated the gene density and found a gene poor region (1 gene / 6 Mb) and a gene rich region (24 genes / 250 kb). On 8q22-qter, there are several disease genes mapped, including a familial epilepsy BAFME/FAME. The BAFME/FAME is an autosomal dominant idiopathic epileptic syndrome characterized by adult-onset tremulous finger movement, myoclonus, epileptic seizures, and a nonprogressive course, recognized mainly in Japanese families. Although the disease locus was assigned to 8q23.3-q24.1, the causative gene has not been identified. We listed more than 40 candidate genes within the disease locus based on our detailed gene map of 8q23.3-q24.1. We are now doing mutation analysis of these genes using DNA from BAFME patients.

Program Nr: 1539 from 2003 ASHG Annual Meeting

**Statistical Inference of Haplotype Reconstruction From SNP Alignment.** *J. Kim*<sup>1</sup>, *L. Li*<sup>2</sup>, *M.S. Waterman*<sup>2</sup>. 1) Computer Science, USC, Los Angeles, CA; 2) Computational Biology, USC, Los Angeles, CA 90089.

The goal of shotgun sequencing is to reconstruct the underlying target chromosome from random fragments. It usually consists of two steps: alignment that results in an assembly matrix; construction of consensus. In some sequencing projects, the targets contains two homologous chromosomes and our aim is to distinguish between polymorphisms and sequencing errors. The difficulty lies in the fact that origins of fragments are unknown. Li, Kim and Waterman proposed a method of haplotype reconstruction from SNP Alignment. It is based on a probabilistic model that includes sequencing error rates, compositional information of nucleotides, and haplotype frequency. The method assumes that the parameters are known. For example, the chance of one fragment being generated from one parental chromosome is assumed to be half. In practice, these parameters need to be estimated. We develop inference procedures for haplotype reconstruction. First we obtain a fast algorithm to calculate the likelihood of the observed assembly matrix as a function of haplotype frequency. It is based on an interesting Markov structure along fragment alignment. The complexity of the algorithm is linear with respect to the number of SNP loci. Consequently, this allows us to find the maximum likelihood estimate of the haplotype frequency. We explain an irregular phenomenon due to the the complicated data structure of shot sequencing. To estimate other parameters, we develop an EM algorithm. In addition, we can take the quality values such as Phred scores into consideration. We will present our simulation results with different settings of parameters. Reference: 1. Churchill, G.A., and Waterman, MS. The accuracy of DNA sequences: Estimating sequence quality. *Genomics*, 14:89-98, 1992. 2. Li, L, Kim JH, Waterman MS. (2003). Haplotype reconstruction from SNP alignment. RECOMB03.

**Towards a Complete Transcript Map of Human Chromosome 22: Comprehensive Gene Search and Functional Analysis of Novel Genes.** S. Minoshima, T. Sasaki, A. Shiohama, K. Hosono, H. Yang, T. Izumiyama, S. Asakawa, J. Kudoh, N. Shimizu. Dept Molecular Biol, Keio Univ Sch Medicine, Tokyo, Japan.

We built the first milestone of human genome research that is the completion of chromosome 22 sequencing (*Nature* **402**: 489-495, 1999). In the report, we identified 545 genes with semi-automatic computational procedure. Since then, we have been doing extensive manual annotation and experimental isolation of cDNAs to draw a complete transcript map substantiated with information of all exons, alternative transcription, expression profile and function for each gene.

To date, we finished analyzing the proximal 40% of 22q (14 Mb), which includes the Cat Eye Syndrome (CES) region, DiGeorge Syndrome (DGS) region, IGL-IGLL region, and CRYBB region, and identified 15 new genes. Of these, we report here the initial characterization of 2 genes, DGCR8 and PIWIL3. DGCR8 is located in the DGS region. Northern blot analysis revealed that DGCR8 is transcribed in three forms, and expressed ubiquitously in various organs/tissues of both human and mouse origins. We isolated a cDNA of mouse homolog Dgcr8 that has 95.3% amino acid identities with human DGCR8. The protein domain analysis revealed one WW motif and 2 double stranded RNA binding motifs. Expression patterns of developing mouse embryo indicated this gene appears to be associated with some clinical phenotypes of DGS (*BBRC* **304**: 184-190, 2003). Further analyses on the DGCR8 protein function and phenotype-gene copy number relation are in progress. PIWIL3 is a novel member of the Argonaute family locating between GGT.2 and TOP1P2 in the IGL-IGLL region. A cloned cDNA was 3,504 bp in length including ORF of 2,652 bp. The PIWIL3 protein has PAZ and Piwi motifs that are considered as a common architecture of the Argonaute family. Since PIWIL3 associated with DICER, we postulated it might be involved in the mechanism of RNAi (*Genomics*, in press). Further studies on the interaction of RNA with PIWIL3/DICER proteins are in progress. We will also present the data on the remaining 13 new genes (CESK1, GAB2L, DGCRK8, DGCRK9, LUK1, C22orf13, ZNF70, C22orf15, C22orf16, SLC2A11, C22orf14, LLN12 and LLN14).

**A model of Measurement Error for Shotgun Sequencing.** *M. Li, L. Li.* Mathematics, Univ. of Southern California, Los Angeles, CA.

In shotgun sequencing, statistical reconstruction of the consensus from alignment requires a model of measurement errors. Churchill and Waterman proposed such a model and an EM algorithm to estimate these sequencing error rates from assembly matrix. From another perspective, Ewing and Green defined quality scores for base-calling from sequencing traces in such a way that it has a probabilistic interpretation. To achieve the goal, the training of the model that defines the Phred scores has to take a large amount of data. However, in practice sample preparations and sequencing machines may work under different conditions and thus quality scores need to be adjusted. Also the information given by quality scores are incomplete in the sense that they evaluate chances of base-calling errors but they do not tell us the error pattern. We do observe that each nucleotide base has its own specific error patterns. We develop models of measurement error for shotgun sequencing by combining the above two perspectives. One option is to represent the error pattern of each nucleotide by a multinomial model. Since the true sequence is unknown, we develop an EM algorithm to deal with missing data. In a more sophisticated way, we propose a model with logistic parameterization taking quality scores as covariate. To represent the nonlinear effect of quality scores, we adopt smooth spline models or simple piecewise linear functions in the regression. We apply the method to an assembly of a BAC, and more than 70% errors from the majority rule are corrected.

**DEVELOPMENT OF A RE-SEQUENCING PIPE-LINE FOR HIGH-THROUGHPUT SEQUENCING OF CANDIDATE DISEASE GENES.** *I. Yakub, D. Burgess, A. Goldman, H. Arredondo, D. Khurna, H. Dinh, B. Patel, D. Muzny, J. Noebels, R. Gibbs.* Baylor College of Medicine, Houston, TX.

In order to better understand complex disorders caused by multiple genes with genetic heterogeneity and lack of penetrance, genome wide methods that allow us to screen for mutations in multiple loci in a large sample set need to be developed. We have established a pipeline to re-sequence large numbers of candidate disease genes in several individuals in a high-throughput manner. A batch primer design software is being used to design primers to amplify all coding regions of every candidate disease gene. All primers also contain a 20mer universal forward or reverse sequencing primer tail. PCR is carried out at a standardized condition and the products are purified. The purified products are then sequenced using the universal primers and the sequences are analyzed for SNPs using a mutation detection software. Several of these steps have been automated allowing re-sequencing to be carried out in a high throughput manner with increased efficiency and lower cost. This pipeline is being used to re-sequence 208 channelopathy genes, several of which have been associated with various forms of epilepsy. In general, epilepsy shows a complex mode of inheritance, although occasionally, a mendelian pattern of inheritance is observed. Epilepsies are grouped into 3 different sub-classes known as idiopathic, symptomatic and cryptogenic. Several epilepsy genes have been identified for each type that elevates the risk of the disorder in individuals carrying variant alleles. This re-sequencing effort is being carried out in 46 epileptic individuals and 46 unaffected controls.

**Comprehensive analysis of conserved non-genic sequences (CNGs) on human chromosome 21.** *E.T. Dermitzakis<sup>1</sup>, A. Reymond<sup>1</sup>, C. Ucla<sup>1</sup>, E. Kirkness<sup>2</sup>, L. Excoffier<sup>3</sup>, S.E. Antonarakis<sup>1</sup>*. 1) Div Medical Genetics, Univ Geneva, Geneva, Switzerland; 2) The Institute of Genome Research, Rockville, Maryland, USA; 3) Zoological Institute, University of Bern, Bern. Switzerland.

The recent comparison of the human genome and mouse genomes brought to light a large number of conserved non-genic sequences (CNGs) (Dermitzakis et al. 2002, Nature 420: 578, Waterston et al. 2002, Nature 420: 520). Although their conservation is high enough to strongly support their functionality, the actual role of these sequences remains unknown. We have performed a comprehensive analysis of CNGs on human chromosome 21 (Hsa21) looking at i) sequence conservation across multiple mammalian species including a marsupial and a monotreme, ii) sequence comparison with a 1X dog genome shotgun, and iii) patterns of polymorphism within a sample of 10 French CEPH individuals and 10 West Africans. The comparison of 220 of the CNGs across 14 mammalian species showed very high conservation and distinct characteristics and lower rate of evolution from coding and ncRNA genes. In addition there appears to be subcategorization within CNGs suggesting the presence of different functional classes. Comparison of 1628 CNGs and 950 conserved exons of Hsa21 between human, mouse, and dog reveals that selective constraint does not depend on the position on the chromosome or proximity to genes and suggests a different role more global than the regulation of genes in cis. Finally, analysis of variation of 95 CNGs and comparison with exons, introns, regulatory regions and random intergenic sequences on Hsa21 within humans suggests that the levels of polymorphism, although lower than the average of the genome, is higher than the one observed in exons, which suggests that there could be considerable genetic variation harbored in these regions. We conclude that many of the CNGs have functional characteristics that are unique and probably constitute a new class of functional genomic elements with only partial similarity to already known ones. Our data also suggest that CNGs are good targets for functional variation in human populations and mutation searches for phenotypic consequences should focus on such regions as well.

**Whole Genome BAC Microarrays: Development and Applications.** *W.W. Cai<sup>1</sup>, J. Li<sup>1</sup>, T. Jiang<sup>1</sup>, E. Rajcan-Separovic<sup>2</sup>, Q. Li<sup>1</sup>, B. Bejjani<sup>3</sup>, S.W. Cheung<sup>1</sup>.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030; 2) Department of Pathology, University of British Columbia, 4480 Oak Street, Vancouver, V6H 3V4, British Columbia; 3) Basic Medical Sciences Program, Washington State University Spokane Health Research and Education Center, P.O. Box 1495, Spokane, WA 99210-1495.

Chromosomal Deletions and duplications are common genomic abnormalities in a wide range of human syndromes. It has long been suspected that a substantial proportion of many human developmental deficiencies currently classified as idiopathic might be caused by small genomic rearrangement beyond the resolution of current technologies. To enable detection of such subtle rearrangements, we have developed DNA array-based whole genome (WG) BAC arrays that can scan the genome at a resolution of exceeding 200kb. Our human WG arrays contain 21,500 sequenced BAC/PAC clones, which covers the human genome at an average resolution of 7 clone/MB, with virtually all regions with sufficient unique sequences covered in contigs. We validated the human WG arrays blindly using a set of samples with known chromosome abnormalities. We have applied the HWG arrays to analyze samples from families in which the child is mentally retarded but the parents have normal IQs. Karyotypic analysis of these families did not reveal any chromosomal abnormalities. However, HW array analysis of these patients samples indicated that there were a considerable number of chromosomal rearrangements of small size, with most of them localized in the subtelomeric regions. Most of the abnormalities were de novo. Some of the abnormalities were consistent between different families. We also detected consistent rearrangements in patients as well as both parents. These results corroborate the hypothesis that some of the idiopathic syndromes indeed have a genetic basis. We also developed WG BAC arrays to cover the entire mouse genome in contigs. The mouse arrays have been extensively used to analyze chromosomal abnormalities in mouse tumors and to detect genomic imbalance polymorphisms between inbred mouse strains.

**EXO-Free SNP Genotyping Assay Based On Fluorescence Polarization Detection.** *S. Duan*<sup>1</sup>, *P. Taillon-Miller*<sup>1</sup>, *R. Miller*<sup>1</sup>, *P-Y. Kwok*<sup>2</sup>. 1) Division of Dermatology, Washington University, St. Louis, MO 63110; 2) Cardiovascular Research Institute and Department of Dermatology, University of California, San Francisco, CA 94143.

Template-directed dye-terminator incorporation with fluorescence polarization (FP-TDI) detection assay is a widely used homogeneous SNP (single nucleotide polymorphism) genotyping method. The assay basically includes 4 steps: 1) PCR reaction; 2) PCR product clean up with *E. coli* exonuclease I (EXO) and shrimp alkaline phosphatase (SAP) to degrade the excess PCR primers and dNTPs; 3) single base primer extension; and 4) FP reading. In further development of this assay, we have eliminated the EXO degradation part of the PCR clean-up step by designing PCR primers so that the base immediately 3' to each primer is different from the polymorphic bases of the SNP. With this design, the PCR primers will not interfere with the primer extension step of the assay. The simplified PCR clean-up step therefore requires only degradation of dNTPs with SAP. For example, the PCR primers for a SNP with C/T alleles will be designed such that the bases 3' to the primers will only be A or G (but not C or T). In this assay, the excess PCR primers in the primer extension step of the assay will not get extended. Assays for 50 SNP markers based on this design principle were genotyped in both directions and the results were in strict concordance with previously determined results. Elimination of EXO in the FP-TDI assay further reduces the cost of this simple SNP genotyping method.

**High throughput assay identifying a LINE insertion to confirm species ID in humans.** *P. Bender<sup>1</sup>, J. Beck<sup>1</sup>, D. Bartnik<sup>1</sup>, K. Smith<sup>1</sup>, L. Mathews<sup>2</sup>, G. Swergold<sup>2</sup>*. 1) Coriell Inst Medical Research, Camden, NJ; 2) Department of Medicine, Columbia University, New York, NY.

The Coriell Cell Repositories distribute both human and non-human primate DNA and cell lines. Any laboratory environment that works with biomaterials from more than one species needs a high-throughput, cost effective assay to verify species. We have developed a PCR-fluorogenic assay for identifying human DNA using unique properties of LINEs (long interspersed nuclear elements). LINEs are retrotransposable elements, many of which are no longer actively amplifying and transposing. The youngest LINEs in the human genome (L1) are useful for species identification because they inserted soon after the emergence of the human lineage. Forward and reverse primers were designed bordering a L1 insertion that amplify a 6.4 kb L1 insert unique to humans. In all other non-human hominoid species, an "empty" band of <1kb is amplified from the conserved sequences that border the insertion site. We tested over 80 individuals representing diverse ethnic origins such as African American, Chinese American, European American, and Mexican American. All samples amplified the expected fragment of 6.4 kb and no sample amplified the "empty" band. These results support the claim that this L1 insertion is fixed in humans. The assay was modified to create a PCR-fluorogenic assay, by designing a new reverse primer that anneals to a L1 sequence approximately 340 bp downstream from the forward primer. These primers direct amplification of the 5 L1 insertion site. A fluorogenic probe was designed with a FAM reporter and TAMARA quencher. The probe is complementary to the 8 locus-specific bases bordering the insertion and the first 13 bases of the L1 insertion. This probe is predicted to anneal only at the locus-specific insertion site. The fluorogenic assay generates fluorescence in all 80 human samples tested and no fluorescence was generated from over 25 chimpanzee samples tested. This new method for identifying species-specific LINE insertions is a specific, high throughput, and economical assay for confirming species identification.

Program Nr: 1547 from 2003 ASHG Annual Meeting

**Shape Encoded Particles For Biological Probes.** *Z. Chen<sup>1</sup>, J. Tsai<sup>2</sup>, B. Merriman<sup>1</sup>, J. Chen<sup>1</sup>, C. Kim<sup>2</sup>, S. Nelson<sup>1</sup>.* 1) Dept of Human Genetics, Univ California, Los Angeles, CA; 2) Dept of Mechanical and Aerospace Engineering, University of California, Los Angeles, CA.

We have developed a new system of encoding micro-particles to be used as probe-carriers in massively-multiplexed biological assays. Particle identity is encoded by its shape, and this provides the means to track which binding-reaction probe is coupled to its surface. The particles are fabricated as ~100x100x10 micron square silicon particles cut from wafers using standard Micro-Electro-Mechanical Systems (MEMS) technology. The different shape types are created by unique patterns of 20 notches etched along the edge of the square, which allows production of millions of distinct Shape Encoded Particles(SEP). To apply the system, each distinct probe (e.g., oligonucleotide) is permanently coupled to a corresponding unique SEP in a separate reaction. After the attachment, the different types of SEPs are mixed. A small portion of the mixture, containing representatives of every type of probe-particle, is used in a hybridization assay of a labeled sample. Shape decoding information and probe signal intensities are obtained simultaneously by imaging the particles spread out on a flat surface. Immediate applications of this technology include SNP genotyping and gene expression profiling. We demonstrate the system applied to a SNP genotyping assay. Oligonucleotide tags were attached to the shape encoded particles and specific hybridization was achieved with complimentary dye labeled oligos generated by a Single-Base-Extension reaction. We have also developed analysis software that reads the scanned images, decodes the shapes, computes the fluorescent signal intensities and displays the results.

Program Nr: 1548 from 2003 ASHG Annual Meeting

**Solving The Problem of Limited DNA samples; Comprehensive Whole Genome Amplification Using Multiple Displacement Amplification.** *R.S. Lasken, S. Hosono, C. Bornarth, A. Raghunathan, M. Wisniewski, O. Alsmadi, X. Pan, M. Egholm.* Molecular Staging Inc., New Haven, CT, CT.

Recently we described a new method for whole genome amplification by multiple strand displacement amplification (MDA)(Proc. Nat. Acad. Sci, USA. 99(8), pp. 5261-5266 (2002); Gen. Res. 13:954-964 (2003)). Because of the high level of amplification the procedure can be carried out directly on minute amounts of gDNA, lysed blood, frozen buffy coats, buccal cells or cells from culture generating assay ready DNA for genetic testing. For small samples like laser microdissected cells and needle aspirates, and where large quantities of DNA are required for testing of many SNPs, MDA promises to change the paradigm of genetic testing. A rapid method is demonstrated for bypassing laborious sample preparation steps with DNA amplified from cells or blood being added directly to genetic assays. A high fidelity DNA polymerase assures preservation of correct sequence. Accurate genotyping free of heterozygote dropout results from remarkably unbiased amplification of alleles.

**Use of a three-color microarray platform to control support-bound probe for improved data quality and enable automated image analysis.** *M.J. Hessner<sup>1</sup>, L. Meyer<sup>1</sup>, S. Khan<sup>2</sup>, H. Jacob<sup>2</sup>, S. Ghosh<sup>1</sup>, X. Wang<sup>1</sup>.* 1) Dept Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) Dept Physiology, Medical College of Wisconsin, Milwaukee, WI.

DNA microarray fabrication methods have lacked the means to assess quality for all arrays prior to hybridization, thus leaving the array an uncontrolled experimental variable. We have developed a three-color cDNA array platform where printed probes are tagged with fluorescein, which is compatible with Cy3 and Cy5 target labeling dyes when using confocal laser scanners possessing narrow bandwidths. Previously, we have used this three-color approach to 1) develop a tracking system to monitor the printing of probe plates at predicted coordinates; 2) define the quantity of immobilized probe necessary for quality hybridized array data to establish prehybridization array selection criteria; and 3) investigate factors that influence probe availability for hybridization. Recently, we have examined hybridized data filtering using element fluorescein intensity, ratio compression as a function of support-bound probe, and the feasibility of using the third dye image, which possesses less noise and fewer artifacts, for automated processing of the Cy3 and Cy5 images. A direct and significant relationship ( $R^2=0.73$ ,  $p<0.001$ ) between prehybridization average fluorescein intensity and subsequent hybridized replicate consistency was observed, illustrating that data quality can be improved by selecting arrays that meet defined prehybridization criteria. Using printed control probes and transcripts at defined input ratios, we found output ratio compressions of 57% +/-24% versus 81% +/-15% when immobilized probe levels were <5,000 and >10,000 RFU/pixel (fluorescein), respectively. Using these data to establish thresholds, we show our three-color approach provides a means to filter spots from hybridized data sets that possess insufficient bound probe for improved data quality. Lastly, initial results indicate that automated image processing may be considerably enhanced through the use of the third dye image. Collectively, this strategy will improve microarray data and increase its utility as a sensitive screening tool.

**Evaluation of Whole Genome Amplification Methods.** *K.A. Haque<sup>1</sup>, M.B. Beerman<sup>1</sup>, V. Puri<sup>1</sup>, S. Yadavalli<sup>1</sup>, A.T. Crenshaw<sup>1</sup>, R.A. Welch<sup>1</sup>, M. Yeager<sup>1</sup>, B.R. Packer<sup>1</sup>, M. Garcia-Closas<sup>2</sup>, N. Rothman<sup>3</sup>, S.J. Chanock<sup>4</sup>, A.W. Bergen<sup>4</sup>.* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI/NIH, Gaithersburg, MD; 2) HREB, DCEG, NCI, NIH, Bethesda, MD; 3) OEB, DCEG, NCI, NIH, DHHS, Bethesda, MD; 4) Core Genotyping Facility, NCI, NIH, Bethesda, MD.

The promise of whole genome amplification (WGA) is that genomic DNA (gDNA) does not need to be the limiting factor during the design and implementation of molecular genetic studies. Two new methods to perform WGA on gDNA have been presented: one method uses the highly processive Phi29 bacteriophage DNA Polymerase with random hexamers by a multiple strand displacement mechanism, and the other method uses chemical fragmentation, linker ligation, and PCR. Validation of three WGA protocols [GenomiPhi DNA Amplification Kit (AB), Amersham Biosciences; REPLI-g 2500S Whole Genome Amplification Kit (MS), Molecular Staging; and OmniPlex (RG), Rubicon Genomics] was performed in the winter of 2002 using the recommended protocols to prepare WGA DNA (wgaDNA) to evaluate concordance of molecular genetic assay results between gDNA and wgaDNA. DNA samples (N=60) extracted from three tissue types were subjected to WGA and quantified to establish wgaDNA yield. DNA yield is dependent on WGA method and is in the range of 6-40 ug (Rank Order ABRGMS), and the CVs were in the range of 9-14% (RGMSAB). Discordance between replicate analyses of gDNA and wgaDNA was assessed through STR (N=9), SNP (N=49 TaqMan), and re-sequencing (N=23 amplicons) assays. STR genotype discordance rates are ~8-12% (ABRGMS) vs. 0.5% using a minimum allelic ratio threshold of 40%. SNP genotype discordance rates are 1% (RGABMS) vs. 0%. SNP undetermined rates are 3-7% (ABMSRG) vs. 1%. SNP non-amplification rates are similar, ~0.4%. SNP completion rates are 92-96% vs. 98% (RGMSAB). Sequence discordance rates will be evaluated comparing quality scores obtained from PhredPhrap. There are differences with respect to overall genotype failure rates among the three methods, where most of the discordant and undetermined genotypes are due to allelic ratio changes and decreased genotype clustering for STR and SNP assays, respectively.

**Robust Dosage-PCR for Detection of Heterozygous Chromosomal Deletions.** *V.Q. Nguyen, J. Shi, X. Li, J.S. Chen, Q. Liu, S.S. Sommer.* Dept Molecular Genetics, City of Hope Medical Ctr, Duarte, CA.

Robust dosage-PCR (RD-PCR) was developed to detect heterozygous large deletions, an important class of mutations missed by conventional PCR strategies. PCR-based methods are available for distinguishing between the dosage of one or two template copies, but general application is limited by the laborious nature of the method and/or the optimization required for each new set of gene exons to be analyzed. RD-PCR depends on a combination of (i) co-amplification of an autosomal and an X-chromosomal segment so that internal dosage controls is integral for any segment to be analyzed and (ii) a robust primer design that includes a 5' tail and a 3' sequence-specific regions in the PCR protocol. The ratio of yields (ROY) of the target to the internal control segment is directly proportional to the ratio of the two input templates over a wide range (at least 1:1 to 1:258 with a correlation coefficient of 0.99). The ROY is not dependent on the amount of genomic DNA or the number of cycles of amplification under typical conditions. RD-PCR eliminates errors in the preparation and manipulation steps by using an endogenous internal dosage control. A blinded analysis of gene dosage was performed to detect deletions of the human factor IX gene with 100% accuracy. RD-PCR assays are presently being utilized to detect chromosomal deletions, insertions, and/or duplications in Hemophilia A and Hereditary Nonpolyposis Colorectal Cancer (HNPCC) patients and family members.

Program Nr: 1552 from 2003 ASHG Annual Meeting

**Detection of extremely rare alleles by bidirectional- pyrophosphorolysis activated polymerization allele-specific amplification (Bi-PAP-A): towards measurement of mutation load in mammalian tissues.** *Q. Liu, S. Sommer.* Dept Molecular Genetics, City of Hope Natl Medical Ctr, Duarte, CA.

A method of detecting one single nucleotide mutation in  $10^6$ - $10^9$  wild type allele would be advantageous for multiple applications including: i) detection of minimal residual disease, especially in solid tumors, ii) cancer risk assessment by searching for elevated mutation load due to endogenous DNA repair defects or environmental mutagen exposures (i.e., measuring the frequency and pattern of somatic mutations present in normal tissues), and iii) prenatal diagnosis of paternally derived mutations within fetal cells in the maternal circulation. Pyrophosphorolysis activated polymerization (PAP) has been developed to detect extremely rare mutations in complex genomes. In theory, PAP can detect a single mutation present in  $3 \times 10^{11}$  copies of wild type alleles. In practice, the selectivity of detection is limited by polymerase extension errors, a bypass reaction, from the unblocked oligonucleotide. Bi-directional PAP allele-specific amplification (Bi-PAP-A) is a novel method that uses two opposing pyrophosphorolysis activatable oligonucleotides ( $P^*$ ) with one nucleotide overlap at their 3' termini, thus eliminates the problematic bypass reaction. The selectivity of Bi-PAP-A was examined using Lamda phage DNA. Bi-PAP-A could selectively detect two copies of a rare mutated allele (A190T) in the presence of as much as  $2 \times 10^9$  copies of the wild type allele in Lamda phage DNA. Bi-PAP-A was further validated using mouse genome. Spontaneous somatic mutations were directly detected in BigBlue mouse DNA at a frequency as low as  $3 \times 10^{-9}$ . Bi-PAP-A is a simple, rapid, general method capable of automation and particularly suited to detection of rare mutations.

**Comparative Gene Expression Analysis of Microdissected Brain Tissues in a Mouse Model of Idiopathic Parkinsons Disease Using a Novel RNA Amplification System.** *J. Heath<sup>1</sup>, A. Brooks<sup>2,3</sup>, E. Richfield<sup>4</sup>, M. Thiruchelvam<sup>2</sup>, D. Cory-Slechta<sup>2</sup>, M. Wang<sup>1</sup>, P. Chen<sup>1</sup>, A. Dafforn<sup>1</sup>, G. Deng<sup>1</sup>, D. Iglehart<sup>1</sup>, S. Koritala<sup>1</sup>, S. Lato<sup>1</sup>, S. Pillarisetty<sup>1</sup>, R. Purohit<sup>1</sup>, M. Herrler<sup>1</sup>, J. Stanchfield<sup>1</sup>, N. Kurn<sup>1</sup>.* 1) NuGEN Technologies, Inc., San Carlos, CA 94070; 2) Department of Environmental Medicine, University of Rochester Medical Center, NY 14642; 3) Functional Genomics Center, University of Rochester Medical Center, Rochester, NY 14642; 4) Department of Pathology, University of Rochester Medical Center, Rochester, NY 14642.

Most biological processes involve global changes in gene expression. High throughput transcriptome/gene expression analysis using microarray technology has made it possible to study these global changes in expression patterns. However, the application of these technologies has been limited by the need for relatively large amounts of RNA. Global gene expression changes in limited tissue samples, such as those obtained by microdissection and fine needle aspiration, are outside the grasp of these powerful tools. This makes the development of reliable amplification technologies essential to progress in these fields. To meet these requirements, NuGEN has developed the Ovation<sup>TM</sup> Nanosample RNA Amplification system for gene expression analysis on spotted arrays. It uses the Ribo-SPIA process, a novel rapid, isothermal, linear global mRNA amplification method. The simple three-step method produces highly reproducible amplified aminoallyl cDNA in less than 4 hours from samples as small as 1ng total RNA. Ribo-SPIA generates microgram amounts of single stranded DNA product, homologous to first strand cDNA, while maintaining excellent representation of all transcripts over a 10,000 fold dynamic range. The technology has been used to profile individual animals in a mouse model of idiopathic Parkinsons disease (PD) by correlating transcript profiles of microdissected brain tissue with behavioral phenotypes. In this study of the molecular mechanism of PD, we specifically address the question as to whether insults sustained developmentally or cumulative damage across life can contribute to the etiology of the disease.

**Gene expression and endurance training- induced changes in insulin sensitivity: the HERITAGE Family Study.**

*M. Teran-Garcia*<sup>1</sup>, *T. Rankinen*<sup>1</sup>, *T. Rice*<sup>2</sup>, *A.S. Leon*<sup>3</sup>, *D.C. Rao*<sup>2</sup>, *J.S. Skinner*<sup>4</sup>, *J.H. Wilmore*<sup>5</sup>, *C. Bouchard*<sup>1</sup>. 1) Human Genomics, Pennington Biomedical Research Center, Baton Rouge, LA; 2) Division of Biostatistics, Washington University School of Medicine, St Louis, MO; 3) School of Kinesiology, University of Minnesota, Minneapolis, MN; 4) Department of Kinesiology, Indiana University, Bloomington, IN; 5) Department of Health and Kinesiology, Texas A&M University, College Station, TX.

The beneficial effects of regular physical activity on insulin sensitivity and glucose metabolism are well documented. However, the molecular mechanisms associated with the heterogeneity in responsiveness to exercise training (T) remain unknown. The objective of this study was to find novel candidate genes for endurance T-induced improvement in peripheral insulin action by using the microarray technology. Total RNA was isolated from vastus lateralis before and after 20 weeks of exercise from individuals participating in the HERITAGE Family Study. Insulin sensitivity (S) index was derived from a FSIVGTT using MINMOD analysis. Sixteen subjects were selected for the experiment: 8 showed no changes in S (low responders; LSR) and 8 displayed marked improvement in S (high responders; HSR) after the intervention. S increase after exercise T was ~5 times greater in HSR compared to LSR (4.60.7 vs. -0.780.2U/ml/min), whereas age, BMI, body fat, and baseline S were similar between the groups. Pooled RNA samples from the HSR and LSR individuals were analyzed for differences in gene expression before and after T using microarrays. Both pre- and post-T experiments were repeated 3 times. Overall, differences between LSR and HSR were more evident in the samples obtained after T. Almost twice as many genes showed 2-fold difference in expression levels between the HSR and LSR as compared to the pre-T samples. 18 genes were consistently up-regulated (2.0), and 8 down-regulated (0.5) both at pre- and post-T in the HSR, whereas expression level of 56 and 42 genes increased and decreased, respectively, after T in the HSR group. Differentially expressed genes include those involved in pathways of glucose transport, signaling and energy metabolism, along with structural genes.

**Flow-through porous microarrays: a novel platform for gene expression profiling.** *Y. Wu<sup>1</sup>, P. de Kievit<sup>1</sup>, L. Vahlkamp<sup>1</sup>, D. Pijnenburg<sup>1</sup>, M. Smit<sup>1</sup>, M. Dankers<sup>1</sup>, M. Stax<sup>2</sup>, T. Satoh<sup>3</sup>, P.J. Boender<sup>1</sup>, C. Ingham<sup>1</sup>, H. van Damme<sup>1</sup>, T. Raap<sup>2</sup>, A.B. Chan<sup>1</sup>, R. van Beuningen<sup>1</sup>.* 1) PamGene International BV, Burgemeester Loeffplein 70a, s-Hertogenbosch, The Netherlands; 2) Department of Molecular Cell Biology, Leiden University Medical Center, Leiden, The Netherlands; 3) Genome Medical Business Division, Olympus Optical Co., Ltd., Tokyo, Japan.

The application of high-density microarrays has been extremely valuable in the identification of new classes of biomarkers that could be useful for therapeutic intervention and clinical diagnosis. However, subsequent validation and use of these biomarkers require focused microarrays that offer speed, robustness and reproducibility. Methods such as quantitative PCR analysis provide tremendous sensitivity but those technologies are not easy to multiplex. A novel technology platform, a flow-through porous microarray (porous array), has been developed for rapid and robust molecular biological testing. The new concept of this technology involves the use of a porous aluminium-oxide substrate as a solid support. This facilitates the flow-through incubation of a sample solution through its structure, which assures much faster and more efficient hybridization. To assess its utility in gene expression analysis, we performed a heat shock treatment on cultured Jurkat cells and analyzed the transcriptional regulation of 23 genes. The results obtained by porous arrays were confirmed by real-time quantitative PCR. Individually labeled transcripts were generated to determine the sensitivity of these arrays. Our results show a good correlation between porous arrays and quantitative PCR (73%). The minimal detectable amount with individually labeled transcripts is 20-80 amol in 20ul solution. This enables the detection of 1 in 300,000 copies of transcripts in approximately 10ug of amplified RNA. In addition, porous arrays show uniform spot morphology, high reproducibility between arrays (10.4% CV), a broad dynamic range (4 orders of magnitude) and fast hybridization kinetics. Based on these results we conclude that the flow-through porous microarray is a novel strategy that offers speed, robustness and reproducibility for gene expression profiling.

**Highly multiplexed locus-specific SNP genotyping using high-density oligonucleotide arrays.** *M.H. Shapero, A. Loraine, W. Liu, J. Zhang, X. Di, K.W. Jones.* Genotyping Research, Affymetrix, Santa Clara, CA.

With the completion of the human genome, SNPs are emerging as the marker of choice for genetic association studies. Additionally, the ongoing international effort to build a haplotype map will further identify SNPs which are expected to improve the ability to carry out genome scans and should provide the framework for new studies designed to identify the underlying genetic basis of complex diseases. Due to these applications, there is still a need for the development of robust, cost-effective platforms for large scale SNP genotyping. We are developing a new locus-specific target preparation method called MARA (Multiplexed Anchored Runoff Amplification). The approach uses a single primer per SNP in conjunction with adaptor-ligated, restriction enzyme digested human genomic DNA. Each primer contains a common sequence at the 5' end and locus-specific sequence at the 3' end. A primary reaction generates single strand extension products which are then used in a secondary amplification with common primers. Following labeling of the target DNA, allele discrimination is achieved by hybridization to high density DNA oligonucleotide arrays. We have carried out multiplex reactions containing 250 primers and 20 ng of adaptor-ligated genomic DNA across 9 DNA samples. The results show an average call rate of 99% with 36 discordant genotype calls, attributed to 9 primers, out of 2250 (250 calls x 9 people) total calls for an overall primer failure rate of less than 5%. The same DNA samples were assayed at 775-plex with an average call rate of 98% and less than 10% overall primer failure rate. We currently are in the process of a systematic analysis of the multiplex limit using SNPs from human chromosome 21, testing 1000-, 2000-, 3000-, and 4000-plex reactions using MARA. In addition, genotyping data is being used to reconstruct haplotypes using a diverse panel of DNA samples. Potentially MARA may improve the through-put of SNP genotyping by allowing levels of multiplexing during target generation that far exceed the capacity of traditional multiplex PCR.

**An efficient highly multiplexed SNP genotyping assay and application to the International HapMap Project.** *R. Shen, W. Chang, D. Campbell, J. Chen, D. Doucet, C. McBride, J.-B. Fan, S. Shaw, M. Chee, M. Hansen, A. Oliphant.* Scientific Operations, Illumina, San Diego, CA.

Millions of single nucleotide polymorphisms (SNPs) have been identified in the human genome. It is currently impractical to perform genetic association studies utilizing all of them. However, a goal of the International HapMap Project is to identify a minimal set of SNPs that can be used to detect common haplotype patterns in multiple populations. This will enable comprehensive genome-wide genetic association studies, potentially revolutionizing the search for the genetic basis of common diseases. The goal of the HapMap project will be accomplished by carrying out large-scale genotyping in different populations. The ability both to develop and effectively utilize the HapMap for genetic association studies is dependent upon tools for large-scale genotyping that are flexible, cost-effective and easy to use.

We have developed an efficient SNP genotyping assay that is easy to use and is capable of multiplexing at greater than 1,152 simultaneous assays in a single well. The assay consists of designing two allele-specific oligos and a single locus specific oligo per SNP. The assay oligos for 1,152 loci (3,456 oligos) are combined and then hybridized to a single sample of genomic DNA. After the genomic DNA hybridization, processes are performed that remove excess and mishybridized oligos prior to an allele-specific extension reaction. Extended products are ligated by a DNA ligase, and the reaction products are PCR amplified and hybridized to a Sentrix<sup>TM</sup> Array Matrix. This assay is being used by the international community to genotype 50% of the loci for the human HapMap project and by Illuminas Genotyping Services which has run >100M genotype calls. We have utilized this platform to develop a high resolution SNP linkage panel and a higher resolution fine mapping panel. The SNP linkage panel contains approximately 4,600 uniformly spaced loci and the fine mapping panel contains 40,000 loci uniformly spaced throughout the genome.

**Accumulation of random mitochondrial DNA deletions and phenotypic consequences in aged human skeletal muscle.** *G. Stepien, B. Chabi.* Laboratoire de Nutrition Humaine, UMR INRA 1019, Clermont-Ferrand, France.

Several works supported that mitochondrial respiratory chain deteriorates with age, mostly in tissues with high-energy requirements. Damage to mitochondrial DNA (mtDNA) by reactive oxygen species is thought mainly to contribute to this impairment. However, the overall extent of mtDNA mutation in aging is still not evaluated.

To quantify mitochondrial damage in aging, we are carrying out molecular and biochemical analysis in muscle biopsies from young and old healthy subjects. Deleted mtDNA accumulation with age was followed by both real-time quantitative PCR analysis that allows us to quantify mtDNA copy number with high sensitivity and Southern-blot hybridization coupled to quantification of the radioactive signals that led us to determine deleted to full length mtDNA ratio. We first settled both techniques by quantification of mtDNA alterations in patients with mitochondrial disorders: both quantifications were performed on patient samples: skeletal muscle with large-scale mtDNA deletions, tissues and cultured fibroblasts with mtDNA depletion, and liver with mtDNA over-replication. The results obtained by the two methods showed concordant data for most of the patients.

Our results underline no increase of specific mtDNA deleted sequences with age contrary to the accumulation of single or multiple large scale deletions observed in patients with mitochondrial pathologies. Deletion events should appear randomly in all mtDNA regions with aging and more than 60 percent of mtDNA copies should be deleted in the oldest subjects (more than 80 years old). Moreover, a significant increase in mtDNA copy number (deleted and full length) was detected in old subjects. Several respiratory chain enzymatic activities were simultaneously measured in all subjects. A progressive and significant decrease of all these activities with aging was observed. However, physical activity, nutritional and hormonal status, and genetic background should be further considered as major parameters that could modulate such enzymatic activity alteration in aging.

Program Nr: 1559 from 2003 ASHG Annual Meeting

**Automated transcript mapping detects brain-specific gene transcripts in a region on 16p13 associated with autism.** *A.L. Scardovi<sup>1</sup>, C. Ottolenghi<sup>1</sup>, F. Soli<sup>1</sup>, I. Stanghellini<sup>1</sup>, E. Caffo<sup>2</sup>, A. Forabosco<sup>1</sup>.* 1) Genetica Medica, University of Modena, Italy; 2) Neuropsichiatria Infantile, University of Modena, Italy.

Genome scan linkage analyses suggest that the short arm of chromosome 16 contains a locus associated with autism. In order to detect potential tissue-specific isoforms in this region, we developed a computational approach combining retrieval of data on human EST tissular distribution with exon identification in a 10 Mb sequence that contains the markers with multipoint maximum LOD scores suggestive of linkage. We screened for putative exons by EST mapping and ranked them according to their abundance in brain libraries. Two novel genes and two isoforms of a known gene showed a pattern suggestive of high expression in brain. Selective expression in brain was confirmed by RT-PCR and further characterization of the gene structures and expression patterns is under way. This approach may be highly effective in pointing to expression-based candidate genes in large genomic regions associated with complex traits.

Program Nr: 1560 from 2003 ASHG Annual Meeting

**DNA preservation using genomic libraries constructed with standard plasmid vectors.** *R. Dana.* Committee for World Health, Foothill Ranch, CA.

Preservation of large fragments of genomic DNA (100-200 kB) with bacterial artificial chromosome (BAC) vectors may also be performed with many of the standard plasmid vectors used for gene cloning. The hypothesis that DNA rearrangements are minimized when only one copy of the construct is present per bacterial cell does not appear to be true. Thus, large DNA genomic libraries may be constructed and provide a stable system for long term DNA preservation and renewal with many of the standard plasmids. These results suggest that the wide variety of cloning vectors which are now available should be evaluated with large DNA methodologies, thereby facilitating genomic research. These findings can save time and lower the cost of DNA preservation research.

**Shuffling of genes within low copy repeats on 22q11 (LCR22) by Alu-mediated recombination events during evolution.** *B.E. Morrow<sup>1</sup>, A. Pavlicek<sup>2</sup>, M. Babcock<sup>1</sup>, C.D. Kashork<sup>3</sup>, L. Shaffer<sup>3</sup>, J. Jurka<sup>2</sup>.* 1) Dept Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY; 2) Genetic Information Research Institute, Mountain View, CA; 3) Health Research and Education Center, Washington State University, Spokane.

Low copy repeats or segmental duplications are highly dynamic regions in the genome. Low copy repeats on chromosome 22q11.2 (LCR22) mediate chromosome rearrangements associated with velo-cardio-facial syndrome/DiGeorge syndrome, der(22) syndrome and cat-eye syndrome. The LCR22s are a complex mosaic of genes and pseudogenes, formed by duplication and transposition processes. The ability to trace the substrates and products of recombination events provide a unique opportunity to identify the mechanisms responsible for shaping LCR22s. We examined the genomic sequence of known LCR22 genes and their duplicated derivatives. We found Alu (SINE) elements at the breakpoints in the substrates and at the junctions in the products of recombination for USP18, GGT and GGTLA, consistent with Alu-mediated unequal crossing-over events. In addition, we were able to trace an Alu-mediated rearrangement event between IGSF3 on 1p13.1 and GGT on 22q11.2. Most breakpoints examined occurred in the 5' or 3' ends of the Alu elements. A possible stimulus for these rearrangements may be the high sequence similarities between different Alu elements, combined with the potentially recombinogenic role of retrotransposon target site duplications flanking the Alu element, containing potentially kinkable DNA sites. Such sites may represent focal points for recombination. Thus, genome shuffling by Alu-mediated rearrangements has contributed to genome architecture during primate evolution. The availability of individuals with chromosome rearrangement disorders provides an additional opportunity to understand recombination mechanisms in a single meiosis. It is possible that some of the same mechanisms are responsible for both events.

**Genomic architecture involved in *PLP1* duplication causing Pelizaeus-Merzbacher disease.** *J.A. Lee*<sup>1</sup>, *M. Dean*<sup>3</sup>, *B. Gold*<sup>3</sup>, *J.R. Lupski*<sup>1,2</sup>, *K. Inoue*<sup>1</sup>. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Human Genetics Section, Laboratory of Genomic Diversity, NCI-Frederick, Frederick, MD.

Genomic architecture, a higher order structural feature of the human genome, can provide molecular substrates for recurrent submicroscopic chromosomal rearrangements, including deletion and duplication. Such rearrangements lead to gene dosage alterations within the rearranged genomic segment that may result in genomic disorders. Many disease-causing genomic rearrangements are mediated by homologous recombination between flanking low-copy repeats (LCRs), yielding common recombinant genomic segments. Pelizaeus-Merzbacher disease (PMD) is a genomic disorder that most commonly (60-70%) arises from genomic duplications of the dosage-sensitive proteolipid protein gene (*PLP1*). Interestingly, the breakpoints of the *PLP1* duplication are not common, yielding duplicated genomic segments of varying lengths. This suggests that the molecular mechanism underlying *PLP1* duplication events is likely distinct from the common mechanism. To determine whether genomic architecture also facilitates *PLP1* duplication events, we performed large-scale genome sequence analyses and identified several LCRs within the *PLP1* region. To further examine whether these LCRs may stimulate the genomic rearrangements leading to *PLP1* duplications, we employed pulsed-field gel electrophoresis (PFGE). PFGE analyses using probes adjacent to these LCRs detected recombination-specific junction fragments in 6 of 9 families with *PLP1* duplications. These data suggest that these LCRs may be involved in mediating the duplication events. Our study provides evidence that genomic architectural features may result in susceptibility to the genomic duplications responsible for the majority of PMD cases.

**Human chromosome 7: DNA sequence, biology, and medical genetics.** *S.W. Scherer*<sup>1,2</sup>, *J. Cheung*<sup>1</sup>, *L.R. Osborne*<sup>2</sup>, *J.R. MacDonald*<sup>1</sup>, *K. Nakabayashi*<sup>1</sup>, *J. Herbrick*<sup>1</sup>, *J. Skaug*<sup>1</sup>, *R. Khaja*<sup>1</sup>, *J. Zhang*<sup>1</sup>, *M. Li*<sup>1</sup>, *M. Haddad*<sup>1</sup>, *A.R. Carson*<sup>1</sup>, *L. Parker-Katirae*<sup>1</sup>, *G.E. Duggin*<sup>1</sup>, *J. Vincent*<sup>1</sup>, *J.M. Rommens*<sup>1,2</sup>, *J.C. Venter*<sup>3</sup>, *R.J. Mural*<sup>3</sup>, *M.D. Adams*<sup>3</sup>, *L.-C. Tsui*<sup>1,2</sup>. 1) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto, ON, Canada; 3) Celera Genomics, Rockville, MD, USA.

We have generated an assembly of the complete DNA sequence of human chromosome 7 and an initial annotation of the biological features relevant to development, variation, and disease (*Science*, 2003). In order to establish the most comprehensive sequence database, we combined unpublished Celera scaffolds and our new sequence (comprising 85% of the assembly) with data from public repositories (15%). The compilation consisted of 157,953,789 bp encompassing all DNA markers and known genes. In our dataset there were 1,022,294 bp of sequence not present in the last NCBI build, 204,066 bp at 8 sites inverted between assemblies, and 508,332 bp at 132 sites with variable sequence. The DNA sequence framework served as a reference for annotation of all relevant molecular and biomedical information. We identified 1917 genes and gene segments; 100 of these were not in other databases, and for another 200 our description was more complete. In addition, an international group of 70 scientists from 10 countries (for complete list of authors see *Science*, 2003) contributed new experimental data and this work continues. Over 1400 clinical records of individuals having defined phenotypes and chromosome 7 rearrangements have been catalogued. For 500 of these, the breakpoints were precisely mapped along the DNA sequence providing a rich resource for medical genetic discovery (we provide examples of how this has been used to study autism). To facilitate further community-based structural and functional annotation of human chromosome 7 we have implemented the Generic Model Organism Database to display all of this chromosome 7 data (<http://www.chr7.org/>), which is continually updated and curated.

**Genomic inversion polymorphism in parents of patients with Williams-Beuren syndrome.** *K. Wakui<sup>1</sup>, K. Inoue<sup>1</sup>, C. Kashork<sup>1</sup>, L.G. Shaffer<sup>1,4,5</sup>, J.R. Lupski<sup>1,2,3</sup>*. 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children Hospital, Houston, TX; 4) Health Research and Education Center, Washington State University, Spokane, WA; 5) Sacred Heart Medical Center, Spokane, WA.

Williams-Beuren syndrome (WBS; MIM #194050) is a contiguous gene syndrome caused by a deletion of multiple genes within chromosome 7q11.23. The common ~1.5 Mb deletion likely results from non-allelic homologous recombination between directly oriented DNA blocks of low-copy repeats, LCR7s. Recently, inversion of the same segment has been described as a polymorphic variant in 4 of 12 (33%) parents of WBS patients with common deletion, as well as in 1 of 8 atypical WBS patients without deletion, and 3 atypical WBS patients with balanced chromosomal rearrangement (Osborne et al. 2001). We studied 15 WBS families by PFGE analysis, and identified the presence of 7 PFGE junction fragments in parents (47%). Our data confirm the previous findings of high rate of genomic inversion polymorphism in parents of patients with WBS, and support the hypothesis that the presence of a heterozygous inversion polymorphism may increase susceptibility to non-allelic homologous recombination that results in WBS deletion.

**The search for genetic modifiers of asthma through expression profiling of peripheral blood lymphocytes. S.**

*Hilmer<sup>1</sup>, N.N. Hansel<sup>2</sup>, S.N. Georgas<sup>2</sup>, L.M. Cope<sup>2</sup>, J. Guo<sup>2</sup>, R. Irizarry<sup>2</sup>, E.P. Hoffman<sup>1</sup>, G.B. Diette<sup>2</sup>.* 1) Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Department of Pulmonary and Critical Care Medicine, The Johns Hopkins Hospital.

Asthma is a common chronic inflammatory disease of the lungs, which affects over 10 million adults in United States alone. This disease has considerable public health consequences due to the enormous variability in disease progression. As a result of this variability, those patients with more severe disease have a disproportionately high morbidity, mortality risk, and impact on the health care system. Additionally, severe and poorly controlled asthma may lead to inappropriate tissue remodeling which results in irreversible disease and prolonged disability. Although a few candidate genes have been suggested, research focused on the possible genetic predisposition for severe asthma is scarce. Furthermore, little is known about the molecular mechanisms underlying disease progression and degrees of severity. CD4+ Th2 lymphocytes may play an important role in airway inflammation and hyper-responsiveness. However, the relationship between lymphocytes and their effector function in asthma progression has not been fully explored. Here we aim to develop a better understanding of lymphocyte activity through expression profiling using the Affymetrix Human Genome 133 GeneChip series. The up-regulation of genes involved in the Ras-MAPK pathway (namely, RAB14, RAB2, KRAS2 and CAPRI) in severe asthmatics, suggests the importance of T cell proliferation in asthma severity. Severe asthmatic subjects also had increased expression in genes involved in T cell activation (CD6, CD3E), cytoskeletal changes (ARPC4, PLEC1, RAC2, SEPT1) and cell adhesion (NK4, B4ALT1) supporting the concept of lymphocyte recruitment to tissues or areas of inflammation. Comparing and contrasting transcriptional programs of severe and mild asthmatics may contribute to a better understanding of asthma severity and progression as well as lead to the identification of markers for those who have an increased risk of severe asthma.

**Transcriptional profiling of adult mouse muscle and bone marrow SP cells.** *K.N. Liadaki, D. Sanoudou, J. Schienda, A. Kho, A. Beggs, L.M. Kunkel.* Harvard Medical School, Children's Hospital, Boston, MA.

Stem cells have the capacity to self-renew and the ability to generate differentiated cells. The identification of genes that govern the specific properties of stem cells is important for basic cell biology and stem cell-based therapy. Stem cell sources vary depending on the tissue and the isolation procedure. A technique based on the exclusion of the DNA binding dye Hoechst 33342 has been used to identify and purify, using a fluorescence activated cell sorter (FACS) a sub-population of cells, termed side population (SP) cells, from the main population (MP) cells. SP cells have been isolated from adult bone marrow (BM) and skeletal muscle and are enriched in stem cell activity, based on the expression of stem cell markers, and on transplantation experiments. We used the Affymetrix U74Av2 microarrays to characterize the transcriptional profiles of over 12000 probe sets in SP cells isolated from murine adult skeletal muscle and BM. We have found significant changes in the gene expression involved in multiple cellular pathways including signal transduction pathways (11%) (specifically receptor molecules -8%), regulation of cell cycle and development (7%) and transcription/translation mechanisms (11%). A large number of genes of unknown molecular function (25%) were significantly up-regulated in SP, compared to MP cells, and are currently under investigation. Although many differences were evident between muscle and BM SP cells, their similarities may enable the identification of common pathways of SP function in different tissues, as well as the identification of tissue-specific SP markers, which could facilitate the isolation of SP cells and improve their engraftment into recipient tissues.

**The Effect of Vitamin E on Gene Expression in Patients With Age-Related Macular Degeneration (AMD).** *J.D. Flippin<sup>1</sup>, N. Strunnikova<sup>2</sup>, S.C. Hilmer<sup>1</sup>, E.P. Hoffman<sup>1</sup>, K.G. Casky<sup>2</sup>*. 1) Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) National Eye Institute, National Institutes of Health, Bethesda, MD.

One in three people 65 and over has a form of eye disease. Of these diseases Age-Related Macular Degeneration (AMD) is the leading cause of blindness. With the baby boomer generation reaching this age category, the need to better understand the disease is crucial. While there is significant use of antioxidants in clinical trials, it is important to understand the pathogenesis of the disease. The eye is susceptible to oxidative stress due to a high exposure to sunlight, content of polyunsaturated fatty acids, and consumption of oxygen. In AMD patients there seems to be abnormal cell response to the injury caused by this oxidative stress. It has been reported that similar abnormal cell response to injury is occurring in other tissues like skin. Although there is no pathological phenotype, there is a change of histology of the skin of AMD patients. Ironically, like the eye, the skin has a high exposure to sunlight making it susceptible to oxidative stresses similar to those affecting the eye. Our study uses dermal fibroblast cells from patients with either nonexudative form of AMD; Drusen or Geographic Atrophy. Cultured fibroblasts isolated from patients were expression profiled both pre- and post- injury induced with menadione both with and without pre-treatment with vitamin E. Expression changes were evaluated for the 22,284 genes and ESTs represented on the Affymetrix HG\_U133A GeneChip. Results indicate differential expression of genes with known antioxidant function, including antioxidant protein 1 (ATX 1) and genes with important roles in lipoprotein inhibition such as tissue factor pathway inhibitor (TFPI). The results of our study have important implications for understanding the pathogenesis of AMD and the use of antioxidants in treatment regimes.

**Haplotype-specific BAC libraries for identifying amyotrophic lateral sclerosis (ALS) loci through integrative genomics.** *Y. Yoshinaga, M. Nefedov, K. Osoegawa, P.J. de Jong.* BACPAC Resources, Children's Hospital Oakland Research Institute, Oakland, CA.

Complex traits are caused by variation at multiple interacting loci. The underlying genetic defects are thus difficult to identify and require genetic analysis from small pedigrees to ensure that all cases are inheriting the trait in a Mendelian way. We are collaborating with a consortium of research groups with access to distinct pedigrees of familial ALS patients with dominant disease-predisposing alleles. The small pedigrees permit genetic localization to chromosomal regions in the range of 5-10 cM. To identify the predisposing alleles, multiple sources of information will be combined to indicate likely candidate FALS genes. One source of information is the complete haplotype-specific sequence for the affected chromosomal interval. This can conceivably be accomplished through a long-range PCR strategy or a molecular cloning approach. Molecular cloning has the advantage that single DNA molecules are isolated and cloned, thus establishing a single haplotype intermediate for sequencing. The use of human-mouse hybrid cell lines facilitates this approach by providing an option for the selective cloning BACs from a single haplotype, thus reducing the need for high-resolution haplotype mapping to distinguish clones derived from the allelic autosomes. Using the completed human genome sequence, synthetic probes can be designed at regular intervals and pooled for library screening. This permits the rapid isolation of a BAC contig and the identification of a minimal set of BAC clones defining the region, to be used for the shotgun sequencing of the affected regions. We have prepared two BAC libraries derived from FALS patients with predisposing alleles on human chromosome 16 and 18, and are progressing toward the mapping of the affected chromosomal regions. In addition to providing an intermediate for sequencing the affected haplotypes, the BACs also provide a source of candidate genes for functional gene assay, for instance by integrating EGFP reporter constructs for cell based or transgenic animal approaches. Our research is supported in part by a grant from the ALS Association.

**HLA typing for determination of type 1 diabetes associated DQA1, DQB1 and DRB1 alleles.** *M. Sjoroos, J. Seppala, H. Grey.* Life & Analytical Sciences, PerkinElmer, Turku, Finland.

The most important gene loci defining risk for type 1 diabetes are located within HLA region. The HLA-DQ molecules are of primary importance, but HLA-DR products can modify the risk conferred by HLA-DQ. Thus, HLA-DQA1, -DQB1 and DRB1 assays for the detection of type 1 diabetes associated alleles (alleles associated with risk or protection) were developed for pathogenesis and prevention studies. Currently, these assays are used as large-scale screening tests for the risk estimation of type 1 diabetes. The assays are based on the combined use of the polymerase chain reaction (PCR) amplification of the relevant exon 2 polymorphic regions of the three genes and solution hybridization with lanthanide-labeled allele-specific oligonucleotides using time-resolved fluorometry for detection. The biotinylated PCR products are attached onto streptavidin-coated microtitre wells for hybridization. After a denaturation step, the hybridization reactions are carried out with europium, samarium or terbium-labeled probes. For the interpretation of the results, a MultiCalc can be used. The assays support a direct use of dried blood spots as template material in PCR without any sample pre-treatment steps. Alternatively, isolated genomic DNA can be used as well. To confirm the specificity of the three assays, selected samples were genotyped using sequencing as a reference method. Method comparison with sequencing showed a 100 % concordance in recognizing all the probe specific alleles present.

**Megabase Linkage Disequilibrium in *Canis familiaris*.** *N.B. Sutter*<sup>1</sup>, *H.G. Parker*<sup>1</sup>, *M.A. Eberle*<sup>1</sup>, *E.F. Kirkness*<sup>2</sup>, *E.A. Ostrander*<sup>1</sup>, *L. Kruglyak*<sup>1</sup>. 1) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) The Institute for Genomic Research, Rockville, MD.

The 156 breeds of registered dogs in the U.S. offer an unparalleled opportunity to map genes important in disease susceptibility, morphology, and behavior. Linkage disequilibrium (LD) is of current interest for its application in whole genome association mapping, since the extent of LD determines the feasibility of such mapping. We have measured LD at two loci, neither of which is under obvious selective pressure, in the Golden Retriever, Pekingese, and Akita breeds in order to evaluate the utility of association mapping in the canine. The Golden Retriever was created only 150 years ago from the mixing of several distinct breeds reported to include the Tweed Water Spaniel, Yellow Retriever, Bloodhound, and Irish Setter. The breed as a whole has not experienced any major population bottlenecks. By comparison, the Pekingese is an ancient breed, and its population in the U.S. is purportedly derived from a small number of founders. The Akita has been geographically isolated until this century, when small numbers founded the U.S. population. To create a marker set suitable for measuring LD, we carried out SNP discovery by resequencing major portions of two sequenced BACs. Both BACs map to canine chromosome 14. Five unrelated dogs from each breed were used for SNP discovery; 252 SNPs were found in 130 Kb of sequence. Common SNPs in each breed were then genotyped by resequencing in an additional 15 unrelated dogs. Using the  $D$  and  $r^2$  statistics, we find that in both breeds LD extends with little or no diminution for over 2 Mb at one locus, but does not extend between the two loci (50 Mb). LD in canines appears more extensive than in humans; we are working to characterize its precise extent.

Program Nr: 1571 from 2003 ASHG Annual Meeting

**Knowledge-Driven Selection of SNP Markers for Genetic Association Studies of Complex Diseases.** *H. Avi-Itzhak, F.M. De La Vega.* Applied Biosystems, Foster City, CA.

Applied Biosystems developed a first generation whole-genome, gene-centric reference SNP map for use in candidate-gene, candidate region, and eventually whole-genome disease association studies. The selected candidate SNPs were validated by individually genotyping 180 DNA samples from African-American, Caucasian, Chinese, and Japanese individuals. The current set of validated markers comprises over 120,000 SNPs of high heterozygosity in at least one population available as ready to use 5 nuclease assays with TaqMan MGB probes. The individual genotypes generated thus far in the validation have enabled us to survey the profile of linkage disequilibrium (LD) and haplotype diversity across most gene regions of the human genome. This data offers a foundation for an empirically driven, rational design of association studies according to the specific population and region of the genome of interest. We developed a visualization tool to represent the location of SNPs, genes, and haplotype blocks across both physical and LD maps. These LD maps use a metric unit system developed by Maniatis et al., (PNAS 99: 2228-33, 2002) that reflects the variation in the strength of LD across genomic regions. In the design of association studies, it is often useful to examine the impact of making different choices for variables such as sample size, assumptions on the disease relative risk, mode of inheritance, as well as mutation allele frequency, taking into account the empirically determined patterns of LD at each loci of interest. The summary of power calculations under the assumptions of the common variant/common disease hypothesis is also represented in the visualization. Finally, we developed strategies to show SNP type, population-specific minimum-subsets of SNPs (tagging SNPs), and for identifying regions that will benefit from supplementary SNPs. The visualization tool presented here is intended to guide the cost-effective selection of validated SNP assays for the design of genetic association studies exploiting the a priori knowledge of the LD profile obtained on a reference set of population samples.

**Whole-genome amplification template combined with highly multiplexed SNP typing enables large-scale association studies from archived DNA samples.** *R. Pask, H. Rance, N. Walker, A. Lam, L. Smink, D. Smyth, B.J. Barratt, J.A. Todd.* JDRF/WT Diabetes and Inflammation Laboratory, CIMR, University of Cambridge, Cambridge, UK.

Sustainable DNA resources and reliable genotyping methods are essential to any large genetic association study. In the genetic dissection of common disease it is now recognised that thousands of samples and tens of thousands of markers, mostly single nucleotide polymorphisms (SNPs), will have to be analysed. To help alleviate the burden on DNA stocks and genotyping budgets this imposes, we have investigated Molecular Staging's Multiple Displacement Amplification (MDA) template in combination with Illumina's highly multiplexed BeadArray genotyping technology.

The MDA method for whole-genome amplification provides a uniform representation of all loci tested so far across the genome. After several successful small scale studies, we carried out a 100-SNP evaluation using ABI's Taqman Assay on 88 individuals, directly comparing genomic DNA (gDNA) with MDA, obtaining a concordance rate of >99.7%. The failure rate was acceptable, <2% higher for MDA than for gDNA. We then investigated the compatibility of MDA with Illumina's BeadArray method. We compared MDA to gDNA template by genotyping 86 samples at 345 SNPs. For a subset of 15 SNPs against >3000 samples we compared Illumina-generated genotypes with data generated by other technologies. In the 86-sample MDA versus gDNA comparison, the concordance rate in Illumina data was 98.8%. In the 15-SNP subset there was a concordance rate of 99.6% between Illumina and other technologies. The data Illumina presented was almost complete (>99.9%), however, samples that performed badly, 10.5% for MDA compared to 5.8% for gDNA, were excluded.

Our evaluation demonstrates that Molecular Staging's MDA template is compatible with Illumina's BeadArray technology. In combination, these technologies solve the problems of stock DNA limitations and provide a part-solution to the cost problems of ultra high throughput genotyping.

**Physical and transcript map of the autosomal dominant colobomatous microphthalmia locus on chromosome 15q12-q15 and refinement to a 3.4 Mb region.** *L. Michon*<sup>1</sup>, *L. Morle*<sup>1</sup>, *M. Bozon*<sup>1</sup>, *L. Duret*<sup>2</sup>, *J.-C. Zech*<sup>3</sup>, *J. Godet*<sup>1</sup>, *H. Plauchu*<sup>4</sup>, *P. Edery*<sup>5</sup>. 1) Molecular and Cellular Biology, CNRS, LYON, FRANCE; 2) Biometry and Evolutive Biology, CNRS, LYON, FRANCE; 3) Ophthalmology Service, Hospices Civils de Lyon, LYON, FRANCE; 4) Genetics Service, Hospices Civils de Lyon, LYON, FRANCE; 5) Genetics Unit, Hospices Civils de Lyon, LYON, FRANCE.

Congenital microphthalmia is a developmental disorder characterized by shortened axial length of the eye. We have previously mapped the gene responsible for autosomal dominant colobomatous microphthalmia in a 5-generation family to chromosome 15q12-q15. Here, we set up a physical and transcript map of the 13.8 cM critical region, bounded by loci D15S1002 and D15S1040. This region includes 5 contigs containing 17 novel polymorphic markers and at least 84 genes and 38 retinal ESTs. Physical mapping and genetic linkage analysis in this microphthalmia family allowed the refinement of the disease locus to two intervals in close vicinity, namely a centromeric interval, bounded by microsatellite DNA markers m3 and m17, and a telomeric interval, D15S165-m25, encompassing respectively 0.7 and 2.7 Mb. Thereafter, we excluded three candidate gene, *CKTSF1B1*, *KLF13* and *CX36*. In addition, as a phenomenon of anticipation was suggested by phenotypic and pedigree data, we analyzed 3 trinucleotide repeats located within the telomeric candidate interval and found no abnormal expansion in affected individuals compared to controls. We are now carefully checking new information on chromosome 15 DNA sequence annotation in order to identify the disease-causing gene.

**Efficient Construction of User Specified Genetic Maps Based on Publicly Available Physical and Genetic Map**

**Data.** *A. Pluzhnikov*<sup>1</sup>, *W. Wen*<sup>1</sup>, *S. Luban*<sup>2</sup>, *Y. Chen*<sup>1</sup>, *N.J. Cox*<sup>1</sup>. 1) Department of Human Genetics, The University of Chicago, Chicago, IL; 2) Department of Computer Sciences, Purdue University, W. Lafayette, IN.

Creating accurate fine scale genetic maps is a crucial step in human genetic analysis. We have developed a fast and efficient set of tools that enables a user to generate a genetic map for a specified set of markers. The tools consist of programs (Perl scripts) and data sets containing the current version of human genome assembly STS and RefSeq gene maps (downloaded from [genome.cse.ucsc.edu](http://genome.cse.ucsc.edu)) and two commonly used genetic maps (Marshfield and deCode) in a flat file format, as well as the files containing Marshfield's cryptic duplicate marker names and alias names for all markers in the STS map. As a preliminary step, comprehensive joint physical/genetic maps were constructed for both Marshfield and deCode markers (available at <http://hg-wen.uchicago.edu/maps>) comprising 97% of Marshfield and over 99% of deCode markers. A marker name supplied by the user is matched against these maps to obtain the physical location of the marker and its coordinate in one or both of the genetic maps, if available. If a match is not found, we proceed by trying to match any of the available aliases or cryptic duplicates associated with this marker. Those markers that are not found can still be located in the physical map, and their genetic map location be interpolated using the genetic and physical map coordinates of two closest flanking markers. It should be noted that the procedure is purely deterministic. The resulting map can be used on its own, or as a starting point to improve convergence and accuracy of likelihood-based algorithms for map construction, e.g. CRIMAP.

All data are stored and accessed locally rather than online thus greatly reducing execution time and allowing for more flexibility in exchange for a tolerable increase in memory and disk space usage (< 30 Mb in total).

**Sizing of long DNA fragments by capillary gel electrophoresis: Practical issues for genetic analysis.** *M. Dobbs, B. Archer.* Biomedical Research Division, Beckman Coulter, Inc., Fullerton, CA.

Most STRs can be genotyped by analyzing amplicons of less than 500 nucleotides in length. There are a number of applications, however, where reproducible sizing of longer fragments is required. Three of the major sources of difficulty in the sizing of longer DNA fragments are:

- Insufficient electrophoretic resolution

- Migration effects due to sequence differences between unknown samples and size standards

- Size standard curve-fitting limitations

A group of highly polymorphic STRs was initially typed on a set of random human genomic DNAs using closely flanking primers, and then with more distantly flanking primers. A comparison of allele fragment sizes between closely flanking and distantly flanking primers demonstrated reproducible and consistent size estimates to nearly 1000 nucleotides when analyzed by capillary gel electrophoresis. Several different curve fitting models and strategies were examined for effectiveness in precise DNA fragment sizing and binning on Beckman Coulter's genetic analysis system. In general, a subset of size standards that most closely flanked the size range of interest enabled the best curve fitting. The ability to reproducibly estimate the sizes of fragments up to 1000 nucleotides in length has implications for sizing longer STRs as well as for multiplex primer design and data analysis. Several practical considerations in performing the sizing will be discussed.

Program Nr: 1576 from 2003 ASHG Annual Meeting

**A Comparison of Multiple Microarray Platforms for Gene Expression.** *S. Nelson, B. Merriman.* Rm 5506b Gonda, UCLA Medical Ctr, Los Angeles, CA.

There are currently a variety of microarray platforms available for doing whole genome gene expression measurement. A new Microarray Consortium sponsored by the NINDS and NIMH has been chartered to provide expedient access to such technologies for sponsored researchers. As a first phase of this effort, we Consortium members have undertaken a large scale comparison of the currently available technologies, in order to characterize the levels of repeatability, accuracy, sensitivity and agreement between the diverse platforms. In this report, we summarize our findings. The study is based upon assaying aliquats from the same four total RNA samples (samples derived from bulk Human Liver, Kidney, and Spleen, plus the Stratagene Human Reference pool) on diverse platforms, each sample done in triplicate, with the assays carried out at centers/facilities well-versed in the respective techniques. The platforms include whole genome pre-fabricated oligo arrays from Affymetrix, Agilent and Amersham, plus custom spotted arrays from whole genome oligo sets from Operon, ClonTech and Sigma, plus 33,000 clone custom spotted cDNA arrays. In addition to testing for repeatability and consistency, independent validation of accuracy and sensitivity is provided by assaying the same samples via large scale quantitative RT-PCR (over 1000 genes assayed by the Standard Expression Measurement Center), targeted RT-PCR on the 100 genes most discordant between microarray platforms, and SAGE analysis (a form of direct molecular transcript counting). We summarize the many dimension in which these approaches agree and disagree, although overall there is good repeatability and concordance between the major commercially fabricated microarray platforms, as well as spotted cDNA arrays.

**FVBS/Ant, a sighted variant of the FVB/N strain suitable for behavioral analysis.** *R.F. Kooy<sup>1</sup>, V. Errijgers<sup>1</sup>, I. Gantois<sup>1</sup>, G. Nagels<sup>2</sup>, A.W. Grossman<sup>3</sup>, P.P. De Deyn<sup>2</sup>, R. D'Hooge<sup>2</sup>.* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Dept Neurochemistry and Behavior, Univ Antwerp, Belgium; 3) Beckman Institute, University of Illinois, Urbana-Champaign, IL, USA.

Mice of the FVB/N strain are severely visual impaired as a result of genetic defects in the tyrosine kinase gene and the cGMP phosphodiesterase gene, resulting in albinism (*c/c*) and retinal degeneration (*rd/rd*), respectively. Nevertheless, FVB/N mice are commonly used for the generation of transgenic animals because of their large, strong pronuclei and high breeding performance. However due to visual impairment of the FVB/N animals, the resulting transgenic animals cannot be used in tests that depend on vision, including tests of cognitive behavior. Therefore we have bred a sighted version of FVB/N by intercrossing the FVB/N strain with 129P2/OlaHsd followed by repeated backcrossing with FVB/N mice while selecting against albinism and homozygosity of the retinal degeneration mutation. After 11 generations of backcrossing, sighted animals were intercrossed to generate the congenic FVBS/Ant strain, that is pigmented (*c-ch/c-ch*) and devoid of the genetic predisposition to retinal degeneration. The visual abilities of the FVBS/Ant mice were demonstrated by eye histology, a clear visual evoked potential in response to light stimuli and by increased performance in the Morris water maze test.

**Microarray-based molecular diagnosis of calpainopathy.** *M. Bakay, Y. Chen, E.P. Hoffman.* Center for Genetic Medicine, Children's National Medical Center, Washington, DC.

Most monogenic defects have straightforward molecular diagnostic tests. In the muscular dystrophies, biochemical testing of biopsies has remained one of the front line methods of providing a molecular diagnosis, however one of the more common muscular dystrophies (LGMD2A; calpainopathy) has proven difficult to diagnose with either DNA or protein-based tests. Indeed, there are no clinical or research services for providing a diagnosis for this most common form of limb-girdle muscular dystrophy.

To develop a novel molecular diagnostic approach, we hypothesized that an RNA-based expression signature might prove to be a diagnostic method of choice for the calpainopathies. Towards this end, we have expression profiled 54 muscle biopsies with Affymetrix U133A chips for a series of muscular dystrophies (BMD, DMD, FKRP, Dysferlinopathy, and Calpainopathy with 5, 9, 7, 9, and 12 samples in the group respectively) and normal control group (12 samples) to derive a specific expression signature potentially diagnostic of calpainopathies. Both MAS5.0 and dChip probe set analysis software were used. We also compared data both before and after streptavidin-phycoerythrin amplification of microarrays.

The calpainopathy profiles showed significant signatures, although they varied dependent on analysis method (12 diagnostic genes by dChip and 61 by MAS5.0). These calpainopathy-specific genes are likely to shed light on the pathophysiology of this disorder, while also permitting test of RNA-signature-based molecular diagnostics. The sensitivity and specificity of the microarray analysis methods will be presented, as well as the effectiveness of the signature of identifying LGMD patients harboring calpain III mutations.

**Muscle specific transcriptional changes in nemaline myopathy mice.** *D. Sanoudou<sup>1</sup>, M.A. Corbett<sup>2</sup>, J.N. Haslett<sup>1</sup>, M. Han<sup>1</sup>, L.M. Kunkel<sup>1</sup>, E.C. Hardeman<sup>2</sup>, A.H. Beggs<sup>1</sup>.* 1) Dept Genetics, Enders 5, Harvard Med Sch/Children's Hosp, Boston, MA; 2) Children's Medical Institute, Wentworthville, Australia.

Nemaline myopathy (NM) encompasses a clinically and genetically heterogeneous group of disorders characterized by nemaline rods and skeletal muscle weakness. Mutations in 5 sarcomeric thin filament genes (including alpha-tropomyosin) have been identified. We previously reported significant transcriptional changes in glycolytic pathway, muscle satellite cell and connective tissue related genes, in NM patients skeletal muscle.

Using Affymetrix U74Av2 GeneChips we analyzed the expression patterns of ~12,000 probe sets in 5 different skeletal muscles of transgenic alpha-tropomyosin-slow (Met9Arg) and wild type (wt) mice. For each muscle 8 independent RNA pools (from 3-5 mice each) were generated (4 wt and 4 transgenic). Significance analysis of microarrays (SAM) was used to identify genes with significant expression differences between wt and transgenic muscles.

Dramatic disease related differences were evident between the 5 muscle groups studied in transgenic compared to wt mice. At a false discovery rate <12%, diaphragm had 1,524 significantly changed probe sets while, at the other extreme, extensor digitorum longus had only 4. In diaphragm 99.6% of significantly changed probe sets were underexpressed, yet in all other muscles 100% of altered transcripts were overexpressed. The most similar muscles were tibialis anterior and plantaris, sharing 19 of their altered probe sets. Only two genes were consistently overexpressed across 4/5 muscles: *Ankrd2*, a putative sarcomeric gene, and *Csrp3*, thought to be myogenesis-related.

Determining muscle specific transcriptional changes will point to similarities characteristic of the primary steps in disease pathogenesis. Identifying mouse muscle groups best reflecting the pathogenic transcriptional changes seen in NM patients may serve as a reliable experimental system for further study of disease development and potential evaluation of therapeutic targets.

Program Nr: 1580 from 2003 ASHG Annual Meeting

**Large scale variation scanning using Mismatch Repair Detection (MRD).** *M. Faham, H. Fakhrai Rad, J. Zheng, K. Wong, M. Moorehead, A. Boudreau, J. Eberle, C. Bruckner, H. Jones, M. Jain, T. Willis.* ParAllele BioScience, SoSan Francisco, CA.

In order to directly identify variations involved in complex disorders, we have developed a technology which can be used to search comprehensively for variations in large numbers of genes. This technology which we call Mismatch Repair Detection (MRD) is a multiplexed variation scanning technology capitalizing on the bacterial mismatch repair system. A bacterial strain called the Mutation Sorter Strain has been engineered to be able to sort amplicons from thousands of genic regions (typically exons) into those that are identical to a reference sequence and those that contain variations. The fragment content of these 2 pools can then be identified using a standard tag chip readout. We have demonstrated this technology by investigating a linkage peak in a case/control study for a complex disease. The study examined all coding sequence for 160 candidate genes in 425 patients and controls. For each patient we have tested ~1,000 amplicons making the total number of amplicons analyzed close to a million and the total DNA sequence analyzed ~300 Mb. Using this technology we achieved a throughput of 30 Mb of sequence analyzed per day using 4 FTEs. Results of this scan are presented.

**De Novo Human Germline Mutations: Enhanced Mosaicism for G:C to A:T nonCpG transitions and the first observation of a single nucleotide bi-mutation are consistent with events in early embryogenesis.** X. Li, A. Halangoda, A. Karlea, W. Scaringe, K. Hill, S. Sommer. Molecular Genetics, City of Hope Medical Center, Duarte, CA.

Mutation origins are difficult to delineate. In the largest collection to our knowledge, analysis of 59 mutation origins in the Factor IX gene (F9) showed that Bayesian-based sex ratios of F9 germline mutation vary significantly with mutation type (Ketterling et al. 1999 Hum Genet 105:629). We now double the sample size of F9 origins and triple the sample size when Factor VIII (F8) and Duchenne muscular dystrophy (DMD) mutation origins are added. Among >770 independent mutations in F9, 61 male and 67 female origins and 10 mosaics were determined by direct examination of genomic DNA from the origin individuals blood leukocytes. Dramatic differences occur in the male to female sex ratio of G>A relative to A>G transitions (1.35 vs. 8.9). Six of the mosaics were G>A non-CpG mutations, consistent with the recent observation that nonCpG methylation occurs in early embryogenesis. Interestingly, the first case of a nucleotide bi-mutation was identified. Two different mutations at the same base position were identified in a hemophilia A probands mother (395A>C) and maternal aunt (395A>G). The maternal grandfather, the mutation origin, shows a nucleotide bi-mutation, carrying the normal and two mutant alleles. Relative to the normal A allele, the C and G mutations in the grandfathers blood leukocytes are about 1/10 and 1/160, respectively. Nucleotide bi-mutations with one allele at such a low frequency would not be commonly detected yet may be frequent. This observation is consistent with a highly mutagenic DNA adduct or lesion present in the zygote. Analysis of F8 and DMD origins shows similar sex ratios of mutation for different mutation types. The origin data from these X-linked genes, in combination, allow a robust appraisal of the circumstances in the human germline under which certain mutational events occur.

**Do spontaneous multiple mutations cluster?** *S. Sommer, J. Wang, K. Hill, X. Li.* Dept Molecular Gen, 2nd Floor, City of Hope, Becker Res Inst, Duarte, CA.

Multiple mutations are sometimes found in patients when all gene regions of likely functional significance are examined. In 1000 consecutive hemophilia B families and 772 independent mutations, three families with two likely causative mutations in the human factor IX gene were identified. Analysis of the mutation origin in two families showed that both mutations occurred in the same germline. Transmission of a second germline mutation is enhanced about 1700-fold relative to the chance occurrence of two mutations. Interestingly, the two doublets involving single nucleotide mutations show closely spaced events (9 and 356 nucleotides separation in a 32 kb region). Similarly, a high rate (about 660-fold) of enhancement is observed for somatic multiple mutations measured by the Big Blue transgenic mouse mutation detection system. The spacing between mutations in lacI mutants is also generally close. The frequency and proximal spacing of spontaneous multiple mutations are consistent with a co-ordinate mutational event. Clustering of multiple mutations was further assayed directly by sequence analysis of an additional 5.3 kb in multiple regions adjacent to the lacI transgenic mutation reporter. Mutants with non-tandem and tandem multiple mutations (66 and 69 mutants, respectively) were examined for additional mutations relative to control mutants with single mutations (135 singlets). Ten additional mutations were identified in six doublets/multipliants, two were found in 66 tandem mutations, while none was found in 135 singlet mutants. Three of the mutants have multiple clusters of mutations: mutant one, a 4 bp new cluster 1477 bp from the original 177 bp cluster; mutant two, a new 113 bp cluster 1411 bp from the original 2 bp cluster; and mutant three, a new 76 bp cluster 1993 bp from an original 391 bp cluster (i.e., there are clusters of mutation clusters). A subset of closely spaced doublets has additional doublets. More sequence is being analyzed. These observations are consistent with the co-ordinate occurrence of spontaneous multiple mutations by a mammalian polymerase that is innately error-prone or in a transient error-prone condition.

**Moving Pharmacogenetics to the Forefront of Modern Medicine: Identifying the Players and Solving the Bottlenecks.** *F.W. Frueh*. Managing Partner, Stepoutside Consulting, LLC, Gaithersburg, MD.

Every year, more than 100,000 deaths occur in the United States that can be attributed to severe adverse drug reactions. Associated with these events are annual health care costs of approximately \$200 billion. At the same time, individualized medicine promises a safer and more effective drug therapy based on the identification and evaluation of key genetic factors present in the patients genome. Even though pharmacogenetics, touted to deliver personalized medicine, has progressed from academic laboratories to large pharmaceutical companies, the research has not yet reached the consumer. The question therefore remains: Why is pharmacogenetics not moving more quickly to the forefront of modern medicine?

In this report, we identify and characterize the players and the steps in the process to illustrate the challenges that need to be overcome and to propose solutions. The key players include (1) the biotechnology industry, including bioinformatics and toolmakers, (2) the pharmaceutical industry, (3) regulators, (4) health care providers, (5) hospitals and physicians, and (6) the patients. Factors to be addressed include standardization of tests, guidelines created by regulators and legislature including the identification and elimination of ethical issues, and the education of physicians and patients. For example, important criteria for an economically feasible introduction of pharmacogenetic testing include the scientific merit and predictive value of the test, the price per test, and the reimbursement through health care providers. The pharmaceutical industry is using pharmacogenetics in the drug development process since a number of years, but without guidelines on how to submit such data to the regulators. The recent announcement by the FDA to release guidance on pharmacogenetics is generally welcomed and a step towards technology standardization and encouragement for the pharmaceutical industry to embrace the challenge for developing better and safer drugs. This and other examples are presented and criteria for each of the key players are identified, prioritized and evaluated.

**Genotyping of single nucleotide polymorphisms by single-base extension and separation by denaturing high performance liquid chromatography.** *P. Chen*<sup>1</sup>, *E.K. Kohlmeir*<sup>1</sup>, *E.H. Cook*<sup>1,2</sup>, *S. Das*<sup>1</sup>. 1) Human Genetics, University of Chicago, Chicago, IL; 2) Psychiatry, University of Chicago, Chicago, IL.

The number of methodologies for the genotyping of single nucleotide polymorphisms (SNPs) has exploded in recent years. While several different methodologies for SNP genotyping exist, no single methodology has been effectively used for all SNPs assayed. We have been using and developing single-base extension in combination with denaturing high performance liquid chromatography (SBE-DHPLC) for the genotyping of several pharmacogenetically relevant SNPs in the field of anti-cancer agents. To date, we have genotyped twenty different SNPs by SBE-DHPLC in the following genes: *CES2*, *UGT1A1*, *UGT2B7*, *MDR1*, *VitD receptor*, *RFC*, *GSTP1*, *MTHFR*, and *HNF-1*. In order to increase the efficiency and throughput of the SBE-DHPLC technique, we have developed duplex PCR and SBE reactions for several of the SNPs genotyped. We have most recently performed a pooled analysis of SBE products allowing successful genotyping of three SNPs in the *CES2* gene simultaneously, per sample. We are currently working on genotyping 4-5 SNPs simultaneously by SBE-DHPLC for novel SNPs identified in the *UGT2B7* gene. The SBE-DHPLC method of genotyping, while not suited for large-scale genotyping, is very well suited for small and medium-scale genotyping projects (up to ~500 samples) and the ability to perform multiplex SBE-DHPLC will result in an increased throughput and decreased cost per genotype. An advantage of the SBE-DHPLC method over other genotyping methods that use labeled primers is the ability to genotype accurately SNPs that contain more than two different alleles. This was important for a SNP in the *MDR1* gene at nucleotide position 2677 where three different alleles were detected. The greatest advantage of the SBE-DHPLC method in our experience is the robustness of the assay and its successful use for genotyping of all conventional SNPs tested in our laboratory to date. Results of our data will be presented and factors important for genotyping by multiplex SBE-DHPLC will be discussed.

Program Nr: 1585 from 2003 ASHG Annual Meeting

**A whole genome amplification strategy for pharmacogenetic studies.** *S. Marsh, C.M. Rose, H.L. McLeod.* Molecular Oncology, Washington University, St Louis, MO.

The recent explosion of information in publicly available polymorphism databases, and the accompanying technology for high throughput genotyping, is a major boon for pharmacogenetic studies. Analysis of single nucleotide polymorphisms with the goal of identifying markers for drug response is no longer limited by the availability of information, rather the finite supply of patient DNA samples. We have used degenerate oligonucleotide primed PCR (DOP-PCR) to prolong the life-span of clinical samples. Using the original DOP-PCR method we assessed 14 different polymorphisms by Pyrosequencing from 12 different chromosomal locations on 10 different chromosomes. With 1ng of DNA there was an overall 7% failure rate of the genotyping assays. Previous studies have found DOP-PCR techniques to over and under-represent areas of the genome. A novel DOP-PCR method using 3 degenerate primers to improve genome representation has recently been described. For each sample, three 20ul DOP-PCR reactions are carried out using three different DOP-PCR primers and 0.5-1ng of DNA. PCR products from the three reactions are pooled. Using this method we assayed markers of pharmacogenetic significance using Pyrosequencing. In addition, Pyrosequencing was carried out on the same samples prior to DOP-PCR amplification. 100% concordance was seen for both the pass rate and results for all samples analyzed. DOP-PCR is a reliable method to prolong the use of clinical samples. Using three different degenerate primers allows for greater genome representation. This technique is highly adaptable to all sources of genomic DNA, including DNA extracted from blood, serum, plasma and fixed tissues.

**Construction of a physical map for human-chimpanzee Y chromosome comparative analysis.** *Y. Kuroki<sup>1</sup>, T.D. Taylor<sup>1</sup>, A. Toyoda<sup>1</sup>, H. Watanabe<sup>1,2</sup>, T. Yamada<sup>3</sup>, S. Morishita<sup>3</sup>, T. Itoh<sup>4</sup>, M. Hattori<sup>1,5</sup>, Y. Sakaki<sup>1,3</sup>, A. Fujiyama<sup>1,6</sup>.*  
1) RIKEN Genomic Sciences Center, Yokohama, Japan; 2) Nara Institute of Science and Technology, Nara, Japan; 3) University of Tokyo, Tokyo, Japan; 4) Mitsubishi Research Institute Inc., Tokyo, Japan; 5) Kitasato University, Sagamihara, Japan; 6) National Institute of Informatics, Tokyo, Japan.

The completion of the human genome sequence allows us to compare genome sequences between human and other species. Comparative genome analysis of human and its closest relative, the chimpanzee, will reveal critical regions which are conserved between the two species or are species-specific. Previously, we have made a human-chimpanzee whole genome comparative analysis\* to begin to understand human-specific characteristics. This study, which placed 52,881 chimpanzee BAC clones on the whole human genome, showed that the degree of conservation of the Y chromosome sequence in human-chimpanzee was much lower in comparison to the other chromosomes.

To address the question of lower coverage of the Y chromosome, we have started comparative analysis between human and chimpanzee Y chromosomes. By using the human Y chromosome sequence, we have designed 300 STSs and screened them against both genomes. The results revealed that some of the male-specific STSs showed human-specific amplification. We are constructing the chimpanzee Y chromosome map from a whole-genome BAC library and a Y-specific fosmid library, both of which were made from a single male chimpanzee. The chimpanzee Y chromosome-specific fosmid library is estimated to cover 20X of the chimpanzee Y chromosome. Furthermore, the sequencing of 800 chimpanzee Y fosmid clone ends is currently in progress. In this analysis we have found that some fosmid clones do not map to any human chromosomes by FISH, although they clearly map to the chimpanzee Y chromosome. This indicates that these clones contain sequences specific to the chimpanzee Y chromosome.

**Fine Mapping of Genes Deleted on Mouse Chromosome 18 in Hepatocellular Carcinoma, and Relationship to Human Chromosome 5q.** *J. Hozier*<sup>1,2</sup>, *L. Davis*<sup>2,3</sup>. 1) Dept. Pathology, Univ New Mexico, ABQ, NM; 2) Applied Genetics Labs, Inc. Mellbourne, FL; 3) Exagen Corp., ABQ, NM.

The B6C3F1 mouse is used worldwide to gauge the carcinogenic hazard posed to humans by chemical agents. Evaluation of this model for predicting human neoplasia requires a comparison of the genetics of tumor development between the two species. In previous work we used simple sequence repeat (SSR) loci to find regions of loss of heterozygosity (LOH) that might be associated with tumor suppressor gene function in liver tumors of B6C3F1. In that study we found recurrent LOH associated with hepatocellular carcinoma (HCC) on chrs. 2,5,8,9,14 and 18. In the study described here we have determined the critical region on chromosome 18 using a denser set of 14 SSR markers. We analyzed the chr.18 LOH region for frequency and size of deletions, gene content, and the orthologous genomic region on human chromosome 5q, and found the following: 1.LOH on mouse chr.18 occurs in about 30% of the tumors studied with the denser SSR set, compared to 3.5% found with the original set of chr.18 SSR markers. That is, most LOH events on mouse chr.18 are subchromosomal. 2.The minimum size of the LOH as measured with the denser SSR marker set is about 1.4 Mb. 3.This region of mouse chr.18 contains 5 known genes and a small number of relatively uncharacterized expressed sequences, which become candidates for tumor suppressor loci in mouse HCC. 4.By comparing the mouse chr.18 LOH region with the orthologous region on human chromosome 5q, using the comparative mapping functions available in the Golden Path (UCSD) and Ensembl genomic databases, we find that the minimal region of LOH on mouse chr.18 has been conserved intact in the human genome, but an evolutionary breakpoint has occurred within about 100kb of one end of this region, placing the HCC minimal region in a different genetic environment in the human (relative to mouse) genome. In the context of loss of tumor suppressor gene function caused by deletion of fairly large regions of the genome, deletions associated with particular tumors may affect different sets of genes in two species due to evolutionary shifts in the linear organization of genes.

**A Novel Method for Molecular Haplotyping Combining an Improved AS-PCR Technique with Base Specific Cleavage of Nucleic Acid Analyzed by Mass Spectrometry.** *M. Beaulieu, D. Kosman, M.R. Nelson, D. van den Boom.* Sequenom Inc., San Diego, CA.

Haplotypes, the units of inheritance, can provide additional power in detecting disease association. Here we describe a novel approach that enables direct molecular haplotyping of multiple polymorphic markers in a single reaction. To perform haplotyping the chromosomes must be isolated prior to genotype analysis. Allele-Specific PCR (AS-PCR) is a popular method to selectively amplify a locus from the desired allele/chromosome from which genotypes data can be inferred into haplotypes. However, available AS-PCR methods are often leaky, leading to ambiguous results. We have developed a novel AS-PCR technique to improve specificity. A non-extendable and exonuclease resistant competitor oligonucleotide is added to the reaction. The latter feature allows the use of proofreading polymerases permitting long-range AS-PCR. We called this novel strategy: Non-Extendable Exonuclease Resistant AS-PCR (NEER-AS-PCR). The amplicons can be used as template for genotyping assays. We have used quantitative base extension reactions, using MassEXTEND, and demonstrated significant reduction in leakage when using 10-fold excess of the competitor. Regions from the CETP gene locus were analyzed to assess accuracy. For multiple marker haplotypes, markers usually must be genotyped individually. To circumvent this issue we combined NEER-AS-PCR with base-specific cleavage of nucleic acid (MassCLEAVE method). The NEER-AS-PCR product was subject to in vitro transcription and cleaved in four reactions. The cleavage products were analyzed by MALDI-TOF MS generating sequence specific mass signal patterns. Cross-comparison of theoretical and experimental mass pattern allowed haplotype determination. We applied this method to the determination of molecular haplotypes in the CETP gene and provide a comparison to haplotypes inferred from individual genotyping. Because the analysis is not exclusive to known markers, novel variations associated with sub-haplotypes were discovered. Combined with MALDI-TOF MS this method allows the generation of comprehensive haplotype information at un-precedented speed and accuracy.

**A multiplexed ultra-high throughput genotyping platform based on the oligonucleotide ligation assay: Design pipeline, conversion rate, and genotyping accuracy.** *J.P. Day<sup>1</sup>, R.T. Koehler<sup>1</sup>, N. Peyret<sup>1</sup>, C. Scafe<sup>1</sup>, R. Lippert<sup>1</sup>, M. Rhodes<sup>1</sup>, J. Ziegle<sup>1</sup>, K.C. Hayashibara<sup>1</sup>, C. Chen<sup>1</sup>, M. Wenz<sup>1</sup>, K. Hennessy<sup>1</sup>, E.G. Spier<sup>1</sup>, D. Gordon<sup>2</sup>, F.M. De La Vega<sup>1</sup>.* 1) Applied Biosystems, Foster City, CA; 2) Rockefeller University, NY, NY.

The feasibility of whole-genome genetic association studies requires the ability to accurately genotype hundreds of thousands of SNPs in thousands of samples at a reasonable cost. Applied Biosystems has developed the SNPLex System; a multiplexed ultra-high throughput genotyping platform based on the oligonucleotide ligation assay (OLA) which utilizes capillary electrophoresis as the detector. This platform has several advantages: the OLA has been previously shown to be an accurate and robust assay which requires only a small amount of genomic DNA samples; no locus-specific PCR is required; multiplex levels of up to 96 assays per tube are expected on the first generation; and the endpoint readout in a Applied Biosystems 3730xl 96 capillary electrophoresis instrument can resolve 9,216 genotypes per 15 min run, or over 500,000 genotypes per day. Since high-throughput capillary electrophoresis instruments are common in laboratory settings for use in sequencing applications, the technology adoption is very fast and cost effective. An algorithm pipeline was developed for the design of the assays, including the OLA probe designs and the multiplex pooling scheme. Steps are taken to identify and remove SNPs in repetitive and duplicated regions, to select the optimal strand to target probes, and to avoid deleterious probe interactions and spurious ligation templates. Statistics of the in silico assay design, successful assay conversion, and genotype call rates are presented. Using as a baseline for comparison the genotypes from high quality dideoxy sequencing allele calls (over 1,000 SNPs with genotypes in at least 14 samples), the accuracy and genotype misclassification rates of the 5 nuclease and the SNPLex assays are compared.

**Improving the odds in comparative sequence analysis Mass spectrometry for sensitive detection of sequence variations.** *C. Honisch<sup>1</sup>, M. Ehrich<sup>1</sup>, N. Storm<sup>2</sup>, S. Bocker<sup>3</sup>, M.R. Nelson<sup>1</sup>, P. Stanssens<sup>4</sup>, M. Zabeau<sup>4</sup>, D. van den Boom<sup>1</sup>.* 1) SEQUENOM Inc., 3595 John Hopkins Court, San Diego, CA 92121,USA; 2) SEQUENOM GmbH, Mendelssohnstr. 15d, 22761 Hamburg, Germany; 3) Technische Fakultaet Universitaet Bielefeld, AG Genominformatik, Bielefeld, Germany; 4) Methexis Genomics NV, Technologiepark 4, B-9052 Zwijnaarde, Belgium.

With the sequencing phase of the Human Genome Project completed, researchers have been stepping into the next endeavour of elucidating the genetic code and its interindividual variation.

We introduce a novel scheme for high-throughput comparative sequence analysis by MALDI-TOF mass spectrometry.

A single-stranded copy of a PCR amplified target sequence of interest is generated by in vitro transcription and cleaved in four reactions at positions corresponding to each of the four bases. The cleavage products are analysed by MALDI-TOF mass spectrometry generating four sequence specific mass signal patterns.

Reference sequences are used to construct an in silico cleavage pattern enabling cross-comparison of theoretical and experimental mass patterns. Pattern identity results in sequence validation. Pattern deviations in form of additional and missing signals allow for the detection, identification and localization of sequence changes. Data of the four separate cleavage reactions substantiate redundancy and reliability of results.

The combination of mass spectrometry with base-specific cleavage offers significant advantages in speed and accuracy of data acquisition.

The expansion of the portfolio of available molecular methods by base-specific cleavage and mass spectrometry is a significant milestone in the field of comparative genomics and genetics and opens new routes in the detection of epigenetic modifications - DNA methylation analysis. Mutation detection and pathogen identification are additional fields of application.

Program Nr: 1591 from 2003 ASHG Annual Meeting

**Construction of SNP marker sets for genome-wide association studies.** *G.E. Marnellos, S. Kammerer, M.R. Nelson, C.R. Hoyal, A. Braun.* Sequenom Inc., San Diego, CA.

DNA sequence variations between individuals are an important tool for identifying genetic contributions to disease. Single nucleotide polymorphisms (SNPs), with their dense distribution across the genome, are excellent markers for association studies. We have created working assays for over 200,000 publicly available putative SNPs in gene regions and tested them on pooled DNA samples from 94 CEPH Caucasians with a method based on primer extension and MALDI-TOF mass spectrometry. More than 100,000 SNPs mapping uniquely onto the genome were found to be polymorphic with minor allele frequency greater than 5%. These polymorphic SNPs cover the genome with a density that reflects the distribution of genes.

In order to create sets of SNP markers for genome-wide association studies, we developed an algorithm to select subsets of these polymorphic SNPs with more regular spacing and satisfying other criteria, such as proximity to genes, location in coding versus non-coding regions, and high minor allele frequency. The algorithm sets up regularly spaced posts at a specified density across the genome, identifies the SNPs within each post neighborhood, ranks them by the above criteria and by their distance to the post, and picks the top-ranking SNP in each neighborhood. Using this algorithm we have selected sets of about 25,000 and 50,000 SNPs located within 10Kb of more than 65% of known and predicted genes. These marker sets have been used successfully in 12 genome-wide scans for common diseases and quantitative traits, including breast, lung and prostate cancers, type II diabetes, hypertension and HDL-cholesterol levels.

As more public SNPs and annotation become available, we are using the algorithm to update and expand our SNP sets and fill gaps as needed, focusing primarily on gene regions; the goal is to have a SNP every 10Kb within all currently known and predicted genes. For SNPs not yet validated, our algorithm selects SNPs with features we have found to predict polymorphic SNPs. When haplotype maps become available, that information will also be used to select the most informative SNPs for genome-wide association.

**Association of the 4qA allele with Facioscapulohumeral Muscular Dystrophy (FSHD) in British and Turkish Populations.** *M. Upadhyaya*<sup>1</sup>, *K. Wiseman*<sup>1</sup>, *P. Serdaroglu*<sup>2</sup>, *M. MacDonald*<sup>1</sup>. 1) Dept Medical Genetics, Univ Wales Col Medicine, Cardiff, UK; 2) University of Istanbul, Istanbul, Turkey.

Facioscapulohumeral muscular dystrophy is an autosomal dominant disorder affecting one in 20,000 and is caused by the deletion of D4Z4 repeat units located to 4q35. Recently a polymorphism in the -satellite repeats distal to the D4Z4 repeat units on chromosome 4, with two allelic forms (4qA and 4qB), has been identified. Allele 4qA was found to co-segregate with FSHD-specific short D4Z4 alleles in the Dutch population. In the normal population, both polymorphic alleles (4qA/4qB) are present in equal frequency. In order to ascertain whether the 4qA allele segregates with the small FSHD allele in different populations, we have studied a panel of 65 unrelated FSHD individuals, of whom 50 were British and 15 were of Turkish origin. Fifty unaffected individuals of mixed origin were also examined as controls. High molecular weight DNA was extracted from blood samples, and p13E-11 short fragments were identified by digestion with the restriction enzymes *EcoRI*, *XapI* and double digestion with *EcoRI* and *BlnI*. DNA was resolved using pulsed field gel electrophoresis. The Southern blots were hybridised with radiolabelled 13E11 probe and visualised by autoradiography. To study the distribution of alleles 4qA and 4qB, DNA samples were digested with the restriction enzyme *HindIII*, and the Southern blots were hybridised consecutively with probes specifically designed to illuminate alleles 4qA and 4qB (probes A and B). In all 65 affected individuals, allele 4qA was always found to segregate with the FSHD specific small fragments identified with the probe 13E-11. In contrast an equal frequency of alleles 4qA and 4qB was observed in the un-affected control individuals. This study confirms the specific association of the allele 4qA with the FSHD disease allele in both British and Turkish populations. This study not only contributes to the molecular biology of FSHD but will also refine the molecular diagnosis for FSHD in the patients with borderline short *EcoRI/BlnI* fragments. These findings further emphasise that allele 4qA may well have some functional relevance in the pathophysiology of FSHD.

**Detection of gene variants utilizing Surveyor CEL Nuclease Detection Technology and various DNA separation platforms.** *J.G. Rudolph III<sup>1</sup>, J. Durocher<sup>1</sup>, J. Breen<sup>1</sup>, B. Walters<sup>1</sup>, P. Qiu<sup>2</sup>, H. Shandilya<sup>2</sup>, J.M. D'Alessio<sup>2</sup>, S. Lilleberg<sup>1</sup>, G.F. Gerard<sup>2</sup>.* 1) Biosciences Discovery Services, Transgenomic, Inc, Gaithersburg, MD; 2) Research and Development Transgenomic, Inc, Gaithersburg, MD.

The discovery of mutations and SNPs within the human genome is a crucial step towards the elucidation of both inherited and spontaneous diseases ranging from schizophrenia to cancer. Identifying genetic variants will provide a better understanding of the underlying causes of specific diseases and, consequently, novel and improved treatments are likely to be discovered. DHPLC (denaturing high performance liquid chromatography) technology has always been an efficient and useful tool for screening candidate genes for these deleterious mutations. There are certain gene sequences however, due to their sequence content, which do not lend themselves to accurate and efficient DHPLC screening. We have developed a fast and efficient alternative known as Surveyor CEL Nuclease Mutation Detection Technology. This enzymatic method is highly sensitive and can be used to detect both known and unknown mutations including all base substitutions as well as insertions/deletions up to at least 12 bases. In addition, there are no limitations placed on the DNA fragment being analyzed, either in total length, position of the mutation, or sequence content of the fragment and multiple mutations within the same fragment can be detected. This system is based on a new class of mismatch specific endonucleases, called CEL Nuclease, which can be used with a variety of DNA detection platforms including the WAVE, manual gel electrophoresis, or automated gel or capillary electrophoresis platforms. The detection of mutations in a number of genes including APC, Kras, and -tubulin, with genomic DNA obtained from a variety of sources including cell lines, human tissue, and lymphocytes is compared. We find that the results obtained using Surveyor correlate closely with those obtained using DHPLC alone, and in some circumstances can be used in a wider variety of situations compared to DHPLC.

Program Nr: 1594 from 2003 ASHG Annual Meeting

**Determination of Y-Haplogroups Utilizing Suspension Arrays.** *D. Carlson, C. Rowe, Z. D'Aoust.* Marligen Biosciences, Inc, Ijamsville, MD.

The purpose of this study was to develop a method for rapid determination of Y-haplogroup of DNA samples. Forty-two Y-chromosome single nucleotide polymorphisms (SNPs) were selected based on their association with a particular ancestral haplogroup. Each polymorphic region was amplified in a multiplexed PCR reaction utilizing primers labeled with a fluorescent reporter dye. Oligonucleotides specific for each allele in the multiplex were immobilized on the surface of latex microspheres containing fluorescent identifiers. Labeled PCR products were then hybridized to the microspheres in multiplexed mode. Reporter dyes and identifier dyes were read simultaneously for each microsphere in a flow analyzer. Allele-calling software (MasterPlexGT, MiraiBio) automated the genotyping. The flow reader required 1.5 hr to analyze 96 wells of multiplexed reactions. The most frequent Y-haplogroups were found to be E1a for African Americans and R1b for U.S. Caucasians. The percentage of admixture of Caucasian Y-haplogroups in the African American samples was slightly more than 30%. Frequency of African markers in the Caucasian samples was less than 5%.

**The UV wavelength-specific role of p53 in transcription-coupled nucleotide excision repair is not through differential binding of the p53 protein to its consensus sequence of downstream effectors such as p21, GADD45, XPC and p48-XPE genes.** *W. Dridi<sup>1</sup>, R. Fetni<sup>2</sup>, E.A. Drobetsky<sup>3</sup>, R. Drouin<sup>1</sup>.* 1) Medical Biol, Hosp St Francois, Laval Univ, Quebec, PQ, Canada; 2) Cytogenetics Montreal Children's Hospital, Montreal, Quebec, Canada; 3) Guy-Bernier Research Center, Maisonneuve-Rosemont Hospital, Montreal, Quebec, Canada.

**Introduction:** In response to UV, p53 degradation is decreased and p53 transcription is activated.. It is also well established that this tumor suppressor regulates nucleotide excision repair (NER) of cyclobutane pyrimidine dimers (CPD), the main UV-induced DNA photoproduct. The role of p53 in transcription-coupled NER (TCNER, a sub-pathway of NER) is UV wavelength dependent (Mathonnet G et al. PNAS 100:7219, 2003), since functional p53 is required for TCNER after irradiation with polychromatic UVB (280-320-nm) but not after 254-nm UVC. **Objective:** We aimed to investigate the mechanism underlying this UV wavelength specificity by using an in vivo footprinting approach in order to determine the kinetics of p53 binding to its consensus sequence along the promoters of downstream effectors such as p21, GADD45, XPC and p48-XPE genes following either UVC or UVB irradiation. **Methods:** Primary human fibroblasts were irradiated with low doses of UVB or UVC. At different time points (0, 60, 120, 240 and 480 min), cells were treated with either one of the three footprinting agents (dimethylsulfate, UVC and DNaseI were used), DNA was purified, and ligation-mediated PCR was carried out for the p21, GADD45, XPC and p48-XPE gene promoters. **Results:** The presence of footprints confirmed the binding of p53 to its consensus sequence at all promoters examined, however no differences were noted in this respect following UVB vs. UVC irradiation. **Conclusion:** The UV wavelength-dependency for p53 in TCNER does not involve differential DNA binding kinetics of p53 to its consensus sequence along the promoters of critical downstream effectors.

**High throughput digital typing of human-specific L1 insertions.** *R.M. Badge*<sup>1</sup>, *J.V. Moran*<sup>2</sup>. 1) Genetics, University of Leicester, Leicester, UK; 2) Human Genetics, University of Michigan Medical School, Ann Arbor, USA.

ATLAS (amplification typing of L1 active subfamilies) is a genomic screening method that selectively amplifies the termini of young L1s and their flanking genomic sequences. Primers directed to active L1 subfamily-specific sequence variants ensures strong enrichment. High resolution gel electrophoresis enables the display of hundreds of amplicons that can be identified by PCR isolation and sequencing. Previously we demonstrated (*Badge et al*, 2003) that ATLAS can successfully identify full length novel (i.e. absent from the reference human genome sequence) human-specific L1s some of which are able to retrotranspose at high frequency in cell culture. One of the characterised insertions, obtained from a screen of only ten unrelated individuals, was apparently private- it was restricted to the individual in which it was discovered. This suggests that such insertions are much more common than previously suspected and that typing of many such insertions could be an effective individual identification method. By combining ATLAS and sequential oligonucleotide hybridisation we have developed a high throughput digital typing method which allows ongoing analysis of novel L1 insertions as they are identified. We present a pilot study on the efficacy of this method by comparison with genotyping data obtained by traditional PCR typing assays. The method is simple, rapid and extensible, and takes advantage of the largely unique sequences generated at the insertion points of full-length human-specific L1 retrotransposons. We demonstrate that it is also possible to "invert" the assay by immobilising the insertion-specific oligonucleotides as a macro or microarray, enabling the simultaneous typing of many loci in a given individual. In addition since the amplicons selectively enriched by ATLAS are short (100-1000bp) DNA integrity is not critical. As a result we have investigated the use of isothermal whole genome amplification to generate templates for ATLAS, potentially allowing the systems application to forensic samples. *Badge RM, Alisch RS, Moran JV. ATLAS: a system to selectively identify human-specific L1 insertions. Am J Hum Genet. 2003 Apr;72(4):823-38.*

**Use of the L1 retrotransposon for functional genomics.** *E.M. Ostertag, J.L. Goodier, J.M. Choi, D.V. Babushok, A.H. Farley, H.H. Kazazian.* Dept. of Genet., U. of Pennsylvania, Philadelphia, PAA.

Previously we described a mouse model of human L1 retrotransposition in which L1 elements retrotranspose in male meiosis. In the most active transgenic line the new insertion rate was estimated by breeding to be 1 in 68 sperm. We had sequenced two insertions and found that they had all the characteristics of endogenous L1 insertions. We have now improved the retrotransposition estimate in this line to 1 in 40 sperm by finding insertions in 5 offspring among 200 tested. Recently, we developed new transgenic lines that had the same L1 element and heterologous promoter. In order to estimate the retrotransposition frequency in these mice without cumbersome breeding, we developed a quantitative PCR method on sperm DNA sufficiently sensitive to detect one retrotransposition event in 1000 sperm. Of 15 new transgenic lines, we found 3 (20%) with retrotransposition frequencies 2-4 fold greater than the previously studied line, or 1 insertion in every 10-20 sperm. Knowing that we can readily obtain transgenic lines with substantial retrotransposition frequencies, we hypothesized that L1 elements would be ideal for use in random mutagenesis. In addition to a high rate of insertions, L1s insert randomly and stably throughout the genome. Importantly, mutagenesis using L1s occurs in the germline without the need to proceed through embryonic stem cells. Therefore, we developed a bi-directional splice acceptor gene trap and showed that it does not interfere with L1 retrotransposition in cultured cells. Using Thermally Asymmetric Interlaced-PCR (TAIL-PCR), we were able to rapidly map 22 of 27 new inserts (81%) in cultured cells. With these new advances, we are proceeding to create new transgenic lines using 1) improved promoters to boost L1 expression in meiosis, 2) a newly-discovered human L1 that is 50% more active than the previously tested element, and 3) a new gene trap cassette to increase the detection rate of new insertions. In the near future, we expect to obtain transgenic lines with one gene trapped in every 5-10 sperm. Since these lines will allow production of gene knockouts by natural reproduction, they should be very useful for mouse functional genomics.

**Evolution of LINEs and great apes genomes.** *G.D. Swergold, S. Chi, M. Ulz, L. Mathews.* Department of Medicine, Columbia University, New York, NY.

Comparisons of gene sequences reveal a high level of conservation between humans and the other great apes despite the existence of large physiological and behavioral differences. This suggests that other types of genomic change may account for some of the phenotypic differences and may have played an important role in the evolution of our species. LINE-1 (L1) retrotransposons have been amplifying throughout the mammalian radiation and comprise ~17% of the human genome but little is known about their biology in the other great apes. We report our investigations into the role of L1s in the evolution of great ape genomes. PCR genotyping of L1PA2-6 insertions in great apes and old world monkeys established the periods of amplification of these subfamilies during great ape evolution. A molecular method (LOAF library construction) was developed to sample great ape genomes for recent L1 insertions. From the proportion of lineage-specific insertions in the libraries we determined that the accumulation of full-length L1s has been 2-3 fold more rapid in *Pan* than in *Homo* since their divergence. We identified and fully sequenced 4 chimpanzee, 5 gorilla and 6 orangutan lineage-specific insertions. One gorilla insertion was polymorphic in the modern lowland gorilla population. A molecular phylogeny constructed using these sequences and a large number of human-specific and shared subfamily L1 insertions indicates that most are quite young and may retain retrotransposition ability. Based on the sequence alignment (and confirmed by PCR amplifications using sequence shared variants) we describe specific L1 subfamilies for each of the major non-human great ape lineages. Phylogenetic analysis also revealed that a large majority of human-specific and *Pan*-specific L1 insertions, as well as a gorilla-specific L1 subfamily descended from a subset of L1PA2 elements. Our data also suggest that certain older insertions that to date have been classified as separate subfamilies may not be distinct evolutionary units. Our results provide a framework for understanding the molecular evolution of L1s in the great apes and their impact upon the evolution of their host species.

**Expansion of GAA triplet-repeats in the human genome: A ticking bomb?** *R.M. Clark*<sup>1</sup>, *G.L. Dalgliesh*<sup>1</sup>, *D. Endres*<sup>2</sup>, *S.I. Bidichandani*<sup>1</sup>. 1) Dept Biochem & Molec Biol, Univ Oklahoma Health Sci Ctr, Oklahoma City, OK; 2) Math & Stats, Univ of Central Oklahoma, Oklahoma City, OK.

Friedreich ataxia is caused by expansion of a GAA triplet-repeat (GAA-TR) in the *FRDA* gene. Normal alleles contain <30 triplets, and disease-causing expansions (66-1700 triplets) arise via hyperexpansion of premutations (30-65 triplets). To gain insight into GAA-TR instability we analyzed all triplet-repeats in the human genome. We identified 988 (GAA)<sub>8+</sub> repeats, 291 with 20 triplets, including 29 potential premutations (30-62 triplets). To compare the observed size distribution of GAA-TR sequences we extended our study to include all other nine possible triplet-repeat motifs. We found that most triplet-repeats were restricted in length to <20 triplets and that GAA-TR sequences were clearly the longest. The reason for the elongation of GAA-TR sequences in the human genome is presently unclear. A theoretical estimation of the expected maximum length for GAA-TR sequences in the human genome indicated that (GAA)<sub>6+</sub> sequences should be extremely rare. Analysis of the flanking sequence showed that 89% of (GAA)<sub>8+</sub> sequences have arisen within large G/A-rich islands, and 58% map within poly-A tails of *Alu* elements. GAA-TR sequences located within evolutionarily old *Alu* J elements were significantly longer than those within younger *Alu* elements, indicating that they have undergone continued expansion throughout primate genomic evolution. Over 40% of the (GAA)<sub>8+</sub> sequences, including five potential premutations with >30 triplets mapped within genes (mostly introns, some in UTR sequence). We identified at least one other GAA-TR sequence that has undergone a similar multi-step expansion process, displaying normal, premutation and expanded alleles as seen at the *FRDA* locus. Therefore, GAA-TR expansions analogous to Friedreich ataxia mutations are not likely to be limited to the *FRDA* locus. These data indicate that GAA-TR sequences have a significant predisposition for undergoing expansions. They have undergone continued expansion throughout primate evolution, resulting in several potentially mutagenic tracts, many of which map within genes and may therefore be potentially disease-causing.

**Defining 6p25 segmental duplication and deletion breakpoints with a high-resolution genomic microarray.** *O.J. Lehmann*<sup>1,3</sup>, *D.M. Beare*<sup>2</sup>, *H. Fiegler*<sup>2</sup>, *C.F. Langford*<sup>2</sup>, *P.T. Khaw*<sup>1,3</sup>, *N.P. Carter*<sup>2</sup>, *I. Dunham*<sup>2</sup>, *S.S. Bhattacharya*<sup>1</sup>, *A.J. Mungall*<sup>2</sup>. 1) Dept Molecular Genetics, Institute of Ophthalmology, London, UK; 2) Wellcome Trust Sanger Institute, Cambridge, UK; 3) Moorfields Eye Hospital, London, UK.

Mutations and dosage changes in *FOXC1* result in ocular and non-ocular developmental anomalies as well as early-onset glaucoma. The existence of 6p25 segmental duplications and deletions encompassing *FOXC1* in multiple unrelated pedigrees, indicates that a common mechanism mediates these chromosomal rearrangements. Having previously determined the approximate extent of these segmental duplications/deletions with microsatellite marker genotyping and fluorescent *in situ* hybridisation, we have constructed a high-resolution genomic microarray extending over 680kb of 6p25, a region that includes the duplicated interval. This tiling path of 544 individual PCR products (mean size 1.25 kb) is being arrayed onto amine-binding slides. The (tiling path) arrays will be interrogated with DNA samples from 5 pedigrees with 6p25 chromosomal anomalies (4 segmental duplications, 1 segmental deletion) in which the breakpoints have been localised to single bacterial artificial chromosome clones. It is anticipated that array analysis will define the position of these breakpoints to regions of less than 5kb, and potentially to within a single PCR product, allowing the sequences mediating these rearrangements to be identified.

**RPGR gene mutations cluster upstream of a degenerated coding polypurine/polypyrimidine minisatellite in exon ORF15.** *I. Bader*<sup>1</sup>, *M. Hergersberg*<sup>2</sup>, *A. Meindl*<sup>3</sup>, *T. Meitinger*<sup>1</sup>. 1) Inst Human Genetics, GSF-Natl Research Ctr, Munich-Neuherberg, Germany; 2) Kantonsspital Aarau, Switzerland; 3) Department of Medical Genetics at the Ludwig-Maximilians-University Munich, Germany.

Mutations in the X-chromosomal RPGR gene account for up to 20% of all cases of retinitis pigmentosa, a figure higher than for any other single locus of the more than 20 different RP loci mapped throughout the genome. This high degree of sequence variation is due to a large 3terminal exon (ORF15) of an alternatively spliced transcript predominantly expressed in retina. It contains a repetitive purine-rich sequence coding for an acidic tail (>250 glutamic acid residues). We performed dot-matrix, tandem-repeat and PCR analyses of the RPGR genomic sequence. Comparative analyses in mouse, cattle and pufferfish indicate that the polypurine/polypyrimidine sequence of exon ORF15 shares features of a minisatellite in all species. These features include a tandem array with repetitive motives ranging in length from 18 bp (*Mus Musculus*) to 39 bp (*Fugu rubripes*) and a length variability of the array detected in control chromosomes of man, mouse and cattle. In addition we looked at the spectrum and distribution of mutations of four comprehensive mutational screens (486 X-linked RP patients, including 58 own cases) and found that the majority of the 106 disease-causing mutations (frameshifts caused by small deletions and nonsense mutations) cluster in the sequence adjacent to the 5' end of the diverged minisatellite. In contrast in-frame sequence variations (~34% of controls) with consequent losses or gains of tandem repetitive units are located throughout the degenerated polypurine/polypyrimidine minisatellite. From this observation we hypothesize the presence of two mutational mechanisms in the human exon ORF15: a) a slipped stranded mispairing mechanism leading to loss or gain of tandem repetitive units and b) a "gratuitous" DNA repair mechanism, triggered by the triplex-formation of the polypurine/polypyrimidine tract inducing enhanced mutagenesis in the flanking sequence.

**The Gene Expression Patterns of Cultured Embryo Rat Cortexes Induced by Hyperphenylalanine.** *X. Gu*<sup>1</sup>, *H.W. Zhang*<sup>2</sup>. 1) Xin Hua Hosp, Shanghai Second Medical University, Shanghai, China; 2) Shanghai Institute for Pediatric Research, ShanghaiChina.

Phenylketonuria is marked by hyperphenylalaninemia and mental retardation, the purpose of this work is to study the expression specturm of cultured embryo rat cortexes induced by hyperphenylalanine and to understand the mechanism of neuronal injury in PKU patients. Cultured embryo rat cortexes for 3 days were randomly assigned to the two groups: hyperphenylalanine and control. Neurons in group hyperphenylalanine were induced by 0.9M hyperphenylalanine for 12 hours. The control group was treated with same volume of medium. Total RNA was extracted and hybridized with the Affymetrix gene chip U34 according to the protocol provided by the Affymetrix Company. Some gene expression results were validated by real-time PCR technique. The expression of 167 probe sets (16,6%) plotted on the chip were increased among the whole of 1323 probe sets, which could be functionally categorized to signal transduction, neuron related, cytoskeleton, metabolism, ion channel, transcription factor, cytokines, apoptosis related and so on. Especially, CaMKRasP38Ca<sup>2+</sup> channel, some genes related to vesical forming, releasing of neurotransmitter, and some glutamate receptors and transportors were up-regulated in the environment of hyperphenylalanine. Seven probe sets were decreased, which account to 0.5% of tested gene. We conclude that the process of neuron injury induced by hyperphenylalanine was multifactorial, hyperphenylalanine could activate the axis of NMDR-Ca<sup>2+</sup>- CaMK- Ras- P38, releasing of neuron transmitter may be abnormal in this condition and neuroexciting transmitter glutamate could take part in the process.

**Identification and detection of the 6.3kb deletion breakpoint in the PAH gene located between L1 and Alu repetitive elements.** *N. Gal<sup>1</sup>, G. Schwartz<sup>1</sup>, R. Loewenthal<sup>2</sup>, Y. Anikster<sup>1</sup>.* 1) Safra children hospital , Sheba Medical Center, Tel Hashomer, ISRAEL; 2) Tissue Typing Unit, Safra Children's Hospital, Sheba Medical Center, Tel-Hashomer, Israel.

Phenylketonuria (PKU), one of the most common autosomal recessive inborn errors of metabolism, is caused by mutations in the gene encoding the hepatic enzyme phenylalanine hydroxylase (PAH). The average incidence worldwide is 1/10,000. However, the incidence varies widely across different geographic areas and ethnic origins. Prevalence is highest in Ireland, western Scotland and among Yemenite Jews (YJ). A founding-father origin of the PKU mutation was found in YJ. Southern-blot analysis of this mutation showed a ~6.7kb deletion spanning the third exon of the PAH gene (Nature, V. 344, p. 168-170, 1990). In order to identify the exact deletion breakpoints we designed PCR primers from the genomic sequence data of the PAH gene (Genebank accession no AF404777). One set of primers amplified an 812bp fragment present only in the deletion alleles. Aligning the breakpoint sequence to the normal genomic sequence revealed a deletion of 6296 bp which included 2317bp of IVS2, 184bp of exon 3 and 3795bp of IVS3. Interestingly, the 5' and 3' breaks occur within the repetitive elements LINE- L1 and SINE-Alu Sx, respectively. This could suggest an explanation of the mechanism involved in the deletion formation. The addition of exon 3 primers (281 bp apart) to the PCR with the deletion primers created a multiplex PCR system, which allows identification of patients with zero, one or two alleles bearing the 6.3kb deletion. This methodology constitutes a significant advance over current detection of the PAH deletion in Yemenite Jews. By using this method we confirmed the high prevalence of the deletion in the YJ community and are able to detect compound heterozygotes in mixed origin families and to offer prenatal diagnosis.

**A Slc7a7 null mouse model of lysinuric protein intolerance.** *M.P. Sperandeo<sup>1,2</sup>, V. Ammendola<sup>1,2</sup>, V. Fiorito<sup>1</sup>, A. Pepe<sup>1</sup>, M. D'Armiento<sup>3</sup>, R. Vecchione<sup>3</sup>, G. Andria<sup>1</sup>, G. Borsani<sup>4</sup>, V. Marigo<sup>5</sup>, S. Banfi<sup>5</sup>, A. Ballabio<sup>5</sup>, G. Sebastio<sup>1</sup>.* 1) Dept. of Pediatrics, Federico II University, Naples, Italy; 2) Dulbecco Telethon Institute, Rome, Italy; 3) Dept. of Pathology, Federico II University, Naples, Italy; 4) Dept. of Biomedical Sciences and Biotechnology, University of Brescia, Italy; 5) Telethon Institute of Genetics and Medicine, Naples, Italy.

Lysinuric protein intolerance (LPI, MIM 222700) is an autosomal recessive defect of cationic amino acids transport at the basolateral membrane of epithelial cells in the intestine and kidney, caused by mutations of the SLC7A7 gene. The unknown pathogenesis of the multisystem involvement of LPI, which includes a life-threatening alveolar proteinosis, and the lack of an effective treatment has prompted the creation of a LPI animal model. A constitutive knockout of *Slc7a7* was generated by random insertional mutagenesis in embryonic stem cells (Lexicon Genetics Inc, Texas). More than 400 *Slc7a7*<sup>+/-</sup> intercrosses led to only one *Slc7a7*<sup>-/-</sup> live male. Since birth, this null animal showed a severe failure to thrive compared to siblings. The null animal, still alive at 12 months of age, shows also a strong reduced fertility compared with <sup>+/-</sup> and <sup>+/+</sup> littermates. It is currently fed on a low protein diet and citrulline supplementation. Five additional *Slc7a7*<sup>-/-</sup> died within the first day of life, all showing severe growth failure. To establish the timing of the apparent lethality of *Slc7a7*<sup>-/-</sup> mice, embryos were collected at E 16.5 and E 18.5 stages, respectively. The proportions of *Slc7a7* genotypes were found as expected for an autosomal recessive transmission. These data suggest that *Slc7a7*<sup>-/-</sup> pups die early in the perinatal period and not during the embryogenesis. Most of *Slc7a7*<sup>-/-</sup> pups were probably lost at birth because of cannibalism. At E 16.5 stage, the *Slc7a7*<sup>-/-</sup> embryos were already smaller than <sup>+/-</sup> or <sup>+/+</sup> sibs. None of the null embryos showed gross morphological abnormalities. In humans, LPI does not cause clinical manifestations until weaning is started, neither increased rate of spontaneous abortion is known. In mice the absence of *Slc7a7* gene might cause an early severe metabolic derangement underlying the intrauterine growth failure.

**A metabolomics-guided screening of ENU mice for mouse models of human metabolic diseases.** *J. Wu<sup>1, 2</sup>, H. Kao<sup>1</sup>, S. Li<sup>1</sup>, R. Stevens<sup>3</sup>, S. Hillman<sup>3</sup>, D. Millington<sup>3</sup>, Y. Chen<sup>1, 3</sup>.* 1) Inst. of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Dept. Medical Research, China Medical College Hospital, Taichung, Taiwan; 3) Department of Pediatrics, Duke University Medical Center, Durham, North Carolina, USA.

Our laboratory has long interests in rapid analysis of metabolites at the whole-organism level (a metabolomics approach), using methods such as tandem mass spectrometry, HPLC and GC/MS. Here we reported the use of tandem mass spectrometry screening for amino acid and acyl carnitine profiles to detect the derangements in the pathways of amino acid and fatty acid metabolism in mice treated with the N-ethyl-N-nitrosourea (ENU). Treatment of ENU efficiently generated single-nucleotide mutation in mice. In a recessive screening of --- G3 mice from --- families, we identified mice with striking elevation of blood branched chain amino acids (BCAAs, valine, leucine/isoleucine 20-30 folds) and mice with elevation of hydroxy-butryl carnitine (C4-OH, 3 to 5 folds). Mice with elevation of C4-OH were clinically asymptomatic, however, mice with elevation of BCAAs were failure to thrive (body weight 60-70% of controls), weak with decreased spontaneous movement, hairs were thin and scanty and luster decreased, and many died before weaning. Urine organic acids showed the presence of -ketoisovaleric acid, -ketoisocaproic acid and -keto-methylvaleric acid; the branched chain ketoacids derived from valine, leucine and isoleucine, respectively. These clinical and laboratory findings resemble human maple syrup urine disease (MSUD) caused by the deficiency of branched-chain alpha-keto acid dehydrogenase (BCKD) complex. Affected mice responded to the MSUD diet low in the BCAAs, with amelioration of the clinical symptoms and normalization of the abnormal amino acid pattern. Our data suggested that the metabolomics-guided screening coupling with ENU mutagenesis is a powerful approach to uncover novel enzyme deficiency / important pathway and to generate mouse models for human genetic metabolic disorders.

**Biochemical and molecular basis of prognosis in nonketotic hyperglycinemia.** *J. Van Hove<sup>1, 4</sup>, V. Mahieu<sup>1</sup>, E. Schollen<sup>1</sup>, K. Vande Kerckhove<sup>1</sup>, J. Hennermann<sup>2</sup>, D. Applegarth<sup>3</sup>, J. Toone<sup>3</sup>, G. Mathijs<sup>1</sup>.* 1) Pediatrics, Catholic University Leuven, Leuven, Belgium; 2) Humboldt University Berlin, Berlin, Germany; 3) University of British Columbia, Vancouver, B.C., Canada; 4) University of Colorado Health Sciences Center, Denver, Colorado.

Nonketotic hyperglycinemia (NKH) is caused by deficient activity of the glycine cleavage system, consisting of the P-, T-, H-, and L- protein. In order to study prognostic determinants in NKH, 15 patients with NKH were categorized according to neurodevelopmental outcome. 8 patients with severe NKH made no developmental progress, required 2 to 4 anticonvulsants, and some had brain malformations. 4 patients with intermediate NKH made developmental progress up to DQ <25, and required 1 or no anticonvulsants. Mild NKH patients made developmental progress beyond DQ 25 following special education, and seizures were controlled with benzoate only. Mild NKH patients tended to have late-onset, and severe to intermediate NKH neonatal-onset, but several exceptions occurred. Low CSF/plasma glycine ratio (<0.08) only occurred in mild NKH. Benzoate therapy dosing was adjusted to achieve steady state low-normal plasma glycine levels; then the whole body glycine balance was calculated from the benzoate dose and the dietary glycine and serine intake, reflecting in vivo glycine cleavage activity. The whole body glycine balance differed between severe NKH (2 to 4.1 mmol/kg/day), and intermediate or mild NKH (< 2 mmol/kg/day). Residual glycine cleavage enzyme activity in vitro did not differ between prognostic categories. 6 patients had T-protein mutations with 11/12 alleles identified. A P-protein mutation was identified in 6 families with 10/12 alleles identified. In 3 patients with severe neonatal NKH, no mutation was identified despite sequencing all exons of the P, T, and H protein genes. The private nature of most identified mutations did not allow relating specific mutations to outcome.

Program Nr: 1607 from 2003 ASHG Annual Meeting

**Overexpression of human alanine:glyoxylate aminotransferase in E. coli.** *M. Coulter-Mackie, Q. Lian.* Dept Pediatrics, Univ British Columbia, Vancouver, BC, Canada.

Primary hyperoxaluria type 1, PH1, results from a deficiency of alanine:glyoxylate aminotransferase (AGT) activity. AGT is a liver peroxisomal enzyme in humans. The AGT gene occurs as either of two normal variants the major and minor alleles, the latter with an allele frequency of about 20% in the general population. We have inserted the cDNAs for both variants into pET vectors where the expression is under the control of the T7 promoter and can be induced with IPTG. E. coli expression is a suitable approach because AGT does not undergo post-translational modification. E. coli does not produce AGT endogenously although it does synthesize the AGT co-factor, PLP. The overexpression of AGT reaches levels of 20-25% of cellular protein. The AGT produced is enzymatically active. The cloned gene has been used to demonstrate the effects of missense PH1 mutations on activity. Normal and mutant AGT products have been compared with respect to their relative affinities for PLP. Normal AGT produced in E. coli has been used as a source of antigen for AGT-specific antibody production. A number of missense mutations have now been identified in the AGT gene and several have now been demonstrated to act synergistically with the polymorphic changes of the minor allele. Expression in E. coli provides a system where mutations, singly and in combinations can be generated easily, manipulations can be performed rapidly and the enzyme can be studied in isolation from effects of organelle transport chaperones. This work was funded by a grant from the Garrod Association of Canada and the Hospital for Sick Children Foundation.

**Functional characterization of a second mouse mitochondrial ornithine transporter, MmORNT2.** *J. Camacho, N.R. Camacho, D. Andrade.* Dept. Human Genetics, Univ Oklahoma , Oklahoma City, OK.

The Hyperornithinemia-Hyperammonemia-Homocitrullinuria (HHH) syndrome is a disorder of the urea cycle caused by a deficiency in the human mitochondrial ornithine transporter (HsORNT1). We have recently reported the characterization of a second human mitochondrial ornithine transporter (HsORNT2). HsORNT2 (5q31) is a functional retroposon with 88% identity to HsORNT1 (13q14) that is localized between two clusters of beta and gamma protocadherin genes and has the ability to rescue the deficient ornithine transport in cultured fibroblasts of HHH patients. We identified the mouse ORNT2 (MmORNT2) by screening the Expressed Sequence Tag and High Throughput Genome Scan (HTGS) databases. The MmORNT2 gene is 81% identical to HsORNT2, but has a single base deletion (AC-) in the predicted fourth codon. MmORNT2 (Ch18) is also intronless and localized between the beta and gamma protocadherin gene clusters. Northern and PCR analysis demonstrated MmORNT2 is expressed only in the testis. Functional studies demonstrated that wild type MmORNT2 did not rescue the deficient ornithine metabolism in cultured HHH fibroblasts. Immunofluorescence and in-vitro transcription/translational studies with a C-myc-tagged construct, demonstrated that MmORNT2 is not translated. We generated an N-myc-tagged-MmORNT2-Asn4 (Asn4 is conserved in several ORNT from different species) construct that targeted to the mitochondria but did not rescue the deficient ornithine transport of HHH fibroblasts. Examination of the *Saccharomyces*, *Neurospora*, *Drosophila*, *Gallus* and *C. elegans* HTGS databases did not reveal the existence of ORNT derived retroposons, but in the *Rattus* an intronless clone 78% identical to the rat ORNT1 was observed. Our results suggest that ORNT was duplicated a second time after the diversification of the Eutheria mammals into the rodent and New World Monkey. Most likely MmORNT2 lost its ornithine transporting capacity before the single base deletion occurred in the predicted fourth codon. Interestingly, MmORNT2 was copied from an autosomal MmORNT1 (Ch8) contrary to other testis specific retroposons that are duplicated from X-linked genes (i.e. Glycerol kinase).

**Functional and structural bases of carnitine palmitoyltransferase 1A deficiency.** *S. Gobin*<sup>1, 2</sup>, *L. Thuillier*<sup>1, 2</sup>, *G. Jogl*<sup>3</sup>, *A. Faye*<sup>1</sup>, *L. Tong*<sup>3</sup>, *A. Munnich*<sup>2</sup>, *J.P. Bonnefont*<sup>2</sup>, *J. Girard*<sup>1</sup>, *C. Prip-Buus*<sup>1</sup>. 1) INSERM U567, 24 Rue du Fg Saint-Jacques, Paris, France; 2) INSERM U393, 149 Rue de Sevres, Paris, France; 3) Department of Biological Sciences, Columbia University, New-York, USA.

Carnitine palmitoyltransferase 1A (CPT1A) mediates the transfer of long-chain fatty acids (LCFA) into liver mitochondria. Its tight inhibition by malonyl-CoA, the first intermediate of fatty acid biosynthesis, provides a physiological regulation of LCFA beta-oxidation and cellular fuel sensing. Human CPT1A deficiency is mostly characterized by hypoketotic hypoglycemia leading to coma with risk of sudden death or neurological sequelae. We have identified six CPT1A mutations, five of them being missense mutations (A275T, A414V, Y498C, G709E, and G710E) in a series of three CPT1A deficient patients. Their heterologous expression in *S. cerevisiae* allowed to validate them as disease-causing mutations. To gain further insights into their deleterious effects, we localized these mutated residues into a 3-D structure model of the human CPT1A that was created from the crystal structure of the mouse carnitine acetyltransferase (Jogl and Tong, 2003, Cell 112, 113). These combined functional and structural analyses demonstrated for the first time that disease-causing CPT1A mutations can be divided into two categories depending on whether they affect indirectly (structural determinant) or directly the active site of the enzyme (functional determinant). A275T, A414V and Y498C, which cause decreased catalytic efficiency, clearly belong to the first class. They are located at more than 20Å... away from the active site and mostly alter the stability of the protein itself and/or of the enzyme-substrate complex. By contrast, G709E and G710E mutations, which abolish CPT1A activity, belong to the second category. Indeed, they affect Gly residues that are not only essential for the structure of the hydrophobic core in the catalytic site, but also contribute to chain-length specificity of CPT isoforms. This study could provide basis for pharmacological therapy of CPT1A deficiency due to class I mutations by drugs, such as fibrates, known to upregulate expression of LCFA oxidation genes.

**Long-term follow-up of well treated nephropathic cystinosis patients.** *I. Bernardini, M. Ueda, C. Phornphutkul, D. Krasnewich, R. Kleta, W.A. Gahl.* Section on Human Biochemical Genetics, MGB, NHGRI, NIH, Bethesda, MD.

Cystinosis is an autosomal recessive inborn error of metabolism with intralysosomal cystine accumulation when untreated leads to glomerular kidney failure within the first decade of life and other nonrenal complications. The gene CTNS, mutated in cystinosis, codes for the protein cystinosin, which contains 367 amino acids and transports cystine out of lysosomes. A free thiol drug, cysteamine, depletes lysosomes of cystine, retards glomerular deterioration, and enhances somatic growth if begun in the first 2 years of life. Cysteamine is given orally every 6 hours at doses of 1.3-1.95 g/m<sup>2</sup> of free base or 60-90 mg/kg per day. Here we report the clinical outcomes of two siblings treated with cysteamine from the ages of 20 months (Pt. #1) and 2 weeks (Pt. #2). The siblings were compound heterozygous for the common 57 kb deletion involving CTNS and for a missense mutation in exon 12, c1015G>A (1354G>A), G339R. Both siblings complied well with oral cysteamine therapy. The leucocyte cystine value in Pt. #1 was 10.3 nmol half-cystine/mg protein (normal, < 0.2) at diagnosis; under treatment with cysteamine (35 mg/kg day at age 14 years), it was 0.5. Pt. #2 had a leucocyte cystine of 9.7 nmol half-cystine/mg protein at diagnosis and 0.3 on cysteamine (60 mg/kg day at age 8 years). Leucocyte cystines, checked yearly have reflected compliance with cysteamine therapy. Neither child received growth hormone. Pt. #1 is now 159 cm (10-25th percentile); Pt. #2 is 139 cm (90th percentile). The glomerular filtration rates, based upon 24 hour urine collections, are 84 and 101 ml/min 1.73m<sup>2</sup>, respectively. The patients' urines show signs of renal Fanconi syndrome, but both children have normal thyroid function. These cases illustrate the excellent clinical outcome possible for nephropathic cystinosis patients treated early and diligently. Early diagnosis is critical.

**Genetic and Biochemical dissection of a complex neurological disease: Leighs syndrome.** *J.M. Cameron, V. Levandovskiy, N. MacKay, B.H. Robinson.* Dept of Metabolism, Hospital for Sick Children, Toronto, Ontario, Canada.

Leighs disease is an early onset disease characterized by severe, progressive encephalopathy. Diagnosis of the disease is made by recognition of the distinct neurological symptoms and disease progression, but the actual cause of disease in a patient is variable: it can be associated with the deficiency of a number of enzymes involved in energy metabolism as well as with some mitochondrial DNA mutations. There are however, patients for whom no specific enzymatic deficiency can be attributed, representing half the patients in the literature.

We are conducting an exhaustive metabolic analysis of patients to determine the specific enzyme deficiencies causing disease (n=24). All known causes of Leigh's disease have been eliminated to select patients affected by novel mechanisms. We found that seven skin fibroblast cell lines displayed rates of 2-<sup>14</sup>C pyruvate to <sup>14</sup>CO<sub>2</sub> oxidation which were in the deficient range, despite the absence of any abnormality of PDH or the respiratory chain complexes: 0.600.05 (n=16) compared with control values of 1.530.18 (n=6). The rest of the Leighs patient group had oxidation rates of 1.700.18 (n=7), indistinguishable from controls.

These seven cell lines then underwent a further set of tests to evaluate capacity for ATP synthesis. This yielded one cell line with a major block in ATP synthesis with all substrates tested. Patient values (n=4) are shown for each substrate with average control values (four different control cell lines, each assayed up to four times): 10.783.08 [control=16.904.39 (no substrate)], 28.775.37 [control=108.3135.93 (5mM pyruvate, 1mM L-malate)], 27.687.05 [control=100.0130.35 (1mM L-malate, 5mM glutamate)], 38.6810.29 [control=84.1717.70 (1mM rotenone, 10mM succinate)] and 16.472.63 [control=26.925.64 (2mM antimycin, 2mM ascorbate, 0.1mM TMPD)].

Analysis of the defective cell lines for intracellular citrate and coenzyme A revealed further differences from control values. These findings are now being used to pinpoint the site of oxidative compromise and thus the identity of gene(s) responsible.

**Presence of Lactic Acidemia and Elevated Lactate-Pyruvate Ratio in Patients with Autism.** *S. Carlo*<sup>1,2</sup>, *N.J. Arciniegas*<sup>2</sup>, *D. Valencia*<sup>2</sup>, *J.R. Acevedo*<sup>3</sup>, *I. Ramos*<sup>2</sup>, *A.A. Reis*<sup>1</sup>, *J.M. Massanet*<sup>1</sup>, *N. Ramirez*<sup>2</sup>, *A.S. Cornier*<sup>1,2</sup>. 1) Dept Biochemistry, Ponce Sch Medicine, Ponce, PR; 2) Genetic Diagnostic Group, Mayaguez, PR; 3) University of PR, Arecibo, PR.

Autism is defined behaviorally as a syndrome consisting of abnormal social skills development, sensorimotor deficits, and verbal and non-verbal communication problems. The study of this disorder has intensified in the last few years because incidence has increased to 7 of every 10,000 children. Even though the etiology of autism is unknown, neuro-psychiatric problems, fragile X, lead poisoning, chromosomal disorders and metabolic diseases has been implied in the pathophysiology of the disease. The clinical phenotype of the disorder is wide and is divided according to the level of functioning of the individual ranging from autism as the most severe and Asperger syndrome being the least affected phenotype. During the years of 2001 and 2002, 65 patients with the diagnosis of autism or pervasive developmental disorder were evaluated at our clinics. Thorough past medical history and physical examination was performed, familygrams were gathered. Metabolic work up included plasma amino acid, lactate, pyruvate and ammonia levels, urine organic acids and if dysmorphic features were identified blood chromosomes were also included in the laboratory work up. Patients with chromosomal abnormalities were discarded from the study. Out of the 65 patients evaluated 3 were found with chromosomal abnormalities, and 49 returned with completed metabolic work up. In this group of 49 patients 18 had a diagnosis of autism and 31 of PDD, only one patient was female, average age was 5.4 years. Sixty percent of the patients had elevated lactate levels (normal levels 3 to 12 mg/dl); 37% had decreased pyruvate levels (normal levels 0.3 to 0.7 mg/dl) and 60% had elevated lactate/pyruvate ratio (normal 10 to 30). Even though these results are not conclusive, the fact that a high percentage of these patients presented lactic acidemia and elevated lactate/pyruvate ratio point toward the possibility of an oxidative metabolism disorder or an intra-mitochondrial disorder to be involved in the expression of the autism phenotype.

**Clinical and Molecular Genetics of ARC syndrome.** *P. Gissen*<sup>1, 2</sup>, *C.A. Johnson*<sup>1, 2</sup>, *K.M. Eastham*<sup>5</sup>, *P. McClean*<sup>3</sup>, *A.A.M. Morris*<sup>4</sup>, *J.E. Wraith*<sup>4</sup>, *S.A. Lynch*<sup>5</sup>, *O.W.J. Quarrell*<sup>6</sup>, *D.A. Kelly*<sup>2</sup>, *P.J. McKiernan*<sup>2</sup>, *E.R. Maher*<sup>1</sup>. 1) Section of Medical and Molecular Genetics, University of Birmingham, Birmingham, UK; 2) The Liver Unit, Birmingham Children's Hospital, Birmingham, UK; 3) St James's University Hospital, Leeds, UK; 4) Willink Biochemical Genetics Unit, Manchester, UK; 5) Department of Human Genetics, Newcastle Upon Tyne, UK; 6) Department of Medical Genetics, Langhill, Sheffield, UK.

ARC (arthrogryposis, renal dysfunction, cholestasis) syndrome (OMIM 208085), also known as Nezelof syndrome is a rare autosomal recessive metabolic disease. Fewer than 40 cases have been described in the literature. We have undertaken a UK national study of ARC to define the phenotypic expression and prognosis and provide a basis for gene mapping and identification. 8 ARC kindreds containing 21 patients were identified within the UK over the last 10 years. All cases were of Pakistani origin and all were born to consanguineous parents. The clinical features were reviewed: Liver pathology: All patients had a degree of cholestasis with low gamma glutamyl transpeptidase activity. However, the bilirubin level and elevation in liver transaminases vary from mild to moderate. Renal pathology: Most patients showed abnormalities on renal ultrasound examination. The typical clinical picture is of generalised aminoaciduria, associated with metabolic acidosis and glycosuria. These manifestations may appear at a later stage in the disease and are associated with intercurrent infections. Patients tend to develop nephrogenic diabetes insipidus with a variable time of onset. Arthrogryposis: All patients had hypotonia and severe motor delay. In the one family with 7 affected individuals 2 had no significant arthrogryposis while the other 5 had severe contractures of lower and upper limbs. Other manifestations: Platelet abnormalities were present in all investigated patients. 2 out of 21 patients had intracranial abnormalities. All patients failed to gain weight and suffered recurrent systemic infections. All patients died in the first year of life during systemic illness. Gene mapping studies are in progress. To date we have excluded linkage to ABCB11 ATP8B1.

**Natural history of isovaleric acidemia.** *R. Ensenauer<sup>1</sup>, S. Gruenert<sup>3</sup>, J. Willard<sup>1</sup>, D. Matern<sup>2</sup>, U. Wendel<sup>4</sup>, W. Lehnert<sup>3</sup>, K.O. Schwab<sup>3</sup>, M. Brandis<sup>3</sup>, A-W. Mohsen<sup>1</sup>, J. Vockley<sup>1</sup>.* 1) Dept Medical Genetics, Mayo Clinic, Rochester, MN; 2) Dept Laboratory Medicine & Pathology, Mayo Clinic, Rochester, MN; 3) University Children's Hospital Freiburg, Germany; 4) University Children's Hospital Duesseldorf, Germany.

**Background:** Isovaleric acidemia (IVA) is caused by a deficiency of isovaleryl-CoA dehydrogenase (IVD), an enzyme in leucine catabolism. Clinical presentation of IVA is extremely variable. The mechanism for this is unclear. We present the results of a study designed to characterize the clinical history of IVA and correlate it to molecular and biochemical phenotype. **Methods:** 22 patients with IVA diagnosed in Germany in the past 30 years were characterized clinically, biochemically (metabolite/enzyme analyses) and by molecular methods. **Results:** 27% of patients were detected by newborn screening, and 50% of patients were diagnosed in the first weeks of life, while the remainder presented in childhood. Most common signs of metabolic crisis were recurrent emesis and acidosis (70% and 55% of decompensations, respectively). No crises were observed after 11 years of age. Most patients showed normal growth (77%) and development (73%). The IQ did not correlate with the number of crises but was decreased with later diagnosis. Patients on carnitine had a similar number of crises per year of treatment to patients treated with carnitine and glycine. Differences in urine isovalerylglycine (IVG) and plasma C5 carnitine among patients did not correlate with clinical condition. Total metabolite excretion was the same on therapy with carnitine plus/minus glycine. IVD activity was undetectable in transformed lymphocytes from all patients. Immunoreactive enzyme protein in the lymphocytes correlated with clinical severity. 20 new *IVD* gene mutations were identified, and some correlation of genotype with phenotype was apparent by molecular modeling. **Conclusions:** Favorable neurological long-term outcome of patients with IVA depends on early diagnosis. Expanded newborn screening helps to prevent disease manifestation and allows early management. The data provide a basis for prospective therapeutic studies.

**Functional characterization of mutant -galactosidase A, identified from Korean patients with Fabry disease.** S-S. Kim<sup>1</sup>, Y. Kim<sup>1</sup>, G-H. Kim<sup>1</sup>, H-W. Yoo<sup>2</sup>. 1) Genomic Res Ctr for Gen Dis, Asan Medical Ctr, Seoul, Korea; 2) Dept of Ped, Asan Medical Ctr, Ulsan University College of Medicine, Seoul, Korea.

Fabry disease is an X-linked recessively inherited metabolic disorder, which results from the deficient activity of the lysosomal hydrolase alpha-galactosidase A (-Gal A) leading to the systemic deposition of glycosphingolipids with terminal alpha-galactosyl moieties. In previous study, we have identified mutations of -Gal A in Korean patients with Fabry disease, which resulted in substitution of E66Q, R112C and D266N amino acid residues. In order to evaluate the effects of these mutations on the -Gal A activity, we constructed E66Q, R112C, and D266N cDNA from a wild type -Gal A. COS-7 cells transfected with these mutant (R112C, D266N) cDNA showed complete loss of its enzyme activities (about 4 and 2 % of wild type -Gal A, respectively), except E66Q. In E66Q mutant form of -Gal A, it has a residual activity (about 30%), and then a optimal pH range of E66Q mutant form was between 4 and 5, same as the range of wild type. In *in vitro* stabilization study, the E66Q mutant enzyme was relatively unstable compared to wild type. Furthermore, those cotransfected with a mutant and a wild type cDNA showed a lower -Gal A activity than those with wild type alone (~50% of wild type alone), which suggested the dominant negative effect of this mutant.

**Respiratory chain complex III deficiency presenting as isolated cardiomyopathy.** *A. Maltret<sup>1</sup>, E. Vilain<sup>2</sup>, S. Lebon<sup>1</sup>, D. Genevieve<sup>1</sup>, S. Romano<sup>1</sup>, D. Sidi<sup>2</sup>, D. Bonnet<sup>2</sup>, A. Munnich<sup>1</sup>, A. Rotig<sup>3</sup>, P. Rustin<sup>3</sup>.* 1) Department de Genetique, Hopital Necker-Enfants Malades, Paris, France; 2) Department of Pediatrics, Hopital Necker-Enfants Malades, Paris, France; 3) INSERM U393, Hopital Necker-Enfants Malades, Paris, France.

Mitochondrial respiratory chain deficiency due to Ubiquinol cytochrome c reductase (CIII) deficiency is a rare and clinically heterogeneous condition. It represents between 5% to 10% of cases of respiratory chain deficiency. We reviewed the reported cases of CIII deficiency with known molecular bases and found that 13/27 reported cases had mitochondrial cardiomyopathy including 6 hypertrophic cardiomyopathies, 4 dilated cardiomyopathies, 1 ischemic cardiomyopathy and 2 Wolf-Parkinson-White syndrome. Most cases presented with neurological features and progressive exercise lactic acidosis and sometimes myoglobinuria. Moreover, 9/27 reported cases also displayed exercise intolerance. Here, we report on a 10-years-old boy with no familial history who had syncopes ascribed to a documented ventricular fibrillation. He was resuscitated by external cardioversion. After recovering, neurological examination was normal. The patient received an implantable cardiovector defibrillator (ICD) and is doing well after a 5 month follow-up. Heart ultrasound displayed asymmetric cardiac hypertrophy with no obstruction. Extensive blood and urinary metabolic screening was negative. Histopathological analysis of the endomyocardial biopsy was normal but investigation of respiratory chain activity in endomyocardial biopsy and skin fibroblasts displayed a decreased absolute CIII activity with an abnormal activity ratio with respect to other respiratory chain complexes suggestive of a CIII deficiency. Cytochrome b mutations were excluded by molecular studies. This observation and the review of the literature suggest that cardiomyopathy is frequent in CIII deficiency and, apart from exercise intolerance presentation, could be the presenting symptom of the disease.

**Abnormal localization of OCTN2 carnitine transporters in primary carnitine deficiency.** *N. Longo, N. Miller, C. Amat di San Filippo.* Dept Pediatrics and Pathology, Div Med Genetics, Univ Utah, Salt Lake City, UT.

Primary carnitine deficiency (OMIM 212140) is an autosomal recessive disorder of fatty acid oxidation characterized by hypoketotic hypoglycemia, encephalopathy, and acute liver failure in younger patients or by skeletal/cardiac myopathy in older children. It is caused by mutations in the OCTN2 transporter (encoded by the SLC22A5 gene) that is responsible for tissue carnitine uptake and renal reabsorption of filtered carnitine. Nonsense and missense mutations in this transporter have been identified in patients with primary carnitine deficiency. When expressed in CHO cells, some of the missense mutations completely abolished carnitine transport, while others retained residual carnitine transport activity. To determine the mechanism by which natural mutations impaired carnitine transport, normal and mutant OCTN2 transporters were tagged with the green fluorescent protein and their subcellular distribution was assessed using confocal microscopy and markers of intracellular organelles. The normal OCTN2 transporter localized on the plasma membrane and there was no overlap with markers of the endoplasmic reticulum or the Golgi. Several OCTN2 carnitine transporters carrying missense mutations, including R83L, R169W, G242V, W283C, Y447C, did not reach the plasma membrane. These transporters co-localized with markers of the endoplasmic reticulum, with an increased perinuclear distribution. Most of these mutations completely abolished carnitine transport in the patients fibroblasts and when expressed in CHO cells. By contrast, the R19P-, A142S-, A301D-, E452K-, Y449D-mutant OCTN2 transporters reached the plasma membrane in a manner indistinguishable from the wild type OCTN2 and retained residual carnitine transport activity. These results indicate that natural mutations in the OCTN2 carnitine transporter can impair carnitine transport by affecting maturation of the protein to the plasma membrane. Mutant OCTN2 transporters capable of reaching the plasma membrane have minimal residual carnitine transport activity, while mutants retained inside the cells are completely ineffective.

**NOVEL MOLECULAR DEFECT OF CARNITINE PALMITYL TRANSFERASE I DEFICIENCY (CPT I) IN SAUDI ARABIA.** *M.S. Rashid<sup>1</sup>, L. Ijlst<sup>2</sup>, J. Ruiten<sup>2</sup>, R.J. Wanders<sup>2</sup>, A.I. Al Aqeel<sup>1, 3</sup>.* 1) Dep. of Genetics, King Faisal Specialist Hospital & Research centre, Riyadh, Saudi Arabia; 2) Dep. of Clinical Chemistry, University of Amstradam, The Netherland; 3) Dep. Of Pediatrics, Riyadh Military Hospital, Riyadh, Saudi Arabia.

Carnitine Palmitoyl Transferase I is the key enzyme in the carnitine dependent transport of long chain fatty acids across the mitochondrial inner membrane and its deficiency results in a decrease rate of fatty acids  $\beta$ -oxidation with decreased energy production. We report two families of five affected patients who are the product of first degree cousin marriage. Two patients presented with typical Reye-like syndrome with unconsciousness, hepatomegaly, hypoglycemia, hyperammonemia and very high liver enzymes with hemophagocytic syndrome and brain abscess in the second patient. Liver biopsy showed steatosis. On screening of the two families, the other three siblings were found to have hepatomegaly. The five siblings showed an acyl carnitine profile with very high free carnitine with almost absent long-chain acyl carnitines, suggestive of CPT-I deficiency. This was confirmed by enzyme analyses in fibroblast cultures. Molecular analysis on cDNA shows 1574 insertion G in the first family which was confirmed at genomic level and 1950GA transition resulting in glycine 650 aspartic acid change (G650D) in the protein in the second family. These patients were effectively treated with a diet high in carbohydrate, low in long chain fatty acids with medium chain triglycerides. In conclusion, CPT-I deficiency is an important cause of Reye-like syndrome with secondary hemophagocytic syndrome with unique molecular defect in Saudi Arabia, which may be treated easily with very good results if detected early in life.

**Identification of novel mutations in the human ornithine transcarbamylase(OTC) gene and transient expression of the mutant protein *in vitro*.** H-W. Yoo<sup>1</sup>, S-S. Kim<sup>2</sup>, G-H. Kim<sup>1</sup>. 1) Dept Pediatrics, Medical Genetics Clinic & Laboratory, Asan Medical Center, Ulsan University College of Medicine, Seoul, Korea; 2) Asan Medical Center, Genome Research Center for Birth Defects and Genetic Diseases, Seoul, Korea.

The urea cycle, consisting of a series of six enzymatic reactions, plays key roles to prevent the accumulation of toxic nitrogenous compound and synthesize arginine *de novo*. Ornithine transcarbamylase(OTC) deficiency is one of the most common inborn error of urea cycle, which is inherited in X-linked manner. This study was undertaken to characterize molecular defects in Korean patients with OTC deficiency and to correlate them with phenotypes. To investigate molecular lesions in the OTC gene of 22 unrelated Korean patients with OTC deficiency, coding regions with each intron-exon boundary were analyzed by PCR-direct DNA sequencing. Mutant OTC cDNAs were constructed by site-directed mutagenesis and cloned into pcDNA expression vector. After transient expression in COS-7 cells, the OTC activity was determined by HPLC method and Western blot was concomitantly performed using a monoclonal OTC antibody. We characterized molecular lesions in all patients examined. We identified 20 different mutations in 22 unrelated Korean patients; L9X, R26P, R26X, T44I, R92X, G100R, R141Q, N161S, G195R, M205T, M206R, H214Y, K221N, D249G, R277W, F281S, 853 delC, R320X, V323M and 796-805del. Among these, 10 mutations(L9X, R26P, R26X, G100R, K221N, D249G, F281S, V323M, 853 delC, and 796-805del) were novel. The L9X, R26P, and R26X are presumed to lead to the disruption of leader sequences, required for directing mitochondrial localization of the OTC precursor. Their phenotypes were severe, presenting at the neonatal onset. The G100R, R277W, and V323M mutations were uniquely identified in patients presenting at the late onset, with the residual enzyme activity *in vitro* expression. Five mutations(T44I, N161S, G195R, M206R, and R320X) were found in female heterozygote patients without the residual enzyme activity *in vitro* expression. The other genotypes were associated with the phenotype presenting at the neonatal onset.

**Prolidase deficiency in four Amish patients: a novel mutation.** *H. Wang*<sup>1,2</sup>, *B.T. Kurien*<sup>4</sup>, *D. Lundgren*<sup>3</sup>, *N.C. Patel*<sup>4</sup>, *K.M. Kaufman*<sup>4</sup>, *D.L. Miller*<sup>4</sup>, *J. Tumbush*<sup>1</sup>, *D.S. Kerr*<sup>2</sup>, *S. Kurono*<sup>5</sup>, *H. Matsumoto*<sup>5</sup>, *R.H. Scofield*<sup>4</sup>. 1) DDC Clinic Special Needs Child, Middlefield, OH; 2) Dept of Pediatrics, Rainbow Babies & Childrens Hosp, Case Western Reserve University, Cleveland, OH; 3) Biochemical Genetics Laboratory, MetroHealth Medical Center, Cleveland, OH; 4) Oklahoma Medical Research Foundation, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 5) University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Prolidase is a cytosolic enzyme consisting of 493 amino acids that catalyzes hydrolysis of dipeptides with a C-terminal proline or hydroxyproline. Prolidase deficiency (PD) is a rare autosomal recessive disease with less than 50 cases reported in the literature. Recently, a total of four Amish patients were diagnosed with prolidase deficiency in the Geauga Amish settlements of Ohio. A fifth patient, a sibling of one of the four, had a typical clinical course of prolidase deficiency but died from infection in 1998 before confirmation of PD. The five patients were from three families with varying degrees of consanguinity. Two of the three marital-unions were between second cousins and the third were fourth cousins. The common ascendants can be traced back to the seventh generation. The typical presentations of the disease are recurrent infections, petechiae, thrombocytopenia and hepatosplenomegaly. They all have characteristic facies including prominent forehead, ocular hypertelorism and proptosis. The classic skin ulcers developed on lower extremities in three of the five patients. High amounts of iminodipeptides were detected in urine of all diagnosed patients but not in any of the 11 direct family members tested. Serum prolidase activity was measured by mass spectrometry. All patients had undetectable serum prolidase activity. Direct sequencing of PCR amplified genomic DNA from the three homozygous patients revealed the same single nucleotide polymorphism (C-to-T in Exon 11) in each. This resulted in an arginine being replaced by a premature stop-codon at amino acid residue 265. This novel mutation is thought to have resulted in the production of a non-functional polypeptide, which is consistent with both the laboratory and clinical findings.

**Disruption of the 3--hydroxysterol 24-reductase Gene: Development and Characterization of a Murine Model of Desmosterolosis.** C.A. Wassif, F.D. Porter. HBD, NICHD/NIH, Bethesda, MD.

Desmosterolosis is a rare multiple malformation/mental retardation syndrome due to an inborn error of cholesterol synthesis. Desmosterol is a sterol that is normally found in the developing nervous system. Reduction of desmosterol by the 3--hydroxysterol 24-reductase produces cholesterol. Desmosterolosis is due to mutation of the 3--hydroxysterol 24-reductase gene (*DHCR24*). In order to further our understanding of the pathophysiological processes which underlie this human malformation syndrome and the more common Smith-Lemli-Opitz syndrome, we produced a mouse model of desmosterolosis by disrupting the *Dhcr24* gene in mouse embryonic stem cells. *Dhcr24* +/- mice were phenotypically normal, thus they were intercrossed to obtain homozygous mutant pups. *Dhcr24* -/- pups were not viable. The mutant embryos are however alive just prior to birth at embryonic day 18.5 (E18.5). Sterol analysis of serum, liver, kidney, cortex and midbrain from E18.5 *Dhcr24* -/- embryos showed significantly increased levels of desmosterol compared to tissues from either *Dhcr24* +/+ or *Dhcr24* +/- embryos. Both cholesterol and total sterol levels were significantly decreased in mutant embryonic tissues. Phenotypic examination and detailed histological analysis revealed no significant differences between *Dhcr24* -/- and control E18.5 embryos. This later result is in distinct contrast to teratogenic models of desmosterolosis using triparanol and is in contrast to our previously reported SLOS and lathosterolosis mouse models. It is likely that the differences observed in these three mouse models are due to differences in the respective ability of desmosterol, 7-dehydrocholesterol and lathosterol to substitute for cholesterol during development. We suspect, and will investigate the possibility, that the neonatal death of the desmosterolosis mice is related to neuronal dysfunction.

**Making the diagnosis of alkaptonuria: Unusual skin findings in an alkaptonuria patient.** *C. Phornphutkul<sup>1</sup>, P. Suwannarat<sup>1</sup>, W. Introne<sup>1</sup>, I. Bernardini<sup>1</sup>, M. Turner<sup>2</sup>, R.D. Heekin<sup>3</sup>, R. Kleta<sup>1</sup>, W.A. Gahl<sup>1</sup>.* 1) Section on Human Biochemical Genetics, MGB, NHGRI, NIH, Bethesda, MD; 2) Dermatology Branch, NCI, Bethesda, MD; 3) Orthopaedic Surgery Service, Walter Reed Army Medical Center, Washington, DC.

Alkaptonuria is a rare inborn error of metabolism in which the degradation of tyrosine is compromised by decreased activity of homogentisate 1,2 dioxygenase leading to increased homogentisic acid (HGA) in the body. Alkaptonuria is characterized by vertebral disk collapse, arthritis, joint destruction requiring replacement, and ochronosis, or dark pigmentation of tissues due to HGA and its oxidation products. The increased urinary excretion of HGA, and its subsequent oxidation, often causes blackening of the urine ("alkaptonuria") and leads to the diagnosis in early childhood. In 58 patients seen at the National Institutes of Health Clinical Center, the diagnosis of alkaptonuria was made based upon dark urine in 32. In the remaining 26 patients, the diagnosis was suspected by finding black cartilage upon surgical replacement of joints or ochronotic ears or eyes in adulthood. Here we report unusual skin findings in a 46 year old Florida fisherman who never had darkening of his urine. The patient presented with clearly visible blackening of his nose, first noticed 4 years previously, and of his hands (lateral aspects of thumb and index finger), first noticed 7 years prior to our examination. He also showed typical ochronotic pigmentation of his ears, noticed 10 years previously. The patient underwent left arthroscopic knee surgery because of increasing pain. Black cartilage and black menisci prompted the orthopedic surgeon to consider alkaptonuria. An elevated urinary excretion of 4000 mg/day of HGA (normal, < 40) confirmed the diagnosis of alkaptonuria. The patient had no renal insufficiency, which could exacerbate the ochronosis of the skin and cartilage. Blackening of sun-exposed skin areas besides the ears and eyes should alert physicians to the possible diagnosis of alkaptonuria.

**Effect of vitamin C on collagen and lysyl hydroxylase RNA in fibroblasts from patients with Ehlers-Danlos syndrome type VI.** *E. Schwarz*<sup>1</sup>, *N. Longo*<sup>2</sup>, *M. Pasquali*<sup>2</sup>. 1) ARUP Inst Clin Exp Pathol; 2) Dept Pathology and Pediatrics, University of Utah, Salt Lake City, UT.

Ehlers Danlos Syndrome type VI (EDS VI, OMIM #225400, kyphoscoliotic type) is a recessive disorder of connective tissue characterized by hyperextensible skin, joint hypermobility, scoliosis and ocular fragility. This disease is caused by defective lysyl hydroxylase (PLOD1), the vitamin C dependent enzyme that converts lysyl residues to hydroxylysine in procollagen peptides. Hydroxylysine is essential for the formation of pyridinium cross links, pyridinoline (Pyr) and deoxypyridinoline (Dpyr), in mature collagen. Pyr and Dpyr are excreted in the urine as products of collagen degradation, with a Dpyr/Pyr ratio = 0.20-0.30 in normal controls. Patients with EDS VI have an abnormally high Dpyr/Pyr ratio (>4), which is diagnostic for this disease. There are at least two additional lysyl hydroxylases (PLOD2 and PLOD3) with different substrate specificity that are encoded by genes not defective in EDS VI. Vitamin C improves the clinical manifestations of Ehlers-Danlos syndrome type VI. Here we evaluate the effect of vitamin C on collagen, pyridinium cross links production, and mRNA levels for different types of lysyl hydroxylase (PLOD1, PLOD2, and PLOD3). Vitamin C increased collagen production and pyridinium cross-link formation in long-term cultures of normal and EDS VI fibroblasts. However, in normal fibroblasts vitamin C decreased the relative abundance of Dpyr while it had the opposite effect in fibroblast of patients with EDS VI, reproducing the Dpyr/Pyr ratio observed in vivo. Vitamin C increased mRNA levels for PLOD1 and PLOD2, but did not affect significantly PLOD3 mRNA levels in normal cells. Some cells of patients with EDS VI had no detectable levels of PLOD1 mRNA and vitamin C could not restore normal levels. However, PLOD2 responded to vitamin C as in control cells. These results indicate that vitamin C might improve clinical symptoms in EDS VI by stimulating collagen production and cross link formation. This effect could be mediated, at least in part, by stimulating one form of lysyl hydroxylase (PLOD2) not impaired in EDS VI.

**Decreased abundance of epidermal growth factor receptor (EGFR) in galactose-1-phosphate uridylyltransferase (GALT) -deficient patient cells.** *T. Slepak, K. Lai.* The Dr. John T Macdonald Foundation Center for Medical Genetics, Department of Pediatrics, University of Miami, Miami, FL.

In humans, deficiency of GALT (E.C. 2.7.7.12) produces the disorder Classic Galactosemia. Although newborn screening and a galactose-restricted diet prevent the acute toxicity associated with this disease, secondary complications such as premature ovarian failure persist in some patients. The pathogenic mechanisms producing dysfunction of multiple organs remain largely unknown. Previously we demonstrated, in galactosemic patient fibroblast cell lines, reduced level of glycoproteins that are specifically detected by the *Sambucus nigra* agglutinin (SNA) (Lai et al. (2003), *Glycobiology* 13: 285-94). SNA lectin recognizes terminal sialic acid linked (2-6) to the penultimate galactose molecule of the oligosaccharide chains found in the complex glycoproteins. In this new study, we revealed that glycosylation defects in GALT deficiency are not be limited to the absence of (2-6)-linked sialic acids, but also terminal sialic acid linked (2-3) to the galactose molecules of the complex sialylated carbohydrate chains and (2-3)-linked sialic acids in o-glycans.

Aberrant protein glycosylation has been reported in galactosemic patients, but the few proteins involved were limited to secreted or cytosolic proteins. In all cases, aberrantly glycosylated proteins exhibited altered biological activities. Since many membrane proteins are glycoproteins, we decided to examine if aberrant glycosylation occurs in membrane proteins when GALT is deficient. In Western Blot analysis using anti-EGFR antibody, we compared the abundance of EGFR in two primary fibroblast cell lines derived from Classic Galactosemic patients and cell lines derived from normal controls. We found significantly reduced level of EGFR proteins in both galactosemic cell lines, but such decrease was not accompanied by the corresponding decrease in EGFR mRNA level. This study is significant as we demonstrated for the first time that normal galactose metabolism is needed for normal EGFR function and the galactose metabolic pathway can provide novel cancer therapeutic targets.

Program Nr: 1625 from 2003 ASHG Annual Meeting

**Clinical research center for neuronal ceroid lipofuscinoses (NCLs) at the New York State Institute for Basic Research in Developmental Disabilities.** *N. Zhong, W. Ju, A. Wronska, A. Golabek, E. Kida, S. Sklower-Brooks, M. Keogh, M. Rattazzi, J. Currie, M. Flory, R. Freedland, R. Kascsak, J. Vietze, C. Wang, P. Vietze, W.T. Brown, K.E. Wisniewski.* New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY10314.

Neuronal ceroid lipofuscinoses (NCLs) are a group of progressive neurodegenerative disorders characterized by intralysosomal accumulation of ceroid lipopigment. The NCLs consist of at least eight forms, for which six genes have been identified, and possibly more variants are being recognized. Although research studies are making progress for this group of lethal disorders, the nature of the clinical process and the progression of the NCLs are yet unclear. Therefore, a clinical research center has been formed recently at the New York State Institute for Basic Research in Developmental Disabilities (IBR) to accelerate clinical research studies for NCLs, with an emphasis on clinical diagnosis and treatment. Currently, we are maintaining the largest worldwide NCL database and NCL cell lines, having a broad connection with, and support of, national and international family groups and the international NCL clinical research consortium. We are performing clinical evaluations, including neuropathological studies, biochemical enzyme test, and DNA mutation analyses, for NCLs. A phase II clinical trial of Cystagon™ treatment on four patients with NCL1, the infantile onset of NCL, underlied by gene CLN1, is being studied. In addition, identification of uncharacterized NCL families, demonstrating new biomarkers, correlation of genotypes with phenotypes, determination of the epidemiology of NCLs, and searching for a novel therapeutic approach are the major focuses being carried out. For more information, please visit [www.NCLatIBR.com](http://www.NCLatIBR.com), or e-mail to [NCL.IBR@OMR.STATE.NY.US](mailto:NCL.IBR@OMR.STATE.NY.US).

**UDP-GlcNAc 2-epimerase activity in Hereditary Inclusion Body Myopathy.** *S. Sparks*<sup>1</sup>, *M. Lalor*<sup>1</sup>, *E. Orvisky*<sup>2</sup>, *M. Huizing*<sup>1</sup>, *D. Krasnewich*<sup>1</sup>, *M.-S. Sun*<sup>1</sup>, *M. Dalakas*<sup>3</sup>, *W. Gahl*<sup>1</sup>. 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) NSB, NIMH, NIH, Bethesda, MD; 3) NINDS, NIH, Bethesda, MD.

Uridine diphosphate-N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase (UDP-GlcNAc 2-epimerase/ManNAc kinase), encoded by the *GNE* gene on 9p12-13, is the bifunctional and rate-limiting enzyme involved in the biosynthesis of sialic acid (N-acetylneuraminic acid). The epimerase converts UDP-GlcNAc to N-acetylmannosamine (ManNAc) and the kinase converts ManNAc to ManNAc-6-phosphate. Sialic acid, as a terminal sugar on cell surface oligosaccharides, is important in cell-cell interactions and signal transduction. Mutations in either or both the epimerase and kinase domains of *GNE* cause Hereditary Inclusion Body Myopathy (HIBM), an autosomal recessive disorder characterized by adult-onset, progressive distal and proximal muscle weakness sparing the quadriceps muscle. We employed cultured fibroblasts as a model system to investigate epimerase activity in cells from three HIBM patients. Patient #1, with two epimerase domain mutations (G455T and C787T) had epimerase activity (measured by conversion of <sup>3</sup>H-UDP-GlcNAc to <sup>3</sup>H-ManNAc) 38% of control (n=2). Patient #2, with one epimerase mutation (T698C) and one kinase mutation (C1943T), had epimerase activity 48% of control (n=4). The third patient (#3), with homozygous kinase mutations (T2186C), had epimerase activity 83% of control (n=4). These findings indicate a rough correlation of epimerase activity with the number of *GNE* epimerase domain mutations.

**Fatal Medium-Chain Acyl-CoA Dehydrogenase (MCAD) Deficiency in a previously a symptomatic 8-year old female.** *N. Quintanilla*<sup>1</sup>, *R. Garola*<sup>2</sup>, *G. Allen*<sup>3</sup>, *M. Dasouki*<sup>4</sup>. 1) Department of Pathology, Truman Medical Center, Kansas City, MO; 2) Department of Pathology, Children's Mercy Hospitals & Clinics, Kansas City, MO; 3) Sec Pediatric Intensive Care, Children's Mercy Hospitals & Clinics, Kansas City, MO; 4) Sec Med Genet & Molec Med, Children's Mercy Hospitals & Clinics, Kansas City, MO.

MCADD is the most common mitochondrial fatty acid oxidation defect, usually manifest during infancy with hypoglycemia, acute encephalopathy and occasionally with sudden, un-explained death. Newborn screening may prevent morbidity and mortality associated with MCADD. Herein we describe a previously healthy 8-year old girl with MCADD diagnosed on post-mortem examination. She was found unresponsive at home. The day before, she complained of stomachache, dizziness, headache and fever. On admission, she was febrile and unresponsive. EEG was consistent with subclinical status epilepticus; a head CT scan showed diffuse cerebral edema and features of severe hypoxic insult. She had leukocytosis with left shift; hyperglycemia, no ketones in urine, increased creatinine and BUN; elevated liver enzymes, prolonged PT and PTT and elevated CPK. Meningoencephalitis was suspected. Over the following three days, her hepatic and renal function deteriorated further and the neurologic exam was consistent with brain death. Post-mortem examination revealed marked jaundice, anasarca, submassive hepatic necrosis with macro and microvesicular steatosis. Lipid deposits were not found in myocardium or skeletal muscle. Brain showed diffuse ischemic hypoxic changes. Swollen mitochondria with fragmented cristae were seen on EM. No morphologic or microbiologic evidence of meningoencephalitis was found. Elevated plasma medium chain acylcarnitines were consistent with MCADD. DNA extracted from skin fibroblasts was homozygous for the "A985G" MCAD mutation. In addition to this patient, only 2 other previously asymptomatic older MCADD patients were reported in the literature. A 30-year old man with rhabdomyolysis [Ruitenbeek et al, J Neurol Neurosurg Psychiatry, 1995] and a 19-year old year woman with fatal encephalopathy [Yang et al, Mol Genet Metab, 2000].

**Mitochondrial porin deficient mice: a Murine model for Mendelian respiratory chain defects and encephalopathy.** *F. Scaglia<sup>1</sup>, Z.J. Cai<sup>1</sup>, K. Anflous<sup>1</sup>, D.A. Armstrong<sup>2</sup>, E. Weeber<sup>3</sup>, J.D. Sweatt<sup>3</sup>, W.J. Craigen<sup>1</sup>.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pathology, Baylor Col Medicine, Houston, TX; 3) Div Neuroscience, Baylor Col Medicine, Houston, TX.

Voltage dependent anion channels (VDACs; porins) are small pore-forming proteins that form the main pathway for metabolites across the mitochondrial outer membrane. VDACs constitute one component of the permeability transition pore that opens in response to apoptotic signals. Mammals have four VDAC isoforms encoded by three separate genes. To determine the physiological function of each isoform, gene targeting has been used to delete them in cultured cells and mice. VDAC1<sup>(-/-)</sup>, VDAC3<sup>(-/-)</sup>, and VDAC1/3<sup>(-/-)</sup> mice have been generated and exhibit abnormalities in spatial, and associative learning, and hippocampal synaptic plasticity that are reminiscent of the neurological deficits seen in patients with respiratory chain (RC) defects.

Since a reduction in cytochrome c oxidase activity is observed in the skeletal muscle of VDAC1<sup>(-/-)</sup> mice, we evaluated whether brain mitochondria from VDAC<sup>(-/-)</sup> mice exhibit any RC defect that could correlate with the observed cognitive deficits. Mitochondrial RC enzyme assays of brain mitochondria of VDAC deficient mice reveal significant RC defects. Immunoblotting and differential display exhibit reduced expression of brain RC proteins. Aconitase activity is reduced in the brain of VDAC1/3<sup>(-/-)</sup> mice. Preliminary data suggest that there is an increased oxidative modification of proteins by reactive oxygen species (ROS) in the brain of VDAC<sup>(-/-)</sup> mice. These data point to a role for VDACs in the modulation of the mitochondrial RC. Further experiments are being carried out to evaluate whether this regulation may be exerted via the flux of small metabolites across the mitochondrial outer membrane, altered calcium homeostasis, or through impaired mitochondrial translation.

**A WORLDWIDE COLLABORATION TO CAPTURE ALL HUMAN MUTATIONS.** *R. Cotton<sup>1</sup>, O. Horaitis<sup>1</sup>, A.D. Auerbach<sup>2</sup>, A.F. Brown<sup>3</sup>, S. Callaghan<sup>4</sup>, A.J. Cuticchia<sup>5</sup>, J.T. den Dunnen<sup>6</sup>, P.M. Nadkarni<sup>7</sup>, C.R. Scriver<sup>8</sup>, S. Teebi<sup>9</sup>, and a consortium of the Human Genome Variation Society.* 1) Genomic Disorders Res Ctr, Melbourne, and The University of Melbourne, Dept of Medicine, Melbourne 3010, Australia; 2) Laboratory of Human Genetics & Hematology, The Rockefeller University, New York, NY, U.S.A; 3) MRC Human Genetics Unit, Edinburgh EH4 2XU, UK; 4) Victorian Bioinformatics Consortium, Monash University 3800, Australia; 5) Research Triangle Institute, North Carolina, U.S.A; 6) Leiden University Medical Center, Leiden, The Netherlands; 7) Yale University, Connecticut, USA; 8) McGill University, Montreal, Canada; 9) Hospital for Sick Children, Toronto, Canada.

There has been an exponential rise in the number of disease causing mutations discovered in the last few years. To ensure future availability to health care professionals, researchers and others, it is essential that this information, together with the corresponding phenotype, is collected, quality controlled, documented and stored safely. So far there has been no systematic way to collect, store and display all of these data while general databases such as OMIM or HGMD only store selective parts. Through their interactions, a number of members of the Human Genome Variation Society have addressed many problems regarding these issues such as nomenclature, standard software to curate mutations in gene specific databases, a WayStation to collect and review new mutations from research and diagnostic laboratories and a Central database to store and display these mutations and their associated phenotypes. Some of these projects are well developed for example the WayStation will begin collecting mutations shortly, Editors for 391 genes have already been recruited and nomenclature is now well defined for the commonest types of mutation with work continuing on systematically naming the more complex types. Other projects such as dedicated specialized software for locus specific databases are in the early stages of development. The central database is at the planning stage whilst phenotype representation has been planned. A source of all this information is available at [www.hgvs.org](http://www.hgvs.org).

**Delineating the OI/EDS Region of the 1(I) Chain and the Shared Mechanism of OI/ED and EDS VIIA.** *W.A.*

*Cabral*<sup>1</sup>, *E. Makareeva*<sup>2</sup>, *S. Leikin*<sup>2</sup>, *A. Colige*<sup>3</sup>, *A.D. Letocha*<sup>1</sup>, *J. Ty*<sup>1</sup>, *H.N. Yeowell*<sup>4</sup>, *G. Pals*<sup>5</sup>, *J.C. Marini*<sup>1</sup>. 1) BEMB, NICHD, NIH, Bethesda, MD; 2) Section on Physical Biochemistry, NICHD, NIH, Bethesda, MD; 3) Laboratory of Connective Tissue Research, University of Liege, Liege, Belgium; 4) Division of Dermatology, Duke University Medical Center, Durham, NC; 5) Dept of Human Genetics, VU Medical Center, Amsterdam, The Netherlands.

Patients with OI/EDS are a distinct subset of osteogenesis imperfecta patients. In addition to OI skeletal fragility, they have characteristics of EDS, including severe joint laxity and scoliosis. In 7 children with OI/EDS, we delineated mutations in the first 90 residues of the helical region of the 1(I) chain. We have determined that these collagen mutations cause abnormal N-propeptide processing, incorporation of pN-collagen into matrix and decreased dermal fibril diameters.

Mutations were identified by sequencing of RT-PCR products of 1(I) mRNA, since the proband collagen was electrophoretically normal. On Differential Scanning Calorimetry, all mutants show decreased stability of collagen compared to procollagen, suggesting that the secondary structure of the mutant collagen is stabilized by the presence of the N-propeptide. In vitro cleavage with N-proteinase processed only 25% of proband pro1(I) chains for exon 7 mutations, and 65-85% of pro1(I) chains for exon 8-11 mutations. Pericellular processing of proband procollagen was also delayed. pN-1(I) collagen is incorporated into matrix deposited by cultured fibroblasts and is prominent in newly incorporated and immaturely cross-linked fractions. Electron microscopy of dermal biopsies from 6 probands revealed smaller fibrils than matched controls, as is seen in EDS VII.

The data delineate a folding region of the 1(I) chain in which mutations alter the secondary structure of the N-proteinase cleavage site, causing N-propeptide retention and limiting fibril diameter. Thus the mechanism of EDS symptoms in OI/EDS patients is shared with patients who have EDS VIIA due to absence of the N-proteinase cleavage site.

**Physical Performance Measure for Individuals with MPS I.** *S. Haley<sup>1</sup>, M.A. Fragala<sup>1,2</sup>, H.M. Dumas<sup>2</sup>, A. Skrinar<sup>3</sup>.*  
1) Rehabilitation Sci, Sargent Col Health & Rehab Sci, Boston, MA; 2) Franciscan Hospital for Children, Boston, MA;  
3) Genzyme Corporation, Cambridge, MA.

**Objective:** To develop a physical performance measure (PPM-MPS I) for individuals with Mucopolysaccharidosis I (MPS I), a lysosomal storage disorder that results in impaired joint mobility and cardiovascular endurance. **Methods:** Twelve motor performance and two functional endurance items were developed based on a comprehensive literature review, feasibility in various clinical settings, and equipment and training needs. A script was constructed for administration, and instructions were developed for rating each scale. Following trial administration, five expert clinicians provided feedback for face validity and script utility. The final PPM-MPS I performance items are as follows: Subtest I-Arm Function (7 items), Subtest II-Leg Function (5 items), and Subtest III-Functional Endurance/Walking Efficiency (2 items). Pilot data were collected for nine subjects (ages 6- 29 years) with MPS I. **Results:** Seven of nine subjects completed all Arm Function items but speed of performance varied. All subjects exhibited reduced shoulder mobility. Only two of nine subjects completed all five Leg Function items. Subjects had most difficulty with stand to squat. Comfortable and fast walking speeds were consistently below norms for subject ages. Energy expenditure values were lower with comfortable walking speeds than fast speeds. **Conclusions:** The PPM-MPS I is designed for administration by clinicians as a comprehensive motor performance assessment of common functional limitations. These data confirm that individuals with MPS I have difficulty with tasks using arms and legs and experience overall reductions in functional endurance. PPM-MPS I can be administered at pre-determined intervals before, during and following intervention to quantify changes in arm, leg and cardiovascular function, or to monitor the natural history of disease progression. Further work is needed to develop normative scores for rating performance and speed and for determining minimal clinically important differences of the PPM-MPS I for future intervention trials.

**Bone and Joint Disease in the Mucopolysaccharidoses.** *C. Simonaro*<sup>1</sup>, *M. D'Angelo*<sup>2</sup>, *M. Haskins*<sup>3</sup>, *E. Schuchman*<sup>1</sup>. 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) Dept Anatomy, PCOM, Philadelphia, PA; 3) Dept Pathobiology, U Penn, Sch of Vet Med, Philadelphia, PA.

A major feature of the mucopolysaccharidoses (MPS) is abnormal cartilage and bone development leading to short stature, dysostosis multiplex, and degenerative joint disease. We have previously shown that articular chondrocytes from MPS animals undergo apoptosis due to glycosaminoglycan storage and stimulation by proinflammatory cytokines, including TNF-alpha and IL-1beta. However, despite the enhanced apoptosis, no extensive cell loss was observed. To investigate this further, we performed BrDU incorporation studies and found that MPS chondrocytes had increased proliferation rates. This was explained by elevated levels of TGF-beta in the MPS cartilage, a growth factor known to prevent bone degeneration by enhancing cell proliferation and counteracting the deleterious effects of IL-1beta. However, despite elevated TGF-beta expression and enhanced chondrocyte proliferation in the MPS animals, extensive bone and joint disease was observed, suggesting that other factors were involved in promoting the degenerative effect. Therefore, we investigated the expression of metalloproteinases (MMPs) in the MPS animals since proinflammatory cytokines, such as TNF-alpha and IL-1beta, have been shown to upregulate MMP gene expression. The activity and mRNA expression of two MMPs known to be involved in the pathogenesis of arthritis, MMP-2 and MMP-9, were elevated in the MPS animals when compared to age-matched, normal controls. Overall, these results suggest new therapeutic targets for the MPS disorders, including drugs that inhibit apoptosis, proinflammatory cytokines, and/or MMPs, or drugs that augment the protective effect of TGF-beta.

**Subtle neuropsychological abnormalities in patients with type I Gaucher disease.** *D. Elstein, J. Guedalia, P. Rosenberg, V. Antebi, Y. Arnon, A. Zimran.* Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel.

Because of a complaint of memory loss in a patient participating in the clinical trial with miglustat, an oral substrate inhibitor for Gaucher disease, a battery of tests relating to frontal-parietal lobe function was administered to trial participants plus patients receiving enzyme replacement therapy or untreated. The purpose of this study was to tease out the concern about drug-related cognitive dysfunction among patients with type I Gaucher disease. The tests administered were: MiniMental State Examination, Rey Osterreith Complex Figure Test, Rey Auditory Verbal Learning Test, Word Fluency Test (FAS), Semantic Fluency Test (Animals), Trail Making Tests A and B, Tower of Hanoi, Wisconsin Card Sorting Test. Of 108 patients, 55 had received miglustat, 31 were enzyme-treated, and 22 were untreated. The z-scores for all tests for all groups were below normal except for the MiniMental test, which were normal. In the miglustat group, there was no correlation between individual scores and duration of therapy. Based on these results, the clinical trial, which had been halted, was re-instated; miglustat today is approved for marketing in Europe and Israel. Like other glycolipid storage disorders, Gaucher disease phenotypic expression is probably a continuum from virtually asymptomatic to lethal neurological involvement. This study underscores visual-spatial defects that correlate with parietal lobe dysfunction. Albeit subtle, the aberrant results are pervasive among all patients tested and imply that there is a nidus of neurological pathology even in patients with the mutation that is protective of neuronopathic involvement.

**Do mutations in the glucocerebrosidase gene modify the course of Parkinson disease? Family studies in patients with Gaucher disease.** *O. Goker-Alpan*<sup>1, 2</sup>, *R. Schiffmann*<sup>3</sup>, *A. Lwin*<sup>1, 2</sup>, *E. Sidransky*<sup>1, 2</sup>. 1) NSB/NIMH,NIH, Bethesda, MD; 2) MGB/NHGRI, NIH, Bethesda, MD; 3) DMNB/NINDS, NIH, Bethesda, MD.

Gaucher disease, the inherited deficiency of glucocerebrosidase, can present with a wide range of symptoms of varying severity affecting the skeletal, hematologic and nervous systems. Parkinsonian symptoms are now included in the spectrum of associated neurologic manifestations based upon the concurrence of Gaucher disease with parkinsonism in about 20 recently reported cases. Parkinson disease, the second most common neurodegenerative disorder, results from multiple etiologies. Genetic, epigenetic and environmental factors may all contribute to this phenotype. In an earlier report, we showed that patients with Gaucher disease and parkinsonism have an increased number of family members affected with Parkinson disease. In this study, we present six unrelated families of probands with Gaucher disease, in which eight obligate carriers of glucocerebrosidase gene mutations had signs and symptoms of parkinsonism. The parkinsonian symptoms were associated with an early age of onset, often with an atypical course. Three families carried the L444P allele; one a recombinant allele and one the N370S mutation. It has been suggested that mutant glucocerebrosidase may be a risk factor contributing to early onset, L-dopa refractory parkinsonian symptoms. These findings provide further evidence that glucocerebrosidase gene mutations, even in the heterozygous state, might act as modifiers, altering the phenotype in individuals genetically prone to Parkinson disease.

**Mucopolysaccharidosis type IIIB: Identification of the causative mutation in the canine model.** *N.M. Ellinwood<sup>1</sup>, P.S. Henthorn<sup>2</sup>, U. Giger<sup>2</sup>, M.E. Haskins<sup>1</sup>*. 1) Dept Pathobiology, Univ Pennsylvania Sch Vet Med, Philadelphia, PA; 2) Dept Clinical Sciences, Univ Pennsylvania Sch Vet Med, Philadelphia, PA.

Mucopolysaccharidosis type IIIB (MPS IIIB) is a severe and lethal lysosomal storage disorder caused by a deficiency in activity of the enzyme *N*-acetyl-a-D-glucosaminidase (NAGLU), and subsequent lysosomal accumulation of the substrate heparan sulfate. To better utilize the canine model of MPS IIIB, we have identified the disease-causing mutation in the canine NAGLU gene.

Using the normal sequence of the canine NAGLU cDNA, primers were designed to amplify the genomic sequence of the canine NAGLU gene from the 5 to 3 UTRs. The genomic sequence of an affected dog was amplified and sequenced revealing the mutation to be a poly(A) insertion (~45 adenines) in the sixth exon of the NAGLU gene. The poly(A) insert is flanked on the 3 border by a 13 bp repeat of the native NAGLU sequence immediately 5 to the poly(A) insert. The insert was found to be polymorphic in the affected individual, differing by the number of adenine residues present. The insert is predicted to lead to the insertion of ~15 lysine residues starting after amino acid 704 of the unmodified protein sequence. Such a large insertion would likely disrupt normal enzyme activity, regardless of whether the number of adenine residues present lead to an in-frame insertion or not.

The presence of a poly(A) sequence and the flanking of the insert by a repeat of 5 native sequence at the 3 end of the insert, lead us to conclude that the insertion mutation was mediated by a LINE element. This would be the first recognition of an inherited disease causing mutation of this type in the dog, and the first in a species other than humans or mice. Supported by NIH grants RR002512 and RR007063, and by a grant from the National MPS Society, Inc.

**Familial mitochondrial myopathy: New insights into the T14709C mitochondrial tRNA mutation.** *A.M. Schaefer<sup>1</sup>, R. McFarland<sup>1</sup>, J.L. Gardner<sup>1</sup>, S. Lynn<sup>2</sup>, C.M. Hayes<sup>1</sup>, M.J. Barron<sup>1</sup>, M. Walker<sup>3</sup>, P.F. Chinnery<sup>1</sup>, R.W. Taylor<sup>1</sup>, D.M. Turnbull<sup>1</sup>.* 1) School of Neurology, Neurobiology and Psychiatry, The Medical School, Framlington Place, University of Newcastle upon Tyne, NE2 4HH, UK; 2) Dept. of Neurology and Neurological Sciences, Stanford University, Stanford, CA 94305; 3) School of Clinical Medical Sciences, The Medical School, Framlington Place, University of Newcastle upon Tyne, NE2 4HH, UK.

We have defined the genetic defect in a large family first described in one of the earliest reports of suspected mitochondrial myopathy, as the mutation T14709C in the mitochondrial tRNA<sup>Glu</sup> (mt-tRNA<sup>Glu</sup>) gene. Extraordinarily, this mutation has attained homoplasmy (100% mutated) on at least three independent occasions in this family and has done so in one individual who as yet remains asymptomatic and has no clinical evidence of disease. In all previous descriptions of the T14709C mutation, it has always been documented as heteroplasmic (co-existing wild type and mutated mitochondrial DNA [mtDNA]). Heteroplasmy is usually regarded as one of the primary diagnostic criteria for pathogenic mtDNA mutations but often does not provide an adequate explanation for phenotypic variation within families. Although a few homoplasmic mt-tRNA mutations have now been described, they have generally been regarded as rare and of low pathogenicity, resulting in organ-specific phenotypes such as deafness. Discovering that T14709C, a common and severe mt-tRNA mutation, can attain homoplasmy without symptoms or clinical signs of disease has profound implications for the identification and prevalence of other pathogenic mt-tRNA mutations. Furthermore, the observed variation in phenotype between individuals harbouring this homoplasmic mutation implies a crucial contribution from the nuclear genetic environment in determining the clinical outcome of mt-tRNA mutations.

**Amish microcephaly due to mitochondrial deoxynucleotide carrier deficiency is associated with lactic acidosis and agenesis of the corpus callosum.** *V.M. Siu, C.A. Rupa*. Depts of Pediatrics, Biochemistry and Pathology, University of Western Ontario, and CPRI, London, ON, Canada.

Amish microcephaly is an autosomal recessive mitochondrial disorder recently described in the Old Order Amish of Lancaster County. Reported features include severe congenital microcephaly with lissencephaly, hypoplastic pons and cerebellar vermis, death within the first year of life, and elevated urinary excretion of 2-ketoglutaric acid. Rosenberg (2002) found a homozygous mutation within the mitochondrial deoxynucleotide carrier (DNC) in affected infants. We report a male infant with microcephaly first noted at 20 weeks gestation. He was born at term weighing 3.3 kg with head circumference of 29 cm to consanguineous parents of Mennonite background. Amish microcephaly was suspected, based on MRI scan showing features described above. Agenesis of the corpus callosum was also present. However, urine organic acid analysis revealed no elevation of 2-ketoglutaric acid. At 5 months, he was admitted to hospital with failure-to-thrive and vomiting. Initial plasma lactate level was 6.7 mmol/L. While in hospital, he had 2 episodes of tachypnea and lethargy due to metabolic acidosis with plasma lactate rising to 16 mmol/L. Treatment with a mitochondrial metabolic cocktail and sodium bicarbonate resulted in lactate levels ranging between 8 to 10 mmol/L. Initiation of a modified ketogenic diet resulted in a dramatic decrease of plasma lactates to normal levels, accompanied by improved oral feeding, increased alertness, decreased hypertonicity and significant weight gain. Repeat urine organic acid analysis during metabolic acidosis failed to demonstrate elevated levels of 2-ketoglutarate, although urine lactate level was elevated. Mutation analysis of the DNC gene confirmed the same homozygous mutation as previously described in the Amish. We conclude that 2-ketoglutaricaciduria is not an obligatory finding and that lactic acidosis may be present in Amish microcephaly. We confirm the CNS malformations and add the feature of agenesis of the corpus callosum. Treatment with a ketogenic diet may help to correct lactic acidosis and potentially avert episodes of metabolic decompensation.

**Cerebral involvement in Mucopolysaccharidosis II: correlation between brain magnetic resonance findings and clinical manifestations.** *I.V.D. Schwartz<sup>1</sup>, L. Vedolin<sup>2</sup>, A.C. Puga<sup>1</sup>, L. Pinto<sup>1</sup>, F. Goncalves<sup>1</sup>, A. Pires<sup>1</sup>, R. Boy<sup>3</sup>, E.S. Santos<sup>3</sup>, I. Monllo<sup>3</sup>, M. Fontes<sup>3</sup>, E. Ribeiro<sup>3</sup>, C.A. Kim<sup>3</sup>, E. Valadares<sup>3</sup>, M. Damaso<sup>3</sup>, G. Carakushansky<sup>3</sup>, E. Kahn<sup>3</sup>, D. Norato<sup>3</sup>, R.O. Sobrinho<sup>3</sup>, R. Giugliani<sup>1</sup>.* 1) Medical Genetics Service, HCPA, Porto Alegre, Brazil; 2) Diagnostic Medicine, MDC, Porto Alegre, Brazil; 3) Brazilian MPS II Study Group.

Mucopolysaccharidosis type II (MPS II) is a rare lysosomal disorder caused by the deficiency of the enzyme iduronate L-sulfatase (IDS). To evaluate the effects of the IDS deficiency on the CNS, we studied 19 Brazilian MPS II male patients. These patients underwent brain MRI, as well as ophthalmologic, neurological and psychological evaluation, the latter including an IQ test. Mean age at evaluation was 9.3 ys (3-26 ys). 14/19 (74%) were classified as having the neurological form (N) and 5/19 (26%) the non-neurological form (NN). Isointense and hyperintense lesions were the most frequent findings in MRI, and were found in 16 patients (12/14 N, 4/5 NN); prominent cortical sulci were found in 12 (10/14 N, 2/5 NN), megacisterna magna was found in 7 (6/14 N, 1/5 NN), bilateral enlargement of the optic nerve sheath was found in 4 (3/14 N, 1/5 N), and hydrocephalus was found in 8 patients (8/14 N). Among patients with hydrocephalus, the most frequent clinical manifestation found was cognitive deficit (100%), followed by hyperreflexia (25%); papilledema and convergent strabismus were found in 1/8 patients. Alterations in spectroscopy were found in all patients, and are suggestive of axonal/white matter lesions. Our results suggest that brain isointense and hyperintense lesions, prominent cortical sulci, hydrocephalus, and megacisterna magna are frequent findings in MPS II. Among these findings, only hydrocephalus and megacisterna magna seem to be associated to the N form. Patients presented with hydrocephalus do not usually present signs/symptoms of acute intracranial hypertension (ICH), but they do present signs/symptoms of chronic ICH. Therefore, it is our understanding that the early diagnosis and treatment of ICH are essential for the preservation of the cognitive function of these patients (NORD/CAPES/TKT).

**Genetic variation of methylen tetrahydrofolate reductase gene in Iranian patients with coronary artery disease.**

*M. Ghaedi*<sup>1</sup>, *A. aleyassin*<sup>1</sup>, *S. Davoodi*<sup>2</sup>, *H. Abbasi*<sup>2</sup>. 1) National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran; 2) Tehran haert center, Shariati Hospital Tehran medical University, Tehran, Iran.

Several studies showed that elevated plasma homocysteine is a risk factor for coronary artery disease. common mutation C677T , A1298C of methylenetetrahydrofolate reductase (MTHFR) and A66G of methionine synthase reductase(MTRR) genes is reported to be associated with decreased enzyme activities and significant increased level of blood homocysteine. This study was to analyze the frequency of this mutation in 100 patients with CAD compared to the 100 normal control. It shows the higher prevalence of the C677T mutation in CAD patients compared to the normal control in Iranian tested patients. The C677T MTHFR was significantly linked to the CAD, supported by a P value <0.001 and Chi-square 51.82. Our observation showed the prevalence and significance of this mutation in studied cases compared to the normal control in Iranian cases.but the prevalence of the A1298C and A66G in CAD patients and normal control were equal. The A1298C MTHFR and A66G MTRR weren,t significantly linked to the CAD, supported by a P value 0.706 and chi-square 0.697 for A1298C and a Pvalue 0.052 and chi-square 5.923 for A66G mutations.However no significant corralation were obtained for A1298C and A66G MTRR mutation.

**MURR1: a new copper transport protein?** *L. Klomp<sup>1</sup>, P. de Bie<sup>2</sup>, A. Klomp<sup>1</sup>, B. van Oost<sup>3</sup>, C. Wijmenga<sup>2</sup>*. 1) Dept Pediatric Gastroenterolog, Wilhelmina Children's Hosp, Utrecht, Netherlands; 2) Dept Biomedical Genetics, University Medical Center Utrecht, the Netherlands; 3) Department of Veterinary Sciences, Utrecht University, the Netherlands.

Copper is an essential trace element for the survival of all organisms, although it is highly toxic above a certain threshold. To ensure proper copper homeostasis, copper import, distribution and export are well-regulated processes. Two homologous copper transport proteins have been identified which, when dysfunctional, cause either copper deficiency (Menkes disease) or copper accumulation (Wilson disease) in man. Non-Wilsonian hepatic copper toxicosis in man has been described to be phenotypically very similar to copper toxicosis (CT) in Bedlington terriers, which is a frequent genetic disease unique to this breed. We recently established that canine CT is due to a deletion encompassing exon 2 of MURR1. We also performed MURR1 mutation analysis in 23 patients with non-Wilsonian hepatic copper toxicosis. Although no mutation was found the MURR1 gene remains to be a candidate gene for other non-Wilsonian copper toxicosis patients. The function of the MURR1 gene is still unknown but we hypothesize that this gene is essential for biliary copper excretion downstream of ATP7B. Orthologs of MURR1 have been identified in a number of mammalian organisms, but could not be detected in lower eukaryotes and prokaryotes. MURR1 is most abundantly expressed in liver. Bedlington terriers with copper toxicosis accumulate copper in their lysosomes, suggesting that MURR1 is essential for excretion of copper into the bile. A polyclonal antiserum against MURR1 was successfully developed which showed that MURR1 is undetectable in the livers of affected Bedlington terriers. A yeast-two hybrid screen led to the identification of a yet unknown protein, which interacts with MURR1. A mouse knockout with a mutation comparable to the terriers is underway. Further characterization of MURR1, and its pathway, may lead to disentangling the complexities of copper metabolism in mammals and to the identification of new genes involved in copper homeostasis, which will be candidates for non-Wilsonian hepatic copper toxicosis.

**Human Acid Ceramidase: Catalytic Reactions and Interactions With Acid Sphingomyelinase.** *X. He, N. Okino, E. Schuchman.* Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY.

Human acid ceramidase (AC) is the enzyme deficient in the lysosomal storage disorder, Farber disease. AC was overexpressed in Chinese hamster ovary cells by amplification of the transfected, full-length cDNA. The majority of the overexpressed, human enzyme was secreted into the culture media and purified to homogeneity. The purified protein contained the same alpha and beta subunits as AC from natural sources, had an acidic pH optimum (4.5), and followed normal Michaelis-Menten kinetics. The purified enzyme also catalyzed ceramide synthesis using C12 fatty acid and sphingosine as substrates. In contrast to the degradative reaction, this reverse reaction occurred at an optimal pH of ~6.0. Cell extracts from patients with Farber disease had reduced reverse AC activity, confirming that the AC polypeptide was responsible for both reactions. Surprisingly, we also found that media from the overexpressing hamster cells had increased acid sphingomyelinase (ASM) activity. RNA studies showed that this increased activity was not due to overexpression of the endogenous ASM gene. Overexpression of AC in normal skin fibroblasts also led to enhanced ASM secretion, but this was not observed in Niemann-Pick disease cells. These studies provide new insights into AC and ASM, and suggest that these enzymes may exist within a multienzyme complex carrying out sphingolipid catabolism. These studies also reveal that patients with Farber disease have a defect in ceramide synthesis, as well as degradation.

**Lysosomal, but not Cytosolic Disulfide, Induces Apoptosis in Human Renal Proximal Tubule Cells.** *A.L. Jones, M.A. Park, J.G. Thoene.* Human Genetics, Tulane University, New Orleans, LA.

We have previously shown that renal proximal tubule epithelial (RPTE) cells show a ten-fold increase in apoptotic rate when exposed to cystine dimethylester (CDME), a compound that causes accumulation of cystine within lysosomes (Park et al, 2003). It is not yet known whether lysosomal localization of the disulfide is required for enhanced apoptosis to occur. We here report that RPTE cells do not show increased apoptosis when treated with equimolar amounts of compounds that do not result in lysosomal disulfide localization. The basal apoptosis rate in these cells is 1.8% (CaspACE and FACS). CDME exposure results in an increased apoptosis rate to 37.0%. The two non-esterified disulfides, cystamine and penicillamine disulfide resulted in 2.5% and 2.4% apoptosis respectively after the cells were exposed to 0.5mM compound for 6 h. The non-disulfide congener of cystine, djenkolic acid caused only 1.9% apoptosis when added to the RPTE cells for the same period at the same concentration. The fluorescent dye, JC-1 is known to reflect the redox state of mitochondria. Exposure of cultured fibroblast cells to CDME for 12 hr at a concentration of 0.5 mM, produced an increase in the proportion of positive cells from 11.7% to 36.6%. We conclude that lysosomal cystine increases apoptosis via a perturbation in the redox state of the cell, which is mediated by lysosomal release of disulfides.

**Mouse Skin Fibroblasts and Renal Proximal Tubule Cells Do Not Display Lysosomal Cystine Enhanced Apoptosis.** *M. Park, A. Jones, J. Thoene.* Dept Human Genetics, Tulane Univ, New Orleans, LA.

Cystinosis is a disease of lysosomal cystine storage characterized by short stature, corneal clouding, renal Fanconi syndrome, and end-stage renal failure by age ten years if untreated. It results from a mutation in the gene CTNS, which codes for the lysosomal cystine transporter. We have recently shown that lysosomal cystine storage causes human fibroblasts and renal proximal tubule cells to display 2-4 fold increased apoptosis (Park et al, J Am Soc Nephrol. 2002; 13, 2878-2887). Cherqui et al (Mol Cell Biol. 2002; 22, 7622-7632), described the first cystinosis knock out mouse. Increased cystine was detected in all tissues observed, however, the mice do not express the renal phenotype seen in man. Human renal proximal tubule epithelial (RPTE) cells treated with cystine dimethylester (CDME, a compound that causes lysosomal cystine storage) yield an apoptosis rate of 88.0% (baseline 2.5%), while primary mouse RPTE cells so treated display an apoptotic rate of only 22.8% (baseline 10.1%). Similar results were obtained with human and mouse skin fibroblasts: Human transformed fibroblast cell line GM00637 displayed an apoptotic rate of 49.9% 9.7 after CDME treatment (baseline 4.9% 2.08), contrasted with mouse L929 fibroblasts, that had an apoptotic rate of 5.8% 0.60 after CDME (baseline 6.3% 2.5) ( $p=0.01$ ). A generalized hypocellularity of critical organs and tissues due to enhanced apoptosis mediated by lysosomal cystine storage can explain the cystinotic phenotype. Failure to display this lysosomal cystine-enhanced apoptosis may account for the failure of the CTNS knockout mouse to faithfully model the human disease cystinosis.

**A new mutation in the EIFAK3 gene, encoding the transmembrane endoplasmic reticulum (ER) kinase PERK, in a patient with Wolcott-Rallison syndrome (WRS).** *F. Durocher<sup>1</sup>, Y. Labrie<sup>1</sup>, L. Pelletier<sup>2</sup>, M.B. Plourde<sup>1</sup>, R. Laframboise<sup>2,3</sup>, R. Faure<sup>2</sup>.* 1) Cancer Genomics Laboratory,; 2) Pediatrics Research Unit; 3) Medical Genetics, CHUL Research Centre, CHUQ, Laval University, Quebec, Canada,;

Wolcott-Rallison syndrome (WRS) is a rare autosomal recessive disorder characterized by permanent neonatal insulin-dependent diabetes, severe epiphyseal dysplasia, osteoporosis and growth retardation. Clues to the regulation of protein synthesis in secretory cells have recently come from the investigation of the unfolded protein response (UPR), an adaptive mechanism which controls the deleterious effects of accumulating unfolded proteins in the ER. The transmembrane kinase EIF2AK3/PERK functions by inhibiting protein synthesis following the dissociation of chaperones associated from its intraluminal domain. In two previous studies, mutations in the EIF2AK3/PERK gene, which encodes a protein of 1115 amino acids, have been found in WRS patients. We report here the finding of a novel nonsense mutation in a French Canadian family. Sequencing analysis of the proband revealed the presence of a homozygous G to T change in exon 5 leading to the nonsense E331X mutation (GAG/TAG). The mutation therefore produces a largely truncated protein of 330 amino acids in which the cytosol-oriented domain of PERK, containing the kinase domain, located from amino acid 577 to 1115 in the wild-type protein, is missing. Both parents were found heterozygous for the same mutation. No other case was present in the family. These results confirm the role of EIF2AK3/PERK in WRS and its utility for diagnoses. The results also further point out the role of intracellular organelles in the control of signaling pathways and physiological glucose homeostasis.

**Clinical and molecular findings in a patient with Griscelli syndrome.** *M. Gunay-Aygun<sup>1</sup>, A. Dobbie<sup>2</sup>, R. Kleta<sup>1</sup>, H. Dorward<sup>1</sup>, Y. Crow<sup>2</sup>, W.A. Gahl<sup>1</sup>, P. McClean<sup>2</sup>, M. Huizing<sup>1</sup>.* 1) Section on Human Biochemical Genetics, MGB, NHGRI, NIH, Bethesda, MD; 2) St James's Hospital, Leeds, United Kingdom.

Griscelli syndrome (GS) is an autosomal recessive disorder characterized by partial albinism (hypopigmented skin and silvery hair) with immunodeficiency and onset of neurological impairment secondary to hemophagocytosis involving the central nervous system. Mutations in *Rab27A*, which codes for a small GTPase involved in vesicle trafficking, lead to GS, while mutations in *Myo5A*, which codes for a myosin interacting with both intracellular vesicles and actin filaments, result in Elejalde syndrome (ES). Both disorders share clinical signs and symptoms, but in ES the neurological involvement is primary and no immune defects occur. Initially it was thought that both these closely localized genes on 15q21 caused GS. Here we present the clinical course of an offspring of first cousins affected by GS who died at the age of 4 years from infection-associated complications. The patient presented at the age of 3 years with recurrent, 2-3 week long episodes of fever associated with splenomegaly, pancytopenia, episcleritis, and a skin rash. The patient had silver grey hair and was small for age. A liver biopsy showed features of advanced chronic hepatitis, and serum titers indicated hepatitis B. IgG levels were persistently elevated. A skin biopsy showed chronic inflammatory cells within the dermis. At age 3 years, the patient developed left hemiparesis during an episode of fever. Brain imaging showed a large porencephalic cyst in the right frontal region with some white matter edema. No vascular malformations could be documented. Bone marrow aspirate, obtained during a healthy period, showed no signs of hemophagocytosis. Sequencing of all coding exons of *Rab27A* verified the clinical suspicion of GS by demonstrating a new homozygote splice site mutation in intron 3, i.e., IVS3-2 A>G. In summary, this patient exhibited clinical signs and symptoms of GS with secondary neurological abnormalities. Differentiating between *Rab27A* and *Myo5A* disorders is important for the clinical management and care of affected patients.

**Fabry disease: Recognition and characterization of the renal variant.** *C. Carter, J. Wiszniewska, B. Roa, C.M. Eng.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Fabry disease, an X-linked deficiency of the lysosomal hydrolase, alpha-galactosidase A, results in the accumulation of glycosphingolipids, primarily GL-3, in the vascular endothelium and other cell types in the body. Classically affected males manifest the typical signs and symptoms of the disorder, i.e., angiokeratoma, acroparesthesias, corneal dystrophy, progressive involvement of the kidneys, heart, and cerebrovascular systems, and follow a predictable disease course. In contrast, several variant presentations of Fabry disease have been recognized that are characterized by milder, sometimes organ specific dysfunction. The previously described cardiac variant consists of individuals who lack the classic signs and symptoms of the disease and have disease manifestations mostly limited to the heart. Recently, several individuals have been identified who lack the classic signs and symptoms, but have renal manifestations that parallel those of classically affected males. A 42 year old male presented with proteinuria (796 mg/24 hr) and renal insufficiency (serum creatinine 1.4 mg/dl). A renal biopsy showed ultrastructural features consistent with Fabry disease and leukocyte alpha-galactosidase A activity was deficient (4 nmoles/hr/mg; nl range 55-126). The patient denied a history of acroparesthesias or hypohidrosis. Exercise tolerance was good. Physical exam revealed no angiokeratoma or corneal dystrophy and cardiac examination was normal. DNA sequencing of the entire alpha-galactosidase A coding region and flanking intronic sequences demonstrated a single nucleotide substitution resulting in the N215S genotype. This genotype was previously identified in several unrelated cardiac variant patients as well as classically affected individuals. Recognition of the variant presentations of Fabry disease adds to the spectrum of disease manifestations that can present in this disorder. The phenotypic spectrum associated with the N215S genotype continues to broaden. The cardiac and renal variants, as well as symptomatic heterozygotes present a diagnostic challenge, however prompt recognition and consideration of treatment may improve the long term outcome.

**Genotype and phenotype analysis in Wilson disease.** *D.W. Cox*<sup>1</sup>, *L.M. Prat*<sup>1</sup>, *J.M. Walshe*<sup>2</sup>, *E.A. Roberts*<sup>3</sup>, *L.M. Cullen*<sup>1</sup>. 1) Medical Genetics, Univ Alberta, Edmonton, AB, Canada; 2) Hemingford Grey, UK; 3) Hospital for Sick Children, Toronto, ON.

Wilson disease (WND), a disorder of copper transport, is extremely variable in type of manifestation (hepatic and/or neurologic) and age of onset (3-50 or more yrs). We carried out mutation analysis on 173 patients diagnosed with WND by clinical, biochemical and molecular analysis: 146 of various European origins (91 from Canada, 55 from UK), 10 Canadians of Chinese origin, and 17 Indian or Pakistan origin from Canada and the UK. Mutation analysis was carried out by assay of the common His1069Gln mutation and sequencing of 10 or more exons of the 21 exons of *ATP7B*. In the European origin group, at least one mutation was identified in 91% of patients: of these mutations, 36% were H1069Q, 17% in exon 8, 8% in each of exons 13 and 18, and less than 5% in other exons. In the total group, 79% were missense, 16% small deletions or insertions, 2% nonsense, and 3% splice site mutations. In comparison, distribution of 262 mutations listed in the WND Mutation Database ([www.uofa-medical-genetics.org](http://www.uofa-medical-genetics.org)) in these classes is 58, 27, 7 and 8%; respectively. A promoter mutation was found only in patients of Sardinian origin. The exon distribution of mutations was similar for neurological and hepatic onset. Type of mutation influences age and type of onset of the disease. Among 60 homozygotes for the same mutation from all ethnic groups, the most informative for phenotype/genotype correlation, age of onset was 11.4 yrs. for those with severe mutations (deletions, insertions, nonsense), with 11 hepatic and 4 neurologic onset. Early onset was usually with hepatic onset. For 16 with various missense mutations, age of onset was 17.8 yrs. The common His1069Gln mutation had an age of onset of 20.3 yrs. In the European group, age of onset was influenced by the class of the mutation: 11.8 yrs for severe homozygous mutations, 18.7 for various combinations of missense homozygotes. Missense mutations need study by functional assays to ensure they are not normal rare variants. Age of onset is due in part to the severity of the mutation present, but other modifying factors appear to be important.

**Role of genetic modifiers in determining the phenotype in Gaucher disease: A closer look at the genotype**

**L444P/L444P.** *E. Sidransky*<sup>1, 2</sup>, *E. Orvisky*<sup>1, 2</sup>, *A. Lwin*<sup>1, 2</sup>, *B. Stubblefield*<sup>1, 2</sup>, *R. Schiffmann*<sup>3</sup>, *O. Goker-Alpan*<sup>1, 2</sup>. 1) NSB/NIMH/NIH, Bethesda, MD; 2) MGB/NHGRI, NIH, Bethesda, MD; 3) DMNB/NINDS, NIH, Bethesda, MD.

Gaucher disease (GD), the inherited deficiency of lysosomal glucocerebrosidase, is classified into three major clinical types depending upon the degree of nervous system involvement. Type 3 GD is a progressive neuronopathic form, and is often associated with severe systemic disease. Homozygosity for the common L444P allele usually correlates with neuronopathic GD. However, previous genotype/phenotype studies indicate that there can be vast phenotypic variation even among patients sharing the same genotype. To define the spectrum of clinical heterogeneity and elucidate the role of genotype and/or modifier genes in defining phenotype, twenty-four children (10M: 14F) with genotype L444P/L444P were identified. Genotyping was performed by both direct sequencing and Southern blots, confirming the absence of a recombinant allele. The residual glucocerebrosidase activity, measured in fibroblast cell lines, ranged from 1-20% and did not correlate with clinical presentation. The phenotypes encountered varied from death in early childhood to relatively asymptomatic college students. The age at diagnosis ranged from 2 months to 2 years, with an average of 15 months. Eighteen patients received enzyme replacement therapy (ERT) and six died by adolescence before ERT was available. The systemic involvement was most severe in the cohort who had undergone splenectomy without receiving ERT. Clinically, all appeared to have isolated supranuclear palsy. Two children had clinical seizures, while most had abnormal EEGs. Less than 20% of patients had developmental delay. Even though ERT significantly decreased the morbidity and mortality, the broad phenotypic variation among L444P homozygotes was still accounted for only in part by therapeutic intervention. These findings implicate the contribution of genetic modifiers in determining phenotype in GD.

**Pseudoxanthoma elasticum development of a mouse model by targeted ablation of ABCC6.** *J. Uitto, Y. Matsuzaki, J. Terlizzi, K. Li, D. Leperi, J. Klement, L. Pulkkinen.* Dermatology/Cutaneous Biol, Thomas Jefferson Univ, Philadelphia, PA.

Pseudoxanthoma elasticum (PXE), an autosomal recessive disorder, is characterized by late-onset calcification of pleiotropic elastic structures in the skin, eyes, and the cardiovascular system. The mutated gene was recently shown to be ABCC6 encoding MRP6, a transmembrane protein of unknown function, expressed primarily in the liver. We have embarked on development of a mouse model for PXE using targeted ablation of the ABCC6 gene. The targeting construct replaced 6.9 kb of genomic sequence resulting in elimination of exons 15-18 from the corresponding mRNA (545 bp), which is out-of-frame predicting a null allele. Southern analysis and genomic PCR showed the final products to be homozygous for the deletion in the ABCC6 gene. Northern analysis of polyA<sup>+</sup> RNA from the liver revealed that the mutant ABCC6 mRNA was not expressed, suggesting that it is unstable. Staining of liver from wild-type mice with antibody anti-MRP6 antibody revealed membrane-associated baso-lateral staining, while the staining was entirely negative in the ABCC6<sup>-/-</sup> mice. These findings confirm that the mice are truly null with regard to MRP6 expression. Examination of elastic structures by histochemical stain (Verhoeff-van Gieson) and by immunohistochemistry with anti-elastin antibody revealed that the elastic structures in the eye (Bruch's membrane), in the skin, and in the aorta were apparently normal in ABCC6<sup>-/-</sup> mice at eight weeks of age, and von Kossa staining for calcium was negative. These findings suggest that the development of the elastic fiber network in tissues affected in PXE is normal in these mice, at least during the early stages of development. Examination of skin at 32 weeks suggested that the elastic fibers were sparse and fragmented in ABCC<sup>-/-</sup> mice, but there was no evidence of aberrant calcification. Thus, the findings in the ABCC6 knock-out mice are consistent with late-onset of human PXE.

**Lysosomal Disease Clinical Research Center WORLD.** *E. Shapiro*<sup>1</sup>, *L. Elsas*<sup>2</sup>, *C. Eng*<sup>3</sup>, *R. Martin*<sup>4</sup>, *D. Marsden*<sup>5</sup>, *G. Pastores*<sup>6</sup>, *R. Steiner*<sup>7</sup>, *W. Wilcox*<sup>8</sup>, *S. Winter*<sup>9</sup>, *C. Peters*<sup>1</sup>, *J. Hegland*<sup>1</sup>, *D. Erickson*<sup>1</sup>, *L. Charnas*<sup>1</sup>, *C. Whitley*<sup>1</sup>. 1) Univ Minnesota, Minneapolis; 2) Univ Miami, Miami; 3) Baylor College of Medicine, TX; 4) Washington Univ, St. Louis, MO; 5) Harvard Univ, Boston, MA; 6) New York Univ, New York, NY; 7) Oregon Health Sciences Univ, Portland, OR; 8) Cedars-Sinai Med Center, Los Angeles, CA; 9) Children's Hosp Central California, Madera, CA.

The Lysosomal Diseases Clinical Research Center WORLD is a scalable multi-center consortium of geographically distributed expert medical centers, together planning and promoting clinical research on rare lysosomal diseases, i.e., mucopolysaccharidoses, glycosphingolipidoses, oligosaccharidoses and ceroid lipofuscinosis. The network is developing longitudinal studies to understand the natural history of health, neuropsychological, and quality-of-life outcomes, with and without treatment. The first longitudinal study focuses on the natural history of MPS I and treatment effects of hematopoietic cell transplantation (HCT) and enzyme replacement (ERT). The linked multi-center approach facilitates the development of common criteria, protocols, nomenclature and methods that will have broad applicability. On an annual basis, the WORLD Advisory Board supports 2 to 6 "pilot" or "demonstration" projects aimed at 1-year hypothesis-driven studies exploiting the combined resources of the center. Four studies for this year are: 1) Introduction of MPS Screening in a Multicultural Medical System, 2) ERT in Conjunction with HCT for MPS I, 3) Ventilatory and Cardiovascular Abnormalities at Rest and During Exercise in Fabry Disease, and 4) Adult/Late-onset Tay-Sachs Disease: A Model for a Rare Lysosomal Storage Disease and Inherited Motor Neuron Disease. The WORLD training program supports a broad group of activities including an annual scientific and educational meeting (May 13-16, 2004), site visits to each of the centers, and fellowships to enhance new clinician-investigators that are needed in the field. A website, [www.world.umn.edu](http://www.world.umn.edu), provides education and training resources for professionals, on-line data management, and information for the lay population.

**Nevo syndrome or kyphoscoliotic type of Ehlers-Danlos syndrome (EDS VIA)?** A. Randolph<sup>1</sup>, C. Giunta<sup>1</sup>, L.I. Gazali<sup>2</sup>, M.E. Kraenzlin<sup>3</sup>, B. Steinmann<sup>1</sup>. 1) Division of Metabolism & Molecular Pediatrics, University Children's Hospital, CH-8032 Zurich, Switzerland; 2) Department of Pediatrics, UAE University, Al Ain, United Arab Emirates; 3) Division of Endocrinology and Diabetology, University Hospital, CH-4031 Basel, Switzerland.

The Nevo syndrome (MIM 601451) is a rare autosomal recessive disorder characterized by overgrowth, muscle hypotonia, joint laxity and kyphoscoliosis. Since its first description in 1974 by Nevo *et al.* only a few cases have been reported. In our opinion some of these patients present clinical features of EDS VIA (MIM 225400), an inherited connective tissue disorder characterized by a deficiency of lysyl hydroxylase due to mutations in *PLOD1*. This enzyme deficiency results in underhydroxylation of lysyl residues and underglycosylation of hydroxylysine residues of collagens and, hence, to an abnormal pattern of pyridinoline crosslinks in the urine. We report on two patients published by Al-Gazali *et al.* (1997) and on an additional case also from an inbred family of United Arab Emirates. The ratio of total urinary lysyl pyridinoline to hydroxylysyl pyridinoline was elevated (3.5 and 8.2) compared to controls (0.20-0.10, range 0.10-0.38) and similar to those in EDS VIA (5.97-0.99, range 4.3-8.1, n=17). Genomic DNA was extracted from blood and the 19 exons of *PLOD1* were amplified by PCR followed by direct sequencing. In the three families, we found that both parents were heterozygous for a point mutation in exon 9 of the *PLOD1* gene, *i.e.* g.23939CGA>TGA (c.954CGA>TGA) which causes a R319X nonsense mutation. The affected offspring in each family was homozygous for the same mutation which has been shown to cause EDS VIA (Hyland *et al.*, Nat Genet, 1992). In addition, a new polymorphic variant (SNP) has been identified in intron 13 for all three families (g.30111G>A) as well as a new SNP in exon 3 for two of the three families (g.15210C>T). We have not yet established if one or both of these SNPs are associated with the mutation.

We conclude that at least some of the reported patients with Nevo syndrome have EDS VIA instead. It will be interesting to corroborate this finding in additional Nevo syndrome patients.

**An Atypical Case of Smith-Lemli-Opitz Syndrome, Both Clinically and Biochemically.** *D. Kostiner*<sup>1</sup>, *L. Merkens*<sup>2</sup>, *K. Crow*<sup>1</sup>, *R. Foxley*<sup>1</sup>, *W. Connor*<sup>4</sup>, *R. Steiner*<sup>2,3</sup>. 1) Genetics, Kaiser Permanente PC, Portland, OR; 2) Pediatrics, Oregon Health & Sci Univ; 3) Mole&Med Genetics, OHSU; 4) Medicine, OHSU.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder caused by mutations in the gene encoding the final enzyme in cholesterol synthesis, 7-dehydrocholesterol delta 7 reductase (*DHCR7*). High levels of plasma 7-dehydrocholesterol (7DHC) and 8-dehydrocholesterol (8DHC) are usually diagnostic for SLOS. We present a baby with unusual phenotypic features who was diagnosed with SLOS based on biochemical analysis and mutation analysis. The phenotype was more severe than predicted by the sterol levels and not very suggestive of SLOS. We suspect the baby has an atypical form of SLOS or a second syndrome that is unrelated. The baby was born at 30 weeks gestation to a 16-year-old G1P0-1 mother via c-section for preeclampsia. She was hospitalized 33 days for poor growth, then readmitted for failure to thrive, respiratory illness, and unexplained hyperkalemia. Exam revealed Ht & Wt <3rd%ile; HC <<3rd%ile; dysmorphic facies; high palate; long fingers with flared tips; 5th finger clinodactyly; short halluces; thin skin; prominent veins; and sparse hair. Workup showed normal results for karyotype (46,XX); cystic fibrosis mutations; biotinidase; brain CT/MRI; EEG; renal US; and hair analysis. SLOS was considered based on hyperkalemia, FTT, microcephaly, and short halluces. Plasma sterol concentrations (mg/dL) showed cholesterol of 92; 8DHC of 0.1 (nml 0); and 7DHC of 0.15 (nml 0-0.3). In our experience, the lowest plasma 7DHC range for mildly affected SLOS patients is 0.3-0.9. Mutation analysis showed 2 mutations in the *DHCR7* gene: 452GA; W151X, and an unpublished mutation 1381CT; R461C. Analysis of the baby's parents showed that the mutations were not on the same allele. We conclude: 1. Children with plasma 7DHC as low as 0.1 mg/dL could be affected with SLOS. Mutation analysis or *DHCR7* enzyme activity levels may be needed for definitive diagnosis in atypical cases. 2. Unusual phenotype (thin skin, prominent veins, sparse hair, short great toes) may be due to an SLOS variant related to the novel mutation, or perhaps to a second syndrome, such as an ectodermal dysplasia.

**CLINICAL STUDY OF 10 BRAZILIAN CASES OF MUCOPOLYSACCHARIDOSIS VI (MAROTEAUX-LAMY SYNDROME).** *C.A. Kim<sup>1</sup>, A.C. Paula<sup>1</sup>, D.R. Bertola<sup>1</sup>, L. Toma<sup>2</sup>, R. Giugliani<sup>3</sup>, M.B. Moreira<sup>1</sup>, V.H. Ferraro<sup>1</sup>, L.M.J. Albano<sup>1</sup>.* 1) Dept Pediatrics, Inst da Crianca, Sao Paulo, Brazil; 2) Disc Biologia Molecular, UNIFESP; 3) Genetica e Bioqumica, UFRGS.

Mucopolysaccharidosis type VI (MPS VI), also known as Maroteaux-Lamy syndrome, is an autosomal recessive lysosomal storage disorder caused by the deficiency of the lysosomal hydrolase, N-acetylgalactosamine-4-sulfatase, formerly known as arylsulfatase B, responsible for the degradation of dermatan sulfate. There are three recognized clinical entities: mild, moderate and severe. The evolution is progressive with multisystem involvement, specially skeletal, cardiac and pulmonary. We report on 10 Brazilian patients with MPS VI. The mean age at diagnosis was 10y 5mo (ranging from 2 years to 19 years) and their current age ranged from 7y 5mo to 19y 11mo. Parental consanguinity was observed in 2/8 families (25%). All patients presented coarse facies, short stature, hepatomegaly, joint stiffness, gibbous vertebrae/kyphosis and normal intelligence. Others findings: cardiac abnormalities (90%), hirsutism (80%), claw-hands (80%), corneal opacity (70%), macrocephaly (60%), motor delay (20%) and speech delay (10%). Evolution: respiratory infections (50%), sleep apnoea (30%), reversible cardiac arrest (30%), surgery (30%), visual deficit (20%), hydrocephaly (10%) and insuccess to oral intubation (10%). Three patients died of heart failure and respiratory distress due to airway obstruction (major survival 21y10mo). The progressive course of the disease and the possibility of enzyme replacement therapy, make an early diagnosis imperative for a better management of these patients with MPS VI.

**Normative data in adult female patients with Fabry disease.** *R. Schiffmann, S. Gupta.* Disorders & Stroke, DMNB/Natl Inst Neurological, Bethesda, MD.

Fabry disease (alpha-galactosidase A deficiency) is an X-linked disorder leading to accumulation of glycosphingolipids, predominantly globotriaosylceramide (GL-3) in cellular lysosomes. Females may be affected due to random inactivation of one X-chromosome. This 7-day prospective study was undertaken to define normative data in female Fabry patients. Fifty-seven female patients were confirmed by genotyping to have Fabry disease. Mean (SD) age was 43 (12) years. The mean age at onset of symptoms was 21 years (n=38). Mean plasma GAL activity was 3.2 nmol/hour/mL (ranged from 1.5-15.9; normal 2.4-23.1 nmol/hour/mL), and mean leukocyte GAL activity was 28.2 nmol/hour/mg (ranged from 4.0-76.7; normal 46-126.4 nmol/hour/mg). Notable specific Fabry-associated medical history included acroparesthesia (74%), cornea abnormalities (67%), angiokeratomas (63%), and pain (58%). Most patients (88%) felt their pain interfered with their daily activities, and 29 (51%) patients took rescue pain medication. Mean urinary GL-3 (331.8 nmole CTH/g creatinine/24 hours) was elevated compared with normal female patients (5.61.0 nmole CTH/g creatinine/24 hours, n=3). Mean and median plasma GL-3 (6.4 and 6.3 g/mL, range 2.1-10.6 g/mL) were normal. Serum creatinine was normal (mean 0.8 mg/dL) for most patients. Estimated glomerular filtration rate (MDRD study equation) was low ( $<90$  mL/min/1.73m<sup>2</sup>) in 24 (42%) patients. Left ventricular hypertrophy and conduction abnormalities were observed in 18% and 26% of patients, respectively, on EKG. Mitral and tricuspid valve regurgitation were the most common echocardiographic abnormalities (each in 75% of patients). Four patients (7%) had a cerebral infarction, and 10 (18%) patients had an abnormal MR angiogram. Minimal accumulations of GL-3 were found in capillary endothelial skin cells. A gender difference in plasma GL-3 levels is evident, and female Fabry patients do not have low plasma and leukocyte GAL levels as observed in males. Genotyping should be the gold standard for diagnosis of Fabry disease among females. This study confirms the very significant, yet heterogeneous, burden of disease in female Fabry heterozygotes.

**Urine glycosaminoglycan measured with the MPStest is a convenient means of monitoring response to treatment, and may be an indicator of clinical phenotype.** *G.S. Sahi, C.M. Erickson, D.C.C. Erickson, N.Q. Lam, S. Lo, C.B. Whitley.* Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

Urine specimens are easily obtained and transported for determination of glycosaminoglycan (GAG) using the *MPStest*. To explore the potential use of this test in the diagnosis and treatment of mucopolysaccharidosis (MPS) diseases, this test was applied in several clinical situations. Specimens demonstrated stability for more than 10 years when stored under ambient conditions without special processing. In patients undergoing a variety of treatments, decreasing GAG/creatinine paralleled other markers of response to therapy, generally corresponding to early indicators of clinical outcome. For example, urine GAG/creatinine decreased in patients demonstrating successful donor engraftment after bone marrow transplantation. In a case of experimental lymphocyte gene therapy for Hunter syndrome, there was no change in GAG/creatinine, a result corresponding to the lack of other clinical indicators of efficacy or surrogate markers. Patients undergoing enzyme replacement therapy have been studied by other, more laborious methods (requiring collection of a 24-hour urine specimen); results from the *MPStest* methodology are being accumulated. Among a limited number of patients with MPS disease, there appears to be a correspondence of urine GAG/creatinine to "severity" of the disease, thus suggesting that urine GAG/creatinine might be useful as a prospective indicator of clinical severity, a postulate under further investigation.

Program Nr: 1656 from 2003 ASHG Annual Meeting

**The MPS I Registry.** *J.T.R. Clarke<sup>1</sup>, G.M. Pastores<sup>2</sup>, D. Viskochil<sup>3</sup>, for the International MPS I Registry Board of Advisors.* 1) Hospital for Sick Children, Toronto, Canada; 2) NYU, NY, NY; 3) U of Utah, Salt Lake City, Utah.

**Overview:** Systematically collected, longitudinal data on large numbers of patients with MPS I, a rare, autosomal recessive mucopolysaccharide storage disorder, are necessary for the rigorous long-term evaluation of any specific treatment for the disease. An international MPS I Registry has been established to provide the mechanism for the collection, storage, and dissemination of this information. **Objectives/Methods:** The objective of the Registry is to systematically enroll patients with the disease and collect clinical information on the natural history, as well as to track the long-term outcomes of treatment with Aldurazyme (laronidase). Over the past 18 months, an International Board of Advisors, working in collaboration with the sponsors, have been developing comprehensive Case Report Forms (CRFs) to support the collection of relevant data on the natural history of MPS I, including clinical events, course of treatment, and related outcomes. **Results:** Drafts of the CRFs for use by participating physicians were extensively reviewed. Annual reports from this Registry will be submitted to the regulatory agency, in part to fulfill post-approval commitments, as well as providing a database for additional sub-studies on specific aspects of MPS I. The infrastructure for implementation is provided by BioMarin/Genzyme LLC. The Registry is modelled after a similar database, developed over 10 years ago by the International Collaborative Gaucher Group (ICGG), for monitoring patients with Gaucher disease. Using well-validated measures of disease pattern and severity, information will be collected on physical and functional well-being, as well as the performance of activities of daily living, to evaluate benefits derived from various therapeutic interventions, including enzyme replacement therapy. **Conclusion:** As uniform data are successfully collected on large numbers of patients with MPS I, the characterization of disease course should enable identification of early predictors and determinants of morbidity and mortality. Close monitoring and the data collected will provide the basis of the assessment of the impact of therapy. (Sponsored by BioMarin/Genzyme LLC).

**Fabry disease: Delineating the natural history of the disorder through the Fabry Registry.** *C.M. Eng<sup>1, 2</sup>, M. Banikazemi<sup>2</sup>, J. Barranger<sup>2</sup>, J. Charrow<sup>2</sup>, L. Clark<sup>2</sup>, D. Bushinsky<sup>2</sup>, R. Hopkin<sup>2</sup>, G. Pastores<sup>2</sup>, C.R. Scott<sup>2</sup>, K. Sims<sup>2</sup>, W. Wilcox<sup>2</sup>.* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) North American Board of Medical Advisors, Fabry Registry.

Fabry disease, an X-linked deficiency of alpha-galactosidase A, results in the accumulation of glycosphingolipids, primarily globotriaosylceramide (GL-3) in the lysosomes of the vascular endothelium as well as other cell types and tissues throughout the body. In general, affected males demonstrate the classical signs and symptoms of the disease, including progressive end organ involvement of the renal, cardiovascular, and central nervous systems. Female heterozygotes have a variable clinical course with disease manifestations ranging from minimal to the full spectrum of clinical findings seen in males. As is typical with orphan disorders, a full understanding of the clinical course and rate of disease progression has been limited by the lack of prospectively obtained data on a significantly large population of affected individuals. To address these issues, a web-based, centralized registry and database was developed ([www.fabryregistry.com](http://www.fabryregistry.com)). In the early stages of this effort, 178 patients (65% male and 35% female) have consented to join the study and their data underwent preliminary analysis. Ninety percent of participants were over the age of 18 years with the median age being 43. The median age at diagnosis was 29.5 and the median age of onset of disease symptoms was 9 years (n=116). At the time of diagnosis, symptoms in the following organ systems were the most commonly cited as the presenting symptom: neurological (pain) (48%), skin (angiokeratoma) (29%), gastrointestinal (17%), and renal (16%). In determining the order of onset of end organ clinical events, a trend toward renal events preceding cerebrovascular and cardiac events was observed. The analysis of clinical information from a large patient population will greatly enhance our understanding of the natural history of Fabry disease in both males and females as well as facilitate the development of monitoring protocols to assess the effectiveness of therapeutic interventions, particularly, enzyme replacement therapy.

**Positive European experience with agalsidase alfa in Fabry disease: update from FOS - the Fabry Outcome Survey.** A. Mehta<sup>1</sup>, M. Beck<sup>2</sup>, F. Dehout<sup>3</sup>, A. Garcia de Lorenzo<sup>4</sup>, G. Hauge<sup>2</sup>, P. Jaeger<sup>5</sup>, C. Kampmann<sup>2</sup>, A. Linhart<sup>6</sup>, R. Ricci<sup>7</sup>, G. Sunder-Plassman<sup>8</sup>, U. Widmer<sup>9</sup>, on behalf of the FOS investigators. 1) Dept of Haematology, Royal Free Hosp, London, UK; 2) Dept of Pediatrics, Univ of Mainz, Germany; 3) Dept of Nephrology, CHU de Charleroi, Belgium; 4) Formación Médica Continuada Hospital Univ, Madrid, Spain; 5) Dept of Nephrology, Hôpital Pasteur, Nice, France; 6) 2nd Dept of Internal Medicine, Charles Univ, Prague, Czech Republic; 7) Institute of Clinical Pediatrics, UCSC Rome, Italy; 8) Division of Nephrology and Dialysis, Univ of Vienna, Austria; 9) Dept of Medicine, Univ of Zurich, Switzerland.

Fabry disease is a rare X-linked lysosomal storage disorder caused by  $\alpha$ -galactosidase A deficiency. This results in progressive lysosomal storage of globotriaosylceramide (Gb3) in various cells throughout the body. Both men and women are affected, with symptoms developing in childhood and premature death occurring usually from renal failure, cardiac disease or cerebrovascular complications. Enzyme replacement therapy (ERT) has now been available in Europe for 2 years. FOS is the largest database for patients with Fabry disease, and contains data on some 400 patients treated with, or candidates for treatment with, agalsidase alfa (Replagal; TKT-5S, Danderyd, Sweden). Of the 65% of patients given agalsidase alfa in FOS, 70% have now been treated for 1 year. Significant beneficial effects of agalsidase alfa treatment have been reported in FOS. Pain, one of the major and early clinical manifestations of the disease, is reduced, as assessed by the Brief Pain Inventory (p0.001), and overall quality of life improved (p0.05). In addition, cardiac function, measured by the QRS duration and Sokolov-Lyon product, is improved (p0.05), consistent with reductions in left ventricular mass. Furthermore, agalsidase alfa can stabilize renal function and even reverse the decline in renal function in patients with a GFR of 60-89 ml/min (p=0.027). These significant clinical improvements indicate that ERT with agalsidase alfa may not only halt the progression of Fabry disease, but can also reverse the organ damage resulting from Gb3 storage.

**First evidence that extra-cerebral recombinant Phenylalanine Ammonia Lyase treatment will reduce brain phenylalanine in Phenylketonuria.** C.N. Sarkissian<sup>1</sup>, Z. Shao<sup>2</sup>, M. Pedneault<sup>2</sup>, D.M. Boulais<sup>1</sup>, R. Heft<sup>2,3</sup>, C.R. Scriver<sup>1</sup>. 1) Departments of Biology and Human Genetics, McGill University, Montreal, QC, Canada; 2) IBEX Technologies Inc., Montreal, QC, Canada; 3) BioMarin Pharmaceutical Inc, Novato, CA.

Phenylketonuria (PKU) is a product of deficient (hepatic and renal) phenylalanine hydroxylase enzyme activity, resulting in a metabolic phenotype with elevated levels of phenylalanine (phe) in body tissues and fluids. Persistent increase in extracerebral phe levels is usually associated with elevated intracerebral phe, altered brain structure/function and impaired cognitive development.

PKU responds to treatment with low-phe diet, which lowers ambient phe levels in body fluid. However, compliance with diet is difficult; and for life (as now recommended for some patients), is probably unrealistic. A new potential modality of treatment, involving enzyme substitution with recombinant phenylalanine ammonia lyase (rPAL), converts phe to harmless metabolites (*trans*-cinnamic acid and trace ammonia). Taken orally, non-absorbable and protected PAL effectively lowers plasma phe in mutant hyperphenylalaninemic mouse models (Sarkissian C.N. et al., *PNAS* 96: 2339-2344, 1999).

Here we report the first evidence that extracerebral rPAL treatment reduces brain phe levels. Brain amino acid profiling of PKU mice with hyperphenylalaninemia, following single dose intra-peritoneal treatment with a minimal single dose of 4 IU of non-absorbable formulated rPAL, reveals the anticipated reduction in blood phe levels apparent as of 8 hours (control 179416 M vs rPAL treated 153175 M; p0.024) and a reduction of brain tissue phe concentration at 24 hours post-treatment (control 81741 M vs rPAL treated 71528 M; p0.033). This reduction in whole brain phe is not accounted for by the change in intra-vascular phe reduction. Our findings further support the rationale for rPAL treatment, and are compatible with oral therapy, which favorably alters the flux and equilibrium of phe between the various compartments of body fluids.

**Development of tandem mass spectroscopy for the detection of lysosomal storage diseases from newborn blood spots.** *C.R. Scott<sup>1</sup>, M.H. Gelb<sup>2,3</sup>, F. Turecek<sup>2</sup>, Y. Li<sup>2</sup>, Y. Ogata<sup>2</sup>, D. Wang<sup>2</sup>.* 1) Dept Pediatrics, Univ Washington Sch Medicine, Seattle, WA; 2) Dept Chemistry, Univ Washington, Seattle, WA; 3) Dept Biochemistry, Univ Washington, Seattle, WA.

We are developing tandem mass spectroscopy as a common platform for the detection of lysosomal storage diseases at birth. We have demonstrated that lysosomal enzymes are stable and detectable from blood placed on newborn screening cards. Their enzymatic activity can be measured by sensitive assays that make use of substrate conjugates and Affinity Capture and Elution/Electrospray Ionization Mass Spectrometry (ACESIMS). The method uses a single analytical platform, uses stable isotopes as an internal standard, requires trace amounts of substrates, and is able to be automated for high throughput assays. Selected assays can be multiplexed to measure several enzymes simultaneously.

We have documented that the enzymes responsible for Gaucher, Fabry and Pompe diseases--disorders for which there exists enzyme replacement therapy--can be assayed on dried blood spots. The enzyme activity is linear with respect to time and protein concentration and is stable for several weeks on dried blood spots held at ambient temperature. Additional disorders that are detectable include Krabbe, Niemann-Pick, and selected mucopolysaccharidoses. We believe the method can be developed as a public health approach for the detection of selected lysosomal storage diseases for which there exist specific therapeutic interventions.

Supported by the NIH and Genzyme Corporation.

**The Impact of MPS I on the Functional Status of Affected Individuals.** *A.M. Skrinar, G.F. Cox.* Genzyme Corporation, Cambridge, MA.

**Objective:** Mucopolysaccharidosis I (MPS I) is an autosomal recessive disorder caused by a deficiency of the lysosomal enzyme alpha-L-iduronidase, which is required for the breakdown of glycosaminoglycans. The resulting accumulation causes clinical manifestations that significantly impair the ability to perform activities of daily living. This study characterized the functional limitations of affected individuals for the purpose of developing a disease-specific functional outcomes measure. **Methods:** A sample of 17 individuals with MPS I participated. Parent proxy responses were solicited for participants under 14 years of age. The sample included 8 males (47%) and 9 females (53%) originating from the U.S., UK, and France. Semi-structured interviews were conducted to collect data on specific limitations in self-care and mobility, as well as caregiver assistance. **Results:** The mean age of participants was 17.7 years (range 7-35). Most had been clinically diagnosed with Hurler-Scheie syndrome (88%). Dressing impairments were reported by 87% of participants and included restrictions in the ability to manage upper and lower body clothing items. Bathing and grooming impairments were reported by 70% of participants and included limitations in the ability to transfer into a bathtub, wash and dry body, and brush hair and teeth. Functional impairments related to feeding were reported by 59% of participants and included difficulty with utensils and the management of food containers. Impaired ability to perform toileting tasks was reported by 47% of participants. Walking device or wheelchair use was reported by 41% of participants. All participants reported some degree of gross motor skill impairment. At least minimal caregiver assistance was required by 88% of participants and none were living independently at the time of the interview. **Conclusions:** Individuals with MPS I presented with heterogeneous functional profiles, although most had significant self-care and motor impairment and required caregiver assistance. These findings provide support for the continued development and validation of a disease-specific instrument to characterize the impact of MPS I on functional status and to assess therapeutic response.

**Clinical response to Enzyme replacement therapy (ERT) with agalsidase beta in a pediatric patient with Fabry disease.** *M.J. Peterschmitt*<sup>1,2</sup>, *P. Della Giovanna*<sup>3</sup>, *N.R. Lago*<sup>4</sup>, *H.A. Repetto*<sup>2</sup>. 1) Neurologia Infantil, Hospital Nacional A. Posadas, El Palomar, Buenos Aires, Argentina; 2) Servicio de Pediatría, Hospital Nacional A. Posadas, El Palomar, Buenos Aires, Argentina; 3) Dermatología, Hospital Nacional A. Posadas, El Palomar, Buenos Aires, Argentina; 4) Catedra de Anatomía Patológica, Universidad de Buenos Aires, Buenos Aires, Argentina.

**Introduction:** In Fabry disease (FD) -an X-linked lysosomal storage disorder- the deficiency of -galactosidase A (-gal A) causes progressive systemic accumulation of glycosphingolipids (GL-3), which leads to the major manifestations of the disease: angiokeratoma, acroparesthesia, renal insufficiency, and cardiovascular and cerebral involvement. ERT with recombinant human -gal A (agalsidase beta) in patients older than 18 years of age has shown improvement of pain and quality of life and clearance of GL-3 deposits in capillary endothelium of kidney, skin and heart. We report the clinical response to agalsidase beta in a pediatric patient with FD. **Case:** An 8 year-old boy presented at 5 years of age with scattered angiokeratoma in his left lower extremity (LLE). Later he developed multiple lesions in his LLE, umbilical region, abdomen and genitalia, teleangiectasia in palms and upper extremities, acroparesthesia, and tortuosity of conjunctival vessels. Decreased -gal A activity confirmed the diagnosis of FD (0.31 nmol/h/ml; NV 2.2-16). Renal function and brain MRI were normal. Ultrastructural examination of renal tissue revealed GL-3 deposits in all cellular types. After approval of Hospital IRB, administration of agalsidase beta (Fabrazyme) was started at 1 mg/kg biweekly. **Results:** The medication was well tolerated. After 2 months on treatment, the extremity pain ceased and the skin lesions began to disappear. **Conclusion:** Our patient showed regression of some of his angiokeratoma, which has not been reported in enzyme-treated FD. Treatment started at an earlier stage of the disease could yield greater benefit. Long-term safety and effectiveness of ERT in the pediatric population should be evaluated in randomized clinical trials.

**Discovery of new members of the acyl-CoA dehydrogenase (ACD) gene family.** *M. He, W. Moshen, J. Vockley.*  
Dept of Medical Genetics, Mayo Clinic, Rochester, MN.

The ACDs are a family of flavoenzymes consisting of 9 distinct members involved in fatty acid -oxidation and amino acid catabolism. Using a bioinformatics approach, we have identified a new group of ACD-like enzymes (ACDXs) that are 20-30% homologous to the ACDs. Two of them, ACDX1 and ACDX2, are 80% homologous between human and mouse, while human ACDX1 is 46% homologous to ACDX2. The human ACDX1 gene is located on chromosome 12 and EST database searches reveal 7 distinct messages from this gene apparently generated by differential splicing. One encodes an ACD-like protein, while the others lead to ACD-like proteins with an aminoglycoside phosphotransferase domain at the N-terminus, an aldehyde dehydrogenase-like sequences at the C-terminus, or both. A second human gene, ACDX2, is located on chromosome 3. EST database searches identify four different apparent RNA species, two ACD-like proteins with N termini of variable length, and two with an aminoglycoside phosphotransferase domain at the N terminus. Computer modeling of ACDX2 based on the structures of known ACDs predicts the catalytic base of ACDX2 to be an Asp instead of Glu as seen in other ACDs. Other residues around the substrate binding pocket are well conserved. An Arg residue located in the substrate binding pocket of ACDX2 is near the catalytic base, in a position homologous to Arg94 in glutaryl-CoA dehydrogenase (GAD). Arg94 is unique to GAD and this suggests that ACDX2 might react with a similar hydrophilic substrate and perform a decarboxylation reaction as does GAD. We have amplified the ACD-like domain of ACDX2 from liver mRNA. In vitro transcription and translation generated two stable proteins, one consistent with translation of the full message (511aa, 57KDa), the other with initiation from an internal Met codon and generating a shorter protein (464aa, 52KD). Only the 52KD protein was imported into isolated liver mitochondria in an in vitro assay. Thus the alternative N-termini of the ACDXs may serve to target them to different subcellular locations as well as confer additional enzymatic functions. Further functional characterization of this new group of ACDs is underway.

**Spectrum of GC gene mutation among Korean Gaucher disease patients and its implications on genotype and phenotype correlation.** *H. Kim, J.A. Yang, S.J. Park.* Dept Medical Genetics, Ajou Univ Col Medicine, Suwon, Korea.

Gaucher Disease(GD) is the most prevalent lysosomal storage disease due to deficient activity of Glucocerebrosidase (GC). The clinical study of Korean GD registry revealed that non-neuronopathic form of GD (type1) to be rather aggressive with early childhood onset and rapid progression of massive organomegaly and skeletal complications leading to high morbidity and mortality, and high preponderance of neuronopathic(NP) form among Korean GD pts (>50%). To understand the molecular basis of these phenotypic characteristics of Korean GD, mutational analysis of GC gene was performed in 25 unrelated Korean GD pts (12 type1, 6 type2, 4 type3A, 3 type3B) and 15 different mutations were identified in 50 alleles; 10 alleles for L444P mutation, 7 alleles for G46E, 4 alleles each for F213I, R257Q and N188S. 3 alleles for G202R, and 9 rare mutations of R48W, L160V, V191G, A232P, F331L, V375V, G377S, D409H and V460V an allele for each. The spectrum of GC mutations found in Korean GD is rather unique compare to those of Jewish & Caucasian population. N370S, the most common GC mutation among Jewish (70%) and other Caucasian ethnic group (60-30%), and well established for its association with mild non-NP and the protective mutation from NP, is not found in Korean. and Thus, the lack of N370S mutation among Korean may explain type 1 being severe and high preponderance of NP form (types 2 & 3). L444P, a common mutation (40%) among non-Jewish Caucasian and Japanese, is known to be associated with NP phenotype, esp. homoalleles in particular. However among 13 Korean NP pts, only 4 alleles (15%) and no homo alleles were detected. Exception of G46E, among next common mutations of F213I, R257Q and N188S were also detected in both type I and NP pts. An interesting finding was G46E mutation, never reported in Caucasian nor Japanese GD, was found to be the most common alleles occurring 50% of type I pts. but none in NP pts. Therefore finding of G46E allele may provide a predictive value for non-NP phenotype esp. DDX in type1 vs. type3B among early onset Korean GD pts.

**Relationship between metabolites, growth and galactose exposure in yeast deficient in the Leloir pathway enzymes.** *K.L. Ross, J.L. Fridovich-Keil.* Human Genetics, Emory University, Atlanta, GA.

The metabolism of galactose via the three enzymes of the Leloir pathway: galactokinase (GALK, *GAL1*), galactose-1-P uridylyltransferase (GALT, *GAL7*), and UDP galactose-4-epimerase (GALE, *GAL10*) is a process that has been conserved from *E. coli* through humans. Impairment of this pathway in humans results in the disorder galactosemia, with precise symptoms and severity a function of which enzyme is impaired, and the degree of impairment. Of the three enzyme deficiencies, transferase-deficiency galactosemia, also known as classic galactosemia, is the most common and clinically significant. Dietary restriction of galactose remains the only known treatment, and despite early detection and intervention, a large fraction of patients experience serious clinical complications. The underlying pathophysiology in galactosemia remains unknown, limiting possibilities for the generation of novel and potentially more effective therapies.

As an approach to understand the biochemical basis of galactosemia, we have begun to explore the functional and metabolic implications of impaired galactose metabolism in yeast. In brief, we have generated strains deficient in *gal1*, *gal7*, and *gal10*, and have systematically tested both growth rates and relevant metabolic profiles for these cells cultured under conditions of exposure to different levels of galactose. Thus far it appears that *gal10* deficient yeast growth arrest at a 10-fold lower concentration of external galactose than do *gal7* deficient yeast. In addition, within 5 min of exposure to galactose there are clear differences in the internal galactose metabolites, specifically galactose-1-phosphate, between wild-type cells and those deficient in *gal7* or *gal10*. Our results clearly demonstrate reproducible changes in both growth and metabolites in these cells in response to galactose, and set the stage for future experiments designed to test the relationship between genetic background, specific Leloir enzyme activities, accumulation and/or depletion of specific metabolites, and galactose-induced growth arrest in yeast.

**Immunological aspects of X-linked ectodermal dysplasia: A dog model for the human disease.** *M. Casal<sup>1</sup>, S. Ryan<sup>2</sup>, J. Rhodes<sup>2</sup>, J. Scheidt<sup>1</sup>*. 1) Dept Medical Genetics, Univ Pennsylvania, Phila., PA; 2) Veterinary School, Univ Pennsylvania, Phila., PA.

As in most human patients with X-linked ectodermal dysplasia (HED), our HED dogs are at an increased risk for pulmonary disorders. Localized immune system defects had been suspected previously in the ectodermal dysplastic dogs because of the frequent infections and unexpected deaths due to opportunistic respiratory tract infections. Experiments were designed to examine systemic and localized (pulmonary) humoral and cellular responses, development and function of T cells and thymic morphology. All dogs (5 normal and 5 affected dogs) used in these experiments were clinically healthy at the time of examination and their immune responses were compared to normal littermates. Serum immunoglobulin concentrations did not differ between normal dogs and dogs affected with HED, and the HED dogs responded appropriately to vaccination with tetanus toxoid suggesting normal systemic B and plasma cell function. Quantitative examination of B cells from blood and lymphoid organs was also within normal limits except in blood from carrier dogs (heterozygous females) when compared to normal dogs. Total CD3 and the percentage of CD8 cells were lower in affected dogs than those in normal dogs. However, all other thymic parameters were within normal limits suggesting normal development of T cells. Thymic morphology was compared between normal and affected dogs and T cells were assessed for functionality. There were no significant differences between normal and affected dogs. Macrophages and neutrophils were examined for cytotoxic and phagocytic ability as well as cytokine production. There was no significant difference between normal and affected dogs. In contrast, the secretory IgA concentrations found in affected dogs were significantly higher than in normal dogs, but secretions such as lachrymal fluids were significantly decreased. These results suggest a compensatory mechanism for secretory IgA, so that the total amount equals that in normal dogs. The results indicate that the HED dogs have a relatively intact immune system.

**Molecular characterization of disease-causing mutations in six patients with GM1 gangliosidosis.** A. Caciotti<sup>1</sup>, T. Bardelli<sup>1</sup>, P. Scarnato<sup>1</sup>, M. Taverna<sup>1</sup>, M.A. Donati<sup>1</sup>, V. Benigno<sup>2</sup>, A. Boneh<sup>3</sup>, V. Kimonis<sup>4</sup>, A. d'Azzo<sup>5</sup>, E. Zammarchi<sup>1</sup>, A. Morrone<sup>1</sup>. 1) Dept of Pediatrics, Florence, Italy; 2) Dept of Pediatrics, Palermo, Italy; 3) Metabolic Service, Gen Health Serv, Victoria, Australia; 4) Children's Hosp Harvard Med School, Boston, USA; 5) Dept of Genetics, St. Jude Hosp, Memphis, USA.

GM1-gangliosidosis is a lysosomal storage disorder caused by a deficiency of beta-galactosidase (GLB1). The severe type I infantile form is characterised by a rapidly progressive CNS involvement, facial and skeletal abnormalities and hepatosplenomegaly. The GLB1 gene gives rise to two alternately spliced mRNAs: the GLB1 lysosomal enzyme and the Elastin Binding Protein (EBP), a major component of the non-integrin cell surface receptor complex. We report the identification of 5 new GLB1 mutations (amino acid substitutions H281Y, T239M, Q355H; c1309delA and IVS6+2TC splicing defect) and 3 known (R482H, R59C and R208C) mutations in the total RNA and DNA preparation of six GM1 Gangliosidosis patients (two American, two Australian, and two Italian). Except for the R208C and the T239M mutations, all genetic lesions detected affect both the GLB1 and EBP proteins. Hot spot regions for the GLB1 mutations have been suggested and both T239M and R208C, mapping to exon 6, confirm this exon to be a hot spot. The R482H amino acid substitution has been previously reported at a homozygous level in one Italian patient and at a heterozygous level in 6 unrelated Italian patients, all of Sicilian origin. In the current work, the R482H mutation was identified in two Australian patients of Maltese origin. Thus, it can be surmised that this mutation has a Mediterranean origin. The R208H mutation has been reported to be of Hispanic origin, although it was found at high frequency in American patients. The involvement of the R59 amino acid has been previously reported in patients of Italian and Brazilian origin. Sequence alignments of GLB1 related proteins, indicated that the R59 amino acid should have a key role. These data could reflect the migratory flux from Europe to America and Australia. The financial support of AMMEC and MPS ONLUS is gratefully acknowledged.

**Neuropathological analysis of Sandhoff disease mouse model.** *C. Bourgoin*<sup>1</sup>, *A. Gelot*<sup>2</sup>, *R. Gravel*<sup>3</sup>, *L. Poenaru*<sup>1</sup>, *C. Caillaud*<sup>1</sup>. 1) Department of Genetics, Institut Cochin, Paris, France; 2) Neuropathology Unit, Trousseau Hospital, Paris, France; 3) Department of Cell Biology, University of Calgary, Calgary, Canada.

Sandhoff disease is an autosomal recessive neurodegenerative disease characterized by the intralysosomal accumulation of GM2 ganglioside. It is due to mutations in the HEXB gene encoding the hexosaminidases beta-chain. A *Hexb*<sup>-/-</sup> knock-out mouse model has been developed. It displays a phenotype close to the human pathology, leading to death at the age of 4 months. Regional and cellular lesions were studied in *Hexb*<sup>-/-</sup> mice brain, as well as cellular storage at different time points. Cellular parameters were cytoplasm distension, vacuolisation and lipid positive staining. Cell counting allowed to assess cell loss, as well as the percentage of neurons overloaded for each region. The main conclusions of the study were: (i) Each cerebral structure studied displays a different chronology in the storage, the earliest overloaded regions being the central grey nuclei of the thalamus, and the Purkinje cells. (ii) A schematic sequence of events was deduced: neurons first display a lipid positive overload, without distension of the cytoplasm. The overload becomes then more diffuse, with a swelling of the cytoplasm, that undergoes vacuolisation and loses lipid staining. (iii) The storage does not lead to early and extensive cell loss, indicating that a cell dysfunction rather than massive cell loss would trigger clinical signs. The clear differential between deep and superficial layers in highly structured regions, as well as between metabolically different cells indicates a role of synaptogenesis in the storage process, likely due to the high membrane turn-over in these cells. In addition to the better understanding of the pathological process, the kinetic data of the storage apparition will allow to evaluate the efficacy of preclinical gene transfer into the brain, in terms of neuron morphology and storage.

**Fabry disease : a comprehensive study of renal function in 28 hemizygous male patients.** *D.P. Germain<sup>1</sup>, D. Erlich<sup>2</sup>, S. Sainte-Croix<sup>1</sup>, T. Le Bricon<sup>2</sup>, Y. Herrera-Guzman<sup>1</sup>, A. Bissery<sup>3</sup>, C. d'Auzac<sup>4</sup>, P.F. Plouin<sup>5</sup>, M. Froissart<sup>6</sup>.* 1) Dept of Genetics, European Hosp Georges Pompidou, Paris, France; 2) Dept of Biochemistry, St Louis Hosp, Paris, France; 3) CIC, European Hosp Georges Pompidou, Paris, France; 4) Dept of Nephrology, European Hosp Georges Pompidou, Paris, France; 5) Dept of Medicine, European Hosp Georges Pompidou, Paris, France; 6) Dept of Physiology, European Hosp Georges Pompidou, Paris, France.

**Background:** Fabry disease (FD) is an X-linked inborn error of metabolism due to the deficient activity of alpha-galactosidase A, leading to the lysosomal accumulation of glycosphingolipids. **Objective:** To characterise renal function in male patients affected with classic FD and to evaluate cystatin C, a new marker of renal function. **Methods:** Serum creatinine, measured creatinine clearance using 24h-urine collection, cystatin C, glomerular filtration rate (GFR) measured by chrome 51 EDTA and 24h proteinuria (24h/P) were performed in 28 consecutive hemizygous men (mean age 32 y, 16-66), excluding patients on dialysis or with kidney transplant. **Results:** Mean Cr51 EDTA GFR (n=20) was 79.5 mL/min (21-114 mL/min). 9 patients had normal kidney function (GFR90mL/min), 6 had mild kidney failure (60-89 mL/min), 3 had moderate kidney failure (30-59 mL/min), and 2 had severe kidney failure (GFR30 mL/min). Mean cystatin C (n=23) was 1.06 ng/L (Normal: 0.50-0.94 ng/L). Mean serum creatinin (n=28) was 106 mol/L (Normal: 50-115 mol/L). For the subset of patients (n=16) for which both GFR and cystatin C were studied, there was a remarkable correlation. Eight patients had no proteinuria, 12 had microalbuminuria (30-300 mg/24h), 5 had non-nephrotic 24h/P (300mg-3g/24h) and 3 had 24h/P >3g/24h. **Discussion:** Kidney failure was frequent in patients with FD. The high prevalence of proteinuria (71%) suggests the potential benefit of angiotensin converting enzyme inhibitors for nephroprotection. The high sensibility of cystatin C for kidney failure (87.5%) was demonstrated by measurement of the gold standard GFR. Evaluation of FD patients should include cystatin C at baseline for easy monitoring of the efficacy of enzyme replacement therapy on kidney function.

**Mucopolysaccharidosis VI: clinical, biochemical and molecular analysis of 28 South American patients. R.**

*Giugliani<sup>1,4,5</sup>, A.C. Azevedo<sup>1,6</sup>, M. Petry<sup>1,7</sup>, A.P. Behregaray<sup>1</sup>, F.T. Souza<sup>1</sup>, M.B. Rosa<sup>1</sup>, C. Giugliani<sup>1</sup>, S. Brustolin<sup>1,6</sup>, L. Kalakun<sup>1</sup>, S. Canani<sup>2</sup>, D. Marinho<sup>3</sup>, P. Esteves<sup>3</sup>, T. Dieter<sup>1</sup>, M. Burin<sup>1,7</sup>, S. Leistner-Segal<sup>1,6</sup>, I.V. Schwartz<sup>1,5</sup>.* 1) Med Genet Serv and; 2) Pneum Serv and; 3) Ophthalm Serv of Hosp Clin P Alegre; 4) Dep Genet and; 5) Postgrad Course Genet Molec Biol and; 6) Postgrad Course Pediat and; 7) Postgrad Course Biochem, UFRGS, Porto Alegre, RS, Brazil.

Mucopolysaccharidosis VI (MPS VI) is a lysosomal disease caused by the deficiency of the enzyme N-acetylgalactosamine-4-sulfatase (ARSB). To perform a comprehensive evaluation of a cohort of South American MPS VI subjects, 28 patients with a clinical and biochemical diagnosis of MPS VI (1/3 of the total number diagnosed at our center), with no history of treatment through BMT and/or ERT, were evaluated by means of anamnesis, physical examination, visual acuity and intra-ocular pressure measurements, biomicroscopy, echocardiogram (ECHO), electrocardiogram (EKG), spirometry, 6-minute walking test (6MWT), polysomnography (PSG), and analysis of ARSB gene. Mean age at evaluation was 97.1 mo.; 25/28 patients reported onset of symptoms before the age of 36 months; mean age at diagnosis was 48.4 mo. ARSB activity was deficient in all patients (means of 5.4 nm/h/mg prot. in leucocytes and 38.4 nm/h/mg prot. in fibroblasts). All patients presented with increased urinary excretion of GAGs (3 times increase in average). Of the 51 signs/symptoms surveyed through anamnesis and physical examination, short stature, coarse facial features, corneal opacification, joint stiffness, and claw hands were reported in all cases. The molecular analysis identified the presence of a new mutation in 6/50 alleles, all of these from the Southeast region of Brazil. Besides providing a better understanding of the natural history of MPS VI, our data confirm that high morbidity-mortality is associated to this disease, and that the identification/treatment of its complications usually takes place in a later stage. The identification of a new mutation in patients may be a clue to investigate the apparently high frequency of MPS VI in Brazil, particularly on the Southeast region (CAPES/CNPq/Biomarin).

**Natural History of Infantile Onset Pompe Disease(IOPD): A Study Report.** *D. Corzo*<sup>1</sup>, *W.L. Hwu*<sup>2</sup>, *H. Mandel*<sup>3</sup>, *M. Nicolino*<sup>4</sup>, *F. Yong*<sup>1</sup>, *P. Kishnani*<sup>5</sup>. 1) Genzyme Corporation, Cambridge, MA; 2) National Taiwan University Hospital, Taiwan, Taipei; 3) Rambam Medical Center, Haifa, Israel; 4) Hopital de Brousse, Lyon, France; 5) Duke University Medical Center, Durham, NC.

**Background.** Reports on the natural history of IOPD are based on data from small number of patients. To fully characterize it, a retrospective chart review was conducted. **Methods.** This was a multinational, multicenter, historical cohort study. Inclusion required documented onset of symptoms by 12 months of age and GAA enzyme deficiency or GAA mutation(s). Data collected included demographics, family history, progression of signs and symptoms by organ system, diagnostic process, ancillary evaluations, treatment modalities, and resource utilization. **Results.** 300 cases were screened; 168 cases from 33 study sites in 9 countries met all eligibility criteria. 93 cases (55%) were born during/after 1995 and 75 cases (45%) were born before 1995. Median age  $\pm$  SD (months) at presentation of first symptoms was  $2.0 \pm 2.5$  (n=166); at diagnosis,  $4.7 \pm 8.8$  (n=165); at first ventilator use,  $5.9 \pm 6.3$  (n=165); and at death,  $8.7 \pm 1.1$  (n=163). By 12 months of age mortality was 78%; by age 18 months mortality reached 88%. The most common signs/symptoms were cardiomegaly (92%, n=154), hypotonia (88%, n=148), cardiomyopathy (88%, n=147), respiratory distress (78%, n=131), failure to thrive (53%, n=89), congestive heart failure (50%, n= 84), and pneumonia (45%, n=76). At least 29% of patients (n=49) were ventilated. 90% (n=151) were treated with  $\geq 1$  medication(s), 77% (n=130) with nutritional support, and 93 (55%) with other supportive therapies. **Conclusions.** This is the largest retrospective case review study performed to date in IOPD. Results from this study support and extend earlier literature reports with regard to the fatal course of the disease and the rapidity of the disease progression. In spite of widespread use of medications and other therapeutic modalities, mortality has changed little across the decades. Although a small group of patients have a longer survival, IOPD is still a rapidly progressive disease, with the majority of patients dying before 12 months of age.

**New mutations in the PPCA gene lead to the alteration of the Lysosomal complex and the EBP-receptor. S.**

*Malvagia<sup>1</sup>, A. Morrone<sup>1</sup>, A. Caciotti<sup>1</sup>, T. Bardelli<sup>1</sup>, A. d'Azzo<sup>2</sup>, G. Ancora<sup>3</sup>, M.A. Donati<sup>1</sup>, E. Zammarchi<sup>1</sup>.* 1) Dept of Pediatrics, Univ. of Florence, Azienda Ospedaliera Universitaria Meyer, Florence, Italy; 2) Genetics, St. Jude Children's Res Hospital, Memphis, TN, USA; 3) Inst of Neonatology, University of Bologna, Italy.

We describe the clinical findings, the biochemical and molecular analyses of an Italian family in which recurrent hydrops fetalis due to Galactosialidosis (GS) occurred. GS is a very rare Lysosomal Storage Disorder caused by a deficiency of the protective protein/cathepsin A (PPCA). This protein forms a high-molecular-weight multicomplex with the hydrolases galactosidase (GLB1) and neuraminidase (NEU1), defending them against rapid proteolytic degradation and allowing them to take on the correct folding. Controversial data shows that PPCA is also present in a second complex, the EBP-receptor, involved in elastogenesis with Elastin Binding Protein (EBP) and NEU1. We investigated the potential role of the PPCA in both complexes. Two new genetic lesions (c60delG and IVS2+1 GT) that lead to a frameshift and a premature stop codon were detected in the patients PPCA cDNA and genomic DNA. The deleterious effect of such mutations was also confirmed by the absence of PPCA with western blot analysis. Since no PPCA protein was detected, analysis of the patients fibroblasts can be considered an effective means of examining the role and effect of PPCA on the two complexes. Interestingly, a reduced amount of both GLB1 and EBP proteins in the patient's fibroblasts was also detected. These data confirm that PPCA is present in two functional complexes, inside lysosomes with GLB1 and on the cell surface with EBP. The reduction in GLB1 and EBP confirms that PPCA is essential for their integrity. We would like to alert physicians to consider an inborn error of metabolism in patients with hydrops fetalis where an immunological cause has been excluded, and with a positive family history. The financial support of AMMEC, MPS Onlus and Az. Osp. Meyer are gratefully acknowledged.

**Substrate specificity and multiple tissue isoforms of glucocerebrosidase in patients with Gaucher disease. E.**

*Orvisky<sup>1, 2</sup>, B.M. Martin<sup>3</sup>, J.M. Walker<sup>1, 2</sup>, E. Sidransky<sup>1, 2</sup>.* 1) Section on Molecular Neurogenetics NIH/NIMH, Bethesda, MD; 2) Medical Genetics Branch, NIH/NHGRI, Bethesda, MD; 3) Laboratory of Neurotoxicology, NIH/NIMH, Bethesda, MD.

Gaucher disease (GD) is an autosomal recessive storage disorder caused by mutations in the gene encoding for the lysosomal enzyme glucocerebrosidase (GC). There are three clinical variants of the disease: type 1, chronic non-neuronopathic; type 2, acute neuronopathic; and type 3, subacute neuronopathic. Genotype-phenotype correlations among the three types are limited. Multiple isoforms of GC have been demonstrated in fibroblasts with molecular weights of 63, 61 and 59 kDa, where the 59 kDa form is believed to be the functional GC. We have previously shown that isoforms of GC from brain differ from those from other tissues. Western blots performed on protein extracts from normal brains consistently showed two GC bands, one at 56kDa and one at 59kDa. After N-Glycosidase F digestion, all samples demonstrated only the lowest 56kDa form of glucocerebrosidase regardless of the tissue source. This form must be minimally glycosylated or unglycosylated and therefore the alternate forms of GC observed in brain are most likely due to alternative or absent glycosylation. Brain samples from patients with all three types of Gaucher disease predominantly had the 56kDa form, but all were deficient in the functional 59kDa form. We were unable to distinguish the neuronopathic from the non-neuronopathic form of Gaucher disease based on either residual GC activity or GC isoforms. However, residual GC activity was markedly reduced by competitive inhibition by the alternate substrate glucosylsphingosine in fibroblasts and tissue extracts from patients with the neuronopathic form of GD but not in patients with type 1 GD. This substantiates the role of glucosylsphingosine in the pathogenesis of Gaucher disease.

**Localization and clathrin binding of the Hermansky Pudlak syndrome type 3 protein.** A. Helip Wooley, H. Dorward, W.A. Gahl, M. Huizing. National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Hermansky Pudlak syndrome (HPS) is a disorder of lysosome-related organelle biogenesis resulting in melanosome dysfunction and absent platelet dense bodies. HPS is characterized clinically by oculocutaneous albinism and prolonged bleeding times due to a platelet storage pool deficiency. HPS-3 is a relatively mild subtype of HPS and results from mutations in the *HPS3* gene located on 3q24. *HPS3* encodes a 1004 amino acid protein of unknown function with no apparent homology to other human proteins or protein domains. HPS3 contains a clathrin binding motif (LLDFE) at residues 172-176 and a potential ER retention signal (KKPL) at residues 1000-1003. To determine if HPS3 binds clathrin, an HPS3-GFP fusion construct was created and site-directed mutagenesis was used to alter the HPS3 clathrin binding motif to non-conserved amino acids, i.e., AAAPG. Wild-type and mutant HPS3-GFP were expressed in normal human fibroblasts, immunoprecipitated with GFP antibodies, and analyzed by western blot using clathrin heavy chain (CLH) antibodies. A band corresponding to CLH (MW 187 kD) was detected in wild-type HPS3-GFP but not mutant HPS3-GFP immunoprecipitates. Normal human melanocyte lysates were immunoprecipitated with either CLH or HPS3 peptide antibodies and western blots performed using the alternate antibody. CLH was immunoprecipitated with HPS3 and vice versa. Fluorescence imaging of HPS3-GFP expressed in human melanocytes demonstrated localization to the perinuclear region as well as punctate structures in the dendrite tips. Immunofluorescence using HPS3 peptide antibodies in untransfected melanocytes confirmed this localization. These studies demonstrate that HPS3 binds clathrin and provide insight into the function of HPS3 and its role in intracellular vesicle trafficking.

**Apoptosis in brain in the type 2 Gaucher mouse: neurotoxicity starts *in utero*.** M.E. LaMarca<sup>1</sup>, O. Goker-Alpan<sup>1</sup>, E. Orvisky<sup>1</sup>, E.I. Ginns<sup>2</sup>, E. Sidransky<sup>1</sup>. 1) Molecular Neurogenetics Section, NIMH and Molecular Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Brudnick Neuropsychiatric Research Institute, U. Mass. Medical School, Worcester, MA.

Gaucher disease, the inherited deficiency of glucocerebrosidase, presents with both non-neuronopathic and neuronopathic phenotypes. Despite many years of research, the mechanisms resulting in neuronopathic Gaucher disease are not fully understood. The presence of perivascular Gaucher cells, neuronophagia and gliosis as the primary neuropathological findings suggest that a toxic metabolite might cause the neuronal dysfunction. Although both glucosylceramide (Glc-cer) and glucosylsphingosine (Glc-sph) accumulate in visceral organs of patients with all types of Gaucher disease, elevated levels in brain occur exclusively in neuronopathic patients. Similarly, in the null allele Gaucher mouse, a model for type 2 Gaucher disease, Glc-sph levels are elevated approximately 100-fold when compared to Glc-sph levels in wild-type littermates. As previously shown, Glc-sph can be detected in homozygous null allele mice by gestational age E-13 and progressively accumulates until birth. Ceramide has been implicated to have a central role in the signaling mechanisms of apoptosis, while both Glc-cer and Glc-sph are associated with growth arrest. To determine the potential neurotoxicity of substrate accumulation, we performed a DNA fragmentation (TUNEL) assay on brain samples from E-19 mouse embryos. A significantly increased number of apoptotic cells were detected in homozygous null allele embryos as compared to heterozygous or normal littermates. Some were localized in bands extending from mid to hindbrain. The presence of apoptotic cell clusters in these embryos in patterns similar to the neuropathology observed in some type 2 patients provides further evidence that substrate toxicity beginning *in-utero* results in irreversible neuronal dysfunction and subsequent death.

**Hermansky-Pudlak syndrome type 5 and type 6: Four new patients.** *R.A. Hess<sup>1</sup>, D.A. Claassen<sup>1</sup>, J. White<sup>2</sup>, W.A. Gahl<sup>1</sup>, M. Huizing<sup>1</sup>.* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) University of Minnesota, Minneapolis, MN.

Hermansky-Pudlak syndrome (HPS) is a rare disorder of vesicle formation characterized by oculocutaneous albinism, a bleeding diathesis due to storage-pool-deficient platelets, and in some patients granulomatous colitis or pulmonary fibrosis. Six genes are now associated with HPS in humans, and there are at least 14 mouse models with the HPS phenotype. Two of the human genes are *HPS5* and *HPS6*, the homologues of the murine *ruby eye-2* and *ruby-eye* loci, respectively. *HPS5*, on 11p14, consists of 23 exons (coding for 1129 aa) and is expressed as at least two alternatively spliced mRNA transcripts differing at the 5' ends. Human *HPS6*, located on 10q24.32, consists of 2 exons coding for a 775 aa protein.

HPS-5 and HPS-6 have been described in only one patient each. We studied 15 patients whose HPS-causing gene was unknown, to identify other individuals with HPS-5 or HPS-6. Using PCR amplification of cDNA and gDNA followed by direct sequencing, we identified 2 new HPS-5 patients bearing a total of 4 different mutations, including 3 frameshift (P239insC, L875delT, R216delAGAT), and one nonsense (R865X). Northern blots showed severely decreased *HPS5* mRNA levels in both patients, attributable to nonsense mediated RNA decay. Molecular analyses also revealed two HPS-6 patients, each carrying a homozygous mutation Q305X and 622delTG. The possibility of hemizygoty will be examined.

Clinically, our HPS-5 and HPS-6 patients exhibited iris transillumination, variable hair and skin pigmentation, and absent platelet dense bodies. Pulmonary fibrosis and granulomatous colitis were not observed in these patients. However, all of the patients were under 27 years old, an age before which lung disease rarely develops in any type of HPS. Hence, it is important that adults with HPS-5 and HPS-6 continue to be followed for the development of restrictive lung disease. The diagnosis of a particular subtype of HPS, such as HPS-5 or HPS-6, might influence future treatment decisions; a clinical trial has recently shown that the antifibrotic agent, pirfenidone, slows the decline in pulmonary function associated with HPS-1 disease.

**Clinical, biochemical and molecular diagnosis of a free sialic storage disease patient of moderate severity. R.**

*Kleta<sup>1</sup>, R.P. Morse<sup>2</sup>, J. Alroy<sup>3</sup>, E. Orvisky<sup>4</sup>, D. Krasnewich<sup>1</sup>, D.A. Wenger<sup>5</sup>, W.A. Gahl<sup>1</sup>.* 1) Section on Human Biochemical Genetics, MGB, NHGRI, NIH, Bethesda, MD; 2) Pediatrics, Dartmouth-Hitchcock Medical Center, Lebanon, NH; 3) New England Medical Center, Boston, MA; 4) NSB, NIMH, NIH, Bethesda, MD; 5) Neurology, Jefferson Medical College, Philadelphia, PA.

The diagnosis of patients with developmental delay in early childhood is difficult and challenging. The allelic lysosomal storage disorders Salla disease and infantile free sialic acid storage disease (ISSD) should be included in the differential. ISSD has a severe phenotype with infantile onset; Salla disease has a milder phenotype with later onset. ISSD and Salla disease result from mutations in SLC17A5, which codes for sialin, a lysosomal membrane protein that transports the charged sugar, N-acetylneuraminic acid (sialic acid (SA)), out of lysosomes. We describe a 26-month old Caucasian (non-Finnish) child with global developmental delay of postnatal onset, hypotonia, mild but progressive coarsening of facial features, and language and motor skills stagnant at a 3-4 months developmental level. Urinary excretion of free sialic acid was elevated. EM of a skin biopsy revealed enlarged secondary lysosomes consistent with oligosaccharide storage. Free SA in fibroblasts was 3.7+/-1.1 nmol/mg protein (normal 1.1+/-1.0); differential centrifugation indicated a lysosomal location. Genomic analysis revealed compound heterozygosity for two new sialin mutations. In exon 2, a heterozygote 291 G>A, "exonic" donor (5') splice site mutation IVS 2-1 leads to skipping of exon 2; cDNA analysis showed a 197-bp deletion. The exon 2 skipping causes termination after 33 amino acids instead of 495. A second mutation in exon 9, 1226 G>A, GGA>GAA, G409E, changes a conserved glycine to glutamate within a transmembrane region. Each mutation was present in one parent. This child's clinical manifestations of a lysosomal free SA storage disease correlate with her sialin mutations and biochemical findings, elevated fibroblast free SA. Thus, in the proper clinical setting, differential diagnosis of postnatal developmental delay should include free SA storage disorders such as ISSD and Salla disease.

**Demography of untreated Type 1 Gaucher disease (GD1) in children.** *P. Kaplan, H.C. Andersson, J. Charrow, A. Prakash-Cheng, E.H. Kolodny, P. Mistry, G.M. Pastores, B. Rosenbloom, C.R. Scott, R.S. Wappner, N. Weinreb.* ICGG Registry, Cambridge, MA.

Data from the International Collaborative Gaucher Group Registry were analyzed to determine childhood manifestation, ethnic distribution, genotypes, baseline spleen, liver, hematologic indices, bone disease & growth. Data were available for 1578 subjects diagnosed <18yrs. In GD1, 66% of all patients are symptomatic by 18 yrs, of whom 53% manifest in the first 5 yrs, 24% from 6-10 yrs & 23% from 11-18 yrs. Male/ female ratio was 47/53 (739/839). Rare/unique genotypes were most prevalent, affected many ethnic groups & were associated with severe disease. N370S/N370S, most common in adults, accounted for only 8% of children <5 yrs, 22% from 6-10 yrs, and 34% from 11-18 yrs. Linear growth: median z scores <5yrs were 1.31 [n=132], 6-10yrs were 1.32 [n=44] & 11-18yrs were -0.94[n=48]. z score -1.56 is equivalent to 5% ile. Baseline median spleen volumes were higher in children with onset in the 1st decade [18.47 multiples of normal (MN) <5yrs, 13.8 MN 6-10yrs] than in the 2nd decade [ MN 9.01 11-18yrs]. Median hepatomegaly was greater in the 1st decade [2.5 MN <5yrs, 1.8MN 6-10yrs] than 2nd [1.48MN 11-18yrs]. Platelet & hemoglobin [Hb] levels were not meaningfully different across the 3 age categories [115K,120K, 99K; 10.3,10.9,11.7gm% respectively]. Splenectomies were done in 7.6% manifesting children. Bone signs/symptoms (pain/crises/osteoporosis /marrow infiltration/necrosis) were less frequent in children manifesting in the 1st decade than the 2nd decade, although due to small numbers of patients with available data only avascular necrosis showed a statistically significant difference being higher in the 2nd decade. Conclusions: GD1 has a high prevalence in childhood, with unusual/rare genotypes linked to manifestation of disease at an earlier age, without predilection for ethnic groups. Somatic and growth manifestations are severe, and are worse in the 1st decade. Bone disease is less frequent in 1st decade than 2nd. It is possible that the introduction of enzyme replacement therapy in 1991 obviated the need for splenectomies.

**Early Presentation of Fucosidosis.** *F.J Stewart<sup>1</sup>, A.C. Magee<sup>1</sup>, C. Lundy<sup>2</sup>*. 1) Dept Medical Genetics, Level A, Belfast City Hosp, Belfast, United Kingdom; 2) Royal Belfast Hospital for Sick Children, Belfast, United Kingdom.

Fucosidosis is a rare autosomal recessive inborn error of metabolism caused by a deficiency in alpha-fucosidase. Many reports tend to describe older individuals who have a characteristic pattern of angiokeratomata on their hands and feet. The proband is the first child of consanguineous parents who are first cousins. She was born at term weighing 2.27kg. It had been noted that there was poor fetal growth towards the end of the pregnancy. As a baby she had a continual nasal discharge and frequent upper respiratory infections. She did not sit unsupported until the age of 14 months and did not walk until the age of 2 years. She was seen in the genetics clinic at the age of 2 years. On clinical examination she had a very round face with a flat broad nasal bridge. The nose was short and slightly widened. She had macroglossia and a tendency to protrude the tongue. Because of the history of chestiness urine was sent for mucopolysaccharide screening and blood for lysosomal enzymes. The result showed an alpha-fucosidase level of 0.4 umol/g/h (normal 50-200) giving a diagnosis of fucosidosis. Recent review at the age of 4 years has shown her to have marked developmental delay. However she is making slow progress and has not lost any skills. She makes some noises but has no proper speech. There is no progress on toilet training. Her physical appearance has changed somewhat and is now more typical of a child with a storage disorder. She has developed multiple angiokeratomata on her legs and her hands. Fucosidosis is a very rare condition and we know of no other cases in Ireland. The condition is often divided into a severe infantile form, type I, with death before the age of 5 and type II which is said to be due to a partial deficiency where survival into adulthood is common. This girl has a very marked enzyme deficiency but is in good health and likely to survive for several more years. We present this case to draw attention to this disorder and to illustrate that screening urine alone will not detect all lysosomal enzyme deficiencies. At the time of writing results of mutation analysis are not available.

**Dissection of the protective domain of saposin C that is required for resistance of acid -glucosidase to proteolytic degradation.** *Y. Sun, X. Qi, G.A. Grabowski.* Dept Human Genetics, Children's Hosp Research Fndn, Cincinnati, OH.

Saposin C is one of the four small sphingolipid activator proteins that are derived by proteolytic processing of a common precursor, prosaposin. Saposin C is essential for optimal *in vitro* and *in vivo* hydrolysis of glucocerebroside by acid -glucosidase (GCCase), the Gaucher disease enzyme. We have shown that saposin C also is required for GCCase resistance to proteolytic degradation, a new property for saposin C. An activation and protection domain map of saposin C was developed by using a series of saposin C peptides and monitoring their effects on GCCase activity in intact prosaposin deficient cells. A chimeric saposin, CB, contained the NH<sub>2</sub>- and COOH- terminal halves of saposin C and B, respectively. CB produced an increase of 2-fold in GCCase activity similar to saposin C. A saposin C with mutations in the activation domain similarly enhanced GCCase activity. However, saposin BC, containing the NH<sub>2</sub>- and COOH-terminal halves of B and C, respectively, had little effect on GCCase activity. These results show that the activation domain is separated from protective domain on saposin C. The amino terminal half of saposin C is important for GCCase proteolytic protective functions. Thus, saposin C appears to be a multifunctional molecule (protection and activation) in maintaining normal GCCase function *in vivo*. These functions of saposin C have implications for understanding the molecular pathogenesis of Gaucher disease and development of more efficient therapies.

**Study of folic acid pathway genes alteration in fragile X syndrome.** *M. Mirakhory, A. Aleyassin.* National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran.

Fragile X syndrome is one of the most common causes of inherited mental retardation in males after Down syndrome. Penetrance of fragile X syndrome is approximately 70% in male and 30% in female. It is due to the expansion of CGG repeat region and methylation of FMR1 gene. To date less attention was to study important genetic factors that may play role in neuropathology and severity of physical characteristic of fragile X syndrome. Folic acid, has been prescribed in some fragile X cases for reduction of hyperactivity and attention deficit in prepuberty. Folic acid derivatives have important roles in DNA methylation and neural development and function as well as in synthesis of neurotransmitters and influence diverse process in the CNS. Our hypothesis was to study impaired folate metabolism in fragile X patients as the first step to evaluate the linkage between folate metabolism dysfunction and methylation of FMR1 gene. This is the first study to assess this hypothesis by comparing the frequency of three common mutations in C677T, A1298C methyltetra hydrofolate reductase (MTHFR) and A66G methionine synthase reductase (MTRR) genes, key enzymes in folate metabolism, in 34 male fragile X patients and 60 males control. These common mutations are reported to decrease folic acid level and increase plasma homocysteine levels less in carriers and more in homozygote forms. All cases have been initially diagnosed with fragile X syndrome by molecular methods. The statistical analysis showed a significant linkage between C677T MTHFR mutations with fragile X syndrome supported with a P value of 0.021 and chi-square of 7.719. However, no significant correlations were obtained for A1298C MTHFR and A66G MTRR mutations. The P value for A66G was stronger 0.148 compared to A1298C 0.241 that is in harmony with the less effect of A1298C mutation in folate metabolism. Significantly high frequency of C677T MTHFR mutation may suggest effect of folate derivatives on neuropathology and methylation process and more investigations to perform on the role of folate metabolism in fragile X syndrome.

**The first case of parental gonadal mosaicism for Fabry disease: low proportion of mutant DNA in paternal sperm leads to multiple affected offspring.** *R. Dobrovolny<sup>1</sup>, M. Hrebicek<sup>1</sup>, L. Dvorakova<sup>1</sup>, J. Bultas<sup>2</sup>, S. Magage<sup>2</sup>, J.C. Lubanda<sup>2</sup>, J. Ledvinova<sup>1</sup>, H. Poupetova<sup>1</sup>.* 1) Institute of IEM, Praha 2, Czech Republic; 2) Second Department of Internal Medicine, General Faculty Hospital, Praha 2, Czech Republic.

Fabry disease is a common X-linked lysosomal storage disorder caused by alpha-galactosidase A deficiency. We present two sisters with Fabry disease of severity comparable to that of affected males of the same age. Each of the sisters developed abnormal renal functions in the third decade of life, one of them underwent successful renal transplantation due to renal failure. Alpha-galactosidase A activities in white blood cells were decreased (8.1 and 33.7 nmol/mg of protein /hour, control range 39-77 nmol/mg of protein /hour ), globotriaosylceramide excretion in the first of the siblings was increased (6600 nmol/24h). X-inactivation was studied using HUMARA method. Both patients had skewed X-inactivation patterns (90:10 and 80:20, respectively) in favor of the chromosome carrying the mutation. This may explain the severity of the phenotype. Both patients were heterozygous for Q330X mutation in the alpha-galactosidase A gene, while their parents were tested negative for the Q330X in leucocytes, cells from urinary sediment and saliva. We hypothesized that gonadal mosaicism in one of the parents may be the cause of multiple affected offspring. The haplotype analysis showed that the mutant chromosome was of paternal origin. Using a PCR based technique we examined DNA isolated from sperm of the father and found a small fraction of mutant DNA. The mutant DNA formed approximately 5% of total as judged by the proportion of mutant and wild-type PCR products. To our knowledge this is the first case of parental mosaicism in Fabry disease. It underlines the importance to consider gonadal mosaicism when counselling families with diseases with low incidence of gonadal mosaicism.

Program Nr: 1683 from 2003 ASHG Annual Meeting

**Comparison of amino acid concentrations using both HPLC and tandem mass spectrometry.** *R. Eusebio, B. Lim, M. Parkhurst, M. Najjar, T. Giudici, M. Jamehdor, Y. Qu.* Dept. of Genetic Testing, Kaiser Permanente, Los Angeles, CA.

Traditionally, amino acids were quantitated using an amino acid analyzer or high performance liquid chromatography (HPLC). Recently, tandem mass spectrometry (MS/MS) has been used for amino acid analysis to screen for some aminoacidopathies in newborns. To validate amino acid levels measured with MS/MS, a comparison study was initiated using both HPLC and MS/MS from the same plasma sample set.

Ten amino acid concentrations were compared using 50 plasma samples. These amino acids were: alanine, arginine, citrulline, glycine, leucine with isoleucine, methionine, ornithine, phenylalanine, tyrosine and valine. The percent errors using amino acid concentrations from HPLC as theoretical values and those from MS/MS as experimental values were calculated. The lowest percent error was found in citrulline level (1%) and the highest percent error, in arginine concentration (29%). The study demonstrated that levels of these ten amino acids quantitated with MS/MS were comparable to those with HPLC. MS/MS can be used to quantitate at least ten amino acids reliably from plasma samples along with acylcarnitine analysis.

**Congenital disorder of glycosylation type Ib: the second North American patient.** *G.M. Enns<sup>1</sup>, R. Gallagher<sup>1</sup>, S. Conrad<sup>2</sup>, J.F. O'Brien<sup>3</sup>, H.H. Freeze<sup>4</sup>.* 1) Div Med Genet, Stanford Univ, CA; 2) Div Endocrinology, CH Oakland, CA; 3) Mayo Clinic, Rochester, MN; 4) The Burnham Inst, La Jolla, CA.

Congenital disorder of glycosylation type Ib (CDG Ib) is a recently described disorder of glycoprotein metabolism caused by phosphomannose isomerase (PMI) deficiency. Clinical features include hyperinsulinemic hypoglycemia, liver disease, protein-losing enteropathy, and coagulation defects. In contrast to other types of CDG, there is no neurologic involvement. In order to increase awareness of this disorder, we report the clinical and biochemical features of the second patient detected in North America. The pregnancy and neonatal period were normal. She had multiple infections in infancy, including enteritis, a UTI, amoebiasis, and pneumonia. She had a seizure associated with an abnormal EEG at 5 months and she is maintained on anticonvulsant therapy. Hepatomegaly was noted at 9 months. At 3 years, she was hospitalized for seizures and was found to have hepatomegaly, elevated transaminases, and hypoglycemia with hyperinsulinism. Liver biopsy showed periportal fibrosis and dilated and tortuous bile duct lobules. Coagulation studies were normal. Frequent feeds and cornstarch supplementation were started. Mass spectrometry showed a type 1 pattern of abnormal glycosylation (mono- to di-oligo ratio=0.589, n10.074; a- to di-oligo ratio=0.065, n10.022). Leukocyte PMI activity was 0.29 nmol/min/mg (3.1% of a simultaneous normal control). The parents had ~50% normal activity, consistent with carrier status. Mannose therapy was started (150 mg/kg q6h) and the glycosylation profile normalized within four months. No side effects have been observed. The hypoglycemia has resolved and liver disease has not progressed. Seizures are well-controlled and her development is normal. We conclude that CDG Ib is a treatable disorder that is likely underdiagnosed. CDG Ib should be considered in any child with unexplained hypoglycemia and/or liver disease (or other chronic GI illness). Because other CDG Ib patients have had seizures unrelated to hypoglycemia, it is possible that a degree of neurologic involvement is present in CDG Ib. Identification of other cases will be needed to clarify this.

**Mutations in Carbamyl Phosphate Synthetase I (CPSI) inactivate the enzyme in in vitro expressed protein.** A. Eeds<sup>1</sup>, M. Yadav<sup>2</sup>, L. Hall<sup>2</sup>, G. Cunningham<sup>3</sup>, B. Christman<sup>3</sup>, J. Haines<sup>1</sup>, M. Summar<sup>1,2</sup>. 1) Dept Molec Physiology, Vanderbilt Univ, Nashville, TN; 2) Dept Pediatrics/Div Medical Genetics, Vanderbilt Univ, Nashville, TN; 3) Dept Pulmonary Medicine, Vanderbilt Univ, Nashville, TN.

CPS-1 deficiency (CPS1D) is a rare autosomal recessive disorder that causes either a lethal or severe defect in the function of the urea cycle. As part of our mutation studies of the enzyme CPSI, we have used site directed mutagenesis to create mutations in a construct containing the cDNA sequence for CPSI. These mutations, 434Ins6 and G2855T, correspond to those seen in patients. The 434Ins mutation codes for two additional amino acids, glycine and arginine, and is located in the region of CPSI known as the interaction subdomain. The G2855T mutation changes a glycine to a valine and is located in a region of unknown function that is thought to be important for structural conservation. Because even low activities of CPSI seem to be protective, we hypothesized that any mutation causing severe neonatal hyperammonemia in a patient would result in severe CPSI activity deficiency. We used site directed mutagenesis to place both mutations in our CPSI producing vector based on a pcDNA3.1 plasmid. We transiently transfected the CPSI vectors into Cos7 cells, which produce no endogenous CPSI. We tested cell lysates for CPSI enzyme activity 48 hours after transfection. Activities were compared to our normal CPSI expression vector in Cos7 cells and hepatic tissue controls. Though western blots showed the presence of CPSI from all clones, there was no detectable CPSI activity following a colorimetric assay to measure citrulline formation for the mutants. These findings demonstrate the utility of this system for determining the effects of deleterious mutations, and the severity of the changes from a simple missense mutation in this large gene.

**Glycerol kinase (GK) splice site mutations associated with nonsense-mediated decay of mutant RNAs and asymptomatic isolated GK deficiency.** *K.M. Dipple<sup>1,2,3</sup>, Y.-H. Zhang<sup>1</sup>, B.-L. Huang<sup>1</sup>, E.R.B. McCabe<sup>1,2,3</sup>*. 1) Dept Peds, David Geffen Sch Med at UCLA, LA, CA; 2) Dept of Hum Gen, David Geffen Sch Med at UCLA, LA, CA; 3) Mattel Children's Hospital at UCLA, LA, CA.

Isolated glycerol kinase deficiency (GKD) is an X-linked inborn error of metabolism that is either symptomatic or asymptomatic. Symptomatic patients have episodic metabolic crises. We showed previously that GKD is due to deletions of, or mutations within, the GK gene coding for 524 amino acids (aa) and that there is no genotype-phenotype correlation. We identified patients with GKD and sequenced the 20 exons and intron-exon boundaries in their DNA. We identified three patients with GK splice-site mutations and studied their RNA stability. The first had 6.8% of normal GK activity and a mutation, IVS3+1 GA that resulted in deletion of exon 3 (107bp), and a frameshift, predicted to give an 79 aa protein. The second had 8.3% of normal GK activity due to a mutation, IVS4-1 GA, which resulted in deletion of exon 5 (77bp) and a frameshift predicting a 119 aa protein. The third had 5.3% of normal GK activity due to a mutation, IVS10+1 GT, resulting in deletion of exon 10 (43bp) and a frameshift predicting a 307 aa protein. To study the effect of splice-site mutations on RNA species, we performed RT-PCR and found only normal sized products for all three, not the anticipated abnormally spliced forms. We hypothesized that abnormal RNA species were lost by nonsense-mediated decay (NMD). When patients' lymphoblastoid cells were incubated with anisomycin to block NMD for two hours, two RNA species were seen in each patient. Sequence analysis revealed that for each patient the larger bands represented wildtype GK RNAs and smaller bands represented mutant misspliced RNAs. Interestingly, all these individuals presented with the asymptomatic form of GKD. These data suggest that these splice site mutations lead to unstable mRNA species that are not stable enough to be translated. Normal RNA species observed in each patient are likely responsible for their mild phenotypes. We speculate that influences on RNA processing and stability represent modifiers of the GKD phenotype.

**Molecular analysis of carnitine-acylcarnitine translocase deficiency.** *J.H. Ding<sup>1</sup>, J.M. Mallory<sup>1</sup>, B.Z. Yang<sup>1</sup>, A.J. Davis<sup>2</sup>, D. Macgregor<sup>2</sup>, C.R. Roe<sup>1</sup>.* 1) Institute of Metabolic Disease, Baylor University Medical Center, Dallas, TX; 2) Health Care Corporation of St. John's, St. John's, Canada.

The carnitine-acylcarnitine translocase (CACT) deficiency, an autosomal recessive disorder, is one of the most severe defects of mitochondrial fatty acid oxidation, which presents as two clinical phenotypes: a severe neonatal onset form with cardiomyopathy and a milder phenotype with hypoketotic hypoglycemia. In this study, the patient is currently a twenty-year-old college girl of non-consanguineous English/Irish parents. She presented at three months of age with hepatomegaly and hypoketotic hypoglycemia. She had carried a diagnosis of "carnitine deficiency" and was placed on IV carnitine. Recently, incubation of her fibroblasts with [16-<sup>2</sup>H<sub>3</sub>]palmitic acid and analysis by tandem mass spectrometry revealed an increased concentration of [16-<sup>2</sup>H<sub>3</sub>]palmitoylcarnitine, suggesting the diagnoses of either CACT or Carnitine palmitoyltransferase II (CPT II) deficiency. CACT activity in fibroblast was almost absent and confirmed the diagnosis of CACT deficiency. To investigate the molecular basis of CACT deficiency, all of CACT exons, including intron and exon boundaries, were amplified and sequenced. RT-PCR was also performed to amplify CACT coding region. A novel mutation was identified, which was a 842C>T transition in exon 8, resulting in an alanine-to-valine substitution at residue 281 of the protein (A281V). This novel mutation was also verified by a PCR/restriction test. Both parents were also tested and found to be heterozygous for 842C>T. In addition, in our total of 6 unrelated patients with CACT deficiency, the correlation of mutant genotype to clinical phenotype was investigated.

**3-methylcrotonyl-CoA carboxylase deficiency (MCC): molecular analysis including patients detected by tandem mass spectrometry (TMS) based newborn screening.** *M.F. Dantas<sup>1,2</sup>, T. Suormala<sup>1</sup>, B. Fowler<sup>1</sup>, M.R.*

*Baumgartner<sup>1,2</sup>*. 1) Metabolic Unit, University Children's Hospital, Basel, Switzerland; 2) Division of Metabolism and Molecular Pediatrics, University Children's Hospital, Zurich, Switzerland.

Isolated MCC deficiency is an autosomal recessive disorder of leucine catabolism. It appears to be the most frequent organic aciduria detected in TMS based newborn screening programs. Patients with MCC deficiency show elevated urinary excretion of 3-hydroxyisovalerate and 3-methylcrotonylglycine, usually combined with secondary carnitine deficiency. The phenotype is variable, ranging from neonatal onset with severe neurological involvement to asymptomatic adults. MCC is a heteromeric mitochondrial enzyme composed of 2 non-identical subunits, an  $\alpha$ -subunit which binds biotin and a smaller  $\beta$ -subunit. The genes encoding the two subunits, *MCCA* and *MCCB*, have been recently cloned. To date 8 *MCCA* and 12 *MCCB* mutant alleles have been reported. We report detailed molecular analysis in a further 17 MCC deficient probands. All showed characteristic abnormal organic acid excretion and severely deficient MCC activity (0-18% of control) was confirmed in cultured fibroblasts. 6 probands were diagnosed because of clinical symptoms, and 11 were asymptomatic newborns detected by TMS based newborn screening. To detect mutant alleles we amplified patient cDNA from fibroblast RNA, sequenced the product directly and confirmed all identified mutations by amplifying and sequencing of genomic DNA. Six of the probands revealed mutations in *MCCA*, and 11 in *MCCB*. We identified 2 new *MCCA* and 8 new *MCCB* mutant alleles including 3 missense, 3 nonsense, 3 splice mutations and 1 mutation which causes the addition of 3 amino acids to the C-terminus of the  $\beta$ -subunit. To test the functional consequences of the missense mutations we transfected all missense alleles into reference MCC-deficient transformed cell lines and measured MCC activity. All missense mutations but one result in loss of function.

Our data demonstrate no clear correlation between genotype and phenotype, suggesting that factors other than the MCC loci must have a major influence on the phenotype of MCC deficiency.

**LDL RECEPTOR GENE MUTATIONS AND LIPID PATTERN IN ITALIAN CHILDREN AFFECTED BY FAMILIAL HYPERCHOLESTEROLEMIA.** *O. Guardamagna, C. Bondone, C. Allora, V. Molini, I. Rabbone.*  
Pediatrics, Univ de Torino, Torino, Italy.

**Background:** Familial Hypercholesterolemia (FH) is a genetic disorder of lipid metabolism caused by different mutations in LDL-receptor (LDLR) gene. **Aim of this study** is to correlate different mutations of LDLR gene in FH children to lipoprotein pattern. **Methods:** we have recruited 18 affected children among patients afferring to our clinic (age 93 ys). Each subjects was analyzed by screening the LDLR gene and lipid profile was tested in all children: total cholesterol (TC), HDL-cholesterol, tryglicerides were evaluated with enzymatic method; apolipoprotein B (apoB) with immunoturbidimetric method. **Results:** we identified 10

LDLR/mutation	exon	TCmg%	LDL-Cmg%	APOBmg%	N

IVSnt-8T>C	in7	225	126	107	1
Q12STOP	2	228	135	91	1.

**Conclusion:** we observed large variation of lipid levels among children with different mutation of LDLR gene, 5 of which were firstly detected. Further study will be necessary to define the relationship between LDLR mutations, biochemical profile and cardiovascular risk.

**Incidence of Hyperphenylalaninemia in Louisiana: 1985-2000.** *H. Andersson<sup>1</sup>, L. Burrage<sup>1</sup>, C. Myers<sup>2</sup>, A. Hagar<sup>3</sup>, H. Bradford<sup>3</sup>, J. Miller<sup>1</sup>.* 1) Hayward Gen Ctr, Tulane Univ Medical Ctr, New Orleans, LA; 2) Louisiana Genetic Disease Program; 3) Louisiana Newborn Screening Lab.

**Purpose:** No previous study has determined the incidence of variant phenylketonuria (untreated plasma phenylalanine 2-20mg/dl). Additionally, the incidence of classical phenylketonuria (PKU) is based primarily on studies from northern European populations, a predominantly white population. Bickel (1981) estimated the incidence of PKU in Europe as 1:9400. No longitudinal study has established the incidence of PKU in the American population. This study examines the epidemiology of hyperphenylalaninemia in Louisiana (LA) in 1,106,909 births over a 15 year period (1985-1999). **Methods:** Complete ascertainment of LA-born patients with hyperphenylalaninemia was obtained thru the Newborn Screening Program of the LA Genetic Diseases Program and the Hayward Genetics Center, the metabolic disease referral center for LA. All positive PKU newborn screens (Guthrie) were referred for confirmatory plasma amino acids. Plasma PHE levels above 2mg/dl were considered abnormal and all such patients were evaluated and followed for hyperphenylalaninemia. **Results:** The overall incidence of hyperphenylalaninemia in LA was 1:15,849. The incidences of classical and variant phenylketonuria (PKU) were 1:18,365 and 1:22,446, respectively, in the white population and 1:113,966 and 1:227,933, respectively, in the non-white population. One patient with 6-pyruvoyl BH<sub>4</sub> synthase deficiency was identified (1:1,061,909). **Conclusion:** The incidences of classical and variant PKU were much higher in the white than in the non-white population but were generally much lower than in the European population. The incidence of classical PKU in the Louisiana African-American population appears to be lower than estimated in Maryland (1:50,000; Hofman et al, 1991). An unusually high incidence of PKU was found in the Acadian area of LA. These figures allow more accurate risk analysis in whites and non-whites for hyperphenylalaninemia.

**Functional consequences of *PRODH* missense mutations associated with hyperprolinemia and/or schizophrenia (SZ).** H.U. Bender<sup>1,2</sup>, S. Almashanu<sup>1,2</sup>, G. Steel<sup>1,2</sup>, A. Pulver<sup>3</sup>, D. Valle<sup>1,2</sup>. 1) Inst Genetic Medicine; 2) Howard Hughes Medical Institute; 3) Dept of Psychiatry, Johns Hopkins Univ, Baltimore, MD.

*PRODH* maps to 22q11 at the centromeric end of the region frequently deleted in DiGeorge Syndrome. *PRODH* encodes proline oxidase (POX) a mitochondrial inner membrane enzyme that catalyzes the first step in the proline degradation pathway and is expressed in liver, kidney and brain. At least 16 *PRODH* missense mutations have been reported, some proposed to be associated either directly or through linkage disequilibrium with increased risk for SZ (Jacquet et al 2002;Liu et al 2002). *PRODH* mutations have also been described in 3 patients with type I hyperprolinemia (Humbertclaude et al 2001;Jacquet et al 2002). The functional consequences of these mutations have been inferred by evolutionary conservation but none have been tested directly. We report the functional consequences of 16 *PRODH* missense mutations. We mutagenized *PRODH* cDNA constructs, transfected them into CHO-C9 cells and assayed POX specific activity. We found 4 alleles (R185Q, L289M, A455S, A472T) with a mild (<30%); 6 (Q19P, A167V, R185W, D426N, V427M, R431H) with a moderate (30-70%) and 5 (P406L, L441P, R453C, T466M, Q521E) with severe (>70%) reduction in POX activity. Interestingly one (Q521R) had the opposite effect, increasing POX activity to 120% of control. In a recent publication, 6 of these mutations (L289M, R431H, L441P, R453C, A455S, Q521R) have been reported in hyperprolinemic patients, some with SZ (Jacquet et al 2002). The activity of these alleles ranges from 0-120% of controls. Three alleles (V427M, R453C, A472T) showed significant association with SZ in populations of distinct ethnic origin with no assessment of proline levels (Liu et al 2002). In our results, POX activity encoded by these alleles ranges from a mild to severe reduction. In summary we find 1) *PRODH* alleles associated with severe hyperprolinemia have <10% enzyme activity; 2) alleles with mild to moderate reduction show no direct association with plasma proline levels; and 3) alleles associated with SZ vary widely in their POX activity, suggesting alterations in POX activity per se do not affect susceptibility.

**Screening for metabolic disorders using tandem mass spectrometry.** *F.W. Lorey, G.C. Cunningham, J. Sherwin, L. Feuchtbaum, B. Currier, K. Velazquez, S. Levine.* Genetic Disease Branch, CA Dept Health Services, Richmond, CA.

California initiated a large-scale research project to investigate the feasibility of testing for multiple metabolic disorders by tandem mass spectrometry. Five tandem mass spectrometers were installed in the state laboratory and a dedicated database was developed. An informed consent was developed and the research plan was approved by the state IRB. From January 7, 2002 through June 13, 2003, there were 331,217 infants screened. Cutoffs for 42 analytes were determined through statistical analysis, workload considerations, and disease-specific factors. They were revised twice after gathering additional data and with input from metabolic specialists. The initial positive rate was 0.49% and final rate was 0.08%. One diagnosed case was confirmed for every 10 positive screens referred. Specificity varies by disorder and analyte. The results are as follows:

MCADD	SCADD	MMA/PA	GA-II	3-MCC	Arg	MSUD	Total
11	18	10	1	2	1	1	44
1/30,000	1/18,400	1/32,000	1/331,000	1/165,600	1/331,000	1/165,600	1/7500

Three cases were missed, including one MSUD included in the prevalence rate, one VLCADD not detectable because of treatment, and one LCHADD. Both the MSUD and the LCHADD would be detected by our latest cutoffs. Cases not screened were reported to us and they were tested subsequently. Older cases prior to the study were tested by pulling frozen stored newborn specimens. Clinical data are being collected on diagnosed cases. This methodology successfully detects most cases of metabolic disease and can prevent serious morbidity by initiating treatment before serious symptoms appear.

**Reverse-hybridization assay for mutations associated with hereditary sugar intolerance.** *G. Kriegshaeuser<sup>1</sup>, W. Krugluger<sup>2</sup>, F. Kury<sup>1</sup>, C. Oberkanins<sup>1</sup>*. 1) ViennaLab Labordiagnostika GmbH, A-1110 Vienna, Austria; 2) Department of Clinical Chemistry, Municipal Hospital Rudolfstiftung, Vienna, Austria.

Dietary carbohydrates for humans include polysaccharides (starch), disaccharides (sucrose, lactose) and monosaccharides (glucose, fructose, galactose). During digestion, specific enzymes will initially hydrolyze poly- and disaccharides into their monosaccharide constituents, which then become absorbed by apical cells of the small intestine and further metabolized. A variety of genetically determined enzyme and transporter deficiencies may cause hereditary intolerance to common dietary sugars. Lactose intolerance (adult-type hypolactasia, lactase non-persistence) is an extremely frequent autosomal recessive condition causing diarrhea, nausea and flatulence. It is highly associated with two mutations located upstream from the lactase-phlorizin hydrolase (LPH) gene locus. Hereditary fructose intolerance is an autosomal recessive disorder caused by mutations in the aldolase B gene. Affected subjects suffer from severe abdominal pain, vomiting, hypoglycaemia, and unless fructose-containing food is strictly avoided may even die from irreversible damage of the liver and kidney. We have developed a reverse-hybridization assay for the rapid and simultaneous detection of two mutations (-13910 C/T, -22018 G/A) upstream to the LPH gene and three mutations (A149P, A174D, N334K) in the aldolase B gene. The test is based on multiplex DNA amplification and hybridization to a teststrip presenting a parallel array of allele-specific oligonucleotide probes for each mutation. The entire procedure from blood sampling to the identification of mutations requires less than 6 hours, and hybridization/detection may be carried out manually or essentially automated using existing instrumentation (e.g. TECAN profiBlot). The test is simple and convenient, requires very small amounts of samples, and can easily be modified to include additional mutations. (oberkanins@viennalab.co.at).

**Somatic mosaicism in a male with an exon skipping mutation in the E1 subunit (*PDHA1*) of the pyruvate dehydrogenase complex results in a mild phenotype.** *K. Okajima*<sup>1,2</sup>, *G.C. Nickel*<sup>2</sup>, *E. Sieverding*<sup>1</sup>, *M.L. Warman*<sup>2</sup>, *D.S. Kerr*<sup>1</sup>. 1) CIDEM, Rainbow Babies & Children's Hospital; 2) Genetics, Case Western Reserve University, Cleveland Ohio.

The pyruvate dehydrogenase complex is essential for aerobic glucose metabolism. Hemizygous, complete loss-of-function mutations of the E1 subunit, (*PDHA1*) which is encoded on chromosome Xp22, are presumed to be lethal in males. In females with heterozygous loss-of-function mutations, a range of phenotypes have been reported, attributable to X-inactivation. We evaluated a 5 year old male with hypotonia, moderate developmental delay and seizures, but normal growth and brain MRI. His lactate was normal to mildly elevated in blood (1.5-2.9mM) and CSF (3.5-4.4mM) with a normal lactate/pyruvate ratio. PDC activity was 27% of controls in skin fibroblasts, 37% in skeletal muscle and 60% in lymphocytes. *PDHA1* cDNA analysis from skin fibroblasts revealed two populations of mRNA; one species was wild type, the other lacked exon 6. Genomic DNA from fibroblasts contained nearly equal amounts of wild-type sequence and sequence harboring g.592GA in exon 6. Flanking introns had no mutation. This 592G is conserved among species, including yeast. This change is predicted to create a novel SRp40 exonic splice enhancer site. Klinefelter syndrome, chimerism or trisomic rescue were excluded as possible explanations for the existence of two X-linked alleles by a normal karyotype (46XY) and a single DNA complement on polymorphic marker analysis. Immunohistochemistry of skin fibroblasts appears mosaic for *PDHA1*. These data indicate that this child is a somatic mosaic for a non-functional *PDHA1*. A lower percentage of mutant genomic DNA in EBV-transformed lymphoblasts implies tissue variation. This is the second report of a *PDHA1* exon 6 skipping mutation in viable males, the first being in two male cousins with Leigh syndrome and a silent mutation that caused partial skipping of exon 6. Somatic mosaicism for a non functional *PDHA1* has also been reported in a newborn male with lethal lactic acidosis. In our patient, the existence of normal mRNA due to somatic mosaicism accounts for his mild phenotype.

**One year experience in diagnosis of inborn errors of metabolism using tandem mass spectrometry.** *B. Lim<sup>1</sup>, R. Eusebio<sup>1</sup>, J. Kane<sup>1</sup>, T. Giudici<sup>1</sup>, M. Najjar<sup>1</sup>, R. Mardach<sup>2</sup>, M. Lipson<sup>3</sup>, J. Baker<sup>3</sup>, K. Johnston<sup>3</sup>, M. Jamehdor<sup>1</sup>, Y. Qu<sup>1</sup>.*  
1) Dept. of Genetic Testing, Kaiser Permanente, Los Angeles, CA; 2) Regional Metabolic Service, Kaiser Permanente, Los Angeles, CA; 3) Dept. of Genetics, Kaiser Permanente Medical Center, Oakland, CA.

Tandem mass spectrometry (MS/MS) has been used for diagnostic work-up for fatty acid oxidation disorders (FAODs), some aminoacidopathies and organicacidopathies. Here we report four inborn errors of metabolism (IEM) diagnosed using MS/MS in one year of time starting March 2002. These diagnoses were made based on the accumulation of diagnostic acylcarnitines and abnormal compounds detected in urine organic acid analyses (UOAA). These IEMs are: medium chain acyl-CoA dehydrogenase deficiency (MCAD), methylmalonic aciduria (MMA), cobalamin C defect (cbl C), and glutaric aciduria type I (GA I).

In MCAD patient, acylcarnitine profile showed increased C8-acylcarnitine (10 times normal value) with more than 700 times elevated suberylglycine in UOAA. In MMA patient, C3- acylcarnitine was elevated 12 times of normal level with highly elevated methylmalonic, methylcitric and 3-hydroxypropionic acids in UOAA. In cbl C patient, C3-acylcarnitine was increased 8 times of normal level with elevated methylmalonic acid, total homocysteine and decreased methionine. In GA I patient, C5-DC- acylcarnitine was twice as high as normal control with highly elevated glutaric and 3-hydroxyglutaric acids. Two hundred fifty samples were received for acylcarnitine analysis from March 2002 to March 2003. The diagnostic rate is 1.6% (4 out of 250). Acylcarnitine analysis and UOAA are a good pair of complementary tests for diagnosis of FAODs and organicacidopathies.

**Mutation and biochemical analysis of patients belonging to the *cblA* complementation class of vitamin B<sub>12</sub>-**

**dependent methylmalonic aciduria.** *J.P. Lerner-Ellis*<sup>1</sup>, *C.M. Dobson*<sup>2</sup>, *T. Wai*<sup>1</sup>, *D. Watkins*<sup>1</sup>, *J.C. Tirone*<sup>1</sup>, *C. Dor*<sup>3</sup>, *P. Lepage*<sup>3</sup>, *R.A. Gravel*<sup>2</sup>, *D.S. Rosenblatt*<sup>1,4,5</sup>. 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Biochemistry and Molecular Biology, University of Calgary, Alberta, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 4) Biology and Medicine, McGill University, Montreal, Quebec, Canada; 5) McGill University Health Centre, Montreal, Quebec, Canada.

Methylmalonic acidemias (MMA) are rare human disorders caused by deficient activity of the mitochondrial methylmalonyl CoA mutase enzyme (MCM). MCM catalyzes the vitamin B<sub>12</sub> (cobalamin, Cbl)-dependent rearrangement of L-methylmalonyl CoA to succinyl CoA and uses adenosylcobalamin (AdoCbl) as cofactor. The *cblA* complementation class of inborn errors of cobalamin metabolism is one of three known MMA disorders uniquely involved in AdoCbl synthesis. The gene responsible for *cblA* has been identified through the examination of prokaryotic gene arrangements and is called *MMAA*. The precise role of the *MMAA* gene product is not known, but previous studies have suggested its involvement in mitochondrial Cbl transport. By sequencing and restriction endonuclease enzyme analysis thirteen novel mutations in the *MMAA* gene of *cblA* patients were identified. Four previously identified mutations in *MMAA* were confirmed. In total seventeen mutations have been identified: eleven result in premature stop codons including two deletions and two insertions, two are splice site defects, and four are missense mutations that occur at highly conserved residues. Forty patients were analyzed. In twelve patients, two causal mutations were identified; in eleven patients, a single mutation was identified. In the remaining seventeen patients, no *MMAA* coding region sequence changes were identified. None of the sequence changes identified in *cblA* patients were found in one hundred alleles from unrelated control individuals. The biochemical profiles of patient fibroblast cell lines were examined for their ability to incorporate radio labeled [<sup>14</sup>C]-propionate into macromolecules and for the distribution of Cbl derivatives in cell extracts as compared to normal fibroblasts.

**Phenotypic characterization of glycerol kinase loci in *Drosophila melanogaster*.** J.A. Martinez<sup>1,2</sup>, E.R.B. McCabe<sup>1,2</sup>.  
1) Department of Pediatrics, David Geffen School of Medicine at UCLA and Mattel Children's Hospital at UCLA, Los Angeles, CA; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Glycerol kinase (GK) deficiency (GKD) is an X-linked, phenotypically heterogeneous metabolic disorder with variable severity of presentation among individuals with similar genotypic mutations. We propose to attempt to understand this variability in phenotypic expression and to dissect its molecular basis by investigating GK in the model organism *Drosophila melanogaster*. We analyzed the fully sequenced fruit fly genome and this revealed two loci with significant sequence homology to mammalian GK at the protein level. Alignment of these sequences revealed conservation of key residues required for GK activity, as well as motifs for protein tyrosine and serine-threonine phosphorylation. In addition, multiple DNA-binding elements for liver- and muscle-specific transcription factors were found to be conserved within 2 kb upstream of their transcriptional start sites. These findings strongly suggest an evolutionarily conserved mode of regulation, both at the transcriptional and post-translation levels. Glycerol kinase transcripts were expressed at high levels during larval stages, particularly in the fat body, the *Drosophila* equivalent of the mammalian liver. P-element mediated mutagenesis of GK loci leads to recessive lethality, demonstrating an essential role of GK in development of this model organism. We are presently characterizing the role of several conserved signaling pathways as potential modifiers of glycerol kinase phenotypes. We speculate that investigation of GK in *Drosophila* will inform us about the role of this enzyme in development and will provide us with a tool to examine genetic modifiers of the GKD phenotype.

**Expression of alternatively spliced glycerol kinase is altered during development.** *R. Ohira*<sup>1</sup>, *E.R.B. McCabe*<sup>1,2</sup>. 1) Dept Hum Gen, David Geffen Sch Med at UCLA, LA, CA; 2) Dept Peds, David Geffen Sch Med and Mattel Children's Hospital at UCLA, LA, CA.

Glycerol kinase (GK) is an enzyme involved in fat and carbohydrate metabolism. Mutations in *GK* result in GK deficiency. Targeted deletion of murine glycerol kinase (*Gyk*) results in *Gyk*-deficient male mice that are normal at birth, then show postnatal growth retardation, hyperglycerolemia, elevated free fatty acids, and death by 3-4 days after birth. Two alternatively spliced forms of GK have been identified: GK with exon 18 (GK+EX18) in human fetal brain and testes, and GK without exon 18 (GK-EX18) in liver. We investigated differences in *GK/Gyk* expression during development. Northern blot analysis with a *Gyk* probe was performed on a murine blot containing RNA from different embryonic stages: 7, 11, 15 and 17 days post coitum. Two transcripts were seen at all stages, with an increase in expression in the latter stages of development. Reverse transcriptase-polymerase chain reaction (RT-PCR) amplification using primers to human Xp21 GK sequence within exon 16 and 3-untranslated region resulted in a 280 bp product for GK+EX18 or a 193 bp product for GK-EX18. RT-PCR on human fetal and adult liver poly-A RNA showed that fetal liver expressed both forms with GK-EX18 more intense; however, adult liver only expressed GK+EX18. RT-PCR using primers specific to murine *Gyk* was carried out on total RNA extracted from fat, heart, liver, kidney, and brain of an adult mouse. *Gyk* could not be detected in fat. Liver expressed only *Gyk*-EX18, heart expressed both at equal intensity, kidney expressed both with *Gyk*-EX18 greater, and brain expressed both with *Gyk*+EX18 greater. We described similar expression patterns in humans. Two splice forms were transfected into Cos7 cells and assayed for GK activity; preliminary results suggest GK+EX18 is compartmentalized. *Gyk* expression increases during embryonic development, and at least in liver, proportions of the alternatively spliced forms of GK vary during development. Preliminary data suggest GK+EX18 may be recruited to a cellular compartment. We speculate that these alternatively spliced forms of GK may have different functions within the cell.

**Essential Fatty Acid Deficiencies in Metabolic Disorders.** *K. Moseley*<sup>1</sup>, *S. Yano*<sup>1</sup>, *A. Moser*<sup>2</sup>. 1) Medical Genetics, Pediatrics, Childrens Hospital Los Angeles, Los Angeles, CA; 2) Kennedy Krieger Institute, Baltimore, MD.

**INTRODUCTION:** Abnormally low blood levels of docosahexaenoic acid (DHA) and arachidonic acid (AA) have been reported in children with phenylketonuria (PKU) who have been following a phenylalanine-restricted diet with supplementation of a medical product. The reduced levels have been attributed to the fact that the phenylalanine-restricted diet provides only small amounts of animal fats which are the main dietary source of long chain polyunsaturated fatty acids (LCPUFA). We conducted fatty acid analyses in 27 adults/adolescents with PKU, demonstrating reductions in LCPUFA including DHA and AA. We expanded the study to include the pediatric age group of PKU and other metabolic disorders.**METHODS:** 28 pediatric subjects with various metabolic disorders including PKU were surveyed to determine their fatty acid status. Plasma vitamin E and carnitine levels were also evaluated.**RESULTS:**1)In the pediatric age group of the PKU subjects, LCPUFA profiles were similar those obtained in the prior study in adult PKU subjects. The results revealed low AA and DHA acid and elevated docosapentaenoic acid (DPA).2)Subjects with Methylmalonic Acidemia and Propionic Acidemia show slightly elevated DPA ( $p=0.10$ ) although DHA and AA levels were not significantly lower than the controls.3)The two subjects with Malonic Aciduria show a similar profile to PKU subjects with elevated DPA and low AA and DHA.4)The Very Long Chain Acyl-CoA Dehydrogenase deficiency (VLCAD) subjects showed elevated alpha linolenic acid and DPA yet, all the other LCPUFA were not significantly different from the controls. 5)The Vitamin E status was normal in all subjects and the plasma carnitine showed no significant differences in the PKU population.**CONCLUSION** The abnormal fatty acid profiles seen in PKU may account for the subtle cognitive impairments seen in treated PKU individuals. Since DHA and AA have important physiological roles particularly in heart and skeletal muscle as well as in development of brain and retina, supplementation of DHA and AA may prove beneficial in preventing neurological and developmental abnormalities in PKU as well as other metabolic disorders.

**Human Coproporphyrinogen Oxidase (CPO): Biochemical Characterization of Wild-Type Enzyme and Its Naturally Occurring Mutant Forms.** I. Mikula<sup>1</sup>, E. Flachsova<sup>1</sup>, R. Rosipal<sup>1</sup>, B. Demeler<sup>2</sup>, J.-M. Camadro<sup>3</sup>, J. Zeman<sup>1</sup>, J.-C. Deybach<sup>4</sup>, C.S. Raman<sup>2</sup>, P. Martasek<sup>1</sup>. 1) KDDL, 1st Faculty of Medicine, Charles University, Prague, Czech Republic; 2) University of Texas, San Antonio, TX, USA; 3) Institut Jacques Monod, Paris, France; 4) INSERM U409, Paris, France.

Heme acts as a prosthetic group for essential hemoproteins. CPO [E.C.1.3.3.3.] catalyzes the sixth step in heme biosynthesis. The inherited deficiency of CPO causes hereditary coproporphyria (HC), inherited in an autosomally dominant fashion. To better understand heme biosynthesis and address the molecular pathology of HC, we studied recombinant wild-type CPO (using a glutathione-S-transferase expression system) and two naturally occurring mutants (R331W and del390Gly). Wt-CPO and mutated-CPO were purified to electrophoretic homogeneity with specific activities of 4265 nmol/hr/mg protein (wt-CPO), 2100 nmol/hr/mg protein for R331W-CPO and a residual (<1%) activity for del390Gly-CPO. In its active form, human CPO is dimeric. According to the hydrodynamic properties derived from analytical ultracentrifugation, CPO has a nearly globular shape. Both mutation of CPO did not affect dimer formation and sedimentation properties, but led to a significant amount of tightly bound coproporphyrin (R331W), respectively no bound of coproporphyrin (del390Gly). The catalytic efficiency (Kcat/Km) of the R331W-CPO was four-fold lower than wt-CPO, the pI for R331W was 5.56 as compared to 6.40 for wt-CPO, but pH optima were similar (6.8 for wt-CPO, 6.6 for R331W-CPO). Similar characterization is in progress for the whole spectrum of naturally occurring mutants, which, together with our crystallization trials, will add to our knowledge of the molecular pathology of HC and heme biosynthesis. [*Supported by Grant from MSMT of Czech Republic (LN 00A079) and grant Barrande*].

**Novel Mutations in the Fumarylacetoacetase Gene Associated with Tyrosinemia Type I.** *J.-Y. Huang<sup>1,2</sup>, D. Schranz<sup>2</sup>, R. Jack<sup>2</sup>, L. Sniderman-King<sup>1</sup>, S.-H. Chen<sup>1,2</sup>, C.R. Scott<sup>1,2</sup>.* 1) Department of Pediatrics, University of Washington School of Medicine, Seattle, WA; 2) Childrens Hospital and Regional Medical Center, Seattle, WA.

Tyrosinemia type I is a rare autosomal recessive disease of tyrosine metabolism caused by a deficiency in fumarylacetoacetase (FAH), the last enzyme within the tyrosine catabolic pathway. In certain populations the incidence of tryrosinemia I is greater than the estimated incidence of 1/100,000 newborns seen in the United States. This has occurred because of apparent founder effects with the introduction of common mutations in specific populations: IVS12+5g>a in French Canadians and northern Europeans, W262X in Finland, IVS6-1g>t in the Mediterranean population and G337S in Scandinavia. We have screened for gene mutations in fifteen patients with tyrosinemia type I within the U.S. We have used PCR amplification followed by denaturing HPLC and DNA sequencing. In this U.S. population, the four most common mutations worldwide were identified in about half of the alleles and four novel mutations were found that represent previously unrecognized nucleotide alterations. These new mutations are: (1) M202R (c.605T>G), (2) P261L (c.782C>T), (3) IVS7-6t>g, and (4) c.1116-1123 deletion CATAGACC. The first two are missense mutations, the third involves a presumed splicing error, and the 8 bp deletion causes a premature stop codon. Thus, the clinical expression of Tyrosinemia I in the U.S. represents the ethnic diversity of the population without a strong founder effect.

**Four metabolic disorders in a genetic isolate: Population screening and disease prevention.** *M. Khayat<sup>1</sup>, H. Shapira<sup>1</sup>, N. Kfir<sup>1</sup>, I. Gurevitz<sup>1</sup>, H. Mandel<sup>2</sup>, T.C. Falik-Zaccat<sup>1</sup>.* 1) Med Genet, Western Galilee Hospital, Naharia; 2) Dep. of Pediatrics, Rambam Medical Center, Haifa, Israel.

The Druze in Israel represents a unique ethnic community that lives in cultural and geographical isolation in several villages in northern Israel and presents high level of consanguineous marriages. We have identified four rare metabolic disorders in a Druze village including Cerebrotendinous Xanthomatosis (CTX), Prolidase deficiency (PD), arginosuccinic aciduria (ASA) and carbamyl phosphate synthetase deficiency (CPSD). The village consists of approximately 13,000 inhabitants that have originated from a small number of founders. The causative mutation of each disease was identified. Affected individuals were found homozygous for these mutations. These diseases represent a major cause of mortality and morbidity in the village. The aim of this study is to develop an effective carrier screening strategy to reduce the prevalence of genetic disorders in this population. We have screened 190 random healthy individuals for 4 causative mutations and found 12 carriers of CTX (1/16), 9 carriers of PD (1/20), 9 carriers of ASA (1/20) and 3 carriers of CPSD (1/60). Three individuals were carriers for both CTX and PD. Thus, the 30 identified carriers represent a carrier frequency of 1/6 for these rare metabolic disorders. The spouse of each carrier was approached for genetic counseling and testing. Twenty-three agreed to be tested (80%), and none was found to be a carrier for the same disease. Six individuals (20%) refused genetic counseling and testing and 1 was not reached yet. Our results indicate that carrier screening for IEM is warranted and medically indicated in this village. Similar villages exist and should be screened as well for specific frequent diseases in order to reduce the prevalence of genetic disorders among the Israeli Druze. Such screening programs will facilitate targeted genetic counseling, better planning of the special needs for each population, and reduction of the heavy burden from the families and health services. Development of population specific attitudes will improve the compliance of individuals at risk despite cultural and religious restrictions.

**Frequency of the P479L mutation causing Carnitine Palmitoyltransferase (CPT) 1A Deficiency in the Canadian Inuit.** *A.M. Stier<sup>1</sup>, L.E. Seargeant<sup>1</sup>, C. Prasad<sup>1</sup>, D. Grewar<sup>1</sup>, A. Chan<sup>2</sup>, F. Bamforth<sup>2</sup>, P. MacLeod<sup>3</sup>, L. IJlst<sup>4</sup>, R.J.A. Wanders<sup>4</sup>, C.R. Greenberg<sup>1</sup>.* 1) Biochemistry and Med. Genetics, University of Manitoba, Winnipeg, Canada; 2) University of Alberta, Edmonton, Canada; 3) University of Victoria, Victoria, BC, Canada; 4) University of Amsterdam, The Netherlands.

**Objective:** To determine the distribution of CPT1A P479L & CPT2 F352C genotypes for CPT1A deficiency and CPT2 deficiency in 3 Aboriginal kindreds. **Methods and Results:** A 33 week Inuit baby was born to a mother with AFLP (Innes *et al*, 2000). The neonate had transient hypoglycemia and was tested for fatty acid oxidation disorders. Whole blood palmitate oxidation (Seargeant *et al*, 1999) was low. With absent CPT1A enzyme activity in fibroblasts, homozygosity for the P479L mutation, and normal CPT2 activity, the child was diagnosed with CPT1A deficiency. Second and third children have had episodes of hypoketotic hypoglycemia, are homozygous for P479L, have near zero enzyme activity of CPT1A, and are also CPT2 F352C homozygotes, identified because of low CPT2 enzyme activity in the second child. A fourth child, healthy to date, is also homozygous for both mutations. Of 23 extended family members studied, 18 are homozygous and 5 heterozygous for P479L. Five are homozygous, 11 heterozygous, and 7 normal for F352C. Unrelated Inuit identical twins, only one with hypoglycemia, are also homozygous for CPT1A P479L; the F352C CPT2 mutation is absent. Seven asymptomatic 1<sup>st</sup> degree relatives of the twins are homozygous for P479L and none have the F352C mutation. A First Nations man from BC presented with recurrent rhabdomyolysis, reduced CPT1A and normal CPT2 activities and is also homozygous for P479L (Brown *et al*, 2000); he is heterozygous for the F352C mutation. **Conclusions:** The P479L mutation in the CPT1A gene correlates well with near zero fibroblast enzyme activity. An unexpectedly high number of individuals from both Inuit families are homozygous for CPT1A deficiency. This suggests P479L may be a mild mutation or may not result in symptomatic disease as previously thought. Molecular interactions between *CPT1A*, *CPT2*, and other intermediates, as well as epigenetic factors, may thus modulate the severity of CPT1A deficiency.

**Molecular genetic analysis of 20 Korean patients with Glycogen- Storage Disease Type 1.** *S.H Van<sup>1</sup>, C.S. Ki<sup>1</sup>, S.Y. Lee<sup>1</sup>, J.K. Seo<sup>2</sup>, J.W. Kim<sup>1</sup>.* 1) Dept Laboratory Medicine, Samsung Medical Ctr; 2) Dept Pediatrics, Seoul National University, College of Medicine, Seoul, Korea.

Glycogen-storage disease type 1 (GSD-1), also known as "von Gierke disease," is caused by a deficiency in microsomal glucose-6-phosphate activity. Mutations of the glucose-6-phosphatase gene (*G6PC*) are responsible for the most frequent form of GSD-1, the subtype 1a, while mutations of the glucose-6-phosphate transporter gene (*G6PT1*) have been shown to cause the non 1a forms of GSD, namely the 1b and 1c. To elucidate a spectrum of the *G6PC* gene mutations in Korean, we analyzed mutations in 20 unrelated Korean patients suspecting GSD-1 by direct DNA sequencing of the *G6PC* gene. All patients showed the typical clinical symptoms of GSD-1, but only 12 patients were confirmed by enzyme assay for the liver biopsy. Thec.727GT was found to be the major cause of GSD-1, accounting 21 of 40alleles. All 11 patients identified alleles mutations were confirmed by the enzyme assay and of these patients, 10 patients were homozygotes for c.727GT mutation and one is compound heterozygote with different mutations in the two *G6PC* alleles(c.727GT/c.611CG). Thec.611CG, converting a proline to an alanine at codon 178 was novel mutation. One patient showed no mutation in this gene was presented with neutropenia and inflammatory bowel disease in addition to typical clinical symptoms of GSD. We then analyzed mutation of *G6PT1* gene because we suspected clinically GSD-1b. Direct DNA sequencing of the *G6PT1* gene revealed the patient to be a compound heterozygote of a novel missense mutation, c.443CT, and another deletion mutation, c.1042-1043delCT, which has been reported previously. Here, we present that the c.727GT was the most prevalent among Korean GSD-1 patients with the allele frequency of 87.5%(21/24 mutant alleles confirmed by enzyme assay) and two novel missense (c.611CG, c.443CT) mutations were identified in the *G6PC* and *G6PT1* gene, respectively. So we suggest that noninvasive molecular genetic analysis for the c.727GT mutation can be a initial diagnostic tool for patients clinically suspected of having GSD-1 in Korean as an alternative to enzyme assay that requires liver biopsy.

**Fatal Neonatal Presentation of Glycogen Storage Disease Type IV in Two Infants.** *S.K.H. Tay<sup>1</sup>, H.O. Akman<sup>1</sup>, W. Chung<sup>1</sup>, M.G. Pike<sup>2</sup>, A.P. Hays<sup>1</sup>, K. Anyane-Yeboa<sup>1</sup>, S. Shanske<sup>1</sup>, S. DiMauro<sup>1</sup>.* 1) Neurology, Columbia University, NY, NY; 2) Department of Pediatrics, Oxford, UK.

Glycogen storage disease type IV (GSD IV) or Andersen Disease is an autosomal recessive disorder due to deficiency of glycogen branching enzyme (GBE). The GBE1 gene is located on chromosome 3p14 and consists of 16 exons. GSD IV exists in multiple clinically, biochemically, and molecularly heterogeneous forms. The typical form of GSD IV is characterized by rapidly progressive liver cirrhosis and death in childhood. Other variants include a cardiopathic form of childhood, a relatively benign myopathic form of young adults, and a late-onset neurodegenerative disorder (adult polyglucosan body disease, APBD). A severe neuromuscular variant resembling Werdnig-Hoffmann disease had been genetically characterized in only two patients. We describe two more infants, who presented with severe hypotonia and GBE deficiency and harbored novel mutations in the GBE1 gene. Branching enzyme assay, Western blot, RT-PCR and sequencing were performed on both patients. The cDNA of Patient 1 was subcloned and sequenced to delineate the mutations. Muscle biopsies showed accumulation of PAS-positive, diastase-resistant storage material in both patients and increased lysosomal enzyme activity in patient 1. GBE activity in muscle was negligible in both patients, and Western blot showed decreased GBE protein. One patient had a large homozygous deletion that spanned 627 bp and included exons 8 to 12. The other infant had 2 single base pair deletions, one in exon 10 (1248delT) and the other in exon 12 (1477delC), and each parent was heterozygous for one of the deletions. The large deletion and frame shift mutations seen in these neonatal cases correlates with the severity and earlier onset of symptoms compared with the other forms of GSD IV. The neonatal form of GSD IV is considered extremely rare, but our encountering two patients in close succession suggests that the disease may be underdiagnosed. This diagnosis should be considered in neonates presenting with severe hypotonia and respiratory distress.

**Toward the Development of Genetic System to Study Propionate Metabolic Disorders in *C. Elegans*. C.**

*Venditti*<sup>1,2</sup>, *R. Howard*<sup>1</sup>, *N. Wehrli*<sup>1</sup>, *R. Chandler*<sup>1</sup>, *R. Deering*<sup>1</sup>, *M. Tsai*<sup>1</sup>, *E. Daikhin*<sup>2</sup>, *M. Yudkoff*<sup>2</sup>, *M. Sundaram*<sup>1</sup>, *H. Kazazian Jr*<sup>1</sup>. 1) Dept of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Childrens Hospital of Philadelphia, Philadelphia, PA.

The model organism *C. elegans* has been utilized to study propionate metabolic disorders, specifically methylmalonic acidemia. Database analysis was used to identify homologues of the propionyl CoA carboxylase A (PCCA) and B subunits (PCCB), methylmalonyl CoA racemase (MMCR), MMAA, MMAB, and methylmalonyl CoA mutase (MMCM) genes. RNAi experiments have been reported for some of these genes but have been inconsistent with respect to the nature of the RNA used to target interference. To more thoroughly examine RNAi-effects mediated by bacterial feeding and to explore the potential of this method to induce *C. elegans* mutant phenotypes, we cloned full length cDNAs for each gene, constructed feeding strains, performed RNAi in the presence of proximal and distal metabolites, and scored phenotypes by inspection and chemical analysis. Metabolite measurements of MMA and succinate were performed with GC/MS. Baseline studies showed that wild-type *C. elegans* as well as a variety of anonymous mutant strains produced low levels of MMA under normal laboratory growth conditions. Our initial experiments using MMCM-directed interference revealed that substrate loading with propionate did not disproportionately increase MMA production or sensitivity to exogenous MMA. A MMCR deletion mutant was also studied. While the mutant did not produce an increased amount of MMA under basal conditions, it exhibited increased sensitivity to exogenous MMA and propionate and displayed a low-penetrant post-embryonic phenotype. The results to date indicate that *C. elegans* possesses the full complement of genes necessary to convert propionate into succinate, can produce MMA and has the potential to display a tractable phenotype that could be studied using forward, reverse and chemical genetic methods.

**Single mitochondrial DNA deletion in identical twin brothers.** *E.L. Blakely, R.W. Taylor, L. He, P.F. Chinnery, R.N. Lightowers, A.M. Schaefer, D.M. Turnbull.* Department of Neurology, University of Newcastle upon Tyne, Newcastle upon Tyne, NE2 4HH, United Kingdom.

Defects of mitochondrial DNA (mtDNA) are an important cause of genetic disease in humans. The defect often takes the form of a large-scale rearrangement or point mutation, with clinical features ranging from severe neonatal illness to mild muscle weakness later in life. A recent epidemiology study has shown that single, large-scale mtDNA deletions account for approximately 25% of adult patients with mtDNA disease and are associated with three major clinical syndromes. These are Pearsons syndrome (PS), a severe systemic illness of childhood associated with sideroblastic anaemia; Kearns Sayre syndrome (KSS) which is also associated with multiple system involvement; and chronic progressive external ophthalmoplegia (CPEO) in which the predominant clinical problem relates to an eye movement disturbance and ptosis. In both PS and KSS, the mtDNA deletion may show a wide-spread tissue distribution, whereas in CPEO, the mtDNA deletion is almost exclusively limited to skeletal muscle.

The overwhelming majority of reported cases harboring single mtDNA deletions are sporadic, although the stage in development at which the mtDNA deletion occurs has not fully been established. We have had the unique opportunity to study identical twin brothers, one of whom presented with CPEO and clear histochemical abnormalities indicative of a mtDNA disorder. Southern blot analysis showed that the affected twin harboured high levels of a single 4,115bp mtDNA deletion in his muscle, which was not evident in muscle from the asymptomatic brother. Using sensitive PCR based techniques however, we have also shown that the same mtDNA deletion is present in the muscle from the unaffected twin at very low levels (0.1%), suggesting that the mtDNA deletion was present in the oocyte prior to the development of the embryo.

**CYTOCHROME C OXIDASE ASSEMBLY IN HEALTH AND DISEASE: THE YEAST MODEL. A.**

*Barrientos*<sup>1</sup>, *A. Tzagoloff*<sup>2</sup>. 1) Department of Neurology, John Macdonald Foundation Center for Medical Genetics, University of Miami, Miami, FL; 2) Department of Biological Sciences. Columbia University, New York, NY.

Cytochrome c oxidase (COX) deficiency is the most frequent cause of mitochondrial neuromyopathies in humans. Patients afflicted with these diseases present heterogeneous clinical phenotypes, including Leigh syndrome, muscle weakness and encephalomyopathy. A complete understanding of COX biogenesis is essential for elucidating the molecular basis underlying this group of diseases. The main objective of our work is to use the yeast *Saccharomyces cerevisiae* as a model to investigate COX assembly in wild type cells and in cells with mutations in evolutionary conserved assembly factors. We have recently reported that Shy1p, the yeast homologue of human Surf1p, responsible for most cases of Leigh's syndrome, catalyzes the formation of a COX assembly intermediate involving Cox1p, a mitochondrially encoded catalytic subunit of COX. More recent evidence indicates that this intermediate regulates Cox1p expression in a process involving other COX metabolism factors. Most COX assembly mutants, including *shy1* mutants, exhibit greatly reduced rates of synthesis of Cox1p but not of Cox2p and Cox3p. This phenotype can be explained in, *mss51*, *pet309*, and *oxa1* mutants based on the known functions of their encoded proteins. Both Mss51p and Pet309p are required for translation of *COX1* mRNA while Oxa1p facilitates membrane insertion of Cox1p, which is highly susceptible to proteolysis under these circumstances. The only exception are *cox14* mutants that show normal rates of Cox1p synthesis when tested by pulse labeling. This is also true of strains carrying a *cox14* null mutation combined with mutations in other COX-specific genes. The dominant effect of *cox14* mutations on the rate of Cox1p synthesis suggests a role of Cox14p in regulation of Cox1p expression. An attractive hypothesis consistent with all the available evidence is that Shy1p may regulate Cox1p synthesis by promoting an assembly step which results in the release of Mss51p from an assembly intermediate (formed by the action of Cox14p) thereby making it available for activation of Cox1p translation. *AB is supported by an MDA grant.*

**Increased markers of oxidative damage in a family with the mtA8344G mutation but lacking the classic MERRF phenotype.** *J. Canter, A. Eshaghian, J. Fessel, M. Summar, J. Roberts, J. Morrow, J.E. Sligh, J.L. Haines.* Vanderbilt University Medical Center, Nashville, TN.

Oxygen-derived free radicals generated in mitochondria attack esterified arachidonate in cell membranes, creating prostaglandin-like compounds, such as F2-isoprostanes. Levels of F2-isoprostanes are increased in a variety of degenerative diseases. Isofurans are products of a newly discovered pathway of free radical catalyzed lipid peroxidation that may better reflect oxidative injury at high oxygen tension. We identified the mtA8344G mutation in multiple generations of a large family that demonstrated significant variability in phenotype. Diagnostic evaluation of the 50-year-old proband with olivopontocerebellar degeneration revealed 95% heteroplasmy for the mtA8344G mutation in a muscle biopsy specimen. He has never had seizures and the muscle biopsy failed to reveal ragged red fibers. The proband's maternal grandmother had 5 sisters. We detected the mtA8344G mutation in the only remaining living member of this sibship and in descendants of each of these women. The mtA8344G mutation has been found in 19 adults in this family. Two family members in whom this mutation was undetectable in blood, including the proband's mother, had the mtA8344G mutation in buccal specimens. Symptoms of myoclonus, muscle weakness, ataxia, or hearing loss are reported by 53% of family members with the mutation. However, no family member with both myoclonic epilepsy and progressive myopathy has been identified. The mean F2-isoprostane level in this family (N=22) was 5840 pg/ml compared to controls, 356 pg/ml ( $p < 0.01$ ). No significant difference in F2-isoprostanes levels could be demonstrated within this family on the basis of presence of the mutation or neurological symptoms, but detection may be limited by small sample size. The mean isofuran level for this family was 12766 pg/ml compared to controls of 7010 pg/ml ( $p < 0.01$ ). The degree of heteroplasmy for mtA8344G from buccal specimens correlated strongly with isofuran levels,  $r = 0.82$  ( $p < 0.01$ ). This family with the mtA8344G mutation demonstrates that oxidative injury is present in a wide range of phenotypes, including currently asymptomatic adults.

**De novo mutations in the mitochondrial ND3 gene as a cause of infantile mitochondrial encephalopathy and complex I deficiency.** *R. McFarland<sup>1</sup>, D.M. Kirby<sup>2,3,5</sup>, K.J. Fowler<sup>2,5</sup>, A. Ohtake<sup>4</sup>, M.T. Ryan<sup>4</sup>, D.J. Amor<sup>2,3,5</sup>, J.M. Fletcher<sup>6</sup>, J.W. Dixon<sup>7</sup>, F.A. Collins<sup>8</sup>, D.M. Turnbull<sup>1</sup>, R.W. Taylor<sup>1</sup>, D.R. Thorburn<sup>2,3,5</sup>.* 1) Dept. of Neurology, Neurobiology and Psychiatry, University of Newcastle Upon Tyne, United Kingdom; 2) Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, Australia; 3) Genetic Health Services Victoria, Royal Children's Hospital, Melbourne, Australia; 4) Dept. of Biochemistry, La Trobe University, Melbourne, Australia; 5) Dept. of Paediatrics, University of Melbourne, Australia; 6) Dept. of Chemical Pathology, Womens and Childrens Hospital, Adelaide, Australia; 7) Central Regional Genetic Service, Wellington Hospital, New Zealand; 8) Dept. of Medical Genetics, Childrens Hospital at Westmead, Sydney, Australia.

Energy generation disorders may be caused by mutations in either nuclear or mitochondrial DNA (mtDNA). Respiratory chain complex I deficiency is the commonest energy generation disorder and a frequent cause of Leigh disease and infantile mitochondrial encephalopathies. Most cases of complex I deficiency have been assumed to be caused by nuclear gene defects, but recent reports of mtDNA mutations in patients with Leigh disease and complex I deficiency together with the work we present here, challenge that assumption. We report the first four cases of infantile mitochondrial encephalopathies caused by mutations in the ND3 subunit gene. Three unrelated children have the same novel heteroplasmic mutation (T10158C), only the second mutation reported in ND3, and one has the previously identified T10191C mutation at near-homoplasmic levels. Both mutations cause a much greater reduction in enzyme activity than in the amount of fully assembled complex I, suggesting the ND3 subunit plays an unknown but important role in electron transport. Three cases appear to have a de novo mutation, with no mutation detected in maternal relatives. Our findings indicate that mitochondrial DNA disease may be considerably more prevalent in the pediatric population than currently predicted, and should be considered in patients with infantile mitochondrial encephalopathies and complex I deficiency.

**High dose Coenzyme Q-10 in the treatment of MELAS syndrome.** *LH. Ngu<sup>1</sup>, YS. Choy<sup>1</sup>, S.K. Tan<sup>2</sup>, PKC. Lim<sup>2</sup>, AK. Raihana<sup>3</sup>, LC. Ong<sup>4</sup>.* 1) Genetic/Metabolism Unit, Pediatric Institute, Kuala Lumpur Hospital, Malaysia; 2) Molecular Pathology Unit, Institute of Medical Research; 3) Neurology Institute, Kuala Lumpur Hospital; 4) National University Hospital, Malaysia.

MELAS syndrome is a progressive neurodegenerative disorder with high morbidity and mortality. Coenzyme Q-10, an essential electron transporter and anti-oxidant, has been widely used to treat the condition. Reports of clinical improvement have been documented in some patients using the recommended dosages of 4 to 10 mg/kg/day. However, many patients deteriorated while taking the dosages recommended. We have followed up 12 patients with MELAS syndrome (10 with 3243 mutation), aged 4 months to 42 years, for the past 4 years. 3 patients identified by family screening remained asymptomatic and healthy taking 4mg/kg/day of Coenzyme Q-10, vitamin C 100mg daily and riboflavin 100mg daily. All other 9 patients had more than 2 episodes of crisis with severe lactic acidosis and stroke-like episodes. All were initially prescribed the maximum 10mg/kg/day of coenzyme Q-10, riboflavin 100mg daily, thiamin 100mg daily, vitamin C 100mg daily for children and 200mg tds for adult, vitamin E 400i.u. daily and L-carnitine 50 to 100mg/kg/day. 7 of the 9 patients (78%) had recurrence of the stroke while taking the above mentioned medications. Two passed away without any changes of the medications made during crisis. 5 others had Coenzyme Q-10 increased to 20mg/kg/day in 2 to 3 divided doses for 2 weeks without any clinical or biochemical side effects. The dosage of vitamin C was doubled. All five patients recovered from the stroke-like episodes and blindness faster with less cognitive regression compared to no changes made in Coenzyme Q-10 during earlier crisis. Two patients have been given maintenance Coenzyme Q-10 15mg/kg/day for more than a year without any side effects. But one of them had a relapse. One patient had total blindness for 3 months but his vision recovered with 20mg/kg/day of Coenzyme Q-10. In short, high dose coenzyme Q-10 is save and helpful during crisis of MELAS syndrome. Larger multi-center study is needed for a better evidence of long-term usage of high dose Coenzyme Q-10 in patients with MELAS.

**MNGIE with lack of skeletal muscle involvement and a novel TP splice-site mutation.** *K. Szigeti<sup>1</sup>, L.C. Wong<sup>2</sup>, C. Perng<sup>2</sup>, G.M. Saiji<sup>1</sup>, K. Eldin<sup>1</sup>, A.M. Adesina<sup>1</sup>, D.L. Cass<sup>1</sup>, M. Hirano<sup>3</sup>, J.R. Lupski<sup>1</sup>, F. Scaglia<sup>1</sup>.* 1) Molecular and Human Genetics, Pediatrics, Pathology, Surgery, Baylor College of Medicine, Houston, TX; 2) Institute for Molecular and Human Genetics, Georgetown University, Washington, DC; 3) Department of Neurology, Columbia University College of Physicians and Surgeons, New York, NY.

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is an autosomal recessive multisystemic disorder caused by thymidine phosphorylase deficiency. Clinically it manifests as severe gastrointestinal dysmotility leading to cachexia; ptosis; external ophthalmoparesis; peripheral neuropathy and leukoencephalopathy. We report a patient with a classical MNGIE clinical presentation, but surprisingly, without skeletal muscle involvement at the morphological, enzymatic and mitochondrial DNA levels. MNGIE was diagnosed by markedly elevated plasma thymidine level and reduced thymidine phosphorylase activity. Molecular genetic analysis revealed a homozygous novel splice site mutation in the thymidine phosphorylase gene (TP). Sequencing of the coding regions and the adjacent splicing junctions revealed the presence of a novel homozygous GC transversion at the splice acceptor site of the second coding exon. RT-PCR analysis followed by sequencing of the expected product revealed that the second coding exon is skipped and an alternative splice donor site becomes activated. The alternative splicing results in deletion of 234 nucleotides from the mRNA sequence that by conceptual translation leads to an in-frame deletion of 78 amino acids from the protein. The deleted fragment contains the catalytic His116 residue, thus its absence likely impairs function. The predicted loss-of-function was confirmed by the markedly reduced enzyme activity measured in peripheral blood. Interestingly, since the deletion is in-frame, the protein preserved its antigenicity to the TP antibody. Immunohistochemistry revealed marked TP expression in the CNS in contradistinction to what has been observed in rodents. We emphasize the necessity to examine the most significantly affected tissue in order to arrive at an accurate diagnosis.

**Tissue, bile and blood carnitine/acylcarnitine profiles during exercise and a cold challenge with fasting in VLCAD knockout mice.** *U. Spiekerkoetter*<sup>1,2,3</sup>, *C. Tokunaga*<sup>2</sup>, *U. Wendel*<sup>1</sup>, *E. Mayatepek*<sup>1</sup>, *F.M. Vaz*<sup>3</sup>, *N. van Vlies*<sup>3</sup>, *J.P.N. Ruiten*<sup>3</sup>, *M. Duran*<sup>3</sup>, *L. Ijlst*<sup>3</sup>, *F.A. Wijburg*<sup>3</sup>, *R.J.A. Wanders*<sup>3</sup>, *A.W. Strauss*<sup>2</sup>. 1) Department of General Pediatrics, University Children's Hospital, Duesseldorf, Germany; 2) Department of Pediatrics, Vanderbilt Univ, Nashville, TN; 3) Academic Medical Center, Amsterdam, The Netherlands.

In human very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency, clinical symptoms are induced by external stressors with involvement of heart, liver and skeletal muscle (SM). The VLCAD KO mouse exhibits stress-induced hypoglycemia, skeletal myopathy and cold intolerance, symptoms resembling human VLCADD, and is a valuable model to study the effects of exercise and a cold challenge with fasting, conditions triggering disease manifestation. We characterized the biochemical phenotype in response to these stressors. Carnitine/acylcarnitine profiles were measured by tandem mass spectrometry using methanol extraction for blood and bile samples and acetonitrile extraction for tissues. During fasting-induced lipolysis, blood C16-C18 acylcarnitines increased 2 to 3-fold in KO mice, more than after exercise. In bile, C16-C18 acylcarnitines were 5 to 10-fold higher than in blood and strongly increased after fasting; bile-blood ratios remained constant. In liver, a 2-fold increase of C16-C18 acylcarnitines was observed after the cold challenge with fasting as reflected by bile and blood profiles. After exercise, liver acylcarnitines did not increase significantly compared to unstressed conditions despite an increase in blood. These acylcarnitines likely derived from production in SM with a 2 to 3-fold increase after exercise. Whereas blood free carnitine significantly decreased after the cold challenge with fasting, liver concentrations remained stable. Exercise resulted in a significant decrease of free carnitine in SM. In conclusion, blood acylcarnitine profiles reflect the overall production of acylcarnitines in various tissues. In response to different stressors, specific organs are affected and acylcarnitine production appears to be tissue-specific. Free carnitine concentrations also decrease tissue-specifically due to different stressors.

**Evaluation of the Mitochondrial Disease Criteria (MDC) scoring system in the South African population. I.**

*Smuts<sup>1</sup>, A.C. Van Brummelen<sup>2</sup>, D.C. Wallace<sup>3</sup>, A. Olckers<sup>2,4</sup>.* 1) Paediatrics, University of Pretoria, Pretoria, South Africa; 2) Centre for Genome Research, Potchefstroom University for CHE, Pretoria, South Africa; 3) Centre for Molecular and Mitochondrial Medicine and Genetics, Univ of California at Irvine, Irvine, USA; 4) DNAbiotec (Pty) Ltd, Pretoria, South Africa.

The clinical diagnosis of mitochondrial disorders is complex and challenging. For this reason, Wolf et al. (2002) proposed consensus diagnostic criteria, the Mitochondrial Disease Criteria (MDC), in order to standardise the clinical diagnosis of this group of clinically heterogeneous disorders. The MDC relies on the following systems being predominantly affected: muscle, central nervous system and multi-system involvement. To date, we have scored 65 subjects according to the proposed MDC scoring system. 27 of our patients we scored to be probable mitochondrial disease, with an MDC score of between 5-7. We assessed eight of our patients to be in the definite mitochondrial disease class, with an MDC score of 8 and higher. Given that muscle biopsies are difficult and sometimes not practical in our environment, the maximum score that we could generate for any of our patients was 8. The four additional points of the MDC score would have been generated via data from a muscle biopsy. The above data demonstrates that the MDC scoring system is able to discriminate between our patient group, based on clinical and biochemical data alone. Genetic studies are underway to elucidate the genotypes responsible for the phenotypes segregating in the above patients.

**Molecular screening of patients with mitochondrial disorders in the South African population.** *A.C. Van Brummelen<sup>1</sup>, I. Smuts<sup>2</sup>, D.C. Wallace<sup>3</sup>, A. Olckers<sup>1,4</sup>.* 1) Centre for Genome Research, Potchefstroom University, Pretoria, South Africa; 2) Dept of Paediatrics, Univ of Pretoria, South Africa; 3) Centre for Molecular and Mitochondrial Medicine and Genetics, Univ of California at Irvine, Irvine, USA; 4) DNAbiotec (Pty) Ltd, Pretoria, South Africa.

In a previous study, gDNA of 53 patients with suspected mitochondrial disorders were screened for 25 reported mtDNA mutations via an RFLP, and subsequently a sequencing strategy encompassing the 3000, 8000 and 9000 regions. The above samples were screened from DNA collected via whole blood and fibroblast cultures. Only one reported mitochondrial mutation (A3243G), associated with MELAS, was detected in a single proband and subsequently in her extended family with different levels of heteroplasmy. However, overall, six novel alterations were also detected. These results raised the question whether the genetic aetiology of mitochondrial disorders in our population was indeed similar to those reported elsewhere, since only one reported mutation was detected in this extensive study. The above study was extended to investigate whether the novel alterations were also present in other South African patients. To this end, an additional subset of 22 well characterised (clinically and biochemically) patients were included, for a total of 75 patients. They were screened via single stranded sequencing of the tRNA<sup>Leu</sup>(UUR), tRNA<sup>Lys</sup> and ATPase 6 mitochondrial genes, for the reported as well as the above six novel alterations.

**Transcriptional responses in nuclear encoded human mitochondrial complex I deficiency.** *F.H. van der Westhuizen*<sup>1,2</sup>, *J. Smeitink*<sup>2</sup>, *L.P. van den Heuvel*<sup>2</sup>, *R. Smeets*<sup>2</sup>, *J.A. Veltman*<sup>3</sup>, *R. Pfundt*<sup>3</sup>, *A. Geurts van Kessel*<sup>3</sup>, *B.M. Ursing*<sup>4</sup>. 1) School for Chemistry and Biochemistry, PUforCHE, Potchefstroom, South Africa; 2) Nijmegen Center for Mitochondrial Disorders, UMC Nijmegen, The Netherlands; 3) Department of Human Genetics, UMC Nijmegen, The Netherlands; 4) Center for Genomics and Bioinformatics, Karolinska Institute, Sweden.

NADH:ubiquinone oxidoreductase (complex I) deficiency is one of the most frequently encountered defects of the mitochondrial energy generating system. A deficient activity of this multi-protein oxidative phosphorylation system enzyme complex can be caused by mutations in the mitochondrial or the nuclear genome and leads to a remarkably wide variety in clinical disease expression. We investigated the transcriptional responses by microarray in fibroblast cell lines harboring nuclear DNA encoded mutations in the NDUFS2, NDUFS4, NDUFS7, NDUFS8, and NDUFV1 subunits of complex I. A microarray containing a selection of approximately 600 genes involved in bioenergetics and other mitochondria-related functions were constructed and evaluated in a novel experimental approach. Transcriptional responses of control and patient fibroblasts were compared by changing the cell culture conditions from glycolytic to oxidative metabolism. Approximately 60 genes displayed differential expression under these conditions in either all mutated cell lines or selected cell lines only. A marked induction of all investigated metallothioneins as well as ATP1G1 transcripts was detected in all patient cell lines. In addition, individual transcriptional responses such as induction of heat shock protein transcripts, decreased PDK1, BNIP3 and mitochondrial genome encoding gene transcripts only occurred in selected patient cell lines. The observed transcript profile in all complex I mutated cell lines pointed to a common, putative defensive response related to oxidative stress. With the exception of one cell line, patient cell lines could be grouped using hierarchical clustering. Although further investigations is warranted, these results underline the great potential of functional genomics to gain new insights into inborn errors of energy metabolism.

**A Yeast Model for McCune-Albright Syndrome.** *R. Pals-Rylaarsdam, M. Koster, J. Mitchell.* Biology, Trinity Christian College, Palos Heights, IL.

Patients with McCune-Albright Syndrome (MAS) suffer from a variety of complications due to the post-zygotic mutation of the alpha subunit of the stimulatory G-protein  $G_s$ . This mutation causes signal-independent activity of the G-protein leading to high levels of cAMP in the affected cells. Patients experience a variety of conditions such as the abnormal development of bone tissue, known as polyostotic fibrous dysplasia, as well as other abnormalities including precocious puberty, ovarian cyst formation, and skin hyperpigmentation. We have developed a model system to study the effects of MAS mutations using an engineered strain of the budding yeast *Saccharomyces cerevisiae*. Haploid yeast identify mating partners by responding to pheromones sensed by G-protein coupled receptors. The downstream signaling pathways are well characterized and homologous to human G-protein signaling pathways. Activation of the yeast pheromone response inhibits cell division; thus an active G-protein prevents colony formation. One normal copy of the G-protein gene, even in the presence of an activated copy of the gene, is sufficient to allow growth. We introduced the MAS mutation into the analogous site in the yeast G subunit, and identified active and inactive mutants in the G-protein based on the ability of the yeast to form colonies on 5-FOA medium, an environment that selected for loss of the normal copy of the G-protein gene. We replaced a section of the yeast G gene with randomly mutated DNA sequences containing approximately five mutations each. A library of 1600 plasmids carrying random mutations was screened in the yeast model system for suppression of the McCune-Albright mutation. From 1046 colonies, four plasmids encoding a G-protein with a corrected phenotype were isolated. The successful identification of these intragenic suppressors may lead to structural prediction of small molecules capable of regulating the defective G-proteins.

**Biotin deficiency in the rat as a model of the genetic expression of inter-organ mammalian carboxylation.** A. Velazquez, N. Rodriguez-Fuentes, S. Cano-Colin. Nutritional Genetics, Natl Univ Mexico, Mexico, D F, Mexico.

Biotin-dependent carboxylation reactions are very important in the metabolism of carbohydrates, lipids and proteins. Their genetic expression rely on processes whose Mendelian defects result in Multiple Carboxylase Deficiency (MCD), its phenocopy being biotin deficiency (BD). To better understand the molecular pathophysiology of MCD we studied the effects of BD on rats liver, adipose tissue, heart, ileum and spleen. There were wide differences among these organs: adipose had the greatest decrease in pyruvate (PC) and propionyl CoA (PCC) carboxylase activities and protein amounts; heart had the lesser decrease; ileum was very deficient in PCC but not in PC. There was no detectable PC activity or mass in control and BD spleen, and PCC was very deficient in this BD organ. To look for an explanation of these results, we measured their mRNAs and the Na-dependent multivitamin transporter (SMVT). PC and PCC mRNAs diminished in ileum and spleen (there was detectable PC mRNA in spleen), but they did not change in liver, adipose and heart of BD animals. The SMVT mRNA increased in BD liver and adipose; decreased in ileum, and did not change in heart and spleen. Therefore, the observed carboxylation changes do not seem to be related to alterations in biotin transport or carboxylases transcription. An additional observation was a very different distribution of carboxylase activities and masses among different organs in the control animals, indicating their differential genetic expression most likely in accordance with the distinct physiological roles of these organs. This investigation complements our previous work on kidney, muscle and brain (J Nutr 2001, 131:1909).

Program Nr: 1719 from 2003 ASHG Annual Meeting

**A PCR/OLA assay for reflex testing of I506V, I507V and C508 mutations in the human CFTR gene.** *E. Swartzman, S. Koepf, L. Nguyen, E. Schreiber.* Celera Diagnostics, Alameda, CA.

Cystic fibrosis (CF) is an autosomal recessive disorder that is caused by mutations in the cystic fibrosis transmembrane conductance regulator gene (CFTR). CF is the most common lethal genetic disease in the US and the American College of Medical Genetics (ACMG) has recommended population-wide, prenatal CF carrier screening. Among the greater than 1000 known mutations, the deletion F508 mutation is the most common and accounts for 60-80% of the CF mutant alleles in certain populations. We have previously developed a single tube PCR/OLA assay for research use to detect 32 common mutations and alleles including the 25 mutations recommended by the ACMG. Here we describe a revised exon 10 reflex assay that is utilized only to verify a homozygous deletion of the F508 or I507 codon and exclude a potential false positive result due to interference by the single nucleotide polymorphisms (SNPs) of V506, V507 or C508. The reflex assay consists of a PCR reaction to amplify exon 10 of the CFTR gene followed by an oligo ligation assay (OLA) using fluorescently labeled probes to detect either normal or mutant CF alleles. The allele specific fragments are subsequently analyzed by electrophoretic sequence coded separation (SCS) using the ABI PRISM 3100 Genetic Analyzer. The normal or mutant genotypes are then automatically identified using GenoTyper or GeneMapper software. The performance of the assay was evaluated using mutant genomic and synthetic DNA templates and the expected results were obtained.

**Neurodevelopmental pattern of succinic semialdehyde dehydrogenase deficiency (4-hydroxybutiric aciduria).** A. PHILIPPE<sup>1</sup>, J. DERON<sup>1</sup>, P. DE LONLAY<sup>1</sup>, K.M. GIBSON<sup>2</sup>, D. RABIER<sup>3</sup>, A. MUNNICH<sup>1</sup>. 1) INSERM U 393, Hopital Necker-Enfants Malades, PARIS, France; 2) Biochemical Genetics Laboratory, Oregon Health Sciences University, Portland,USA; 3) Laboratoire de Biochimie Medicale B,Hopital Necker-Enfants Malades, Paris,.

Succinic semialdehyde dehydrogenase (SSADH Mc Kusick 271980) deficiency is a defect in gamma-aminobutyric acid degradation, resulting in the accumulation of gamma-hydroxybutyric acid (GHB) and causing neurological and cognitive disorders of varying severity. Their non-specific nature and difficulties in detection of urinary GHB explain why this disorder is largely underdiagnosed. At least 150 affected individuals have been hitherto identified but only three adults have been reported. Here, we described two additional cases in adult brothers and emphasize the remarkable similarity of their course from birth into adulthood. Early assessment revealed that their delayed language was due to a verbal agnosia. A review of their early motor development revealed that both sibs presented hypotonia from birth and mild delay of motor milestones. Both sibs also had a broad-based unsteady gait that spontaneously improved at 7 years. During or shortly after adolescence, both experienced hallucinations. Moreover, the elder brother had sleep disturbances since early childhood and some years ago, he experienced daytime attacks of sleep triggered by emotion of delight, which led to the investigation of a possible diagnosis of narcolepsy before SSADH deficiency was recognised. Finally, cerebral MRI in both brothers revealed a moderate cerebellar vermis atrophy and a retrocerebellar cyst and in the younger brother, cerebral MRI also detected an increased T2 signal intensity in the anterior part of the external globus pallidus. We discuss the main clinical features of SSADH deficiency in relation to physiopathologic involvement of GHB and try to identify the most specific neurodevelopmental pattern of this disorder.

**Transport of methylmalonic acid by organic anion transporters.** X. Fu<sup>1</sup>, T.J. Urban<sup>2</sup>, K.M. Giacomini<sup>2</sup>, S. Packman<sup>1</sup>. 1) Dept of Pediatrics, Div of Medical Genetics; 2) Dept of Biopharmaceutical Science, Univ of California San Francisco, CA.

The mechanisms of neurotoxicity in methylmalonic acidemia and other heritable organic acidemias are not understood. For example, in the methylmalonic acidemias of diverse etiologies, therapies that reduce the concentration of methylmalonic acid (MMA) and related metabolites in the systemic circulation and peripheral tissues, do not uniformly ameliorate or arrest progressive neurologic deterioration. It is therefore possible that central nervous system and cerebrospinal fluid (CSF) accumulation of MMA might continue unabated, even in the face of peripheral tissue reductions of metabolite concentrations. To this end, we have begun to ask how MMA is transported into and out of the CSF. As a first step towards characterization of choroid plexus (CP) transport of MMA, we characterized MMA transport by two different and specific organic anion transporters known to be expressed in CP, using a *X. laevis* oocyte expression system. Capped cRNAs encoding the rat sodium-dependent dicarboxylate transporter (rNaDC1) and the human organic anion transporter (hOAT1) were transcribed *in vitro* and injected into mature oocytes, the uptake of <sup>14</sup>C-MMA and prototypic substrates (<sup>3</sup>H-succinate (rNaDC1) and <sup>3</sup>H-p-aminohippurate (hOAT1)) was determined. <sup>14</sup>C-MMA was taken up by both rNaDC1 (41±2.95 pmol/h/oocyte vs. 17±1.22 for the control, p<0.001) and hOAT1 (40±4.13 pmol/h/oocyte vs. 14±1.44 for the control, p<0.001). In addition, the uptake of <sup>3</sup>H-succinate into oocytes expressing rNaDC1 was inhibited 24% by 5 mM MMA (p<0.001), and the uptake of <sup>3</sup>H-aminohippurate into oocytes expressing hOAT1 was inhibited 56% by 5 mM MMA (p<0.001). We conclude that MMA is a low-affinity substrate and inhibitor of both rNaDC1 and hOAT1, in this expression system. The low potency of interaction of MMA with these CP transporters is consistent with the finding that MMA accumulates in the CSF of patients treated for methylmalonic acidemia. We are further characterizing the kinetics and specificity of transport of MMA by these organic anion transporters, and determining their localization in CP epithelial cells.

**A mild variant of Canavan disease with a novel mutation in ASPA gene.** *Y. Anikster<sup>1</sup>, G.S. Salomons<sup>2</sup>, S.H. Korman<sup>3</sup>, V. Barash<sup>3</sup>, N. Gal<sup>1</sup>, J. Zlotnik<sup>1</sup>, T. Masos<sup>1</sup>, B. Ben-Zeev<sup>4</sup>.* 1) Metabolic Disease Unit, Safra Children Hospital, Tel-Hashomer; 2) VU University Medical Center, Amsterdam, The Netherlands; 3) Clinical Biochemistry, Hadassah University Hospital, Jerusalem; 4) Pediatric Neurology, Safra Children Hospital, Tel-Hashomer, Israel.

Canavan disease (CD) is a neurodegenerative disorder caused by mutation in the aspartoacylase (ASPA) gene. The classic phenotype is of severe neurological impairment noticed before 6 months of age, followed by rapidly progressive mental retardation. Life expectancy is usually into the teens, and optic atrophy is typical. We present a mild variant in a 20 year old male descendant of non-consanguineous Libyan-Jewish parents. At 3 months he presented with hypotonia, macrocephaly and nystagmus. However, in the following years he showed developmental progress, was able to walk with a walker from the age of 4, could talk in sentences although with accompanied dysarthria, became toilet trained and had significant hand usage (could draw and feed himself). He was assessed as functioning in the moderate mental retardation range at the age of 5. He never showed any visual impairment and has normal looking optic discs. In his second decade, aggravation of ataxia and spasticity resulted in loss of ambulation, and he became wheelchair bound, but was still alert and interactive. CT scan followed by MRI showed progressive cerebral and cerebellar atrophy and abnormal diffuse white matter signal in cerebrum, midbrain, cerebellum and basal ganglia. Despite normal metabolic screen in the past, urinary organic acids were repeated and elevated NAA was detected. We confirmed the diagnosis by aspartoacylase assay in fibroblasts. By sequencing all the ASPA exons, we found a novel missense mutation. The transversion of G to C at position 610 resulted in one amino acid change the aspartic acid 204 (which is conserved in evolution) to histidine. The mutation creates *EcoRI* restriction site and allows us to show segregation in the family. In screening 174 anonymous Libyan-Jews, we found no allele which harbored this mutation. Our results allow prenatal diagnosis and carrier detection in this family and widen the clinical spectrum of CD.

**A pilot study of nitisinone in Alkaptonuria.** *P. Suwannarat*<sup>1</sup>, *I. Bernardini*<sup>1</sup>, *M. Kaiser-Kupfer*<sup>2</sup>, *E. Tsilou*<sup>2</sup>, *B. Rubin*<sup>2</sup>, *K. O'Brien*<sup>1</sup>, *W. Gahl*<sup>1</sup>. 1) Section on Human Biochemical Genetics, Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Clinical Research Branch, National Eye Institute, National Institutes of Health, Bethesda, MD.

Alkaptonuria (AKU) is an autosomal recessive disorder due to deficiency of the enzyme homogentisic acid dioxygenase in the tyrosine degradation pathway. AKU is characterized by daily excretion of gram quantities of urinary homogentisic acid (HGA), vertebral disk collapse, arthritis, joint destruction requiring replacement, and ochronosis, or dark pigmentation of tissues due to HGA and its oxidation products. No effective therapy exists. However, 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexadine (nitisinone) inhibits 4-hydroxyphenylpyruvate dioxygenase, the enzyme that produces HGA. We treated 3 patients with nitisinone, titrating the dose to lower HGA excretion to less than 0.5 gm/day. The doses were 0.35 mg/day (divided bid) for one week and then 1.05 mg/day for 3 months. Initial HGA levels of 3.4, 3.7, and 2.6 gm/day fell to ~80-300 mg/day. Plasma tyrosine concentrations, initially ~60 micromolar, rose to ~1100 micromolar. Weekly eye examinations revealed no signs of corneal toxicity. After 5 weeks of treatment, patient #1 passed several kidney stones but remained on study. After 11 weeks, patient #3, who previously had asymptomatic aortic stenosis, developed symptoms of lightheadedness and dyspnea on exertion. She was removed from the study and received a valve replacement. The other 2 patients completed 12 and 13 weeks of nitisinone therapy. During the last week of treatment, each received only 40 grams of protein per day, and plasma tyrosine and urinary HGA concentrations were monitored. Long term clinical trials are planned to determine the benefit of nitisinone in preventing joint deterioration and pain.

**Rescue of peroxisome assembly at 30C: expanding the type of responsive mutations in *PEX6* defective cells.** *N. Braverman*<sup>1</sup>, *L. Chen*<sup>1</sup>, *S. Dasinger*<sup>1</sup>, *A. Moser*<sup>2</sup>, *H. Moser*<sup>2</sup>, *S. Steinberg*<sup>2</sup>. 1) Inst Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Kennedy Krieger Inst, Baltimore, MD.

The peroxisome biogenesis disorders (PBD) are a heterogeneous group of autosomal recessive diseases caused by defects in *PEX* genes. Patient phenotypes range from severe Zellweger syndrome (ZS) to milder neonatal adrenoleukodystrophy (NALD) and infantile Refsum disease (IRD). In general, the milder patients have *PEX* mutations predicted to result in residual peroxin function. Recently, several groups have reported that fibroblasts from NALD-IRD patients show improvement in the import of matrix proteins into peroxisomes when grown at 30C. This temperature sensitive phenotype, thus far associated with missense alleles, is of importance as it might reflect a partially functional, but unstable protein at body temperature that could then be supported by stabilizing drugs.

One of the larger PBD groups is caused by defects in *PEX6*, which encodes a member of the AAA family of ATPases. Only 16 probands with *PEX6* defects are reported to date. We present an analysis of *PEX6* in 20 probands from our collection: 12 ZS, 6 NALD and 2 IRD. We amplified and sequenced all 17 exons and adjacent intronic regions, and identified mutations in 37/40 alleles. The majority were unique. 41% were missense, 51% insertion or deletion alleles and 8% were splice site changes. Surprisingly, several NALD patients had mutations that shift the reading frame on both alleles. To investigate genotype-phenotype correlations, we analyzed *PEX6* transcripts by northern analysis and RT/PCR. We also evaluated import of endogenous PTS1 and PTS2-targeted matrix proteins and peroxisome morphology by indirect immunofluorescence microscopy in fibroblasts cultured at 30 and 37. We found dramatic improvement in these parameters at 30 in 5 patients with NALD-IRD and in 2 of 5 ZS patients. Remarkably, temperature sensitive import was observed in cells from patients with ZS and NALD harboring out of frame transcripts. Taken together, these results expand the current observations on temperature sensitivity and implicate the translation of truncated Pex6 peroxins that are stabilized at 30.

**PEX26 mutations and cellular phenotype of patients with complementation group (CG) 8 peroxisome biogenesis disorder (PBD).** *S. Weller*<sup>1</sup>, *S.J. Gould*<sup>2</sup>, *H.W. Moser*<sup>3</sup>, *D. Valle*<sup>1,4</sup>. 1) Inst Genetic Medicine; 2) Dept of Biological Chemistry; 3) Kennedy Krieger Inst; 4) Howard Hughes Medical Institute, Johns Hopkins Univ, Baltimore, MD.

The Zellweger spectrum subgroup of the PBDs comprises a genetically heterogenous group of autosomal recessive diseases characterized by deficiency of multiple peroxisomal enzymes. Eleven CGs are known. Recently PEX26 was identified as the gene responsible for CG8, the only unsolved CG, with a homozygous missense mutation reported in 1 patient. PEX26 is an integral peroxisomal membrane protein of 305 aa with the N-terminus exposed to the cytosol and seems to be essential for the localization of PEX1-PEX6 complexes to peroxisomes. PEX1 and 6 are AAA ATPases and their function in peroxisome biogenesis is controversial. Here we report 8 unrelated CG8 patients with clinical phenotypes ranging from mild to severe. We identified 9 PEX26 alleles that account for all 16 mutant PEX26 genes in this patient group and include 11 missense and 2 splice site mutations, a single bp insertion, a single bp deletion, and a duplication of 122 coding bp. To determine the functional consequences of these mutations, we characterized the cellular phenotype of the PEX26 deficient patients fibroblasts by transfection and immunofluorescence studies with a series of reporter genes designed to test various aspects of peroxisomal protein import and compared them to cells with null mutations in PEX1, 6 or 5 (CG1,4&2). We observed a range of severity in the cellular phenotype of PEX26 deficient cell lines that corresponds, in part, to the clinical phenotype of the patients. A patient with a homozygous splice site mutation (IVS2+1G>T) shows a pronounced deficiency in peroxisomal matrix protein import and a severe clinical phenotype. A patient homozygous for R98W has a milder clinical phenotype and the mildest import deficiency. A compound heterozygote for R98W and L44P had a much more severe cellular phenotype. None of the CG8 cell lines had an import defect as severe as cell lines with null mutations in PEX1, PEX6, or PEX5. This ongoing analysis suggests a rough correlation between PEX26 genotype, cellular and clinical phenotype.

**Identification of novel polymorphisms in cytochrome P450 genes by amplification and sequencing of 93 human DNA samples.** *J. Solus, R. Harris, B. Arietta, J. Steward, D. Sexton, C. McMunn, P. Ihrle, J. Mehall, T. Edwards, E. Dawson.* Research & Development, BioVentures, Inc, Murfreesboro, TN.

Several cytochrome P450 genes known to be involved in drug metabolism were screened for genetic polymorphisms in 186 human chromosomes by genomic amplification and direct sequencing of the exons and flanking intronic regions. The targets screened were CYP1A1, CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4 and CYP3A5. Primers were designed and tested to amplify the genomic target without co-amplification of gene family members or pseudogenes. A total of 59 kb of bidirectional sequence data was generated and scored for each chromosome. Of the 93 self-described human DNA samples screened, 36 were Caucasian, 16 African American, 10 Chinese, 10 Japanese, and 10 Southeast Asian. In addition, 11 samples were of anonymous ethnic origin.

The method of direct sequencing identified 416 polymorphic sites in the eleven CYP450 genes screened. There were 398 single base substitutions and 18 insertions or deletions (indels). Of the polymorphic sites, 183 occurred within the wild type exonic portion of the genes, and the remaining 233 were intronic or intergenic. Of the sites within exons, 4 were in the 5UTR, 49 were in the 3UTR, and 120 were in the coding region. Of these, 50 were silent changes in the coding region. Many of these polymorphisms have been previously reported: 22% by the Human Cytochrome P450 Allele Nomenclature Committee and 18% by NCBI dbSNP. 66% of the polymorphisms have not been reported by either of these sources. Of these novel polymorphisms, 98 are within the exons of the genes, 30 are within the coding regions and result in amino acid changes, and the remaining 24 are silent. There are 3 within the 5UTRs and 41 within the 3UTRs. Of the 175 novel changes in the intronic or intergenic portions of the genes, 8 are within 10 bp of an exon-intron boundary and consequently may have an effect upon splicing.

**Oxidant Stress, Polymorphisms in GCLC, and Pulmonary Hypertension in Congenital Heart Surgery.** *K.L. Dyer<sup>1</sup>, A.S. Willis<sup>2</sup>, F.E. Barr<sup>3</sup>, G. Cunningham<sup>4</sup>, J.L. Haines<sup>5</sup>, T.P. Doyle<sup>1</sup>, T.P. Graham<sup>1</sup>, B.W. Christman<sup>4</sup>, M.L. Summar<sup>5,6</sup>.* 1) Pediatric Cardiology, VUMC, Nashville, TN; 2) Molecular Physiology and Biophysics, VUMC, Nashville, TN; 3) Pediatric Critical Care, VUMC, Nashville, TN; 4) Pulmonary Medicine, VUMC, Nashville, TN; 5) Program in Human Genetics, VUMC, Nashville, TN; 6) Pediatric Genetics, VUMC, Nashville, TN.

Pulmonary hypertension is a potentially serious side effect of congenital heart surgery. Ischemia-reperfusion injury, which is associated with cardiopulmonary bypass and mediated by free radical activity, may contribute to the pathogenesis of pulmonary hypertension. Glutamate cysteine ligase catalyzes the first, rate-limiting step in the synthesis of glutathione, an important biomolecule for the scavenging of free radicals. Eleven polymorphisms have been identified in GCLC, the gene that encodes the catalytic subunit of glutamate cysteine ligase. To determine if a relationship between GCLC polymorphisms, markers of oxidative stress, and development of pulmonary hypertension exist, urine isoprostane levels at several timepoints, immediately before and after surgery and at 12, 24, and 48 hours postoperation were measured in 60 children undergoing surgery to repair congenital heart defects. Each patient was also genotyped for 11 polymorphisms in GCLC. One GCLC polymorphism, 1974-1975insCAGC, had a statistically significant association with development of pulmonary hypertension using chi-square analysis ( $p=0.035$ ). Isoprostane levels immediately following surgery were significantly higher in patients who developed pulmonary hypertension. Isoprostane levels were also significantly higher at the same time point in patients homozygous for the inclusion of the 4 bp insertion at the 1974-1975insCAGC locus. These results may indicate that genotype for the GCLC polymorphism 1974-1975insCAGC may be a risk factor or marker for the development of pulmonary hypertension following cardiopulmonary bypass and cardiac surgery.

Program Nr: 1728 from 2003 ASHG Annual Meeting

**Functional Analysis of a Nonsynonymous Polymorphism in Glutamate Cysteine Ligase Catalytic Subunit Gene.**

A.S. Willis<sup>1</sup>, M.L. Freeman<sup>2</sup>, S.R. Konjeti<sup>2</sup>, J.L. Haines<sup>3</sup>, A. Wilson<sup>4</sup>, B. Kennedy<sup>4</sup>, S.M. Williams<sup>3</sup>, M.L. Summar<sup>4</sup>. 1) Molecular Physiology and Biophysics, VUMC, Nashville, TN; 2) Radiation Biology, VUMC, Nashville, TN; 3) Program in Human Genetics, VUMC, Nashville, TN; 4) Pediatric Genetics, VUMC, Nashville, TN.

Glutamate cysteine ligase catalyzes the first, rate-limiting step in the *de novo* synthesis of glutathione, an important tripeptide. One of the most important functions of glutathione is the scavenging of free radicals to prevent oxidative damage, which is thought to play a role in many diseases, such as neurodegeneration and cancer. We have previously identified 11 polymorphisms in GCLC, the gene that encodes the catalytic subunit of glutamate cysteine ligase. One of these polymorphisms, C1384T, is a nonsynonymous polymorphism. The rare allele changes a proline to serine at position 462 and has not been observed in Caucasians. We have undertaken the study of the functional aspects of this polymorphism. Using clones of the coding region of both human GCLC and GCLM, we have expressed both versions of the GCLC polymorphism in bacteria. Western blot demonstrates expression of soluble normal sized GCLC protein. Enzyme activity assays using measurement of production of radioactive inorganic phosphate demonstrates activity above the baseline in bacterial cells. Comparison of the two forms of GCLC demonstrates an increase in activity for the less common allele seen only in African or African-descent individuals. This change in activity may affect the susceptibility of carriers to oxidative damage and will be examined in populations at risk such as sickle cell anemia, Alzheimers, Parkinsons disease, and others.

**A novel mechanism for the control of biotin utilization in human cells is impaired in patients with multiple carboxylase deficiency.** *D. Pacheco-Alvarez<sup>1</sup>, R.S. Solorzano-Vargas<sup>1</sup>, A. Velzquez<sup>1</sup>, R.A. Gravel<sup>2</sup>, A. Leon-Del-Rio<sup>1</sup>.*  
1) Department of Molecular Biology, Universidad Nacional Autonoma de Mexico; 2) Department of Biochemistry University of Calgary, Calgary, Alberta, Canada.

Biotin is a water-soluble vitamin that functions as cofactor of enzymes known as biotin-dependent carboxylases. Biotinylation of carboxylases is catalyzed by holocarboxylase synthetase (HCS). HCS is also involved in the transcriptional regulation of several genes in human cells. To ensure the biotin supply higher organisms have evolved a complex system composed by a Na-dependent vitamin transporter (SMVT), HCS, five carboxylases and biotinidase responsible for biotin recycling. Here we show that the transcription of genes participating in the biotin cycle is regulated by biotin availability. Biotin deficiency result of a low vitamin diet or the disease multiple carboxylase deficiency, down-regulate the expression of HCS, SMVT and PC mRNAs to 10-20 % of the control. Biotinidase mRNA levels are not affected by neither of these conditions. This suggests that biotin deficiency reduces the transport and utilization of dietary biotin while leaving unaffected the ability to recycle endogenous biotin. To explore the metabolic role of this mechanism we developed an animal model for biotin deficiency. Deficient rats showed a 70%-80% reduction in the mRNA levels of HCS, PC, SMVT in liver, kidney and muscle but the brain mRNA levels were not affected. Biotinidase mRNA did not show a significant change in liver, muscle and kidney but increased 20-30% over control values in the brain. We suggest that, during fasting transcriptional downregulation of SMVT, HCS and carboxylases in liver, kidney and muscle allows a continuous supply of biotin to the brain. Endogenous biotin recycling by biotinidase may allow the survival of peripheral tissues and avoiding competition with the brain for low biotin plasma concentrations. The significance of this process may be related to the fact that 25% of the energy used by the brain is supplied via anaplerosis of the citric acid cycle by biotin dependent enzymes piruvate carboxylase (PC) and propionyl-CoA carboxylase (PCC).

**Fatty acid imbalance in cystic fibrosis associated with pulmonary disease severity.** *J. Hoover-Fong<sup>1</sup>, A. Moser<sup>2</sup>, H. Moser<sup>2</sup>, M. Diener-West<sup>3</sup>, K. O'Brien<sup>3</sup>, A. Hamosh<sup>1</sup>, B. Rosenstein<sup>1</sup>, M. Boyle<sup>1</sup>, G. Cutting<sup>1</sup>.* 1) Johns Hopkins Univ, Baltimore, MD; 2) Kennedy-Kreiger Inst, Baltimore, MD; 3) Johns Hopkins School of Public Health, Baltimore, MD.

**Objective:** Studies indicate fatty acids (FA) in plasma, RBCs & tissues of CF patients differ from controls. The relation between FAs & CF disease severity is unclear. We measured many fasting plasma, RBC & nasal epithelial FAs in CF & age-matched controls to determine if: 1) FAs are different, 2) FA imbalance is related to disease severity. We focused on docosahexaenoic (DHA) & arachidonic acid (AA) since AA is an inflammatory precursor & competes with DHA for membrane phospholipid uptake. **Methods:** 36 controls (7-11y; n=9, 12-17y; n=12, 18-45y; n=15) & 63 F508 homozygous CF patients (7-11y; n=14, 12-17y; n=18, 18-45y; n=31) were included. Ht, wt, BMI, fat folds, 3-day diet composition, & fasting plasma, RBC & nasal FAs were recorded for all. In CF subjects, FEV1, DEXA & Shwachman score were obtained. Subjects were compared by disease status, gender & age group. **Data:**

AA:DHA	7-11y Control	7-11y CF	12-17y Control	12-17y CF	18-45 Control	18-45 CF
Plasma (ug/ml)	5.7+/-1.8	8.6+/-1.1**	5.2+/-1.5	5.8+/-1.5	4.1+/-1.5	6.4+/-2.5*
RBC	5.1+/-1.4	ND	4.4+/-1.3	5.1+/-1.1	3.3+/-1.2	5.1+/-1.7*
Nasal Epithelium	5.1+/-1.8	NA	4.1+/-0.9	4.8+/-0.8**	3.0+/-0.9	4.6+/-2.1*

RBC, nasal: % total FA, ug/mg protein. \*p<0.003, \*\*p<0.09. **Conclusion:** All CF FAs (means, by age) are controls. Higher CF AA:DHA is due to lower plasma, RBC and nasal DHA across age & disease severity strata with DHA trending lower as lung disease worsens. Linear regression (LR) shows no relationship between disease severity & FAs. MLR reveals plasma linolenic or RBC DHA are related to disease severity when age, gender, caloric intake & mid-arm circ (Z) are considered. Support: NIH K23, Johns Hopkins GCRC.

**Surfactant protein D (SP-D) gene mutation in pulmonary alveolar proteinosis patients and healthy controls. M.**

*Tredano*<sup>1</sup>, *M. Griese*<sup>2</sup>, *J. de Blic*<sup>1</sup>, *S. Alix*<sup>1</sup>, *J. Elion*<sup>1</sup>, *R. Couderc*<sup>1</sup>, *M. Bahuau*<sup>1</sup>. 1) Biochimie Biologie Moléculaire, Hôpital Trousseau (MT, SA, RC, MB), Pneumologie, Allergologie Pédiatriques, Hôpital des Enfants-Malades (JB), Fédération de Génétique, INSERM U458, Hôpital Robert-Debré (JE), AP-HP, Paris, France; 2) Kinderklinik und Kinderpoliklinik, Dr. von Haunerschen Kinderspital, Ludwig-Maximilians Universität, München, FRG.

Pulmonary surfactant protein D (SP-D) is a collagenous, calcium dependent, lectin (collectin), secreted by alveolar and bronchiolar cells as well as by a variety of internal or external epithelia. SP-D participates to the innate host defense and inflammatory modulation through binding micro-organisms and various organic complexes. SP-D is also present at the surface of hematopoietic cells such as macrophages, lymphocytes and neutrophils. In addition to its immune properties, SP-D participates to the structural organization of phospholipids within pulmonary surfactant. Mice rendered homozygous for an *Sftpd* targeted mutation have an abnormal surfactant clearance and exhibit a phenotype mostly similar to human pulmonary alveolar proteinosis (PAP). Based on this murine paradigm, we investigated the possible implication of *SFTPD* mutations in 19 human, familial or sporadic, juvenile or congenital, PAP. A heterozygous nonsense mutation (c.238C>T, or p.Gln80Ter) was evidenced in a sporadic case from *Blancs-des-hauts*, an endogamic subpopulation of Réunion Island with a high prevalence of PAP. In addition, and a 4-bp deletion of a consensus splice branch site (c.752-22\_-19delGACT, or IVS7-22\_-19delGACT) was identified in a sporadic case with PAP and interstitial lung disease who had also a *de novo SFTPC* mis-sense mutation (double heterozygote). Since both *SFTPD* mutations were identified as rare coding changes in the general population, although c.238C>T was more common in *Blancs-des-hauts*, we propose that these apparently deleterious changes may be innate risk factors for pulmonary disease, together with action of additional modifying genes of detrimental environmental exposures.

**Global Magnetization Transfer Imaging of the Spinal Cord in Adrenomyeloneuropathy.** *S.A. Fatemi<sup>1,2</sup>, S. Smith<sup>2</sup>, K. Zackowski<sup>3</sup>, A. Bastian<sup>3</sup>, P.C. van Zijl<sup>2</sup>, H.W. Moser<sup>1</sup>, G.V. Raymond<sup>1</sup>, X. Golay<sup>3</sup>*. 1) Neurogenetics Research Ctr; 2) F.M. Kirby Research Center; 3) Motion Analysis Lab, Kennedy Krieger Institute, Johns Hopkins University, Baltimore, MD.

Adrenomyeloneuropathy (AMN) was first recognized in 1976 as the non inflammatory adult variant of X-linked Adrenoleukodystrophy (X-ALD), a genetic disorder characterized by accumulation of very long chain fatty acids in the CNS, the adrenal cortex, and testes. The purpose of this study was to apply Global Magnetization Transfer Imaging to patients with AMN in order to visualize white matter abnormalities of the cervical spinal cord. 10 men with AMN, 10 females heterozygous for X-ALD, and 10 age and gender matched controls were evaluated neurologically and with quantitative tests of vibration threshold in the great toe and postural sway. GMT studies were conducted in all subjects on a 1.5 T MRI system using a 3D-Gradient Echo acquisition technique (TR/TR/alpha=50/12/7), with an MT pre-pulse, and 10 radiofrequency offsets. A region of interest (ROI) was selected in the dorsal column of the cervical spine from C1 C3 of the GMT images and compared to the clinical parameters. The GMT images showed signal hyperintensities in the lateral and dorsal columns of all patients demonstrating loss of MT efficiency. The GMT values of the dorsal column showed highly significant differences between the patient groups and healthy controls. Furthermore, the GMT abnormality in the dorsal column correlated with the degree of vibratory sense loss ( $r=0.67$ ,  $p=0.004$ ) and postural sway ( $r=0.53$ ,  $p=0.02$ ) assessed by quantitative sensory-motor function tests. This method enables the in-vivo visualization of white matter pathology in the spinal cord of AMN patients and may serve as sensitive tool to detect early changes in this condition.

**Genome Wide Linkage Analysis and Evidence of Gene-by-Gene Interactions in A Sample of 362 Multiplex Parkinson Disease Families.** *N. Pankratz<sup>1</sup>, W.C. Nichols<sup>2</sup>, S.K. Uniacke<sup>2</sup>, C. Halter<sup>1</sup>, J. Murrell<sup>1</sup>, A. Rudolph<sup>3</sup>, C.W. Shults<sup>4</sup>, P.M. Conneally<sup>1</sup>, T. Foroud<sup>1</sup>, Parkinson Study Group.* 1) Medical & Molec Genetics, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Division of Human Genetics, Cincinnati Childrens Hospital Medical Center, Cincinnati, OH; 3) University of Rochester, Rochester, NY; 4) University of California, La Jolla, CA and the VA San Diego Healthcare System, San Diego, CA.

Parkinson disease (PD) is the second most common neurodegenerative disorder. We studied 754 affected individuals, comprising 425 sibling pairs, to identify PD susceptibility genes. Screening of the parkin gene was performed in a subset of the sample having earlier age of PD onset or a positive LOD score with a marker in the parkin gene. All subjects were evaluated using a rigorous neurological assessment. Two diagnostic models were considered for genome wide, nonparametric linkage analyses. Model I included only those individuals with a more stringent diagnosis of verified PD (216 sibling pairs) and resulted in a maximum LOD score of 3.4 on chromosome 2. Model II included all affected individuals (425 sibling pairs) and yielded a LOD score of 3.1 on the X chromosome. Our large sample was then employed to test for gene-by-gene (epistatic) interactions. A genome screen using the 23 families with PD patients having a mutation in only one allele of the parkin gene detected evidence of linkage to chromosome 10 (LOD=2.3). The 85 families with a very strong family history of PD were employed in a genome screen and, in addition to strong evidence of linkage to chromosome 2 (LOD=4.9), also produced a LOD of 2.4 on chromosome 14. A genome screen performed in the 277 families without a strong family history of PD detected linkage to chromosomes 10 (LOD=2.4) and X (LOD=3.2). These findings demonstrate consistent evidence of linkage to chromosomes 2 and X and also support the hypothesis that gene-by-gene interactions are important in PD susceptibility. This project was supported by R01 NS37167.

**The Association of COL1A1 with Otosclerosis.** *W. Chen*<sup>1</sup>, *M.J. McKenna*<sup>2</sup>, *G. Van Camp*<sup>3</sup>, *R.J.H. Smith*<sup>1</sup>. 1) Dept Otolaryngology, Univ Iowa Hosp, Iowa City, IA; 2) Department of Otology and Laryngology, Harvard Medical School, Boston, MA; 3) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

Otosclerosis, a type of conductive deafness caused by abnormal bone homeostasis of the otic capsule, represents a frequent cause of hearing impairment among white adults. Three disease loci have been identified, however causative genes and underlying mechanisms of the disease remain unknown. We have identified three single nucleotide polymorphisms (SNPs) in the regulatory regions of COL1A1 that are associated with otosclerosis based on the comparative frequency of these SNPs in 137 persons with otosclerosis and 185 controls. We tested our patient and control populations for ethnic stratification, which may lead to spurious association in case-control study, using the sum of the case-control allele frequency Cochran-Mantel-Haenszel statistics for 23 short tandem repeat polymorphism (STRP) and 2 SNP markers. These randomly chosen markers were distributed over the entire genome, but excluded the three reported otosclerosis loci, COL1A1 and COL1A2. No evidence of ethnic stratification was detected ( $p=0.5238$ ). Because the three disease-associated SNPs are found in regulatory elements, we hypothesize that they impact transcription of COL1A1. To test this hypothesis, we have introduced regulatory fragments of COL1A1 with SNP haplotypes corresponding to those found in otosclerosis patients and controls into a luciferase-based reporter (pGL3 basic). We propose to compare expression levels of luciferase from different constructs to determine whether the SNP haplotype associated with otosclerosis impacts expression of COL1A1 and subsequently bone quality. This research was supported by R01DC05218 (RJHS).

**Molecular Epidemiology of Non-Syndromic Recessive Deafness in the Indian Subcontinent: the emerging spectrum.** *M. Ghosh<sup>1</sup>, T. Smith<sup>2</sup>, R. Vijaya<sup>1</sup>, S. Riazuddin<sup>2</sup>, Z.M. Ahmad<sup>2</sup>, S. Naz<sup>2</sup>, M. Kabra<sup>1</sup>, P.S.N. Menon<sup>1</sup>, T.B. Friedman<sup>2</sup>, E.R. Wilcox<sup>2</sup>.* 1) Genetic Unit, Pediatrics, AIIMS, New Delhi, India; 2) Laboratory of Molecular Genetics, NIDCD, NIH, Rockville, Maryland, USA.

To date, more than 39 loci (DFNB1-DFNB39) and 20 genes for non-syndromic recessive hearing impairment have been identified. There are no large studies on the molecular basis of deafness in Indian families. We report here results of segregation analysis on 161 Indian families having 3 or more affected individuals from consanguineous marriages were analyzed for co-segregation with STRPs linked to known recessive deafness loci. These families were enrolled through deaf schools from various districts of the 5 Southern States- Tamilnadu, Kerala, Andhra Pradesh, Karnataka and Maharashtra, where the social custom of uncleniece marriages among Hindus and 1st cousin marriages in Muslim families occur in a significant proportion of the population. In the Southern States of India, co-segregation was commonly observed to USH1B, DFNB3 (MYO15A), DFNB4 (Pendrin) with higher prevalence in the Mysore and Hubli districts of Karnataka, and DFNB7/DFNB11 (TMC1) with 3 of the 4 families from Andhra Pradesh.

**DFNA53: A new locus for autosomal dominant hearing loss maps to 14q11.2-22.1 in a large family from China.** A. Pandya<sup>1</sup>, S.H. Blanton<sup>1</sup>, D. Yan<sup>2</sup>, X. Ke<sup>3</sup>, X.M. Ouyang<sup>2</sup>, L.L. Du<sup>2</sup>, T. Balkany<sup>2</sup>, W.E. Nance<sup>1</sup>, X.Z. Liu<sup>2</sup>. 1) Dept. Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Dept. of Otolaryngology, University of Miami, Miami, FL; 3) Dept. of Otolaryngology, Beijing Medical School, Beijing, China.

Hearing loss (HL) has many known genetic and environmental causes and affects at least 30% of the population at some time in their lives. It is a genetically heterogeneous disorder, with perhaps 1% (i.e. at least 300) of the total genes suspected of causing deafness. Half of all profound deafness is genetic, and 15-20% of non-syndromic HL is transmitted as an autosomal dominant trait. At present 37 loci for dominant HL have been mapped, and 18 genes have been identified. We report on yet another novel dominant locus at 14q11.2-22.1 for HL in a large multi-generation Chinese family ascertained from Northern China. All affected individuals had onset of HL between the ages of 18-22 years, which was moderate to profound in severity and progression in severity was noted. Intra-familial variation occurred in the age of onset and severity of HL. There was no vestibular dysfunction or other associated abnormalities. Linkage analysis was performed with Simwalk2 assuming a penetrance of 0.9 without phenocopies. A multipoint maximum LOD score of 5.35 was obtained at marker D14S1280 after a genome wide scan. The locus maps to an approximately 50cM region, flanked by the markers D14S742 and D14S587. As this region overlaps with the DFNA9 locus, the coding region of COCH gene was sequenced and excluded in affected probands, with no mutations identified. The interval for DFNA53 does not overlap with the region for DFNA23 which maps telomeric to our locus. We are currently fine mapping with additional markers to narrow the critical region and are screening for mutations in plausible candidate genes.

**Monogenic cochlear otosclerosis: clinical and linkage analysis in a large Greek family.** *M.B. Petersen<sup>1</sup>, K. Van Den Bogaert<sup>2</sup>, V. Iliadou<sup>3</sup>, N. Eleftheriades<sup>3</sup>, G. Aperis<sup>1</sup>, K. Vanderstraeten<sup>2</sup>, E. Franssen<sup>2</sup>, M. Grigoriadou<sup>1</sup>, A. Pampanos<sup>1</sup>, J. Economides<sup>4</sup>, T. Iliades<sup>3</sup>, G. Van Camp<sup>2</sup>.* 1) Dept Genetics, Inst Child Health, Athens, Greece; 2) Dept Med Genetics, Univ Antwerp, Belgium; 3) Dept Otorhinolaryngol, Aristotle Univ Thessaloniki, Greece; 4) Dept Audiol-Neurootol, "Aghia Sophia" Children's Hosp, Athens, Greece.

Otosclerosis, which is a common cause of hearing impairment among white adults, can be considered as a multifactorial disease. About 50% of patients have a positive family history, but until now only three autosomal dominant otosclerosis loci have been reported: OTSC1 (15q25-q26), OTSC2 (7q34-q36), and OTSC3 (6p21-p22). We describe a large multigenerational Greek family with autosomal dominant cochlear otosclerosis. After informed consent, 46 family members were examined. The hearing loss in this family appears in childhood at the age of 10 years as a conductive hearing loss, but soon becomes mixed. Because the additional sensorineural component is progressive, this finally leads to a pure sensorineural hearing loss in some family members. Audiometrical analysis of the affected individuals, by Multiple Linear Regression (MLR) analysis and construction of Age-Related Typical Audiograms (ARTA), showed an age-independent conductive component and a progressive frequency-specific sensorineural component. In addition to this detailed clinical analysis, a genetic linkage analysis was performed for the three known otosclerosis loci as well as for the COL1A1 and COL1A2 genes. These latter genes, involved in the pathogenesis of osteogenesis imperfecta, were analyzed to study a previously suggested shared etiology between otosclerosis and osteogenesis imperfecta. Three microsatellite DNA polymorphisms for each OTSC locus or collagen gene were analyzed, and two-point lod scores excluded linkage to each of these known loci. From a clinical point of view, this is the first detailed audiometrical analysis in a monogenic otosclerosis family. From a genetic point of view, exclusion of the three known otosclerosis loci shows that otosclerosis is a genetically heterogeneous disease involving at least four different genes.

**Comparison between various strategies for the disease-gene mapping using linkage disequilibrium analyses: studies on adenine phosphoribosyltransferase deficiency used as an example.** *S. Kuno<sup>1</sup>, A. Taniguchi<sup>2</sup>, A. Saito<sup>3</sup>, S. Tsuchida-Otsuka<sup>2</sup>, N. Kamatani<sup>4</sup>.* 1) Laboratory for Clinical Genome Informatics, Translational Research Informatics Center, Foundation for Biomedical Research and Innovation, Kobe, Japan; 2) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 3) Advanced Research Laboratory, Hitachi Ltd., Tokyo, Japan; 4) Division of Genomic Medicine, Department of Advanced Biomedical Engineering and Science, Tokyo Women's Medical University, Tokyo, Japan.

Recently, linkage disequilibrium analyses have been used to detect disease-causing loci based on common disease common variant hypothesis. SNPs, STRPs and VNTR have been mainly utilized as markers. The three types of markers have different characteristics. SNPs are present at the highest frequency while STRP and VNTR have multiple alleles at a single locus. Furthermore, the mutation rates at SNP loci are likely to be very low while those for STRP loci may be rather high. What kind of markers and what methods should be used for the effective analyses? To answer this question, we have to apply the methods to the practical data obtained from human population. We extensively performed linkage disequilibrium and haplotype analyses on adenine phosphoribosyltransferase (APRT) genes in both control and the deficiency subjects. To examine the power to detect disease-causing loci, we analyzed SNPs, STRPs and VNTR within and around the APRT gene. When only SNPs were used, P values did not necessarily show significant difference at loci close to the mutation site for APRT\*J that is exclusively observed among Japanese. However, the examination of the same samples with haplotypes based on the haplotype block data gave sufficient significance. In the case of STRP and VNTR, some single marker loci showed significant difference. However, the combination of the SNP, STRP and VNTR for the construction of haplotypes gave more evident results. Our study suggested that the use of haplotype analysis based on the haplotype-block structure is more powerful than single marker locus analysis for the detection of disease-related loci.

**Cartographer: A tool to generate marker maps based on the physical, genomic location of markers.** *A. Metzidis, S. Sammalisto, M. Perola, L. Peltonen, J. Saharinen.* Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland.

A properly ordered marker map is essential for successful linkage analyses. Multipoint linkage analyses are particularly sensitive to the marker order. Typically markers are ordered by using genetic maps or by building maps by hand using online genome databases. Existing genetic marker maps have been shown to be inconsistent with the actual genome sequence, and manual construction of maps is time consuming and error prone. To solve this problem we have developed Cartographer, a web-service that automatically builds a physically-ordered marker map, generated from a list of marker names, using the localization of full-marker and marker-primer sequence data. Cartographer is a web interface to a database derived from data obtained from the UCSC Genome Annotations Database. The UCSC database has annotations for nearly 200,000 STS markers. Location information exists for nearly half of these. Cartographer accepts a simple marker-name list as input, and returns the markers physically ordered with supplemental information including Decode and Marshfield Map positions, chromosomal location and DBSTS ID, among others. In addition, missing genetic map positions are interpolated based on those of neighboring markers, taking into account the physical distance between them. Cartographer works by first mapping marker aliases to their canonical names. Recorded BLAT localizations of marker sequence data are then used to discover the physical location for each marker. Once ordered, marker annotations are retrieved from the database, coupled with the location information, and presented to the user via a web page. The results may then be downloaded as ASCII text files. Cartographer has been developed for GNU/Linux operating systems using PHP, PostgreSQL and GNU tools. Preliminary tests of Cartographer show a high success rate typically over 99% of markers get accurately located and properly ordered. Accurate maps are built in seconds. Currently we are expanding the database to increase the tool's accuracy. SNP markers will be included in the near future. See [www.bioinfo.helsinki.fi/cartographer](http://www.bioinfo.helsinki.fi/cartographer).

**Database Schema for Management and Storage of Single Nucleotide Polymorphisms.** *T. Niu*<sup>1,2,3</sup>, *K. Baclawski*<sup>2</sup>, *Y. Feng*<sup>3</sup>, *H. Wang*<sup>3</sup>. 1) Div. of Prev. Med., Dept. of Med., Brigham & Women's Hosp., Harvard Med. Schl., Boston, MA; 2) Coll. Computer Sci., Cullinane Hall, Northeastern Univ., Boston, MA; 3) Program for Population Genetics, Harvard Schl. of Public Hlth., Boston, MA.

Single nucleotide polymorphisms (SNPs) are the most frequent DNA sequence variations in the human genome. SNPs have a wide range of biomedical applications. The sequencing of the human genome has resulted in huge volumes of bioinformatics data, in general, and SNP data in particular. In spite of the importance of SNPs, there has been limited progress in developing effective techniques for managing the enormous amount of SNP data now being generated. Many labs have devised their own solutions for storing and distributing SNP data, but there is a lack of generic software solutions. In this paper, we describe the design of a database system for SNP information, called the SNP database (SNPDB). The purpose of the SNPDB is to support the acquisition, storage and retrieval of large amounts of SNP information. Because of the complexity of SNP data, an ontology for SNP information was developed in the Web Ontology Language (OWL). Ontologies have significant advantages for modeling complex data, for the interchange of this data between different systems and for integrating complex data from different sources. However, because modern database management systems are based on the relational model, the SNP ontology was mapped to the relational model. SNP data is used for many purposes and is often integrated with other biological data. The paper concludes with some examples of SNP queries to illustrate how the SNPDB is used for these purposes.

**An integrated tool to generate and present LD maps.** *L. Warren<sup>1</sup>, A. Wooster<sup>2</sup>, D. Zaykin<sup>1</sup>, P. St. Jean<sup>1</sup>.* 1) Population Genetics, GlaxoSmithKline, RTP, NC; 2) Bioinformatics, GlaxoSmithKline, RTP, NC.

Case control based pharmacogenetics studies and disease gene association mapping rely on the linkage disequilibrium between some SNP markers and the drug response or disease causing genes. With more than 1.8 million publicly available SNPs currently, there is a need to have an efficient tool to generate and present LD patterns for large numbers of SNPs. There are two challenges: first, to develop an efficient algorithm to calculate LD for hundreds of thousands of SNPs; and second, to construct a user-interface that allows analysts to investigate millions of LD pairs.

The linkage disequilibrium coefficient for alleles A and B is defined as  $D_{AB} = P_{AB} P_A P_B$ , where  $P_{AB}$  is the gametic frequency and  $P_A P_B$  is the product of the allele frequencies. Because its absolute value depends on the allele frequencies,  $D_{AB}$  is not suitable for comparing levels of LD across marker pairs. Alternatively, two standardized parameters,  $r^2$  and  $D'$  are often used to measure the strength of LD.  $r^2$  is the standard Pearson's correlation coefficient and its calculation is straightforward.  $D'$  can be obtained by the EM algorithm, which is also the rate limiting step when calculating  $D'$  for millions of SNP pairs. In addition,  $D'$  from EM relies on the assumption that each individual SNP is in HWE, which may or may not be valid in reality. Here, we propose a method that can calculate the composite  $D'$  on the fly for a large number of SNPs. An additional advantage of using composite  $D'$  is that it does not rely on the HWE assumption. To assess LD significance, P-values are also calculated for the estimated parameters.

To present the LD patterns for a large number of SNPs in a dynamic and user-interactive fashion, we have integrated the Spotfire™ data visualization tool. Several ways to present LD and average LD across regions will be illustrated. These plots can also be directly imported into other applications such as Powerpoint, Word, etc.

**Familial Venous-occlusive Disease of the Liver with Immunodeficiency: Localization to a 1Mb Region of 2q36.3-37.1 via Homozygosity Mapping.** *T. Roscioli<sup>1</sup>, M.F. Buckley<sup>1</sup>, P.J. Taylor<sup>1</sup>, E. Kirk<sup>2</sup>, J. Ziegler<sup>3</sup>, M. Wong<sup>4</sup>, J.A. Donald<sup>5</sup>, R. Lindeman<sup>1</sup>.* 1) Centre for Thrombosis and Vascular Biology, University of NSW, Sydney, Australia; 2) Department of Medical Genetics, Sydney Children's Hospital Randwick, NSW, Australia; 3) Department of Immunology and Infectious Disease, Sydney Children's Hospital Randwick, NSW, Australia; 4) Department of Immunology and Infectious Disease, The Children's Hospital Westmead, NSW, Australia; 5) Department of Biological Sciences, Macquarie University, NSW, Australia.

We present three families of Middle Eastern origin with an autosomal recessive form of venous-occlusive disease of the liver with immunodeficiency (VODI) requiring treatment with intravenous immunoglobulin. Multiple consanguinity in two families, and a shared geographic origin and ethnic origin of all suggests the presence of a founder mutation. This cohort of consanguineous families with a common ethnic origin has allowed the identification of a single 1 megabase candidate interval on human chromosome 2q36.3-37.1 by homozygosity mapping. Sequencing of the eight candidate genes in the critical region is in progress. Venous-occlusive disease of the liver (VODL) consists of fibrous concentric narrowing/obliteration of zone 3 terminal hepatic venules with subsequent damage to centrilobular hepatocytes. This histological appearance was first described in VODL secondary to ingestion of beverages containing pyrrolizidine alkaloids. VODL is now most often seen within twenty days of a post bone marrow transplant and it is an important cause of morbidity and mortality after this therapy. The histological features of VODI are indistinguishable from those of VODL after BMT. This suggests that VODI may provide important information regarding the pathology of the VODL and that defining the genetic aetiology of VODI could lead to the identification of individuals most at risk of hepatic venous-occlusive disease in the context of bone marrow transplantation.

**Fetal akinesia with anterior horn cell loss and congenital malformation in male siblings: Severe X-linked spinal muscular atrophy (XL-SMA) or a new disease entity?** *J. Gerritsen*<sup>1</sup>, *E. Estrella*<sup>2</sup>, *M.E. Ahearn*<sup>2</sup>, *K.O. Yariž*<sup>2</sup>, *L. Baumbach*<sup>2</sup>. 1) Univ. of Calgary, Calgary, Alberta, Canada; 2) Univ. Miami Sch. Med., Miami, FL.

We report clinical and molecular investigations of two brothers (born to unrelated parents) with prenatal-onset anterior horn cell loss. **Clinical Summary:** Prenatal diagnosis of arthrogyriposis was suspected. Both boys shared physical features associated with fetal akinesia: multiple contractures, distinctive craniofacial appearance, gracile ribs on X-ray, and undescended testes/inguinal hernia. Brother 1 had a duplicated left thumb and horseshoe kidney. Both boys displayed unresolving hypotonia at birth. Gag reflexes were also absent, and the ability to protect the upper airway was affected. Respiratory insufficiency resulted in ventilator dependence. Brother 1 also had significant apneas and bradycardias. He died at 2 weeks of age. Brother 2 is currently still living at 5 months old, but awaiting home ventilation. EMG/NCV studies in both were consistent with anterior horn cell loss. Results of muscle biopsy from both boys showed perimyseal fibrosis, atrophied fibers, and nonspecific variation in fiber diameter. Autopsy of brother 1 noted profound loss of anterior horn cells, degeneration of the CN12 nucleus, and a mildly atrophic brain with poor white-gray matter differentiation. **Laboratory Studies:** Both boys had normal karyotypes. Brother 1 had normal CK values, normal myotonic dystrophy DNA testing, and a metabolic evaluation that was normal. Loss of anterior horn cells prompted study of SMA syndromes. Neither boy had deletion of *SMN* exons 7 and 8. Linkage to the XL-SMA region in Xp11.3-Xq11.2 was then performed. Six dinucleotide repeat markers, previously shown to link to this region, were evaluated using the ABI 3100 and GeneMapper software. Haplotype analysis revealed discordant inheritance of these markers in the brothers. Additional DNA markers in the region are being studied to rule out a small recombination event which might link this family to the XL-SMA critical region, as well as other X chromosome markers, to determine if this family represents a new X-linked disease phenotype.

**Genetic linkage of kyphoscoliosis.** *C.M. Justice<sup>1</sup>, B. Marosy<sup>2</sup>, S. Novak<sup>2</sup>, P. Boyce<sup>3</sup>, J. Pettengill<sup>3</sup>, K.F. Doheny<sup>3</sup>, E.W. Pugh<sup>3</sup>, A.F. Wilson<sup>1</sup>, N.H. Miller<sup>2</sup>.* 1) Genometrics Section, NHGRI/NIH, Baltimore, MD; 2) Department of Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD; 3) CIDR, IGM, Johns Hopkins University SOM, Baltimore, MD.

Thoracic kyphoscoliosis is an unusual deformity in which a lateral curvature of the spine is seen in conjunction with thoracic hyperkyphosis in otherwise normal individuals. As part of a large collaborative study of familial idiopathic scoliosis, 202 families (1198 individuals) with at least two affected individuals with a lateral curvature 10 degrees were ascertained and clinically characterized. Ten of these families (68 individuals) had at least one individual with kyphoscoliosis (lateral curvature 10 and thoracic kyphosis 40 ) documented prior to skeletal maturity. Within this group, the average degree of lateral curvature was 48 for individuals with kyphoscoliosis, and 31 for individuals without kyphoscoliosis. The average degree of kyphosis was 53. A genome-wide screen was performed at the Center for Inherited Disease Research using a modified CHLC v.9 marker set consisting of 391 short tandem repeat markers. Sib-pair analysis of the genomic screen of the initial group suggested linkage to regions on chromosomes 2, 5, 13, and 17. In an effort to further restrict the phenotype, the subset was limited to families in which two or more individuals had kyphoscoliosis (7 families; 53 individuals). This resulted in an increase in significance of the p-values for all the regions suggestive of linkage. An additional 25 markers were genotyped in the regions of interest, which helped narrow the candidate regions. The most significant p-values were obtained for regions on chromosomes 5 and 13. In an attempt to narrow further the candidate region and evaluate associations with kyphoscoliosis, 145 SNPs were genotyped in an ~10 Mb region on chromosome 5p13.

**Mapping of a new locus for autosomal recessive nonsyndromic mental retardation in the chromosomal region 19p13.12-p13.2: further genetic heterogeneity.** *L. Basel-Vanagaite*<sup>1, 2</sup>, *A. Alkelai*<sup>3</sup>, *R. Straussberg*<sup>2,4</sup>, *N. Magal*<sup>3,4</sup>, *D. Inbar*<sup>5</sup>, *M. Mahagna*<sup>5</sup>, *M. Shohat*<sup>1,4</sup>. 1) Dept Medical Genetics, Rabin Medical Ctr, Petah Tikva, Israel; 2) Neurogenetics Clinic, Schneider Childrens Medical Center of Israel, Petah Tikva, Israel; 3) Felsenstein Medical Research Center, Petah Tikva, Israel; 4) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 5) Neuropediatrics Unit, Schneider Childrens Medical Center of Israel, Petah Tikva, Israel.

We have identified and evaluated clinically four consanguineous families of Israeli Arab origin with autosomal recessive nonsyndromic mental retardation (NSMR) that included a total of 10 affected and 22 unaffected individuals. All the families originate from the same small village and bear the same family name. Association of the condition in these families with the two known autosomal recessive NSMR loci on chromosomes 3p25-pter and 4q24 (neurotrypsin gene) was excluded. Linkage of the disease gene to chromosome 19p13.12-p13.2 ( $Z_{\max} = 7.06$  at  $\theta = 0.00$  for the marker D19S840) was established. All the affected individuals were found to be homozygous for a common haplotype for the markers cen-RFX1-D19S840-D19S558-D19S221-tel, suggesting that the disease is caused by a single mutation derived from a single ancestral founder in all the families. Recombination events and a common disease-bearing haplotype defined a critical region of 2.6 Mb between the loci D19S226 proximally and D19S1165 distally. Based on the data reported here and in other studies, we conclude that there are at least three genetic loci that can cause autosomal recessive NSMR. Additional autosomal loci are expected to be involved in the etiology of NSMR. Because of the increasing number of possible autosomal recessive NSMR loci, we suggest that formal classification of these genes should be introduced. We suggest the nomenclature ARNSMR1 for the NSMR associated with the locus on chromosome 3p25-pter, ARNSMR2 for that associated with the neurotrypsin gene, and ARNSMR3 for that associated with the locus on chromosome 19p13.12-p13.2.

**Analysis of mapped SCA loci in an Italian family with autosomal dominant Spinocerebellar ataxia.** *C. Cagnoli*<sup>1</sup>, *C. Geller*<sup>2</sup>, *C. Mariotti*<sup>2</sup>, *A. Castucci*<sup>2</sup>, *C. Michielotto*<sup>1</sup>, *S. Di Donato*<sup>2</sup>, *F. Taroni*<sup>2</sup>, *N. Migone*<sup>1</sup>, *A. Brusco*<sup>1</sup>. 1) Dept. Genetics Biol. & Bioch., University of Torino, & Az. Osp. San G. Battista, Torino, Italy; 2) Dept. Biochemistry & Genetics, Istituto Nazionale Neurologico C. Besta, Milano, Italy.

The spinocerebellar ataxias (SCAs) are a group of neurodegenerative disorders, characterized by progressive cerebellar ataxia variably associated with other neurological features. SCAs are genetically heterogeneous comprising 19 distinct subtypes (SCA1-8 and SCA10-14, 16, 17, 19, 21, 22, and SCA-FGF14). Eleven of them have been assigned to specific genes (*SCA1-3, 6-8, 10, 12, 14, 17, and FGF14* genes). We have studied a three-generation Italian family with 6 SCA members and 5 non-affected relatives. Clinical evaluation of the patients showed slowly progressive cerebellar ataxia of gait and limbs with onset between 20 and 25 yr, ocular movement abnormalities, such as nystagmus and ophtalmoplegia, and hyperreflexia. Brain MRI demonstrated cerebellar atrophy. Genetic testing excluded expansions in the known SCA1-3, 6-8, 10, 12, and 17 genes. Anticipation was not a prominent feature, but large CAG/CTG expansions (40 rep.) in unknown genes were ruled out by Rapid Expansion Detection (RED) analysis. In addition, we performed linkage analysis to 8 of the known loci SCA4, SCA5, SCA11, SCA13, SCA14, SCA16, SCA19, SCA21, and FGF14, using microsatellite markers spanning the candidate regions. Haplotype analysis and two-point LOD score -2.0 ruled out a linkage with SCA4, SCA5, SCA14, SCA16, SCA21, and FGF14. The SCA11, SCA13, and SCA19 loci could not be completely excluded, due to the presence of non-informative markers. However, including the 5 available healthy members (age 42-50), and 90% penetrance, linkage could be excluded also for SCA11 and SCA13 loci. The SCA19 locus is still under investigation to cover its 35 cM extension. Additional affected relatives will be collected to complete this study, which may lead to a new putative SCA locus.

**Genetic Linkage of Fibromyalgia to the Serotonin Receptor 2A Region on Chromosome 13 and the HLA Region on Chromosome 6.** *D.M. Dudek<sup>1</sup>, L.M. Arnold<sup>2</sup>, S.K. Iyengar<sup>1</sup>, M.A. Khan<sup>1</sup>, I.J. Russell<sup>3</sup>, M.B. Yunus<sup>4</sup>, J.M. Olson<sup>1</sup>.* 1) Dept. of Epidemiology and Biostatistics and Dept. of Medicine, Case Western Reserve University, Cleveland, OH; 2) Dept. of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, OH; 3) Dept. of Medicine, University of Texas Health Sciences Center, San Antonio, TX; 4) Dept. of Medicine, University of Illinois College of Medicine, Peoria, IL.

The serotonin neurotransmitter and autoimmune systems have been suggested as important to the etiology of fibromyalgia (FM). To assess the genetic basis of FM, we examined markers spanning genomic regions for the serotonin receptor 2A (HTR2A), the serotonin transporter (HTTLPR), and the HLA. 80 multicase families confirmed by ACR criteria were collected as part of the Fibromyalgia Family Study. Severity and quality of pain were measured using a visual analog scale, the McGill short form, and an anatomical sketch (AS). Other measures included the SF-36, the Multidimensional Assessment of Fatigue, the Beck Anxiety (BAI) and Depression (BDI) Inventories, and the Jenkins sleep scale. Participants were also evaluated using standard criteria for the presence of chronic fatigue syndrome (CFS), irritable bowel syndrome (IBS), and restless legs syndrome. Linkage analyses were conducted using LODPAL (S.A.G.E. 2002). Exploratory data analyses determined that a subset of largely-unrelated traits (age-of-onset, AS, BDI, and IBS) exhibited the best evidence of familial aggregation among FM patients and were included as covariates in the affected-relative-pair linkage analysis. No evidence for linkage was found in the HTTLPR region. In the HLA region, results suggest that families of later age-of-onset are linked (lod=3.02, p=.00057). In the HTR2A region, results suggest that linked families are of earlier age-of-onset (lod=1.96, p=.0068), report less pain (lod=3.33, p=.0028) and lower BDI (lod=1.86, p=.0086), and lack IBS (lod=2.46, p=.0021); the best, most parsimonious linkage model includes age-of-onset and AS (lod=5.56, p=.000057). These results support the hypothesis that HTR2A predisposes to an earlier-onset form of FM with milder reported symptoms.

**X chromosome scanning in a family with Lujan-Fryns syndrome recurrence suggests two possible loci in Xp22.3 and Xq28.** A. Ferlini<sup>1</sup>, A. Ravani<sup>1</sup>, A. Venturoli<sup>1</sup>, M. Neri<sup>1</sup>, P. Rimessi<sup>1</sup>, F. Gualandi<sup>1</sup>, D. DeGrandis<sup>2</sup>, E. Calzolari<sup>1</sup>. 1) Section of Medical Genetics, University of Ferrara, Ferrara, (Italy); 2) Dipartimento di Neuroscienze, Ospedale Civile, Rovigo (Italy).

Lujan-Fryns syndrome represents a mendelian condition characterized by aspecific mental retardation, marfanoid habitus, hypotonia, craniofacial anomalies and others inconsistent features. The disease recognizes a transmission compatible with an X-linked inheritance (OMIM\*309520). Although candidate chromosomal regions/genes have been proposed as being associated with this disease (FRAXE and chromosome 5p deletions) the genetic aetiology of the syndrome is still unknown. We performed a wide genome scanning analysis of the X chromosome in a large pedigree with Lujan-Fryns syndrome recurrence compatible with an X-linked mode of inheritance (two affected males, uncle and nephew). Haplotype sharing in nine family members, based on VNTRs segregation analysis (four panels, Applied Biosystem), allowed us to exclude almost all the X chromosome apart from the Xp22.3 and Xq28 regions. The data we provide reduced the X chromosome interval containing the Lujan-Fryns gene. In keeping with observations already reported, the Xq28 possible mapping might confirm the involvement of the FRAXE site. This approach will enable us to refine the actual mapping in order to search for candidate genes.

**Analysis of the interleukin-1 gene complex in LOAD Brazilian patients.** *A.L. Nishimura<sup>1</sup>, F.B. Mury<sup>1</sup>, M. Mitne-Neto<sup>1</sup>, J.R.M. Oliveira<sup>2</sup>, R. Nitrini<sup>3</sup>, V.S. Bahia<sup>3</sup>, P.R. Brito-Marques<sup>4</sup>, M. Neri<sup>4</sup>, S.M.M. Fertuzinhos<sup>1</sup>, M. Zatz<sup>1</sup>.* 1) 1- Human Genome Research Center, Institute of Biosciences, University of S.Paulo, Brazil; 2) 2- Neurology Department of the David Geffen Medical School, UCLA, USA; 3) 3- Department of Neurology, Faculty of Medicine, University of S.Paulo, Brazil; 4) 4- Center of cognitive neurology and of behavior, University of Pernambuco, Brazil.

Several studies have attempted to find a relationship between inflammatory pathways and psychiatric disorders. Recently, three polymorphisms of the interleukin-1 (IL-1) gene complex, including the IL-1 alpha, IL-1 beta and IL-1 receptor antagonist (IL-1RA) have been associated to different psychiatric disorders. The IL-1RA has a variable number of tandem repeats in intron 2, the IL-1 alpha gene has a base exchange at the position -889 and IL-1 beta gene has a base exchange at the position -511. These polymorphisms have been associated to late onset Alzheimer disease (LOAD) pathogenesis inducing the translation and processing of the beta-amyloid precursor protein with possible implications on the progression of the plaque and tangle formation. Moreover, the cytokines can modify the metabolism of neurotransmitters or influence neural development. Here we analyzed 120 LOAD patients (mean age 68.78) diagnosed according to NINCDS-ADRDA criteria. Neurological and neuropsychological testing including Mini-Mental State Exam (MMSE) and Clinical Dementia Rating (CDR) were performed in order to classify their cognitive impairment. The 120 healthy controls (mean age 72.39.75) were selected based on the MMSE and/or Blessed Scale and were matched with the patients group for age, sex, socio-cultural level and ethnic background. All patients and controls were originated from two Brazilian States, São Paulo and Pernambuco. The preliminary statistical analysis did not show any statistically significant association between the polymorphisms of the interleukin-1 gene complex and LOAD Brazilian patients ( $P=0.183$ ,  $OR=1.303$ , 95% C.I.=0.896-1.895 for IL-1 alpha;  $P=0.210$ ,  $OR=0.759$ , 95% C.I.=0.502-1.148 for IL-1 beta and  $P=0.3$  for IL-1RA). Supported by FAPESP-CEPID, CNPq, PRONEX.

**Clinical and genetic study of an Italian family with a new form of autosomal dominant complicated Spastic Paraplegia.** A. Magariello<sup>1</sup>, L. Passamonti<sup>2</sup>, R. Mazzei<sup>1</sup>, A. Patitucci<sup>1</sup>, FL. Conforti<sup>1</sup>, M. Bellesi<sup>2</sup>, AL. Gabriele<sup>1</sup>, T. Sprovieri<sup>1</sup>, G. Peluso<sup>1</sup>, M. Caracciolo<sup>1</sup>, E. Medici<sup>2</sup>, F. Logullo<sup>2</sup>, G. Di Palma<sup>1</sup>, L. Provinciali<sup>2</sup>, M. Muglia<sup>1</sup>. 1) ISN, National Research Council, Mangone, Cosenza, Italy; 2) Department of Neurological Sciences, A.O. Umberto I, Ancona, Italy.

Hereditary spastic paraplegia (HSP) is a heterogeneous group of disorders of the motor system, characterized clinically by slowly progressive lower extremity spasticity and weakness. Clinically, HSP is classified as pure form if neurological impairment is limited to progressive lower extremity and complicated if additional symptoms such as seizures, dementia, amyotrophy, extrapyramidal disturbance or peripheral neuropathy also occur. HSP is inherited with autosomal dominant, autosomal recessive or X-linked traits. To date, 10 loci associated with autosomal dominant HSP (ADHSP) have been demonstrated, two of them (SPG9 and SPG17) have been associated with complicated HSP form. The first type was associated with cataracts, gastroesophageal reflux and motor neuropathy and linked to chromosome 10q23, whereas the second form was accompanied by amyotrophy of hand and feet muscles (Silver syndrome) and linked to chromosome 11q12. We studied an Italian pedigree with ADHSP to determine if this variant of HSP was linked to any of the known autosomal dominant loci. The HSP phenotype in this family was complicated by axonal motor neuropathy without gastroesophageal reflux and cataracts, and by distal muscle weakness and wasting in the lower limbs. Genetic linkage analysis of this family was carried out with DNA markers from current-known ADHSP loci. Negative lod scores were obtained with all microsatellite markers tested. Our family was not linked to any of the known loci associated with autosomal dominant HSP. These data demonstrate further locus heterogeneity for ADHSP and suggest that the current phenotype is caused by another, as yet unmapped, gene.

Program Nr: 1751 from 2003 ASHG Annual Meeting

**No genetic association found between five SNPs on COMT gene and schizophrenia in Korean population.** *E.J. Joo*<sup>1</sup>, *S.H. Jeong*<sup>2</sup>, *Y.M. Ahn*<sup>3</sup>, *Y.S. Kim*<sup>3</sup>. 1) Psychiatry, Eulji Medical School, Seoul, South Korea, MD; 2) Chook-Ryung Evangelical Hospital, Namyangju, South Korea, MD; 3) Psychiatry, Seoul National University, Seoul, South Korea, MD.

**Objective:** This study aimed to explore genetic relation between schizophrenia and COMT(Catechol-O-methyl transferase) gene which plays an important role in metabolizing dopamine, one of the most intriguing neuro-transmitters for schizophrenia. **Methods:** Genotyping was done for five SNPs on COMT gene for 254 patients with schizophrenia and 252 normal controls by SNaPShot method. Patients with schizophrenia were collected when they agreed to participate in this study and wrote the informed consent. DSM-IV diagnosis of schizophrenia was made based on clinical information and/or DIGS(Diagnostic Interview for Genetic Studies). Normal controls were collected among voluntary participants in this study. Subjects who have any kinds neurologic disorder or medical illness possibly having psychiatric features or head trauma were excluded from this study. Allele frequencies, genotype frequencies and simulated haplotype frequencies were compared between patients with schizophrenia and normal controls. **Results:** No significant difference between patients with schizophrenia and normal controls in terms of allele frequencies, genotype frequencies and haplotype frequencies was found in our sample. **Conclusion:** No genetic association between five SNPs on COMT gene and DSM-IV diagnosis of schizophrenia among Koreans was found in this study.

**A newly described neurologic disease Autosomal Dominant Acute Necrotizing Encephalopathy (ADANE) maps to 2q12.1-2q13.** *D.E. Neilson<sup>1,2</sup>, H.S. Feiler<sup>3</sup>, K.C. Wilhelmsen<sup>3,4</sup>, D.S. Kerr<sup>1</sup>, M.L. Warman<sup>1,2</sup>.* 1) Depts. of Pediatrics; 2) and Genetics, Case Western Reserve University School of Medicine, University Hospitals of Cleveland, Cleveland, Ohio; 3) Ernest Gallo Clinic and Research Center; 4) Dept. of Neurology, University of California San Francisco School of Medicine.

We identified a family segregating the novel, incompletely penetrant, neurologic disease ADANE. (Neilson et al. *Neurology*. 2003 Jul;61(2):226-230). ADANE is clinically similar to the sporadically occurring disorder Acute Necrotizing Encephalopathy (ANE). In both disorders, apparently healthy children become comatose following a febrile illness and have necrotizing lesions detectable by MRI, or at autopsy, in their thalami and brainstems. Outcomes of ADANE and ANE include full recovery, permanent brain damage, or death. Infectious triggers, e.g. influenza A, are associated with ANE and have been seen in some family members with ADANE. A muscle biopsy of one child with ADANE demonstrated loose coupling of oxidative phosphorylation. Leigh syndrome (subacute necrotizing encephalopathy) is clinically distinct from ADANE. We now report the map location for ADANE. We used DNA from affected individuals and obligate carriers (based on position within the pedigree) to perform a whole genome scan at 5 cM resolution. Linkage was detected to two markers D2S2264 and D2S293. Saturating this region with markers at 1 Mb intervals yielded a lod score of 3.6 and refined the candidate interval between D2S135 and D2S1896. Of 33 RefSeq genes contained within this interval, none previously have been associated with heritable neurodegenerative disease. We evaluated two genes (BCL2L11 and ST6GalII) having possible roles in apoptosis and viral recognition by sequencing their exons and flanking introns. No disease causing mutations were identified; however, we found an intronic polymorphism within BCL2L11 that is recombinant in one individual enabling us to further narrow the candidate interval. The ADANE locus is in a 6 Mb interval between D2S135 and BCL2L11. The identification of the responsible gene should facilitate our understanding of ADANE's pathogenesis and may provide insight about the more common disorder ANE.

**The analysis of polymorphisms of synuclein family genes in multiple system atrophy (MSA).** *H. Ohtake*<sup>1</sup>, *O. Onodera*<sup>1,2</sup>, *A. Kakita*<sup>2,3</sup>, *A. Hasegawa*<sup>1</sup>, *S. Igarashi*<sup>1,2</sup>, *T. Ozawa*<sup>1</sup>, *K. Okuizumi*<sup>1</sup>, *H. Takahashi*<sup>3</sup>, *S. Tsuji*<sup>4</sup>, *M. Nishizawa*<sup>1</sup>. 1) Neurology; 2) Molecul Neurosci; 3) Pathology, Brain Res Inst, Niigata Univ, Niigata; 4) Neurology, Univ Tokyo, Tokyo, Japan.

MSA is an adult onset neurodegenerative disease, featuring parkinsonism, ataxia, and autonomic failure, in any combination. The condition is progressive and responds poorly to treatment. Argyrophilic inclusion bodies in oligodendroglia, glial cytoplasmic inclusions (GCI), have been established as the pathognomonic pathological findings in MSA. GCI are immunoreactive for ubiquitin and -synuclein (SNCA). The presence of SNCA in GCI suggests a link with Parkinson's disease (PD), and dementia with Lewy bodies (DLB), in which SNCA is also the major component of Lewy bodies. This has led to the term synucleinopathy to embrace this group of conditions. In the rare autosomal dominant PD families, two missense mutations of SNCA have been reported. Others and we have reported the missense mutations of -synuclein (SNCB) and -synuclein (SNCG) in a few sporadic DLB patients. Very recently a missense mutation in synphilin-1 (SNCAIP) gene has been reported in two sporadic PD patients. In addition, the association between SNCA haplotype and development of sporadic PD has been reported. With this background, we hypothesized that MSA, another type of sporadic synucleinopathy with GCI, might also associate with genetic variation of synuclein family genes. We have collected 48 Japanese patients with MSA, including 11 pathologically proven cases, which met Gilman's criteria of MSA. We analyzed the entire coding region of SNCA and 27 single nucleotide polymorphisms (SNPs) surrounding the synuclein family genes, SNCA, SNCB, SNCG and SNCAIP in these cases. We performed nucleotide sequence analysis of SNCA gene using total RNA or genomic DNA. Genotyping was performed by the Taqman Allelic Discrimination Method. We did not identify any mutations in the entire coding region of SNCA in 11 pathologically confirmed MSA cases. We did not find any significant evidence for linkage disequilibrium associated with the SNPs in the synuclein family genes compared with 48 healthy Japanese controls.

**Genome-wide microsatellite association studies for Parkinson's disease by using the pooled DNA method. Y.**

*Hirota<sup>1</sup>, Y. Momose<sup>2</sup>, W. Satake<sup>1</sup>, M. Murata<sup>3</sup>, G. Tamiya<sup>4</sup>, T. Ikuta<sup>4</sup>, S. Makino<sup>4</sup>, I. Mizuta<sup>1</sup>, M. Yamamoto<sup>5</sup>, N. Hattori<sup>6</sup>, H. Inoko<sup>4</sup>, T. Toda<sup>1</sup>.* 1) Div Functional Genomics, Dept Post-Genomics and Diseases, Osaka Univ Grad Sch Med, Osaka, Japan; 2) Dept Clinical Bioinformatics, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 3) Dept Neurology, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 4) Dept Molecular Life Science 2, Sch Med, Tokai Univ, Kanagawa, Japan; 5) Dept Neurology, Kagawa Pref Central Hosp, Kagawa, Japan; 6) Dept Neurology, Sch Med, Juntendo Univ, Tokyo, Japan.

Parkinson's disease (PD) is a complex disorder, with multiple genetic and environmental factors influencing disease risk. Although several causal genes for Mendelian inherited PD (alpha-synuclein, parkin, UCH-L1, DJ-1, NR4A2) have recently been identified, certain genetic factors associated with pathogenesis of idiopathic PD have not yet been clarified. To identify susceptibility genes for PD, we started microsatellite marker-based genome-wide association studies by using the pooled DNA method. For initial screening, we made a pooled DNA each from 124 patients with PD and 124 normal controls and started association studies with 30,000 polymorphic microsatellite markers that are arranged at intervals of approximately 100kb. We analyzed PCR products with the GeneScan<sup>TM</sup> software and compared the pattern of PCR products of pooled DNAs from patients with PD and controls by the software PickPeak. We have finished to check approximately 20,000 markers on all chromosomes and found associations ( $p < 0.05$ ) in about 6~10% of markers tested on each chromosome. Among them, we found a significant association ( $p = 3.9 \times 10^{-6}$ ) with a marker 479C11 on chromosome 1q where another study showed a linkage. Genes in linkage disequilibrium with these markers may be associated with pathogenesis of PD. We will test these markers with pooled DNA from other patients for second and third screenings.

**Significant association between single-nucleotide polymorphisms in the neuron-specific RNA-binding protein ELAVL4 and Parkinson disease.** *M.A. Nouredine, Y-J. Li, L. Zhang, X.J. Qin, R.W. Walters, M.W. Booze, K. Fujiwara, W.K. Scott, M.A. Pericak-Vance, M.A. Hauser, E.R. Martin, J.M. Vance.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Parkinson Disease (PD) is a progressive neurological disorder characterized by the loss of dopaminergic neurons in the substantia nigra. The cardinal symptoms of PD are resting tremor, bradykinesia, and loss of postural flexibility. While a small proportion of familial PD cases can be attributed to mutations in certain genes that control macromolecular transport, protein degradation, or components of the cellular machinery, most PD cases are sporadic. There is mounting evidence that neuroinflammation plays a role in the cascade of events leading to nerve cell death. Compared to age-matched controls, PD brains show elevated density of glial cells expressing inflammation-associated factors such as cyclooxygenase-2 (COX-2) and proinflammatory cytokines including, TNF and IL-1. In the nervous system, a large number of genes are regulated post-transcriptionally via the interaction of their mRNAs with specific RNA-binding (Hu) proteins such as the vertebrate homologs of *Drosophila* ELAV (for Embryonic Lethal Abnormal Vision). The mammalian ELAV proteins are known to bind to AU-rich elements (AREs) in the 3'-untranslated region of inflammation-associated factors such as TNF, COX-2, IL-1, IL-6, among several other genes. Recently we have identified a linkage peak (Chr.1p, LOD = 3.41) using age at onset (AAO) of PD as a quantitative trait (Li et al., 2002). The gene ELAVL4 lies in this linkage region. To determine if ELAVL4 is a candidate gene for AAO in PD, we conducted family based association analysis using the Quantitative Transmission Disequilibrium Test (QTDT) on a dataset of 643 families. We found a significant association ( $P=0.01$ ) in one SNP in ELAVL4 (rs#967582). Using the pedigree disequilibrium test (PDT) we also found marginally significant association ( $P=0.04$ ) between another SNP in ELAVL4 (rs#2494876) and PD risk in a subset of early onset families ( $n=70$  families). We are in the process of examining this gene as a potential factor that links AAO, neuroinflammation, and progression of PD.

**A significant evidence for linkage of febrile seizures to chromosome 18p11 and possible association of a common haplotype in the IMPA2 gene in Japanese families.** *J. Nakayama*<sup>1, 2</sup>, *N. Yamamoto*<sup>1</sup>, *K. Hamano*<sup>3</sup>, *N. Iwasaki*<sup>2</sup>, *M. Ohta*<sup>4</sup>, *S. Nakahara*<sup>5</sup>, *A. Matsui*<sup>2</sup>, *E. Noguchi*<sup>1</sup>, *T. Arinami*<sup>1</sup>. 1) Department of Medical Genetics, University of Tsukuba, Ibaraki, Japan; 2) Department of Pediatrics, University of Tsukuba, Ibaraki, Japan; 3) Kitaibaraki Municipal General Hospital, Ibaraki, Japan; 4) Toride Kyodo General Hospital, Ibaraki, Japan; 5) Kensei General Hospital, Ibaraki, Japan.

Febrile seizures (FS) are relatively common and represent most childhood seizures. In the Japanese population, the incidence rate is as high as 7%. It has been recognized that there is a significant genetic component for susceptibility to this type of seizure. Five susceptibility FS loci have been identified on chromosomes 8q13-q21(*FEB1*), 19p(*FEB2*), 2q23-q24(*FEB3*), 5q14-q15(*FEB4*), and 6q22-q24. To find novel susceptibility loci for familial FS, we conducted a genome-wide linkage screening of 48 Japanese nuclear families (190 members) with FS children (59 affected sib-pairs) using 400 microsatellite markers separated by an average distance of 10cM. We used the GENEHUNTER program to performed nonparametric multipoint linkage analysis. Significant linkage was suggested at the marker D18S1158 on chromosome 18p11.2 ( $P = 0.0001$ ). This region includes the *IMPA2* gene, which codes for myo-inositol monophosphatase (IMPase) 2. Inositol phosphatases play a crucial role in the phosphatidylinositol signaling pathway. IMPase converts inositol monophosphates to myo-inositol. IMPase is inhibited by lithium which has proconvulsant effect, and stimulated by carbamazepine, an anticonvulsant. We performed a systematic search for mutations in 24 unrelated Japanese FS patients and detected seven variants (-708G>A, -461C>T, -207T>C, IVS1-15G>A, 159T>C, IVS5+13-14insA, and 558C>T). Haplotype analysis in 59 Japanese families (223 members) with FS revealed an association of a common haplotype in *IMPA2* with FS ( $p = 0.0009$ ). The present study provided preliminary evidence for the *IMPA2* or near locus on chromosome 18p11 as a candidate genomic region for FS.

**Mapping of a novel form of infantile onset epilepsy syndrome to chromosome 2p.** *C. Proukakis<sup>1</sup>, M. Simpson<sup>1</sup>, A. Pryde<sup>1</sup>, M.A. Patton<sup>1</sup>, H. Cross<sup>2</sup>, A.H. Crosby<sup>1</sup>.* 1) Dept Medical Genetics, St George's Hospital Medical School, London, United Kingdom; 2) Dept of Ophthalmology, University of Arizona School of Medicine, 655 N. Alveron Way, Tuscon, USA.

We have identified an autosomal recessive form of severe intractable epilepsy and extreme developmental retardation which typically presents within the first six months of life. The seizure activity consists of both tonic-clonic and partial seizures. Tonic clonic activity is generally controllable through drug therapy, however, partial seizure activity persists. Developmental retardation appears to be slowly progressive, limb movements of affected individuals have an athetoid character and progress with the loss of ability to grasp objects. We ascertained 8 affected individuals with this syndrome from two families which both originate from the same Amish community in Ohio, USA. All 4 parents of these two families have been linked to a fifth generation common ancestor. Using homozygosity mapping assuming a founder effect, we identified a single region of homozygosity on chromosome 2p. Marker saturation analysis indicated that the critical region spans ~5cM equating to ~16Mb and contains approximately 50 known or predicted genes.

**Rare allele in Synapsin 2 (Syn2) associated with decreased rate of schizophrenia and schizoaffective disorder. V.**

*Saviouk*<sup>1</sup>, *E.W.C. Chow*<sup>2</sup>, *A.S. Bassett*<sup>2</sup>, *L.M. Brzustowicz*<sup>1,3</sup>. 1) Dept. of Genetics, Rutgers University, Piscataway, NJ; 2) Dept. of Psychiatry, University of Toronto, and Schizophrenia Research Program, Queen Street Division, Centre for Addiction and Mental Health, Toronto; 3) Dept. of Psychiatry, University of Medicine and Dentistry of NJ, Robert Wood Johnson Medical School, Piscataway.

Synapsins comprise a family of 5 proteins that are associated with cytoplasmic surface of the synaptic vesicles and implicated in synaptogenesis and neurotransmitter release, and in localization of NO synthase in proximity of its targets in presynaptic neurons. A microarray analysis of dorsal prefrontal cortex showed a decrease in transcripts of Syn2 gene (Mirnics et al., 2000). 337 subjects from 24 Canadian families of Celtic origin and 244 subjects from 39 North European families from NIMH collection were genotyped by pyrosequencing at the following locations in Syn2 gene: rs308969 (intron 1), rs308964 (intron 2), rs1530305 (intron2), rs308965 (intron 3), rs931676 (intron 4), rs3817004 (intron 5), rs795009 (intron 7), rs795010 (intron 8), rs795011 (intron 9), rs732863 (intron 10), and rs2289706 (exon 11). rs1530305, rs732863, and rs2289706 were not polymorphic in our samples. 2 groups of SNPs (rs308969, rs308964, rs308965, and rs795009, rs795010, rs795011) were in complete LD and formed 2 haplotype blocks covering introns 1-2-3 and 7-8-9. Analysis with the programs Pseudomarker and Transmit reveal that the intron 5 SNP is associated with schizophrenia/schizoaffective disorder. For the Canadian sample, the results were significant at  $p=0.012$  with Pseudomarker (recessive pseudomarker model) and  $p=0.06$  with Transmit (empirical p-value based on 10,000 bootstrap simulations). For the NIMH sample, the respective p-values were 0.004 and 0.0001, and for combined Canadian/NIMH sample, they were 0.0001 and 0.0004. The rare G allele was significantly more common in healthy subjects than in subjects with schizophrenia. SNP block 7-8-9 also showed slight evidence for association in the combined sample by Pseudomarker analysis ( $p=0.03$ ). Preliminary results suggest that Syn2 may have a rare allele that is protective against schizophrenia.

**Association study of the NEO-PI Five Factor Model of Personality and Chromosome 18q21-23 SNPs by using a Multiplex genotyping method.** *S. Villafuerte*<sup>1</sup>, *J. Chisa*<sup>2</sup>, *S. Srijan*<sup>3</sup>, *L. Gleiberman*<sup>5</sup>, *D. Burke*<sup>2</sup>, *N. Schork*<sup>6</sup>, *A. Weder*<sup>5</sup>, *M. Burmeister*<sup>1,2,3,4</sup>. 1) Mental Health Research Inst; 2) Department of Human Genetics; 3) Neuroscience program; 4) Department of Psychiatry; 5) Department of Internal Medicine, Univ Michigan, Ann Arbor, MI; 6) Department of Psychiatry, University of California at San Diego, La Jolla, CA.

One emerging strategy is the study of risk factors that are correlated with psychiatric disorders. The NEO-PI questionnaire is a reliable and validated measure of the five-factor model of personality. One of these factors, Neuroticism, measures levels of anxiety, depression and vulnerability. Epidemiological studies showed that some genetic factors predispose to both Neuroticism and Major depression. Recently, it has been reported that high Neuroticism appeared to be associated with increases in depression overtime and high Conscientiousness was associated with increases in manic symptoms among bipolar patients. Our laboratory has found a variant in BDNF associated with high scores of Neuroticism, the same variant Sklar and Lander found associated with Bipolar disorder. A genome scan has been completed on a group of 258 families, who have completed the NEO-PI questionnaire, drawn from a population in Tecumseh, Michigan. For the anxiety and depression facets of Neuroticism, two LOD scores higher than 2 were identified on chromosomes 15 and 18q21-23, the later been implicated with Bipolar disorder by others. Therefore, we conducted an association study in a population-based sample by analyzing 11 validated SNPs with a minor allele frequency of 0.2 on chromosome 18q21-23 spanning a region of approximately 28 MB. These 11 SNPs are the first of 26 selected SNPs to evaluate and optimize a multiplex SNP genotyping method where several SNPs can be analyzed simultaneously in one DNA sample. The method is based on simultaneous locus-specific amplification followed by ligation detection reaction. Ligated-oligonucleotides are resolved by gel-size fragmentation. In addition to the individual association, we will be able to describe the extent of linkage disequilibrium and construct haplotypes since we have access to family information.

**Association of *HOXD1* and *GBX2* allelic variants with autism spectrum disorders.** *C.J Stodgell*<sup>1</sup>, *N. Wanek*<sup>2</sup>, *M. O'Bara*<sup>1</sup>, *S.L. Hyman*<sup>3</sup>, *S. Bryson*<sup>4</sup>, *P.M. Rodier*<sup>1</sup>. 1) OB/GYN, University of Rochester, Rochester, NY; 2) Biology, Rochester Institute of Technology, Rochester, NY; 3) Pediatrics, University of Rochester, Rochester, NY; 4) Pediatrics, IWK Health Centre, Dalhousie University, Halifax, Nova Scotia.

Autism spectrum disorders (ASDs) are developmental disorders with an estimated prevalence of 3-6/1,000. Genome scans have suggested that loci on Chr. 2 are linked to ASDs. We tested two candidates located on Chr. 2q for their association with ASDs. *HOXD1* is important in the formation of the abducens nerve, and has been linked to Duane syndrome, a congenital abnormality of eye muscle innervation that has been reported in autism. *GBX2* is another transcription factor which is important in maintenance of the isthmus organizer (the mid/hindbrain division) and formation of cerebellar deep nuclei. Both regions are likely to be important in ASD's neuroanatomical pathology. We identified two SNPs in noncoding regions of *HOXD1*. The first is a G>C SNP 391 bases upstream of the start codon; it met allele frequency expectations and was not in transmission disequilibrium. The second SNP (T>C) is located at base 125 of the intron. Frequencies for the T and C alleles were .72 and .28, respectively. In 60 informative matings, the C-allele was transmitted significantly more often from mother to affected child (McNemar stat = 5.13, p<.03). The G allele of the 3' SNP and the T allele of the intronic SNP were linked 94% of the time. Analysis of *GBX2* revealed a 12 base insert (ACAG ACGG CGGG) 3' of the start codon. The frequency of the allele with the insert was .36 in 345 individuals (178 parents, 124 ASD cases, and 43 sibs making up trios, singletons, and affected and discordant sib pairs.). Using the method of Sun et al. (Am J Epi 150:97-104, 1999), we calculated that the allele without the insert was in disequilibrium with ASD (Z=5.02, p<.000001). These data further support the hypothesis that genes responsible for brainstem and cerebellar formation are important candidates for the etiology of ASDs. (Supported by grants to PMR 1PO1HD35466, a Collaborative Program for Excellence in Autism, and 1RO1HD34969.).

**A new locus for autosomal recessive microcephaly and mental retardation maps to chromosome 1p11.2-21.1 in an Israeli Arab family.** *H. Shilo*<sup>1</sup>, *R. Shenhav*<sup>1</sup>, *R. Pessó*<sup>2</sup>, *G.J. Halpern*<sup>1</sup>, *T. Shohat*<sup>3,5</sup>, *S. Shalev*<sup>4</sup>, *M. Shohat*<sup>1,5</sup>. 1) Department of Medical Genetics, Rabin Medical Center and Felsenstein Medical Research Center, Petah Tikva; 2) Maccabi Health Organization, Central Laboratories, Rehovot; 3) Israel Center for Disease Control, Ministry of Health, Tel Hashomer; 4) Genetics Unit, Ha'emek Medical Center, Afula; 5) Sackler Faculty of Medicine, Tel Aviv University, Israel.

Microcephaly is defined as a head circumference of 3 standard deviations or more below the age and sex related mean. It comprises a heterogeneous group of conditions characterized by failure of normal brain growth. The etiology can be divided into environmental or genetic causes, and it can be congenital or secondary. Five autosomal recessive primary microcephaly loci have been mapped to date: MCPH1 at 8p22-pter, MCPH2 at 19q13.1-13.2, MCPH3 at 9q34, MCPH4 at 15q, and MCPH5 at 1q31. Two genes have been identified - the microcephalin gene associated with MCPH1 and the ASPM gene associated with MCPH5. We report an Israeli Arab consanguineous family with two children who have microcephaly and developmental delay. These children have four double first cousins who are similarly affected. Two additional children, siblings of the cousins, were identified as affected and have since died. The clinical characteristics of the syndrome include microcephaly, spasticity with hyperreflexia in the lower limbs and moderate to severe mental retardation. Auditory evaluation, MRI, metabolic work up and karyotype were normal. No major dysmorphic features were found apart from a low forehead and a prominent and broad nose. We ruled out the previously reported candidate loci and then commenced genomewide screening and homozygosity mapping in this family. We identified a new locus for this autosomal recessive microcephaly mental retardation syndrome on chromosome 1p11.2-21.1 ( $Z_{\max} = 5.46$  at  $\max = 0.01$ ) for the marker AFM197YG1. Further mapping defined the minimum critical region in an interval of 17.8 Mb defined by the markers AFMA297XG9 and D1S495. Identification of the genes implicated in microcephaly will provide insights into the pathogenesis of this condition.

**A Genomic screen reveals evidence for novel SPG loci.** *L. Zhang, M.T. Kloos, S. West, P.C. Gaskell, I.K. Svenson, M.A. Pericak-Vance, D.A. Marchuk, A.E. Ashley-Koch.* Duke University Medical Center, Durham, NC.

Hereditary spastic paraplegia (HSP) is extremely genetically heterogeneous with at least 20 loci having been identified. Genomic screen results from 5 families excluded for mutations in spastin (SPG4) and by linkage analysis to SPG3A, SPG4, SPG6, SPG8, SPG10, SPG12 and SPG13, provided promising evidence for linkage on chromosomes 2, 5, 7, and 13. Two of the linked families exhibited supportive evidence for linkage on chromosome 2. These two families had been excluded for mutations in spastin, and did not provide evidence for linkage at SPG13 (Fontaine et al. 2000) or the alsin gene (ALS2) (Hadano et al. 2001; Yang et al. 2001; Eymard-Pierre et al. 2002). These families appear to represent a new chromosome 2 HSP locus (MaxLod = 2.672 and 1.45). A third family showed evidence for linkage to chromosome 13 (MaxLod = 1.497) in the same region as the recently reported autosomal recessive HSP locus, SPG20 (Patel et al. 2002). In order to determine if this family represents an alternative phenotype and inheritance pattern of the SPG20 locus versus a novel locus, we performed mutation analysis of the SPG20 gene, spartin. We examined all seven reported exons, an alternatively spliced exon, as well as another potential exon causing a putative alternative start site with an upstream methionine that we identified through examination of the EST database. We did not detect a spartin mutation in this family, suggesting that SPG20 is not responsible for the linkage observed in this family. The remaining two families demonstrated support for linkage to chromosomes 5 and 7 (MaxLod = 2.093 and 1.802, respectively), which also appear to be novel SPG linkage regions. Thus, we conclude that additional SPG loci exist further supporting that HSP is an extremely genetically heterogeneous phenotype.

**Further evidence of linkage between adult-onset autosomal dominant leukodystrophy and chromosome 5q23.** A. Simoes Lopes<sup>1</sup>, S. Verreault<sup>2</sup>, J-P. Bouchard<sup>2</sup>, G.A. Rouleau<sup>1</sup>. 1) Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada; 2) Hôpital de l'Enfant-Jésus, Quebec City, Quebec, Canada.

Hereditary leukodystrophies have been rarely reported in adults and are most commonly seen as autosomal or X-linked recessive disorders of infancy or childhood. We have identified and characterized a large French-Canadian family with an adult-onset autosomal dominant leukodystrophy. The clinical picture in 6 examined individuals was marked by autonomic abnormalities, followed by neurological deterioration with upper motor neuron signs and gait disturbance. Imaging studies revealed mild cerebral atrophy and a marked symmetrical loss of white matter particularly in fronto-parietal regions as well as spinal cord atrophy. Genealogical studies allowed us to identify 15 affected individuals over 5 generations and we were able to collect all live members for genetic studies. Previous reports of a single American-Irish family with similar clinical findings localized the disease gene to chromosome 5. Linkage and haplotype analysis of markers in this ADLD locus revealed a maximal LOD score of 4.08 at marker D5S2039 in our family and a haplotype spanning a 10cM/15Mb region flanked by markers D5S2055 and D5S2110. To our knowledge, this is the second family described worldwide with this disorder and our results provide further evidence for the localization of a gene responsible for ADLD on chromosome 5q23.

**Association of polymorphisms in MTHFR and TGF1 in Alzheimer's disease patients.** *R.T. Perry<sup>1</sup>, H. Wiener<sup>1</sup>, L.E. Harrell<sup>1</sup>, D. Blacker<sup>2</sup>, R.E. Tanzi<sup>2</sup>, M. McInnis<sup>3</sup>, S.S. Bassett<sup>3</sup>, R.C.P. Go<sup>1</sup>.* 1) Univ Alabama-Birmingham, Birmingham, AL; 2) Massachusetts General Hospital, Charleston, MA; 3) Johns Hopkins University, Baltimore, MD.

Subjects with cardiovascular risk factors such as atherosclerosis and a history of stroke have an increased risk of both vascular dementia and AD. Increased plasma homocysteine (Hcy) levels are a major independent vascular risk factor and have been reported in AD patients as compared to controls. MTHFR is a key enzyme in the conversion of Hcy to methionine. *In vitro* studies have shown the 677 CT missense mutation (A222V) in MTHFR results in a more thermolabile enzyme with 50% less activity. Although several factors can influence Hcy levels, AD patients homozygous for the T allele have been reported to have higher Hcy levels than controls or nonhomozygous patients. Using family-based association testing, we found a significant association of the T allele to AD under the dominant model in subsets of families in the NIMH sibling data set with at least two affected and one unaffected sibling that were not homozygous for the APOE4 allele ( $p=0.012$ ) and with an age of onset 70 years ( $p=0.025$ ). TGF1 is a multifunctional cytokine with pro- and anti-inflammatory properties and, in particular is a key regulator of the brain's responses to injury and inflammation. A negative regulatory element in the promoter associated with decreased transcription contains a CT substitution at position -509. The T allele is marginally associated with higher transcription activity than the C allele and is associated with higher plasma concentrations in a dose dependent fashion. Confirming other studies, we found a significant association of the T allele to AD in families with at least two affected and one unaffected sibling ( $p=0.007$ ) and, when stratified, for families that were not homozygous for APOE4 ( $p=0.026$ ) and those with an age of onset 50 ( $p=0.007$ ). Interestingly, both genes reside in chromosomal regions detected in the genomic scan we reported on this year. These results support evidence these chromosomal regions may harbor a gene(s) important to AD especially those in inflammatory and atherosclerotic pathways.

**A New *LGII* Mutation in Familial Temporal Lobe Epilepsy with Auditory Auras.** *N.F. Santos<sup>1</sup>, R. Secolin<sup>1</sup>, F.R. Torres<sup>1</sup>, E. Kobayashi<sup>2</sup>, L.A.C. Sardinha<sup>2</sup>, F. Cendes<sup>2</sup>, I. Lopes-Cendes<sup>1</sup>.* 1) Department of Medical Genetics, UNICAMP, Campinas SP, Brazil; 2) Department of Neurology, UNICAMP, Campinas SP, Brazil.

**Purpose:** A locus for familial temporal lobe epilepsy with auditory auras (FTLEAA) was mapped on chromosome (ch) 10q and mutations in the leucine-rich glioma inactivated 1 gene (*LGII*) have been found in affected individuals belonging to different FTLEAA families. The objective of the present study is to investigate genetic linkage and *LGII* mutations in a large Brazilian family segregating FTLEAA. **Methods:** Blood samples were collected from 30 family members for DNA extraction by phenol-chloroform method. For linkage analysis, these individuals were genotyped for 12 microsatellite markers: D10S1644, D10S1687, D10S1765, D10S1753, D10S583, D10S185, D10S574, D10S1680, D10S577, D10S192, D10S566 and D10S187 flanking the *LGII* gene. Two-point and multipoint Lod scores (*Z*) were calculated using MLINK and LINKMAP programs from LINKAGE package. For mutation analysis, we screened the entire coding region of the *LGII* gene by PCR, using primers that flanked intron-exon junctions. Nucleotide sequence for three affected, three non-affected and normal controls were analyzed using MegaBACE 1000 dye-terminators. **Results:** Linkage analysis showed *Z*3.00 for seven markers, with *Z*<sub>max</sub>=6.35 at *q*=0.00 for D10S185. Nucleotide sequencing analysis revealed a VIIS7(-2)A-G splicing site mutation in affected individuals evaluated. Posterior BstN1 restriction enzyme analysis showed this mutation in all affected individuals belonging to this family. No mutation was found in non-affected members and normal controls. **Discussion:** We have found a new mutation for FTLEAA, VIIS7(-2)A-G, that destroys the splicing site upstream of exon 8, possibly leading to an exon skipping and producing a truncated protein. Other hypothesis is the occurrence of alternative splicing in exon 8, modifying the frameshift and resulting in a non functional protein. Supported by: FAPESP and CAPES.

**Further evidence of linkage of Alzheimer's disease on Chromosome 12.** *K.C. Stanton<sup>1</sup>, L. Jiang<sup>1</sup>, N. Schnetz-Boutaud<sup>1</sup>, S.J. Kenealy<sup>1</sup>, W.K. Scott<sup>2</sup>, S. Schmidt<sup>2</sup>, J. Gilbert<sup>2</sup>, G.W. Small<sup>3</sup>, A.M. Saunders<sup>2</sup>, A.D. Roses<sup>2</sup>, D.E. Schmechel<sup>2</sup>, M.A. Pericak-Vance<sup>2</sup>, J.L. Haines<sup>1</sup>.* 1) Vanderbilt University, Nashville, TN; 2) Duke University, Durham, NC; 3) UCLA, Los Angeles, CA.

Alzheimer's disease (AD) is a complex disease that is the leading cause of dementia and affects over 4 million individuals in the United States. Although four genes have been identified that influence both early and late onset AD, these genes explain only part of the genetic etiology.

Several genomic screens for AD indicate a region of linkage on chromosome 12 between 12p13 and 12q22, but consensus identification of a gene remains elusive. To further investigate this linkage, a dataset was assembled from several centers. The total dataset consists of 2131 individuals (1250 affected, 780 unaffected, 101 unknown). Fifteen microsatellite markers were selected to adequately cover the region from 17-91 cM (DeCODE map).

Analysis of the datasets identified several linkage signals, especially when the ApoE-4 allele status was used as a stratifying variable. The most notable signals were seen within families with ApoE-4 alleles, including a lod=1.43 for the entire dataset at D12S1090 (57 cM) under the recessive model, and a lod=2.59 for that same marker in the NIMH sample set.

Ordered Subset Analysis (OSA) rank-orders families by a continuous covariate and finds the subset with maximum evidence for linkage to a particular map of markers. We used mean age-at-onset in each family as the covariate and ranked the means from low to high for all fifteen markers. The lod score at D12S1632 (72 cM) increased from 0.00 to 1.58 for the entire dataset. This increase was significant ( $p=0.02$ ). These data suggest that an earlier onset subgroup of families is responsible for at least one genetic linkage signal on chromosome 12 and that phenotypic subsetting is a useful approach for dissecting the genetics of complex traits.

***p53* codon 72 polymorphism and cancer risk in Li-Fraumeni syndrome.** L. Yip, S.J. Hwang, L.C. Strong, G. Lozano. M. D. Anderson Cancer Center, Houston, TX.

Li-Fraumeni syndrome (LFS) is characterized by a young age at onset of cancers such as sarcomas and tumors of the breast, brain, and adrenal cortex. Approximately 70% of LFS patients are heterozygous carriers of germline *p53* mutations. A polymorphism at codon 72 has been shown to be a modifier of wildtype and mutant *p53* activity. In the current study we examined whether the codon 72 polymorphism contributed to the phenotypic variability seen in LFS germline *p53* mutation carriers.

Study subjects were composed of 60 mutation carriers ascertained from an index childhood sarcoma case or from referred kindreds that have a history of cancer consistent with LFS. *p53* mutations were detected using SSCP, functional, and/or DNA sequencing assays. DNA sequencing then identified carriers with the Arg/Arg and Pro/Pro codon 72 polymorphisms. Carriers with the Arg/Pro polymorphism had additional cDNA subcloning, SSCP, and sequencing to determine the polymorphism within the *p53* mutant allele. Chi-square test and Kaplan-Meier survival analysis were used to calculate the significance of excess cancer cases and of differences in cumulative cancer risk in carriers by the codon 72 polymorphism within the *p53* mutant or wildtype alleles. Results of the study showed a significantly higher risk of developing soft-tissue sarcoma in carriers with the codon 72 Pro polymorphism within the *p53* mutant allele relative to those with the Arg polymorphism (Log-Rank  $\chi^2 = 4.49$ ,  $p = 0.03$ ). The results also showed a marginally higher risk of osteosarcoma for carriers with the codon 72 Pro polymorphism within the *p53* wildtype allele relative to those with the Arg polymorphism (Log-Rank  $\chi^2 = 2.99$ ,  $p = 0.08$ ). However, carriers with the codon 72 polymorphism within the *p53* mutant allele were significantly different by ethnicity ( $\chi^2 = 45.4$ ;  $P < 0.001$ ); Caucasian and Hispanic carriers predominantly had the Arg polymorphism while all African-American carriers had the Pro polymorphism. Our data suggest that the polymorphism at codon 72 of *p53* contributes to the variable phenotype seen in carriers of heterozygous germline *p53* mutations and that further investigations are needed.

**A whole-genome scan for resting heart rate: The HERITAGE Family Study.** *P. An<sup>1</sup>, T. Rice<sup>1</sup>, T. Rankinen<sup>2</sup>, A.S. Leon<sup>3</sup>, J.S. Skinner<sup>4</sup>, J.H. Wilmore<sup>5</sup>, C. Bouchar<sup>d</sup><sup>2</sup>, D.C. Rao<sup>1,6</sup>*. 1) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO; 2) Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA; 3) Division of Kinesiology, University of Minnesota, Minneapolis, MN; 4) Department of Kinesiology, Indiana University, Bloomington, IN; 5) Department of Health and Kinesiology, Texas A&M University, College Station, TX; 6) Departments of Genetics and Psychiatry, Washington University School of Medicine, St. Louis, MO.

Background - Elevated resting heart rate (RHR) is an independent risk factor for cardiovascular disease. Since evidence has accumulated supporting a genetic component for RHR, it is of interest to identify genomic regions that harbor genes underlying RHR variation. Methods and Results - A multipoint variance components linkage scan using 654 markers was performed to search for quantitative trait loci (QTL) that influence RHR at baseline and in response to 20 weeks of endurance training (post-training minus baseline) in 99 white and 127 black families in the HERITAGE Family Study. Potentially interesting regions were revealed in whites including 4q, 10q and 11p for baseline RHR and 1q and 21q for the training response. Additionally, promising regions on 2q and 7q for baseline RHR and 3p for the training response were found in blacks, which did not replicate the regions identified in whites. The linkage evidence on 11p at the sulfonylurea receptor gene (SUR) locus was enhanced (lods from 1.36 to 1.98) in a high-normal BP (at least 135/80 mmHg) subset of white families indicating probable involvement of BP interactions at this locus. Conclusions - Of the genomic regions identified here for baseline RHR and its training response, 11p and 4q are most noteworthy due to replications across subsamples and studies. Future fine mapping and association studies in these regions are warranted.

**The Hepatic lipase (C-514T) polymorphism affects serum HDL cholesterol levels but not associated with coronary artery disease in Koreans.** *E.Y Cho<sup>1,2</sup>, H.Y. Park<sup>1,2</sup>, Y.G. Ko<sup>1,2</sup>, J.H. Lee<sup>1,3</sup>, J.E. Lee<sup>1,2</sup>, S.H. Jee<sup>1,4</sup>, Y. Jang<sup>1,2</sup>.* 1) Cardiovascular Genome Center, College of Medicine, Yonsei University, Seoul, Korea; 2) Research Institute of Cardiovascular disease, Division of Cardiology, Yonsei University Medical Center, Seoul, Korea; 3) Department of Food and Nutrition, College of human Ecology, Yonsei University, Seoul, Korea; 4) Department of Preventive Medicine and public Health, Yonsei University, College of Medicine, Seoul, Korea.

Hepatic lipase(LIPC) is a key enzyme that is involved in HDL cholesterol metabolism. The aims of this study are to investigate the association between the hepatic lipase gene polymorphism, plasma lipid levels and coronary artery disease. Five hundred two healthy control subjects (m:f=183:319) and 214 CAD patients (m:f = 165:49) were included. The subjects who taking the lipid lowering drugs were excluded. Fasting serum concentration of lipid and apolipoprotein were measured and the genotypes of two polymorphic sites (C-514T, V95M/G-A) in the LIPC were determined by SNP-IT assay. The genotype frequency of CC, CT and TT at C-517T was 0.31, 0.51, and 0.18, respectively in control group. The allele frequency of T allele was 0.43. In control group, -514TT group showed the highest mean apoA1 level (CC: 113.826.1, CT: 129.530.8, TT: 133.541.5 P<0.05, ANOVA in male, CC: 126.828.5, CT: 132.427.8, TT: 142.933.7 P<0.05, ANOVA in female). Mean HDL level in -514TT group was significant higher than that of in -514CC group in female group (51.2 vs. 56.5, p<0.05) but the trend was not significant in males. The genotype frequency of GG, GA and AA at codon 1 was 0.48, 0.44, and 0.08, respectively in control group. The A allele of V95M was associated with increasing of HDL cholesterol concentration in male group but not statistically significant. The two different site of genotype frequency in Hepatic lipase gene between CAD and controls was not different in both gender groups. Conclusively, the LIPC -514T polymorphism is common genetic variant in Korean and associated with plasma HDL levels. But this genetic variant was not an independent risk for CAD in our study.

**Genome Wide Scan for blood pressure in an isolated Sardinian founder population.** A. Angius<sup>1,2</sup>, E. Petretto<sup>1,2</sup>, M. Adamo<sup>1</sup>, R. Piras<sup>1</sup>, G. Biino<sup>1,2</sup>, M. Fanciulli<sup>1</sup>, M. Pirastu<sup>1,2</sup>. 1) Inst Population Genetics, CNR,SS, Italy; 2) SharDNA Life Science, CA, Italy.

Within Ogliastro Project, a large survey conducted in an isolated Sardinian population, we present results of an epidemiological study and of a GWS on blood pressure in Talana village (1200 inhabitants). This population may provide significant power to the identification of QTLs due to slow demographic growth, high endogamy and inbreeding, reduced genetic heterogeneity, low number of founders, stable culture and accurate genealogical records. Genotyping was carried out on 875 volunteers by a total of 654 informative markers (average het 0.71, SD=0.09) distributed over the genome (NHLBI Mammalian Genotyping Service). So far 355 individuals have undergone an extensive evaluation comprehensive of physical examination, serological analyses, anthropometrical and blood pressure measurements according to the British Hypertension Society protocol, structured interviews to collect living habits, exposure to most common risk factors, medical and medication history, information about familial disorders. Mean age is 53.19 years (55% females), SBP and DBP are normally distributed ( $p < 0.05$ ) with average of 135.20 and 80.10 mmHg respectively. Regression models were performed to find associated variables accounting for environmental factors. To retain power and information inherent to large pedigrees, all 355 subjects were included in 3 big inbred families (mean size 283, n=850, 55% genotyped). Using SOLAR, a genome-wide linkage analysis by variance components approach was conducted including all significant covariates: sex, age, alcohol assumption and anti-hypertensive therapy for SBP; sex, BMI, total cholesterol, LDL, alcohol assumption and anti-hypertensive therapy for DBP. Heritability of SBP and DBP was 0.21 ( $P=0.019$ ) and 0.25 ( $P=0.005$ ) respectively, indicating that a substantial portion of trait variation is attributable to genetic factors. Suggestive linkage evidence for DBP was found on chromosomes 1 (LOD 2.02) and 9 (LOD 2.28). We observed  $LOD > 1.7$  on chromosomes 2, 4, 6, 10 and 19 for DBP. No significant LOD score for SBP was obtained. Supported by grants from Telethon, Italy No.E1185.

**Systemic biomarkers of vascular inflammation in the NHLBI Framingham Heart Study: Genome scan evidence for susceptibility loci on chromosome 1q.** *J. Dupuis<sup>1</sup>, M.G. Larson<sup>2</sup>, R.S. Vasan<sup>2,3</sup>, J.M. Massaro<sup>1,2</sup>, P.W.F.*

*Wilson<sup>2,3</sup>, I. Lipinska<sup>3</sup>, D. Corey<sup>2</sup>, J.A. Vita<sup>3</sup>, J.F. Keaney<sup>3</sup>, E.J. Benjamin<sup>2,3</sup>.* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) NHLBI's Framingham Heart Study, Framingham, MA; 3) Department of Medicine, Boston University School of Medicine, Boston, MA.

Vascular inflammation plays a central role in development of atherosclerosis and inflammatory biomarkers predict several cardiovascular disease (CVD) events. There is evidence that genetic variation in inflammation contributes to susceptibility for CVD. Identifying genes influencing markers of inflammation could improve understanding of genetic determinants of CVD. We conducted linkage analyses in 304 extended families from the Framingham Heart Study of 4 systemic biomarkers of vascular inflammation [C-reactive protein (CRP), monocyte chemoattractant protein-1 (MCP-1), soluble intercellular adhesion molecule-1 (ICAM-1), and interleukin-6 (IL-6)]. There were 1054 individuals in the Offspring cohort with measured inflammatory biomarker levels and genotypes available from a 10 cM genome scan, including 172 sibling pairs, 114 sib trios, and 62 sibships of size 4. Another 506 genotyped individuals without phenotype were used in the analyses. Heritability estimates for inflammation markers ranged from 14% (IL-6) to 42% (MCP-1) after log transforming marker data and adjusting for covariates. Variance-component linkage analyses were performed using Genehunter and p-values were computed by a permutation approach. A region with significant linkage to MCP-1 was identified on chromosome 1 (LOD=4.3 at 185.6 cM; genome-wide  $p < 0.002$ ). The 1-locus support interval includes inflammatory candidate genes such as SELE, SELP (E- and P-selectin) and CRP. Other linkage peaks with LOD scores 2 were identified for MCP-1 on chromosome 1 (LOD=2.8 at 69.8cM) and chromosome 17 (LOD=2.4 at 22cM), and for ICAM-1 on chromosome 1 at 228.8 cM (LOD = 2.0) close to the IL10 gene. Our data suggest multiple genes on chromosome 1 may influence inflammation biomarkers, and these genes could have a major role in development of CVD.

**Genome scan of lipid-related traits in Hispanic and African-American families.** *J.E. Hokanson<sup>1</sup>, C.D. Langefeld<sup>2</sup>, S.R. Beck<sup>2</sup>, B.D. Mitchell<sup>3</sup>, J.M. Norris<sup>1</sup>, D.W. Bowden<sup>2</sup>, S.M. Haffner<sup>4</sup>, M.F. Saad<sup>5</sup>, K.D. Taylor<sup>6</sup>, J.I. Rotter<sup>6</sup>, The IRAS Family Study.* 1) Preventive Medicine & Biometrics, University of Colorado Health Sciences Center, Denver, CO; 2) Wake Forest University School of Medicine, Winston-Salem, NC; 3) University of Maryland School of Medicine, Baltimore, MD; 4) University of Texas Health Sciences Center, San Antonio, TX; 5) University of California, Los Angeles, CA; 6) Cedars-Sinai Medical Center, Los Angeles, CA.

Lipid-related traits are known to promote atherosclerosis. These traits have a significant genetic component with significant genetic pairwise correlations. The current study investigates evidence for linkage of genetic markers to lipid-related traits in the IRAS Family Study. Individuals from 45 Hispanic and 21 African-American families provided blood for DNA analysis and phenotypic data. Genotyping was performed by the NHLBI Mammalian Genotyping Service (Marshfield, WI) with an average intermarker distance of 9 cM. Variance components linkage analyses for QTLs were computed using the SOLAR software package. Evidence for co-localization of lipid-related traits are presented in the table (LOD scores).

Chr/Marker	Apo B	Cholesterol	Triglyceride	LDL
1/D1S1596	2.02	2.31		
8/ATT023	1.64	2.46	1.78	
19/D19S559	2.89			0.96

In addition there was evidence for linkage of Apo B to D17S2196 (LOD=1.54), triglyceride to chr 3:TTTA040 (LOD=1.96) and D13S793 (LOD=1.35), and LDL to D6S2439 (LOD=1.77) and chr 15:GATA50C03 (LOD=1.59). Thus, the strongest evidence for linkage potentially represent co-localization of lipid-related traits to chromosomes 1, 8, and 19.

**TWO PROMOTOR GENETIC VARIATION OF APOLIPOPROTEIN A-1 WAS ASSOCIATED WITH HDL-C AND APOA-1 LEVEL IN KOREANS.** *J.Y. Moon<sup>1</sup>, H. Seo<sup>1</sup>, Y.G. Ko<sup>1,2</sup>, S.M. Kang<sup>1</sup>, N. Chung<sup>1</sup>, W. Shim<sup>1</sup>, S.Y. Cho<sup>1</sup>, Y. Jang<sup>1,2</sup>, H.Y. Park<sup>1,2</sup>, E.Y. Cho<sup>1,2</sup>, J.H. Lee<sup>2,3</sup>, J.E. Lee<sup>2</sup>.* 1) Division of Cardiology, Yonsei University College of Medicine, Seoul, Korea; 2) Cardiovascular Genomic Center, Yonsei University College of Medicine, Seoul, Korea; 3) Department of Food and Nutrition, College of human Ecology, Yonsei University, Seoul, Korea.

The large ethnic differences in the lipid profiles and prevalence of coronary artery disease between Caucasians and Asian peoples may relate to both genetic and environmental differences. In this study, we investigated the role of two polymorphisms of apoA1 gene in lipid profiles and serum apoA1 level in healthy Korean subject. We obtained blood samples from unrelated 417 consecutive subjects (M: F=169:248, mean age 47.2 yrs) who dont have any history of CAD, diabetes and hypertension. The apoA1 genotypes were determined by SNPstream 25KTM System. The plasma apoA1 level was determined by immunoturbidometric analyzer. The genotype frequencies of G-75A were 69%, 26%, and 5% for GG, GA, and AA, respectively. The genotype frequency for XmnI site were 57%, 39%, and 4% for CC, CT, and TT, respectively. The T allele frequency in our study population was higher (27.5%) than that of Caucasian(12-14%). The T allele at XmnI site was significantly associated with low triglycerides ( $p=0.009$ ) and high ApoA1 level ( $p=0.049$ ). The A allele at 75 was also associated with higher plasma HDL-C level ( $p=0.040$ ). Significant linkage disequilibrium between two genetic variations was detected ( $p<0.001$ ). Subjects carrying GG genotype at -75 site and TT genotype at XmnI restriction site (GG/TT) were significant lower HDL-C level and lower apoA1 level compared to the other diplotypes(GG/CT, GA/CT, AA/TT). We concluded that the G-75A polymorphism of apoA1 gene is associated to elevated HDL-C level, and two variants in the promoter region of apoA1 gene had strong linkage disequilibrium in Korean. In contrast to previous reports, our study showed that the T variation at XmnI site is associated the decreased triglyceride level and elevated apoA1, suggesting protective effects of T allele.

**Endothelial nitric oxide synthase gene polymorphism in Fabry disease.** *M. Ziv<sup>1</sup>, R. Schiffmann<sup>2</sup>, G. Altarescu<sup>1</sup>.* 1) Genetic Unit, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Developmental and Metabolic Branch, NINDS, NIH, Bethesda, MD.

**Objective:** To determine the frequency of polymorphisms of endothelial nitric oxide synthase gene (eNOS) among Fabry hemizygotes and ascertain their relationship to markers of disease severity. **Introduction:** The gene encoding eNOS is involved in abnormalities of nitric oxide synthesis that mediate endothelial cell dysfunction, a major feature of Fabry disease. Most Fabry patients have private mutations. It is difficult to predict from the mutation the future development of organ involvement. The purpose of the study was to look for possible correlation between eNOS polymorphisms and markers of disease severity. **Methods:** Genotyping for the 897 GT exon 7 polymorphism of eNOS was performed in 44 adult Fabry hemizygotes. The eNOS genotype results were correlated with Fabry genotype, cardiac echo, ECG parameters, lipid profile, and renal function. The polymorphisms in the eNOS gene were compared using ANOVA (both parametric and non parametric) for the three genotype groups (G/G, G/T and T/T). **Results:** The prevalence of allelic variants of eNOS was: 54% G/G, 39% G/T and 7% T/T. This distribution was similar to that of Caucasian populations previously described. A significant association was found between eNOS polymorphisms and ventricular septal thickness ( $p=0.022$ ), aortic root diameter ( $p=0.029$ ) and left ventricular free wall thickness ( $p=0.009$ ), log rank test. The T/T group had the lowest mean left ventricular free wall thickness ( $8.56 \pm 1.38$  mm), septum ( $8.88 \pm 1.64$  mm) and aortic root diameter ( $28.5 \pm 3.96$  mm) and the T/G group had the highest values in these three parameters. **Conclusions:** These results suggest that the eNOS polymorphisms are distributed similar among Fabry patients compared to Caucasians controls. Among patients with Fabry disease the T/T genotype is associated with a milder cardiac Fabry phenotype, implying that eNOS polymorphisms might serve as a mitigating genetic cardiac modifier in Fabry disease as in other vascular disorders.

**Linkage Analysis of a FCH Dutch Population.** *A. van Nas*<sup>1</sup>, *H. Allayee*<sup>1</sup>, *E. Sobel*<sup>1</sup>, *R.M. Cantor*<sup>1,5</sup>, *K.L. Krass*<sup>2,3</sup>, *M. Groenedijk*<sup>6</sup>, *G.M. Dallinga-Thie*<sup>6</sup>, *T.W. de Bruin*<sup>6</sup>, *A.J. Lusia*<sup>1,2,3,4</sup>. 1) Department of Human Genetics University of California, Los Angeles, California; 2) Department of Medicine University of California, Los Angeles, California; 3) Department of Microbiology and Molecular Genetics University of California, Los Angeles, California; 4) Department of Molecular Biology Institute University of California, Los Angeles, California; 5) Department of Pediatrics University of California, Los Angeles, California; 6) Department of Medicine and the Cardiovascular Research Institute Maastricht, Academic Hospital, Maastricht, the Netherlands.

Familial combined hyperlipidemia (FCH) is a common lipid disorder traditionally characterized by elevated levels of plasma cholesterol and triglycerides that is present in 10% to 20% of patients with premature coronary heart disease. Additionally, increased VLDL secretion has been observed in affected patients which has led to a proposal of redefining FCH; namely to consider affected individuals as hypertriglyceridaemic hyperApoB. Twenty Dutch pedigrees (n=388) classified as affected for ApoB and/or triglycerides were analyzed in a genome scan to determine the chromosomal regions harboring genes contributing to FCH. Parametric single-point, multipoint analysis and non-parametric (LOD=3.96, 2.0, 2.8) suggests linkage of ApoB and/or triglyceride levels to a region on chromosome 16. Notably, the degree of allele sharing around this marker was significantly skewed among siblings. The families were re-typed with markers spanning 50cM, reducing the region of interest to 10cM. These data provide evidence that a chromosome 16 locus, may be contributing to plasma ApoB and/or triglyceride concentrations in humans affected with FCH. The region around this locus has been replicated in several different populations of similar disease traits, including Canadian Indian, Chinese Hans, Indo-Mauritians and Scandinavian as well as being syntenic to the QTL region of a mouse model for combined lipase deficiency (CLD). Further analysis involving fine mapping and association studies of candidate genes in the region is currently in progress, as well as the goal to repeat these linkage results in another FCH population.

**The importance of the BamHI-polymorphism in heparan sulphate proteoglycan 2 (HSPG2) for coronary atherosclerosis.** *S. Schulz<sup>1</sup>, C. Glaeser<sup>1</sup>, D. Rehfeld<sup>1,2</sup>, T. Suess<sup>1,2</sup>, U. Mueller-Werdan<sup>2</sup>, K. Werdan<sup>2</sup>, I. Hansmann<sup>1</sup>.* 1) Inst Human Genetics, Univ Halle, Halle, Germany; 2) Dep Internal Med, Univ Halle, Halle, Germany.

HSPG2 is one of the three major classes of heparin sulphate proteoglycans acting within the cardiovascular system and controlling various aspects of vascular development. It is involved in the lipid metabolism by binding lipoprotein lipase and apolipoprotein B and may therefore be related to vascular disease. Methods: In a case control-study we examined the interactions of the BamHI-polymorphism (PM) of HSPG2, lipid metabolism (LDL, HDL, triglycerides, total cholesterol) and coronary atherosclerosis (CAD). We investigated 353 patients with angiographically confirmed coronary diagnosis depending on their angiographically confirmed coronary and lipid state, 126 patients without any coronary symptoms having an abnormal lipid metabolism (mean age: 51.4y) and 227 CAD patients having a distinct pathological lipid profile (mean age: 50.6y). As controls we examined 300 long-standing healthy blood donors with normal lipid metabolism (mean age: 43y). Results: In order to evaluate the interrelation of the HSPG2 BamHI-PM, lipid metabolism and CAD the genotype frequencies were examined according to a dominant, codominant and recessive genetic model within three proband groups. The analysis of the codominant genetic model showed significantly decreased frequencies of the homozygous mutation-carriers TT among CAD patients (0.02) and patients without coronary afflictions (0.04) compared to healthy blood donors with normal lipid profile (0.07,  $p < 0.032$ ). Based on a T-recessive genetic model a comparison of CAD patients showing the most pathological lipid profile and healthy blood donors revealed a 4.2 times higher risk for TT-carriers of developing an unbalanced lipid metabolism connected with severe coronary atherosclerosis ( $p > 0.006$ ; 95% CI: 1.42-12.4). Conclusions: Depending on the pathological lipid profile the TT-genotype of the HSPG2- PM is significantly less frequent. Beside the pathological lipid profile the angiographically confirmed coronary state seems to be only a minor fact in this association study.

**Hypotrichosis simplex of the scalp is caused by nonsense mutations in the corneodesmosin gene.** *E. Levy-Nissenbaum<sup>1</sup>, R.C. Betz<sup>2</sup>, M. Frydman<sup>1</sup>, M. Simon<sup>3</sup>, B. Goldman<sup>1</sup>, N. Jonca<sup>4</sup>, J. Toribio<sup>5</sup>, S. Cichon<sup>2</sup>, M. Guerrin<sup>3</sup>, G. Serre<sup>3</sup>, M.M. Nothen<sup>2</sup>, E. Pras<sup>1</sup>.* 1) Danek Gartner Institute of Human Genetics; Sheba Medical Center, Tel Hashomer, Israel and Tel Aviv University, Tel Aviv, Israel; 2) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 3) Unit of Epidermis Differentiation and Rheumatoid Autoimmunity, FRE2623 CNRS - University of Toulouse III, Toulouse, France; 4) Institute of Human Genetics, University of Bonn, Bonn, Germany; 5) Department of Dermatology, University of Santiago de Compostela, Santiago de Compostela, Spain.

Hypotrichosis simplex of the scalp (HSS) is an autosomal dominant form of non-syndromic alopecia (MIM 146520), characterized by loss of scalp hair in late childhood. We have studied three HSS families of various ethnic origin, all of which showed linkage to chromosome 6p21.3. After reducing the linkage interval to 9.5 Mb, we started to screen candidate genes from the linkage interval preferentially expressed in skin tissue. We identified nonsense mutations in the Corneodesmosin (CDSN) gene in all three HSS families. Full segregation of the mutations was observed in all three families. The mutations were not found in 750 control chromosomes. CDSN, a glycoprotein expressed in the epidermis and inner root sheath (IRS) of hair follicles, is a keratinocyte adhesion molecule. To study the mutations, we examined scalp biopsies using CDSN antibodies. In the patients, biopsies revealed reduced labeling intensity of the stratum granulosum in the epidermis and the IRS of hair follicles. Moreover, we noticed irregularly sized clusters located in ridges of the superficial dermis and at the periphery of hair follicles deeper in the dermis. A dominant negative interaction between the mutant and wild type protein may account for loss of cohesion within the IRS. However, in view of the delayed onset of alopecia, it seems more likely that the observed CDSN aggregates are toxic to the hair follicle cells. Our results underline an important step towards understanding the biological mechanisms underlying scalp-specific hair loss.

**Genome-wide homozygosity mapping and linkage analysis in consanguineous families using 11K SNPs identifies a novel deafness locus.** *C. Rosenow<sup>1</sup>, N. Meyer<sup>2</sup>, R. Mei<sup>1</sup>, S. Dong<sup>1</sup>, R.J.H. Smith<sup>2</sup>.* 1) Affymetrix, 3380 Central Expressway, Santa Clara, CA 95051; 2) Department of Otolaryngology and Interdepartmental PhD Program in Genetics, University of Iowa, Iowa City, IA 52242.

Genome sequences are the foundation for genetic analysis including the identification and mapping of single-nucleotide polymorphisms (SNPs). Association of these polymorphisms with disease phenotypes will enable the development of more effective drugs and improved drug safety (personalized medicine). A novel SNP mapping tool together with an assay that uses a single PCR primer was developed to determine the genotype of more than 11000 SNPs in the human genome. One of the applications for this high-content, high-throughput SNP mapping tool is familial linkage analysis. We have genotyped 3 consanguineous families with deafness symptoms. Hereditary deafness affects 1:2,000 newborns and accounts for greater than 50% of severe-to-profound childhood deafness. The genotyping results from one consanguineous family with 7 members were compared to the analysis results generated using a microsatellite panel. Homozygosity by descent (HBD) analysis using 11K SNPs confirmed one of the previously identified DFNB loci on chromosome 1 and identified a novel locus on chromosome 3. Both regions generated identical lod scores of 2.82 and cover a genomic region of approximately 6 Mb. Using the Online Mendelian Inheritance in Man (OMIM) database we could not identify genes in these regions previously associated with deafness. This finding suggests that digenic inheritance is possible and shows the value of additional genotype information for uncovering undetected linked regions. This novel SNP mapping tool will overcome some of the current limitations for genetic analysis and will enable the generation of high-density genotype maps. This research was supported in part by R01-DC02842 (RJHS).

**A flexible software tool for designing and multiplexing SBE SNP assays for detection by MALDI-TOF.** *P. Boyce<sup>1</sup>, D. Brown<sup>2</sup>, J. Goldstein<sup>1</sup>, D. Witmer<sup>1</sup>, D. Hayden<sup>1</sup>, J. Pettengill<sup>1</sup>, Y. Tsai<sup>1</sup>, E. Pugh<sup>1</sup>, E. Luong<sup>3</sup>, R. Nussbaum<sup>3</sup>, K. Doheny<sup>1</sup>.* 1) Center for Inherited Disease Research, IGM, JHUSOM, Baltimore, MD; 2) University of Waterloo, ON, Canada; 3) IDR, NHGRI, NIH, Bethesda, MD.

We present a flexible software tool that allows a user to choose any number of SNPs and assay them at a chosen plex level. The software allows the user flexibility in design criteria to facilitate performance optimization. Design is based upon standard allelic discrimination by single base extension (SBE) analysis. Method: SNPs are downloaded from public databases in FASTA format, and form the input to the Perl script for PCR and SBE design. User specifiable parameters for PCR primer design include the min, max, and optimum primer size, product size and T<sub>m</sub>, as well as an exclusion region around the SNP. Parameters for SBE primer design are homopolymer, repeat, self-homology, and two base pair extension limits. The Perl script launches Primer3 (Rozen & Skaletsky, 2000), passing it these variables for the design of the PCR primers. SNPs that have PCR primers successfully designed are then automatically processed for SBE primer design. The script outputs files to allow loading of PCR primers and associated Primer3 parameter settings into an Oracle database. The script also outputs a file containing all possible SBE primers designed for each assay. This file is the input for a Python multiplexing script. The variables include plex levels, T<sub>m</sub> for the SBE primers, and minimum separation of SBE product masses. The script chooses panels of markers whose mass peaks should be well separated, and for which there is low probability of hybridization among the different products. The output file contains the panels. Results: We used the default parameters and restricted our panels to 5-plex assays. 4,524 SNPs were queued for PCR design, 69% were returned with successful primers designed. 85% of these successfully designed SBE primers. Multiplexing of the successfully designed assays resulted in 1900 assays. Genotyping these 1900 assays resulted in a median genotype success rate of 75%. This software is available by request.

**A Parallel Algorithm of GENEHUNTER on Multi-Processors.** *Y. Mase<sup>1</sup>, K. Kajitani<sup>1</sup>, N. Kamatani<sup>2</sup>, M.*

*Yanagisawa<sup>3</sup>*. 1) Department of Electronics, Information and Communication Engineering, Waseda University, Tokyo; 2) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo; 3) Department of Information and Computer Science, Waseda University, Tokyo.

GENEHUNTER requires a lot of time to analyze large pedigrees. Our purpose is to decrease the computation time of multipoint linkage analysis with larger pedigrees by parallel processing. In parallel processing, message passing is required to distribute transactions among the processors, connected to each other through LAN. The message delay significantly affects the performance. Conant et al. achieved high performance under Myrinet, the expensive network environment, but their method contains the risk that the performance would suddenly drop under the general network. We propose two parallel processing algorithms and implementation to minimize the performance reduction due to the message delay. One algorithm is concerned about the calculation of inheritance distribution. It is often possible to determine the inheritance by genotypes at marker loci, but it is impossible at uninformative loci and thus the inheritance space becomes quite larger. Inheritance distribution at uninformative loci can be calculated if the forward-backward posterior distribution at adjacent marker loci is known. After this, the calculation of posterior distribution can be done independently by each processor. The other algorithm is concerned about the calculation of score functions. We found the calculation of NPL score by Whittemore et al.'s strategy also takes a long time. This function is calculated for each considerable inheritance, so we have paralleled this part to distribute transactions evenly to each processor. In both part several parallel approach can be considered, and we have adopted the methods which minimize the message delay. We applied our algorithms to data of  $2n-f=18$ , where  $n$  denotes the number of non-founders and  $f$  denotes that of founders. When we used 16 processors, the computation time of our implementation was about 10 times faster than GENEHUNTER. Each processor is Pentium III 1GHz and they are connected with 100Mbps network.

**ldlight: A Fast Haplotype Inference Algorithm for Large-Scale Unphased Diploid Genotype Data based on EM Algorithm and Graph Theoretical Data Structure.** *K. Kajitani<sup>1</sup>, Y. Mase<sup>1</sup>, Y. Ito<sup>1</sup>, R. Sato<sup>1</sup>, N. Kamatani<sup>3</sup>, M. Yanagisawa<sup>2</sup>.* 1) Department of Electronics, Information and Communication Engineering, Waseda University, Tokyo; 2) Department of Information and Computer Science, Waseda University, Tokyo; 3) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo.

Haplotype analysis based on Linkage Disequilibrium (LD) has become an efficient tool for disease-gene discovery. The EM algorithm, one of the most popular haplotype inference methods, is considered to have high accuracy. However, it requires a lot of memory storage and running time to deal with a large number of loci. The EM algorithm needs to store inferred haplotype frequencies for all considerable haplotypes and update all the frequencies in each iteration, therefore time and memory requirement increase exponentially as the number of loci increases. It is impossible to handle haplotypes that consist of more than 30 loci. To solve this problem, explosive growth of considerable haplotypes, we present a new and fast algorithm "ldlight"; to infer diplotype configuration for large-scale unphased diploid genotype data based on the EM algorithm and graph theoretical data structure. The algorithm maintains genotype data on a graph structure (n-partite graph), where n is the number of loci. By representing all haplotypes and their frequencies implicitly on the graph structure, it attained to reduce its computational time from exponential to polynomial. We have implemented this algorithm. As a result, ldlight runs about one thousand times faster at 17 loci, with more than 5 times less storage requirement at 14 loci than an EM-based algorithm. And, nearly one hundred times faster at 50 loci than other algorithms that handle large-scale haplotypes. ldlight runs in at most 4 seconds on 6.6 MByte memory for 100 loci on a Celeron 800MHz PC. As for the accuracy, our algorithm can infer haplotype frequencies almost the same as the EM-based algorithm for studying region on human chromosome 5q31.

**Haplotype Tagging Single Nucleotide Polymorphisms and Association Studies.** *D. Thompson*<sup>1,2</sup>, *D. Stram*<sup>3</sup>, *D. Goldgar*<sup>2</sup>, *J.S. Witte*<sup>2</sup>. 1) CR-UK Genetic Epidemiology Unit, Strangeways Research Laboratory, Cambridge, United Kingdom; 2) Unit of Genetic Epidemiology, International Agency for Cancer Research, Lyon, France; 3) Department of Preventive Medicine, University of South California, Los Angeles, CA.

There is considerable evidence that discrete blocks of low haplotype diversity and high linkage disequilibrium exist within the human genome. Within such blocks, information from some single nucleotide polymorphisms (SNPs) may be redundant; the non-redundant subset of haplotype tagging SNPs (htSNPs) can distinguish the majority of the haplotypes. The genotyping effort of an association study can potentially be reduced by estimating the optimal htSNPs using a small subsample of the study population that have been genotyped for a dense SNP map, and then genotyping just these htSNPs in the remainder of the samples. We investigated by simulation how the size of the subsample affects the power of association studies, and what type of subjects it should include. We used the program tagSNPs, which selects htSNPs to minimise the uncertainty in predicting common haplotypes for individuals with unphased genotype data. We tested for an association between haplotypes and disease with conditional logistic regression, using the expected haplotype dosages in subjects as the independent variables. For a simulated candidate-gene study, an average of 27% of the SNPs were designated as htSNPs. Genotyping as few as 25 unphased individuals to select the htSNPs did not appear to reduce the power of an association study, as compared with using all SNPs. For the disease models considered, selecting htSNPs based on cases, controls, or a mixture of both gave similar results. Several different approaches have been proposed to determine htSNPs, ranging from visual inspection to formal analytical approaches. We used simulations to explore whether the different available approaches identify the same optimal htSNPs. These results suggest that the genotyping effort can be substantially reduced by identifying htSNPs in a small subsample, without significant loss of power.

**Linkage Mapping of Type 2 Diabetes Genes in Multiplex African American Families.** *S.C. Elbein<sup>1,2</sup>, W. Zheng<sup>1</sup>, X. Wang<sup>1</sup>, J.J. Cooper<sup>1</sup>, T. Hale<sup>1</sup>, Z. Zheng<sup>1</sup>, S.J. Hasstedt<sup>3</sup>*. 1) Medicine, Slot LRVA/111J-1, Univ Arkansas for Medical Sci, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR 72205; 3) Dept. of Human Genetics, University of Utah Health Sciences Center, Salt Lake City, UT.

Considerable data support a strong genetic component for type 2 diabetes (T2DM), and several regions have been mapped in Caucasian, Hispanic, and Pima Indian populations. Although the prevalence of T2DM in African Americans is 2-fold higher than Caucasians, only a single scan has been published. We used parametric and nonparametric approaches to test for linkage in 66 African American families comprising 504 individuals, including 224 available affected individuals (mean 3.41.3 per family). A genome-wide scan was conducted using microsatellite markers typed both at CIDR (390 markers) and supplemented by 100 local markers typed on a LICOR sequencer and read by SAGA software to increase density in regions of linkage from previous scans (chromosomes 1, 2, 4, 6, 10, 12, and 18). Of these markers, 41 overlapped between the scans. For overlapping regions, files were prepared using each set of markers and analyzed separately. Pedigree structure was revised to resolve paternity problems after completion of the genome scan, and linkage was analyzed using SimWalkII for nonparametric analysis and dominant and recessive parametric analyses using an age and body mass index determined penetrance function. No significant differences were seen in LOD scores between CIDR data and overlapping laboratory markers. NPL analysis detected regions of  $p < 0.01$  only on chromosome 14. Parametric location scores over 1 were seen on chromosomes 1p, 2p, 4p, 14, and 19. The most striking peak was at 50 cM on chromosome 19, where the dominant lod was 2.5. Regions from other scans, including the published African American scan, were not replicated in this study. Our parametric analysis suggests a possible susceptibility locus on the gene rich region of 19q12, although no obvious candidate genes are present. Work is in progress to place additional markers in putative regions of linkage on chromosomes 1, 2, 14, and 19.

**Localizing a Type 2 Diabetes Susceptibility Gene on Chromosome 1q21-q24 in Utah Caucasians.** *H. Wang<sup>1</sup>, W. Chu<sup>1</sup>, R.L. Craig<sup>1</sup>, S.K. Das<sup>1</sup>, Z. Zhang<sup>1</sup>, S.J. Hasstedt<sup>3</sup>, S.C. Elbein<sup>1,2</sup>*. 1) Dept of Medicine, Univ Arkansas Medical Sci, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR; 3) Department of Genetics, University of Utah Health Sciences Center, Salt Lake City, UT.

We previously mapped type 2 diabetes (T2DM) in extended families from Utah to chromosome 1q21-q24 between 164 cM and 190 cM. A dense linkage map suggested two peaks, with the largest peak (recessive LOD=5; MLS=6) corresponding to the 156 Mb to 159 Mb region. To identify genes in this region, we first collaboratively typed 580 single nucleotide polymorphisms (SNPs) over a 20 Mb region encompassing both linkage peaks in pooled samples from 100 diabetic cases and 100 controls each from Utah, Pima, and Amish family studies. We identified 91 SNPs that were tested in additional assays, of which 14 SNPs were confirmed at  $p < 0.01$ . We designed primers to type 285 total SNPs by Pyrosequencing in the region from 147 Mb to 167 Mb in 384 individual Caucasian samples, including near saturation maps in regions detected in pooled typing. SNPs were selected from a combination of published NCBI SNPs and candidate gene screening. Of these SNPs, 21 were not polymorphic, 52 assays failed, and 67 SNPs are still in progress. From 124 SNPs completed in individual samples, we identified three prominent clusters of associated SNPs ( $p < 0.05$ ). Four SNPs associated with T2DM were located near the PKLR locus (152 Mb; most significant  $p = 0.001$ ), 3 SNPs were located near CASQ1 at 156.9 Mb ( $p = 0.003$ ), and 7 SNPs were located near ATF6 at 158.4 Mb ( $p = 0.0001$ ). The associations found at 156.9 are close to those observed in Amish families, whereas the most significant associations at 158.4 Mb have not been observed in other studies. Associations at 158.4 represented at least two different haplotype blocks and thus are independent observations. Both 156.9 and 158.4 clusters lie under the largest linkage peak in this region for families in the original linkage study that did not carry HNF1 alpha variants. Work is in progress to identify haplotype blocks and to screen genes near the 158.4 cluster, and to extend a dense SNP map across the 156 Mb - 159 Mb region.

**Global distribution of a novel trinucleotide microsatellite polymorphism (ATA)<sub>n</sub> in intron 8 of the SLC11A1 gene and susceptibility to pulmonary Tuberculosis.** A. Awomoyi<sup>1,4</sup>, M. Newport<sup>2</sup>, K. McAdam<sup>3</sup>, S.A. Tishkoff<sup>1</sup>. 1) Dept of Biology, University of Maryland, College Park, MD, USA; 2) Cambridge Institute for Medical Research, Wellcome Trust /MRC Building Addenbrooke's Hospital Hills Road Cambridge, CB2 2XY, UK; 3) MRC Laboratories, Fajara, The Gambia; 4) Dept of Microbiology and Immunology, University of Maryland Baltimore, MD, USA.

Solute carrier family 11 member 1 protein (SLC11A1), formerly called NRAMP1, is a pH dependent proton/divalent cation antiporter involved in macrophage function and is thought to play an important role in susceptibility to inflammatory autoimmune disorders and to certain intracellular pathogens especially Mycobacteria, Leishmania and Salmonella species. We report a novel trinucleotide (ATA)<sub>n</sub> intron 8 polymorphism that was genotyped initially in 485 adult individuals originating from 8 different world populations; Gambia, Nigeria Tanzania, Lebanon, North Europe, Russia China and South America (including 80 Gambian cord blood samples). We compared the range of distribution of alleles of this polymorphism in Gambian cord blood obtained from infants and adult healthy controls and found no significant difference in distribution. Lastly, we determined whether this microsatellite is associated with pulmonary TB by carrying out a TB case/control study in The Gambian population (318 cases and 146 controls). We found no association between this marker and pulmonary TB cases and healthy controls in The Gambian population. This study has identified a novel trinucleotide polymorphism in intron 8 of the SLC11A1 gene in global populations. This will be a useful marker for haplotype analysis and linkage mapping studies of the SLC11A1 region and genetic susceptibility to mycobacterial infection and autoimmune disorders.

**Simple sequence variations and molecular evolution in the WFS1 gene.** *T.A. Sivakumaran<sup>1</sup>, S. Li<sup>2</sup>, J. Zhang<sup>3</sup>, M. Burmeister<sup>2,4,5</sup>, M.M. Lesperance<sup>1</sup>.* 1) Department of Otolaryngology-Head Neck Surgery; 2) Mental Health Research Institute; 3) Ecology and Evolutionary Biology; 4) Psychiatry; 5) Human Genetics, University of Michigan, Ann Arbor, MI.

While mutations in the WFS1 gene are known to cause both recessive Wolfram syndrome type I and dominant low-frequency sensorineural hearing loss, the function of the protein remains unknown. In general, Wolfram syndrome is caused by inactivating mutations, while low-frequency hearing loss is caused by dominant missense mutations in exon 8. WFS1 contains a large number of coding variants, 45% of which are non-synonymous substitutions. Most variants are in exon 8, the largest WFS1 exon. 1812 bp of coding and flanking non-coding regions of exon 8, were sequenced in 105 control individuals with known ethnicity from worldwide populations to determine population-specific sequence variations. 52 variants were identified: 20 were nonsynonymous (5 novel), 27 synonymous, and 5 intronic or small coding deletions. Most variants were rare and population-specific. To gain insight into the function of WFS1, the evolution of the DNA sequence in primates was examined. Sequencing exon 8 in 25 primate species (including great apes, old and new world monkeys, and prosimians) revealed that exon 8 was 90-99% conserved and under strong purifying selection. Although the R allele of H611R is associated with increased suicidality in bipolar patients, no positive selection was seen as both H and R appear to have evolved in parallel in mammals. The alignment of translated sequences including mouse and rat showed that the majority of the non-synonymous varying sites were highly conserved. SIFT analysis correctly predicted 65% of known mutations as deleterious, while the percent of non-synonymous substitutions predicted as tolerant were 63% and 50% for common and rare variants, respectively. The transmembrane, extracellular, and intracellular domains, including the hydrophobic C-terminal domain containing most deafness mutations, show evidence of strong purifying selection. These findings suggest that despite the abundance of non-synonymous variants, these domains hold important functions for the protein that are yet unknown.

**Gene responsible for mitochondrial myopathy and sideroblastic anemia (MSA) maps to chromosome 12q24.33.**

*K. Casas*<sup>1,3</sup>, *Y. Bykhovskaya*<sup>1,3</sup>, *E. Mengesha*<sup>1</sup>, *D. Wang*<sup>1</sup>, *H. Yang*<sup>1</sup>, *K. Taylor*<sup>1</sup>, *A. Inbal*<sup>2</sup>, *N. Fischel-Ghodsian*<sup>1</sup>. 1) Cedars-Sinai Medical Center, Ahmanson Department of Pediatrics, Steven Spielberg Pediatric Research Center, Los Angeles, CA, USA; 2) Institute of Thrombosis and Hemostasis, Sheba Medical Center, Tel Hashomer and Sackler School of Medicine, Tel Aviv University, Israel; 3) Co-first authors.

Mitochondrial myopathy and sideroblastic anemia (MSA) is a rare autosomal recessive disorder of oxidative phosphorylation and iron metabolism. Individuals with MSA present with weakness and anemia in late childhood and may become dependent on blood transfusions. Recently, we reported affected sibling pairs in two related families from a Jewish Iranian kindred living in the U.S. [Casas et al. 2003]. A genome scan and fine mapping of DNA from the two families revealed homozygous alleles in the affected individuals, and a multipoint lod score of 3.3, within 2.3 Mb of chromosome 12q24.33. Previously, [Inbal et al. 1995] described siblings with a similar clinical phenotype who lived in Israel but originated from the same Iranian town as the U.S. families. Focused analysis of DNA from the Israeli family confirmed the presence of identical, homozygous alleles in the affected of all three families within 1.2 Mb of chromosome 12q24.33. Combined multipoint linkage analysis revealed a maximum lod score of 5.41 at the 132 cM position of chromosome 12. Therefore, in three Jewish Iranian families, a disease gene for MSA maps to a 1.2 Mb region of chromosome 12q24.33. This region contains six well described genes (SFRS8, MMP17, ULK1, PUS1, EP400, and GALNT9) and at least fifteen additional putative transcripts. The known genes are expressed in multiple tissues and lack a function specific to mitochondria, making none an obvious candidate. The eventual identification of the disease gene in MSA is expected to provide insight into the tissue specificity and phenotypic variability of mitochondrial disease.

**Linkage of diabetic nephropathy to chromosome 18 in African Americans.** *C.J. Colicigno, B.I. Freedman, M.M. Sale, J.A.E. Dusel, P.J. Hicks, C.D. Langefeld, S.S. Rich, D.W. Bowden.* Center for Human Genomics, Biochemistry, Wake Forest Univ School of Med, Winston Salem, NC.

We have conducted a genome-wide search for linkage to T2DN in 214 affected sib pairs from 171 African American (AA) families (361 total subjects). Among the sibs with DN, 49 had overt DN (serum creatinine concentration > 2 mg/dl or urine albumin:creatinine ratio > 300 mg/g), and 312 had end-stage renal disease (ESRD). Median age of onset of ESRD was 17 + 9.4 years after diagnosis of diabetes. The AA diabetic subjects had a mean + SD (median) age of 59.4 + 9.1 (60) years, mean age at diabetes onset 39.2 + 10.9 (39) years, mean body mass index 30.5 + 6.9 (29.4) kg/m<sup>2</sup>. We tested for genetic linkage between T2DN and 369 polymorphic markers spanning all autosomes using GENEHUNTER-PLUS with ASM (allele sharing model). Genotyping was performed at the Center for Inherited Disease Research.

In our genome scan, strong or suggestive (LOD score > 1.0) evidence for linkage was not detected in the entire set of T2DN affected sib pairs. Subsequent analysis, stratifying on age of onset of diabetes and BMI were performed. Mean age at onset of diabetes was calculated for each sib pair. Analyses were performed by dichotomizing the data into early (below the population median of 39 years) versus late (above the median) age at diabetes onset. In the early age at diabetes-onset sib pairs, the maximum LOD score observed was 2.35 between markers D18S862 and D18S1364, in contrast to a LOD score of 0.00 in the same region for the late age at diabetes-onset group. Stratification for BMI did not reveal additional evidence of linkage.

The 18q22.3-23 region has previously been implicated as harboring type 2 diabetes associated nephropathy (T2DN) susceptibility genes in Turkish and Pima Indian families (Vardarli et al. *Kidney Int* 62:2176-83, 2002). Our results in African Americans replicate evidence for a DN locus in this region. Our results in AAs with T2DN and an early age at diabetes onset suggest that the susceptibility locus in this region may be more frequently involved in progression to ESRD in younger diabetics.

**Genome-Wide Linkage Analysis Identifies Five Candidate Gene Regions in the Cornelia de Lange Syndrome**

**(CdLS).** *L.A. Gillis<sup>1</sup>, T. Strachan<sup>2</sup>, E. Tonkin<sup>2</sup>, M. Kaur<sup>1</sup>, A. Bottani<sup>3</sup>, H.H. Li<sup>4</sup>, L.G. Jackson<sup>5</sup>, M. Devoto<sup>4</sup>, I.D. Krantz<sup>1</sup>.* 1) The Children's Hospital of Philadelphia and University of Pennsylvania School of Medicine, Philadelphia, PA; 2) University of Newcastle upon Tyne, Newcastle upon Tyne, England; 3) Geneva University Hospital, Geneva, Switzerland; 4) AI duPont Hospital for Children, Wilmington, DE; 5) Drexel University School of Medicine, Philadelphia, PA.

CdLS is a dominantly inherited syndrome characterized by typical facial features, defects of the upper extremities, gastrointestinal dysfunction, cardiac and ophthalmologic abnormalities, growth retardation, and neurodevelopmental delay. Identification of the molecular etiology remains elusive due to: 1) lack of consistent chromosomal rearrangements; 2) paucity of familial cases for linkage analysis; and 3) lack of convincing animal models. Children with dup 3q syndrome have partial phenotypic overlap, and a de novo t(3;17) has been reported in a child with CdLS.

We have identified a unique group of familial cases of CdLS and have performed a genome-wide linkage analysis. Previous haplotype analysis indicated that the dup 3q minimal critical region 3q26-q27 does not appear to be responsible for the CdLS phenotype in 9 families. Genome-wide linkage analysis with 400 fluorescently-labeled polymorphic markers at 10 cM intervals showed in this subset of families a positive lod-score 1.0 in 11 separate chromosomal regions. Linkage for all of these regions was subsequently performed on 4 additional families. Positive lod-scores were obtained in 5 regions: 2q36-2q37 (LOD 2.6); 10p12-10p13 (LOD 2.0); 14q24-14q32 (LOD 1.8); 5p13.2 (LOD 1.6); and 17p13.2 (LOD 1.2). High-resolution (1 Mb) linkage analysis of all positively linked regions is being completed in our 13 families, defining minimal critical regions from which candidate disease genes can be isolated.

**A genome-wide scan identifies novel early onset primary open angle glaucoma loci on 9q22 and 20p12. E.**

*DelBono<sup>1</sup>, J.L. Wiggs<sup>1</sup>, S. Lynch<sup>1</sup>, G. Ynagi<sup>1</sup>, M. Maselli<sup>1</sup>, J. Auguste<sup>1</sup>, J.R. Shi<sup>2</sup>, J.L. Haines<sup>2</sup>.* 1) Dept Ophthalmology, Harvard Medical School/MEEI, Boston, MA; 2) Program in Human Genetics, Vanderbilt University School of Medicine, Nashville, TN.

Glaucoma is a leading cause of blindness world-wide. The disease is characterized by a degeneration of the optic nerve that is usually associated with elevated intraocular pressure. The common form of adult onset primary open angle glaucoma is inherited as a complex trait, while the rarer early onset open angle glaucoma (JOAG) exhibits autosomal dominant inheritance. Approximately 10-20% of cases of JOAG are caused by mutations in the TIGR/Myocilin gene. We have identified 26 pedigrees affected with typical early onset primary open angle glaucoma demonstrating autosomal dominant inheritance. We sequenced the TIGR/Myocilin gene in the proband from each family and found mutations in 8 % of this population. To identify novel genes responsible for JOAG, we used families that did not have TIGR/Myocilin mutations for a genome wide screen. 198 total individuals, (105 affected) were included in this study. In this population glaucoma is defined as age of diagnosis before age 35, IOP greater than 22 mmHg in both eyes, glaucomatous optic nerve damage in both eyes, and visual field loss in at least one eye. 238 microsatellite repeat markers spaced at 10 cM intervals were analyzed for linkage assuming an autosomal dominant model, and allowing for genetic heterogeneity (Hetlods). Markers located in five regions on chromosomes 3, 5, 9, 12 and 20 demonstrated initially interesting results (Hetlod > 1.0). Additional markers located in the regions of interest were used for multipoint analysis which resulted in higher lod scores for the chromosomes 9 (Hetlod 4.1) and 20 (Hetlod 4.0). Haplotype analysis confirmed the multipoint analysis and refined the genetic intervals. These results provide evidence for two new loci for early onset primary open angle glaucoma. Evaluation of candidate genes located within these genomic regions is currently underway.

**Issues encountered in analyses confirming previous reports of linkage for dyslexia phenotypes.** *N. Chapman, R. Igo, W. Raskind, J. Thomson, V. Berninger, E. Wijsman.* Univ.of Washington, Seattle, WA.

We use Markov chain Monte Carlo (MCMC) oligogenic segregation and linkage analysis, in addition to variance components based linkage tests, in order to confirm or refute linkage of dyslexia related phenotypes to several previously reported regions of the genome, in our data set of 119 extended families. Careful analyses of a region on chromosome 15q confirm previous reports of linkage, and emphasize the importance of two issues: 1) map specification in multipoint analyses, and 2) calculation of IBD scores using available software.

Single marker analyses showed evidence of linkage of a reading phenotype to one marker in the region. We then conducted multipoint analyses, using 6 markers covering a 9 cM region (Marshfield map) around the initial signal. Several difficulties were encountered. Over such a distance, the published Marshfield map may not be accurate, and two markers were placed at the same location. Consultation of the deCode map placed a subset of the markers. For markers that were placed on both maps, the estimated interval lengths did not always agree well. These challenges led us to try several maps that were consistent with published maps, and to estimate our own from our data set. Linkage results were sensitive to the map used, and we found that the MCMC signal strength could be increased as much as two-fold by use of a slightly different map.

Components of variance were estimated using SOLAR on IBD scores calculated by both Genehunter 2.1 (GH) and Merlin, which perform exact IBD calculations for single and multiple markers. We discovered that even when it does not explicitly trim people from pedigrees, GH may not report IBD sharing for all pairs. Because SOLAR assumes that any pairs not reported share 0 alleles IBD, naively loading the IBD scores from GH into SOLAR results in an incorrect analysis. Merlin reports exact IBD sharing for all pairs in a family, and is therefore more appropriate. In our data set, using the GH scores resulted in a LOD score that was inflated by as much as 52% over those based on Merlin IBD scores.

**Genome scan of asthma and atopy-associated phenotypes in French EGEA families: What is the impact of sample selection on linkage detection?** *E. Bouzigon, M.H. Dizier, D. Torchard, I. Annesi-Maesano, C. Betard, J. Bousquet, F. Gormand, M. Guilloud-Bataille, J. Just, J. Maccario, R. Matran, F. Neukirch, M.P. Oryszczyn, E. Paty, I. Pin, D. Vervloet, J. Feingold, F. Kauffmann, M. Lathrop, F. Demenais.* INSERM EMI0006, Evry, France.

Genome-wide screens of asthma phenotypes have indicated a few consistent regions of linkage. However, the phenotypes linked to a given region differ across studies. This may be partly due to the mode of ascertainment of family samples, which may select different underlying pathways. To investigate this issue further, a genome-wide search for asthma and atopy-associated phenotypes was conducted in the whole sample of EGEA families with at least one asthmatic subject (295 families) and in a subset selected through two asthmatic sibs (110 families). The following phenotypes were considered: asthma, positive skin prick test response to 11 common allergens [SPT], Multi-RAST Phadiatop, total serum IgE levels and blood eosinophil counts [EOS]. A total of 1317 subjects were genotyped for 396 markers. Linkage was investigated by multipoint model-free methods: Maximum Likelihood Binomial approach for binary traits [asthma, SPT, Multi-RAST] and both Haseman-Elston and variance component methods for quantitative measures [IgE, EOS]. While chromosomal regions potentially linked to SPT (5p15, 13q34, 17q22), Multi-RAST (9q21) and total IgE (2q32, 12p13) were mainly found in the whole sample, linkage to EOS (3q13, 13q22) was detected in the subset having a higher proportion of asthmatics and where a potential linkage to asthma (1p33) was observed. The most significant regions were: 12p13 for IgE (LOD score = 2.07;  $p = 0.001$ ) and 17q22 for SPT (LOD = 1.96;  $p = 0.001$ ) in the total sample and 13q22 for EOS (LOD = 3.38;  $p = 0.00004$ ) in the subset. Our results suggest that the genetic determinants underlying blood eosinophil counts may be more closely related to those underlying asthma than to those predisposing to other atopy phenotypes. Identification of the clinical and epidemiological characteristics of the two analyzed samples, which may account for these results, is currently being investigated.

**A mutation of the myosin heavy chain-7 tail domain results in an autosomal dominant hyaline body myopathy.** *P. Carroll, S.N. Abu-Amero PhD, S. Bohlega FRCPC, S.M. Wakil PhD, R. Al-Omar, B. Lach FRCPC, Y. Al Sayed FRCPC, E.J. Cupler MD, B.F. Meyer PhD.* King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia.

Hyaline body myopathy (HBM) is a rare congenital myopathy with unique histopathological features. We describe HBM with autosomal dominant inheritance in a three generation Saudi family. Eight of 15 children, their mother and maternal grandmother are affected. Five of nine patients presented with non-progressive, proximal and distal weakness, no bulbar, facial or ocular weakness, but significant wasting and loss of subcutaneous fat. The other four patients showed early, progressive scapuloperoneal weakness with early loss of ambulation. Muscle biopsies showed discrete sub-sarcolemmal hyaline bodies (HB) in approximately 20% of type 1 skeletal muscle fibres. A whole genome scan of approximately 7 cM resolution and linkage analysis with GeneHunterPlus resulted in a maximum LOD score of 3.01 at D14S1280. High-density mapping surrounding the linked locus was performed with 8 additional fluorescently labeled microsatellite markers. Multipoint parametric linkage analysis showed that the linkage region with a maximum LOD score of 3.01 extended from D14S742 to D14S608 with a peak NPL score of 3.75 at D14S608. The myosin heavy chain (MYHC) genes MYH6 and MYH7 map to the region between D14S742 and D14S1280. Sequence analysis of the coding regions of MYH7 revealed an A to T transversion at nucleotide position 25596 (M57965) resulting in a histidine to leucine amino acid change at residue 1904 (H1904L). Sequencing of an additional 130 chromosomes from random normal individuals in the population showed only the wild type A nucleotide at position 25596 (M57965). Pathogenicity of the H1904L mutation most likely results from disruption of MYHC assembly.

Program Nr: 1794 from 2003 ASHG Annual Meeting

**Identifying a new gene for secundum atrial septal defect.** *J.T. Granados<sup>1</sup>, W. Mohl<sup>2</sup>, J.D. Brook<sup>1</sup>*. 1) Institute of Genetics, University of Nottingham, Nottingham; 2) Department of Cardiothoracic Surgery, University of Vienna.

Secundum atrial septal defect (SASD) is a congenital cardiac malformation characterized by an abnormal communication between the right and left atria during postnatal life. Untreated SASD can cause pulmonary overcirculation and hypertension, right heart overload and premature death. As an isolated (non-syndromic) anomaly it occurs as a multifactorial trait, although families in which it behaves as an autosomal dominant disease have been described. In some families, it has been possible to identify chromosomal intervals containing genes responsible for this phenotype. Mohl and Mayr(1) described three unrelated families with secundum atrial septal defect and found no recombination with HLA I haplotypes. The data presented in this poster represent further attempts to correlate this findings to linkage studies on the original families using microsatellite markers located in HLA region.

Reference:1)Mohl W, Mayr WR. Atrial septal defect of the secundum type and HLA. *Tissue Antigens* 10: 121-122, 1977.

**Genome-wide Scan in Multigenerational and Extended Pedigrees Segregating ADHD From a Genetic Isolate. M.**

*Arcos-Burgos<sup>1, 2</sup>, F.X. Castellanos<sup>3, 4</sup>, F. Lopera<sup>2</sup>, D. Pineda<sup>2</sup>, J.D. Palacio<sup>2</sup>, J.L. Rapoport<sup>3</sup>, K. Berg<sup>1</sup>, J. Bailey-Wilson<sup>1</sup>, M. Muenke<sup>1</sup>.* 1) NHGRI/NIH/DHHS, Bethesda, MD; 2) Neurosciences Group, University of Antioquia, Medellín, Colombia; 3) NIMH/NIH/DHHS, Bethesda, MD; 4) NYU Child Study Center, New York, NY.

Attention-deficit/hyperactivity disorder (ADHD) is a persistent syndrome characterized by difficulty in maintaining and paying attention, excessive motor activity, and impulsivity for a given developmental level. Here we present a genome-wide scan using 16 extended and multigenerational families segregating ADHD derived from a genetic isolate, the Paisa community of Antioquia, Colombia. 390 short tandem repeat markers (average spacing 9cM) were scored. Two point analysis using a parametric model revealed LOD scores higher than 2.0 in individual families at chromosomes 8p12 (D8S1477, LOD score = 3.27), 4q13.2 (D42367, LOD score = 2.54), 17q11.2 (D17S799, LOD score = 2.35) and 11q23.3 (D11S1998, LOD score = 2.18). Previous genome-wide scans have implicated regions 17p11 and 11q25, but our suggested regions on chromosomes 8 and 4 implicated in ADHD are novel. Observing LODs this high in individual families by chance is highly improbable based on the eLOD scores obtained when a non-linked marker is simulated in these pedigrees. Therefore, taking these data together with other previous reports, it is reasonable to conclude that these regions may harbor risk genes for ADHD. Additional non-parametric and multipoint analyses of these data are ongoing and will be presented. In order to define the ADHD minimal critical regions and eventually identify genes involved in ADHD, we are now in the process to perform high-resolution mapping in these regions.

**Genetic heterogeneity at the *CRYBB2* locus: negative mutational analysis of a family with dominantly inherited cataract with microcornea linked to the beta-crystallin cluster on chr22q.** *G. Billingsley*<sup>1</sup>, *C.E. Willoughby*<sup>1,2</sup>, *A.E. Shafiq*<sup>3</sup>, *S.B. Kaye*<sup>4</sup>, *A. Chandna*<sup>5</sup>, *E. Héon*<sup>1</sup>. 1) Dept of Ophthalmology and Vision Sciences, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept of Medicine, University of Liverpool, Liverpool, UK; 3) Royal Victoria Infirmary, Newcastle-upon-Tyne, UK; 4) Royal Liverpool University Hospital, Liverpool, UK; 5) Royal Liverpool Children's Hospital, Liverpool, UK.

Chain-terminating mutations in *CRYBB2* and *CRYBB1* on chromosome 22q11.2-q12.2 have been associated with autosomal dominant congenital cataracts. The Q155X mutation in exon 6 of *CRYBB2* (MIM#123620) has marked phenotypic variability producing cerulean, Coppock-like and sutural/cerulean cataracts. A G220X mutation in exon 6 of *CRYBB1* was also reported in a family with pulverulent cataract. We mapped a family with congenital nuclear cataract with microcornea to the beta-crystallin cluster on chr22q11.2. Seventeen members (11 affected and 6 unaffected) of a three generation Caucasian family from the UK had a full ocular assessment to document the phenotype. All affected individuals had congenital cataracts requiring surgery in infancy, and 10 individuals also had microcornea. The affected status (presence of cataracts) was determined before the genetic analysis. A panel of 10 candidate loci was selected for preliminary linkage analysis and genotyping was performed on a Pharmacia automated sequencer. Two-point linkage analysis used the MLINK program of the LINKAGE package v5.2. Haplotype segregation was detected with markers D22S1174, CRYB2-CA, D22S258, and D22S1144 (8.16cM). A maximum LOD score of 2.6 (theta=0) was obtained with intragenic marker CRYB2-CA. Exon 6 of *CRYBB2* and *CRYBB1*, which harbor the published chain-terminating mutations, and the complete coding sequence of *CRYBB2* showed no alterations on direct sequencing. This work further outlines the genetic heterogeneity of congenital cataracts at the 22q locus.

**Identification of a prostate cancer susceptibility locus in 37 Jewish families.** *D.M. Friedrichsen<sup>1</sup>, J.L. Stanford<sup>2</sup>, S.D. Isaacs<sup>3</sup>, M. Janer<sup>4</sup>, B-L. Chang<sup>5</sup>, K. Deutsch<sup>4</sup>, E. Gillanders<sup>6</sup>, S. Kolb<sup>2</sup>, K. Wiley<sup>3</sup>, M.D. Badzioch<sup>7</sup>, S.L. Zheng<sup>5</sup>, P.C. Walsh<sup>3</sup>, G.P. Jarvik<sup>7</sup>, L. Hood<sup>4</sup>, J.M. Trent<sup>6</sup>, W.B. Isaacs<sup>3</sup>, E.A. Ostrander<sup>1</sup>, J. Xu<sup>5</sup>.* 1) Division of Human Biology; 2) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Dept of Urology, Johns Hopkins Medical Institutions, Baltimore, MD; 4) Institute for Systems Biology, Seattle, WA; 5) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 6) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 7) Dept of Medicine, Division of Medical Genetics, University of Washington; Seattle, WA.

An estimated 220,900 men will be diagnosed with prostate cancer (PC), and 28,900 deaths will be attributed to the disease in the United States this year. Both epidemiological studies and segregation analyses confirm the existence of a genetic component to PC etiology, with an estimated 5-10% of all PC and 43% of early onset (55 years) disease being attributed to an inherited susceptibility. Statistical evidence to date argues for the existence of at least eight PC susceptibility loci. Together these loci account for the disease in less than half of the analyzed hereditary PC (HPC) families.

Ashkenazi Jews represent a well-defined homogenous population with founder mutations previously identified in other cancer susceptibility genes, i.e. *BRCA1* and *BRCA2*. A combined genome wide scan of 37 Jewish HPC families from FHCRC (17 families) and JHU (20 families) identified a region of suggestive linkage with a NPL *P* value of less than 0.01 for nine consecutive markers covering a 40.9 cM region. The maximum NPL score was 2.97 (*P* = 0.002) with a corresponding Kong and Cox Lod score of 3.18 (*P* = 0.00007). Additionally, the maximum multipoint Lod score using a dominant 11-liability class model was 2.47. Analysis is underway to identify recombinants as well as to search for an ancestral shared haplotype. These studies highlight the utility of analyzing defined sets of families with a common origin for reducing locus heterogeneity problems associated with studying complex traits.

**Investigation for the linkage to the 14q13-21 region in 15 French-Canadian families with Restless Legs**

**Syndrom.** A. Levchenko<sup>1</sup>, L. Xiong<sup>1</sup>, A. Desautels<sup>2,3</sup>, J.-B. Riviere<sup>1</sup>, G. Turecki<sup>2</sup>, J.-Y. Montplaisir<sup>3</sup>, G.A. Rouleau<sup>1</sup>. 1) Neurosciences, Montreal General Hospital Research Institute, Montreal, Quebec, Canada; 2) Psychiatry, Douglas Hospital, Montreal, Quebec, Canada; 3) Psychiatry, Sacre-Coeur Hospital, Montreal, Quebec, Canada.

1. Purpose of the study: Restless Legs Syndrome (RLS) is a common sensory-motor disorder characterized by paresthesia of the lower limbs associated with an imperative urge to move. It affects between 5 to 10% of the general population. Many studies have confirmed that a significant fraction of RLS cases are familial. Recently, a novel RLS locus on 14q13-21 was reported by Bonati MT et al in Brain 2003;126:1-8. We aim to determine if this locus is responsible for a fraction of familial RLS cases in the French-Canadian population. 2. Methods: Fifteen kindreds segregating RLS, each with at least five affected individuals, were selected for this study. Four of the microsatellite markers used by Bonati and colleagues to define the locus were typed in our kindreds. Two are within the haplotype shared by the affected members of the family they described - D14S301 and D14S266. Two others are the flanking markers for the candidate region, i.e. D14S70 and D14S1068. Two-point LOD scores were calculated in all families by MLINK (LINKAGE software package), applying the same parameters as in Bonati et al. 3. Results: Only one family presented possible linkage to the markers D14S266 and D14S1068, with maximum LOD score of 1.18 at  $\theta = 0$  for both. The estimated maximum LOD score for this family is 1.5. In the majority of the other families, linkage to the markers D14S301 and D14S266 could not be totally excluded because the shared alleles were also the most common in the general population. Given the high frequency of the disorder in the general population, one cannot exclude an involvement of a common allele in etiology of RLS. 4. Conclusion: Further investigation of this locus is being undertaken using additional microsatellite markers within the described region. This will allow either definitive exclusion of the linkage to that locus in the French-Canadian population or a confirmation of the linkage in at least one family.

**A new locus for non-syndromic autosomal dominant congenital cataract on chromosome 19.** *Vanita. Kumar<sup>1</sup>, D. Singh<sup>2</sup>, HC. Hennies<sup>3</sup>, K. Sperling<sup>4</sup>, JR. Singh<sup>1</sup>.* 1) Centre for Genetic Disorders, Guru Nanak Dev University, Amritsar, Punjab, India; 2) Dr. Daljit Singh Eye Hospital, Sheranwala Gate, Amritsar, Punjab, India; 3) Dept. of Molecular Genetics and Gene Mapping Centre, Max-Delbrueck-Centrum Berlin-Buch, Robert-Roessle-Str. 10, 13125, Berlin; 4) Institute of Human Genetics, Charite Campus Virchow-Klinikum, Augustenburger Platz 1, D-13353, Berlin.

Purpose: To localize and identify the responsible gene for non-syndromic autosomal dominant congenital cataract (ADCC) in an Indian family. Methods: Genome-wide linkage analysis using more than 400 highly polymorphic fluorescently labeled microsatellite markers was carried out in an ADCC family having 15 members in 4-generations as affected with sutural cataract. Genotyping was done on automated DNA sequencer MegaBACE 1000 with Genetic Profiler v. 1.5 software. 2-point and multipoint linkage analysis were performed by means of the program packages linkage v.5.2, Genehunter v.2.1 and simwalk2 v.2.82. Results: In a genome-wide search positive 2-point lod scores greater than 3.0 were obtained with markers on chromosome 19 at 19q13.3. 2-point linkage data at this region was further supported by multipoint lod scores and haplotype analysis. Conclusion: The present linkage data maps a new locus for non-syndromic autosomal dominant congenital cataract at 19q13.3. It further supports the genetic heterogeneity observed for ADCC. Mutation screening in candidate genes at 19q13.3 to identify the molecular defect for sutural cataract in present family is in progress.

**Serotonin 2A receptor (HTR2A) gene polymorphisms: association and linkage with schizophrenia and schizoaffective disorder.** *V. Nimgaonkar, H. Mansour, J. Wood, T. Logue, A. Johnson, K. Chowdari.* Departments of Psychiatry and Human Genetics, University of Pittsburgh School of Medicine, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania, USA.

Several studies have documented an association of schizophrenia with T102C (rs6313), an exonic single nucleotide polymorphism (SNP) of HT2A. However, the association has not been consistently documented. Associations with HT2A SNPs have also been reported for bipolar disorder by several groups, including ours (Ranade et al, in press). To our knowledge, an association with schizoaffective disorder has not been reported. To explore this possibility, we have analyzed 332 Caucasian probands with schizophrenia or schizoaffective disorder (DSM IV criteria). Both parents of 152 patients were also available. Cord blood samples from local live births served as unrelated, unscreened controls (n =274). The putative association with T102C may reflect a primary association with a neighboring polymorphism. Therefore, we have investigated eight SNPs, comprising 4 located at HT2A exons and 4 flanking polymorphisms. In view of artifacts introduced by case-control association studies, we have also utilized the Transmission Disequilibrium Test (TDT). In the schizoaffective group, we detected a significant association at SNP rs6314 using the TDT. Associations at the haplotype level were present using both case-control and TDT analyses. They generally coincided with the haplotypes associated in our earlier bipolar samples. Significant associations were detectable in the schizophrenia sample at rs 1360020 and with related haplotypes using case-control comparisons. Significant TDT results were not observed for the schizophrenia sample. We suggest that associations with HT2A are present across the spectrum of psychoses, but the associated SNPs may vary. This may help explain the discrepancies in the prior studies.

**Haplotype Analysis in Autosomal Recessive Polycystic Kidney Disease (ARPKD) Families and The Determination of Allele Frequencies of Used Markers in The Turkish Population.** *S. Kantarci*<sup>1, 2</sup>, *M.Y. Apak*<sup>3</sup>, *S. Eraslan*<sup>2</sup>, *A. Nayir*<sup>4</sup>, *H. Kayserili*<sup>3</sup>, *B. Kirdar*<sup>5</sup>. 1) Cancer Genome Research Ctr, Cold Spring Harbor Lab, Woodbury, NY; 2) Division of Molecular Genetics, Düzen Laboratories, Istanbul, Turkey; 3) Dpt. of School Medical Genetics, Istanbul University, Istanbul, Turkey; 4) Dpt. of Pediatric Nephrology, Istanbul University, Istanbul, Turkey; 5) Dpt. of Chemical Engineering, Bogazici University, Istanbul, Turkey.

Autosomal recessive polycystic kidney disease (ARPKD) is one of the most important inherited renal diseases with effects on both kidney and liver and causes morbidity and mortality in childhood. The responsible gene, PKHD1, was localized to a 1 cM genetic interval flanked by the D6S1714 (telomeric) and D6S1024 (centromeric) markers on chromosome 6p21.1-p12. Recently, the gene which extends over 469 kb, has been identified. The mutations which cause ARPKD have been found to be scattered throughout the genes 67 exons without evidence of clustering at specific sites. To determine the frequencies of commonly used markers in the Turkish population, we analyzed 200 unrelated chromosomes in the normal population. D6S465, D6S1714, D6S1024 and D6S466 have been identified to have 7, 9, 5 and 9 alleles with a maximum heterozygosity frequency of 0.5900, 0.600, 0.6900 and 0.6900 respectively. Our studies included 20 families with a total of 23 children with ARPKD. Parental consanguinity was present in 12 families. All families analyzed were informative for at least one marker with the exception of the paternal haplotype in one family. Recombination events were detected between D6S1024 and D6S466 in 4 families. A total of 3 prenatal analyses have been performed. Prenatal diagnosis using fetal sonography is of poor reliability, especially in early pregnancy. Haplotype based analysis for prenatal diagnosis is feasible and reliable method in ARPKD families with an unknown mutation.

**Association between asthma in the Japanese population and genes around TNF gene.** *O. Migita*<sup>1</sup>, *E. Noguchi*<sup>1</sup>, *M. Shibasaki*<sup>2</sup>, *K. Ichikawa*<sup>3, 4</sup>, *A. Matsui*<sup>3</sup>, *T. Arinami*<sup>1</sup>. 1) Department of Medical Genetics, University of Tsukuba, Tsukuba city, Ibaraki, JAPAN; 2) Department of Pediatrics, Tsukuba College of Technology, Tsukuba city, Ibaraki, JAPAN; 3) Department of Pediatrics, University of Tsukuba, Tsukuba city, Ibaraki, JAPAN; 4) Department of Pediatrics, Tsukuba Medical Center Hospital, Tsukuba city, Ibaraki, JAPAN.

Tumor necrosis factor (TNF) is a proinflammatory cytokine that participates in the inflammatory reaction in patients with asthma and located within the region encoding the human major histocompatibility complex on chromosome 6p21.3, which showed linkage to atopic asthma in several genome-wide searches for asthma. Previously, we reported that TNF or nearby gene(s) may contribute to the development of asthma. We screened for mutations in the coding regions and promoter regions of BAT1, BAT2, LTA and LTB genes, which is located around TNF gene, in 16 Japanese asthmatics. To determine whether polymorphisms in these genes are associated with the development of asthma, we performed transmission disequilibrium tests of families identified through children with atopic asthma. Genotypes of families were determined by polymerase chain reaction-based restriction fragment length polymorphism, SNaPshot analysis, or direct sequencing method. Transmission disequilibrium tests of 137 asthmatic families revealed that transmission of the -293G allele in the *LTA* and the *LTA*-293G/ *TNF*-1031T/-863C/-857C haplotype to asthma-affected offspring occurred more frequently than expected (-293G allele in the *LTA* gene,  $p = 0.0007$ ; *LTA*293G/*TNF*-1031T/-863C/-857C haplotype,  $p = 0.0001$ ). Our results indicate that the *LTA* 293G/A polymorphism and the *LTA* 293G *TNF* -1031T -863C -857C haplotype may be involved in the development of asthma in the Japanese population.

**Celiac disease is associated to a haplotype on 5q in Scandinavian families.** A.T. Naluai<sup>1</sup>, S. Adamović<sup>1</sup>, A.S. Louka<sup>3</sup>, S. Nilsson<sup>2</sup>, B. Talseth<sup>3</sup>, A.H. Gudjónsdóttir<sup>1</sup>, H. Ascher<sup>1</sup>, J. Ek<sup>4</sup>, L. Samuelsson<sup>1</sup>, L.M. Sollid<sup>3</sup>, J. Wahlström<sup>1</sup>. 1) Clinical Genetics and Pediatrics, Gothenburg, Sweden; 2) Chalmers University of Technology, Gothenburg, Sweden; 3) Inst. of Immunology, Oslo, Norway; 4) Childrens Hospital, Buskerud, Norway.

*Purpose:* To identify the genetic variation or haplotype in our celiac families, that is the underlying cause of linkage to 5q31-33. *Introduction:* Gluten-induced autoimmune disease (GIAD) is among the most common autoimmune diseases in humans. It has features, which make this disease a natural experimental model for other autoimmune diseases.

1. The causative offending agent is known (gluten) and is removable in vivo (by a gluten-free diet).
2. The mandatory HLA genetic component is well known (HLA DQ2-DQ8).
3. The main self-antigen has been recently identified (Human Tissue Transglutaminase ).

*Methods:* We have a well-defined Scandinavian family material consisting of 104 multiplex and 225 simplex families, "trios". Genetic markers are typed using an ABI 3100 Genetic Analyzer and the SNaP-shot kit (ABI). For statistical analysis we use mainly Allegro. *Results:* We obtained strong evidence of linkage to celiac disease (P-value<0.00002) in the region of 5q31-33. A 90% confidence interval has been estimated between markers D5S414 and D5S820 covering 18cM. Starting in the 50% confidence interval (4cM), we have gone further typing a high density of single nucleotide polymorphisms (SNPs). An efficient approach is to combine family-based linkage analysis and association studies. We tested for association in the presence of linkage by the TDT. We located a haplotype, which shows association to the disease (P-value<0.001). Confirmation using various functional genomic approaches will be the next step. Identification of the DNA-variation behind the linkage and association at this locus will give new insight into the cause and development of disease.

**Linkage and association study of allergic asthma with a STAT6 gene polymorphism in a sample of the Italian population.** *G. Malerba<sup>1</sup>, E. Trabetti<sup>1</sup>, R. Galavotti<sup>1</sup>, L. Xumerle<sup>1</sup>, L. Pescollderunn<sup>2</sup>, A.L. Boner<sup>1</sup>, P.F. Pignatti<sup>1</sup>.* 1) Mother-Child & Biol, Genetics, Univ Verona, Verona, Italy; 2) Hospital of Bolzano, Bolzano, Italy.

Several studies reported linkage of chromosome 12 DNA markers with asthma or asthma-associated phenotypes in several populations. Linkage was described either in genome scans or in specific studies of chromosome 12 single regions. Previously we reported linkage of some chromosome 12 DNA markers with allergic asthma in a group of Italian asthmatic families (*Am J Respir Crit Care Med.* 2000. 162: 1587-90). A candidate gene which maps close to the linked region is the Signal Transducer and Activator of Transcription 6 (STAT6) gene. The individuals of the asthmatic families have been genotyped for an intronic biallelic marker of STAT6. The observed frequency of the less frequent allele in the founders was 0.37 and the observed genotype distribution fitted the expected one (Hardy-Weinberg  $\chi^2$ -test=0.07,  $p=0.9$ ). Non parametric linkage analysis did not show a significant value ( $p=0.39$ , simwalk2 program). The transmission disequilibrium test did not show any preferential allele transmission to asthmatic individuals ( $\chi^2$ -test=0.006,  $p=0.9$ , transmit program). These results suggest that STAT6 is not the major susceptibility gene mapping in the previously reported chromosomal region.

**Evidence for an X-linked gene involved in developmental dyslexia.** *F.A. Hol<sup>1,2</sup>, C.G.F. de Kovel<sup>1,2</sup>, J.G.A.M. Heister<sup>1</sup>, J. Willemen<sup>1</sup>, L.A. Sandkuijl<sup>3</sup>, G.W. Padberg<sup>2</sup>.* 1) Department of Human Genetics, University Medical Centre, Nijmegen, The Netherlands; 2) Department of Neurology, University Medical Centre, Nijmegen, The Netherlands; 3) Department Medical Statistics and Bio-Informatics, Leiden University Medical Centre, The Netherlands.

As part of a larger study into the causes of developmental dyslexia, we recruited a three-generation family that reported to have a high proportion of dyslexics among its members. We carried out a genome-wide parametric linkage study to identify the risk locus for this family.

To standardise phenotyping, we administered two reading tests (real words and nonsense words) to all subjects, as well as a so-called verbal competence test. Subjects were labelled dyslexic if they scored low on either one or both reading tests, but also when there was a large discrepancy between reading ability and verbal competence.

Using this compound phenotype we found convincing evidence for a locus on the X-chromosome near marker DXS8043 in Xq27.3 influencing the dyslexia phenotype in this family (multipoint LOD 3.68). We consider this locus co-dominant rather than recessive. In the four carrier males, the risk haplotype was associated with very low reading ability. Although designated affected according to our criteria the phenotype in the nine carrier females was much more variable.

Two key recombinants allowed us to narrow down the region to an 8 cM interval, encompassing band Xq27.3 and small parts of flanking bands. This region contains eight confirmed genes, among which FMR1, the fragile X mental retardation gene, and about 30 predicted genes.

Analysis of 66 affected male sib-pairs and their mothers showed no evidence for contribution of this locus to the risk for dyslexia in the general Dutch population.

**Fine mapping of 10q and 18q for Familial Alzheimer Disease among Caribbean Hispanics.** *J.H. Lee<sup>1,2,3</sup>, R. Mayeux<sup>1,2,3,4</sup>, D. Mayo<sup>5</sup>, V. Santana<sup>2</sup>, J. Williamson<sup>1</sup>, A. Flaquer<sup>1</sup>, A. Ciappa<sup>6</sup>, H. Rondon<sup>7</sup>, P. Estevez<sup>2</sup>, R. Lantigua<sup>8</sup>, M. Medrano<sup>9</sup>, M. Torres<sup>7</sup>, Y. Stern<sup>1,2,4</sup>, B. Tycko<sup>1,6</sup>, J.A. Knowles<sup>5</sup>.* 1) Taub Inst on Alzheimer's Disease and the Aging Brain; 2) Sergievsky Center; 3) Dept of Epidemiology; 4) Dept of Neurology; 5) Columbia Genome Center; 6) Dept of Pathology; 7) Plaza de la Salud Hospital, Santo Domingo, DR; 8) Dept of Medicine; 9) Universidad Tecnologica de Santiago, Santiago, DR.

The genetic basis of familial Alzheimer disease (AD [MIM 104300]) has been a focus of intense investigation, primarily in families of Europeans and Americans of European origin. Although late Alzheimer disease has been linked to regions on chromosomes 10q and 12p, no gene has been identified. Using a unique cohort of Caribbean Hispanic families, we screened the genome using 340 markers on 490 family members from 96 families with predominantly late-onset Alzheimer disease. We observed the strongest support for linkage on 18q (LOD=3.14). However, 17 additional markers (chromosomes 1, 2, 3, 4, 5, 6, 8, 10, 12, and 14) exceeded a two-point LOD score of 1.0 under the affecteds-only autosomal dominant model or affected sibpair models. Based on these results and those of other investigators, fine mapping efforts subsequently focused on the to candidate regions 10q, 12p and 18q. We previously reported the fine mapping effort on 12p showing modest evidence of linkage. To fine map 10q and 18q, we used 521 family members from 104 Caribbean Hispanic families. With additional markers, the evidence for linkage at 10q (134-138 cM) decreased from a NPL score of 3.15 ( $p=0.000486$ ) to 2.1 ( $p=0.0218$ ), but two broad peaks remained overlapping with previously reported peaks. In contrast, the evidence for linkage for 18q strengthened near 107 cM with additional markers, where the 2-point LOD score for D18S541 was 3.37 and the NPL score was 3.68 ( $p=0.000159$ ). This narrow region contains a small number of genes expressed in brain. Our results provide modest support for linkage on 10q in this cohort of Caribbean Hispanic families with familial Alzheimer disease, and strong evidence for a new locus on 18q.

**Linkage Study of Familial Mesial Temporal Lobe Epilepsy: a Progress Report.** *C.V. Maurer-Morelli<sup>1</sup>, N.F. Santos<sup>1</sup>, R. Secolin<sup>1</sup>, R.B. Marchesini<sup>1</sup>, E. Kobayashi<sup>2</sup>, F. Cendes<sup>2</sup>, I. Lopes-Cendes<sup>1</sup>.* 1) Department of Medical Genetics, UNICAMP, Campinas, Sao Paulo, Brazil; 2) Department of Neurology, UNICAMP, Campinas, Sao Paulo, Brazil.

**Purpose:** Recently, we have described a large group of families segregating familial mesial temporal lobe epilepsy (FMTLE). Pedigrees analysis suggest an autosomal dominant inheritance. The objectives of this study is to carry out linkage studies in FMTLE. **Methods:** We studied 53 unrelated families segregating FMTLE. Among these families we have identified two kindreds that are significantly informative for linkage analysis: F-10 and F-26. A total of 57 individuals, including 32 patients were analyzed in this study. DNA was extracted from blood samples from all available families members. A total of 297 polymorphic dinucleotide repeat markers were chosen, using a polymorphism information content (PIC) 0.75%. The screening was performed by PCR amplification. Two-point lod scores (Z) were calculated for each family separately using the LINKAGE package. The region is considered excluded when Z -2 and Z 3 indicates positive linkage. **Results:** Simulation analysis for the two kindreds (F-10 and F-26) indicate a Z<sub>max</sub> of 8.9, 4.5 and 4.4 respectively. To date, we have genotyped 188 markers. The two Brazilian families segregating FMTLE had significant negative lod score for 129 markers, ranging from -2.00 to -10.87 at different recombination fractions. However, 59 markers were non-informative with lod-scores ranging from -1.98 to 1.91 at different recombination fractions. **Conclusion:** By linkage studies we can confirm or exclude genetic linkage between selected markers and disease *loci*. The genotyped markers covered 63% of the genome and significantly excluded about 44% of the human genome. Although the two families selected for the initial study are very informative for linkage, we had 31% of non-informative results with the highly polymorphic markers tested. This results emphasizes the high risk of a genome-wide search by linkage analysis, even in the presence of a good family material. Supported by FAPESP.

**A Second-generation genome scan for human obesity reveals linkage on 12q23-24.** *WD. Li<sup>1</sup>, C. Dong<sup>1</sup>, D. Li<sup>1</sup>, H. Zhao<sup>2</sup>, R.A. Price<sup>1</sup>.* 1) Dept Psychiatry, BehavioralGen, Univ Pennsylvania Medical Ctr, Philadelphia, PA; 2) Departments of Epidemiology and Public Health, Yale University, School of Medicine, New Haven, CT.

A total of 30 genome scans (including our first genome scan) have been completed for obesity and related phenotypes, with more than 150 reports of linkage to more than 70 regions. However, many reports were based on small sample sizes, and few of the many reports reached genome-wide levels of significance. Here we report significant linkage from a scan of a large sample segregating extreme obesity and normal weight. We have used 382 microsatellite markers in 1,297 individuals from 260 European American families. We conducted nonparametric linkage (NPL) analyses for dichotomous body mass index (BMI, using BMI27kg/m<sup>2</sup>, BMI30kg/m<sup>2</sup>, BMI35kg/m<sup>2</sup>, and BMI40kg/m<sup>2</sup>) using GENEHUNTER. We also analyzed quantitative traits (BMI, %fat, and waist circumference) by the family regression method using MERLIN\_regress. We found evidence for linkage on chromosome 12 (125 cM, D12S2070, LOD=3.79, p=0.00001 for %fat; LOD=2.98, p=0.0001 for BMI; LOD=2.86, p=0.00014 for waist circumference), chromosome 21 (58 cM, D21S1446, LOD=4.27, p=0.00001 for %fat), and chromosome 13 (83 cM, D13S779, LOD=2.82, p=0.0002 for BMI, LOD=1.80, p=0.002 for waist circumference) by family regression analyses. We also obtained suggestive linkages on chromosomes 3, 7, 8, 9, 12, and 13 for discrete BMI by GENEHUNTER. Adding 3 additional markers to the intervals flanking the chromosome 12 peak yielded a LOD score of 4.08 (p=0.00001) for %fat at 116 cM and LOD scores of 3.57 (p=0.00003) and 3.05 (p=0.00009) for BMI and waist circumferences, respectively, at 125 cM. Our results suggest multiple loci that could influence obesity; particularly a locus in chromosome region 12q23-24.

**Genome Scan for Loci in Multiplex Nonsyndromic Cleft Lip Families from Colombia and Ohio.** *L. Moreno<sup>1</sup>, M. Arcos-Burgos<sup>2</sup>, M. Marazita<sup>3,4</sup>, M.E. Cooper<sup>4</sup>, T. Goldstein<sup>4</sup>, K. Krahn<sup>1</sup>, C. Valencia<sup>5</sup>, A.C. Lidral<sup>1</sup>.* 1) Dept. of Orthodontics and Dows Institute of Dental Research, Univ. of Iowa, Iowa City, IA; 2) Dept. of Biology, Univ. of Antioquia, Medellin, Colombia; 3) Center for Craniofacial and Dental Genetics Division of Oral Biology, School of Dental Medicine Univ. of Pittsburgh, PA; 4) Dept. of Human Genetics School of Public Health, Univ. of Pittsburgh, PA; 5) College of Dentistry, Univ. of Antioquia, Medellin, Colombia, SA.

Introduction: Nonsyndromic cleft lip with or without palate (CL/P) is a common, genetically complex birth defect. Previous human studies are contradictory, suggesting that population heterogeneity may exist. To date two genome-wide scans for CL/P have been reported revealing evidence for linkage to over 12 different loci (Prescott et al. 2000, Marazita et al., 2002). The purpose of this study is to complete a 10 cM genome-wide scan in 48 families from Colombia-SA and 9 families from Ohio. Methods: Single point (MLINK) and multipoint (SIMWALK) linkage analyses were performed using parametric dominant and recessive models. Results: Preliminary results in the Colombian and Ohio data set showed evidence of linkage for the following loci:

COLOMBIA	3q27	9q22	14q23	15p12	19q13			
MLS	2.99	2.94	2.29	2.78	1.72			
OHIO	1p22	3p14	9q33	10q25	12q24	14q11	17q11	18q12
MLS	3.52	1.73	1.6	1.52	2.36	1.76	1.77	1.23

Conclusions: 7 loci previously identified as having a role in CL/P have been replicated in this study. Furthermore, 6 new loci have been identified confirming population heterogeneity. Efforts are ongoing to complete nonparametric linkage and association analyses in both data sets.

**A Genome-scan for bipolar susceptibility loci among Ashkenazi Jewish families.** *V. Lasseter<sup>1</sup>, M.D. Fallin<sup>2</sup>, P.S. Wolyniec<sup>1</sup>, J.A. McGrath<sup>1</sup>, G. Nestadt<sup>1</sup>, KY. Liang<sup>3</sup>, A.E. Pulver<sup>1</sup>.* 1) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) Dept of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 3) Dept of Biostatistics, Johns Hopkins School of Public Health, Baltimore, MD.

Previous linkage studies in bipolar disorder have been discouraging due to inconsistent findings, small data sets and weak signals. Many of these inconsistencies are likely due to genetic heterogeneity. With this in mind, we have recruited families of Ashkenazi descent in hopes of reducing heterogeneity between families to increase the potential to detect a linkage signal to a particular locus. We have now completed a 10cM autosomal genome-wide linkage scan (382 markers) in 22 multiplex families with a bipolar I phenotype and an additional set of 19 families with bipolar I and bipolar II individuals (41 total). We present results for both allele-sharing and parametric linkage analyses as implemented in Genehunter V2.0, with genome-wide significance levels calculated using simulation.

**A genome wide scan for hypertriglyceridemia loci in a large Icelandic cohort maps a gene to chromosome 10p.** A. Helgadóttir<sup>1</sup>, B. Thorsson<sup>2</sup>, G. Thorleifsson<sup>1</sup>, G. Sigurdsson<sup>2</sup>, J. Gulcher<sup>1</sup>, V. Gudnason<sup>2</sup>, K. Stefansson<sup>1</sup>. 1) Dept Cardiovascular, Decode Genetics, Reykjavik, Iceland; 2) The Icelandic Heart Association, Reykjavik, Iceland.

Hyperlipidemia is a major risk factor for cardiovascular diseases. It constitutes a group of complex disorders that have largely unknown etiology, except in rare cases of Mendelian disorders such as familial hypercholesterolemia. To examine the complex nature of hyperlipidemia, a large population-based genetics study of hyperlipidemia (i.e., high fasting cholesterol and/or triglycerides) is being conducted in Iceland with the primary goal of identifying susceptibility genes for hyperlipidemia. Here we report the results from a genome wide scan for a large cohort of families with hypertriglyceridemia. Blood samples from over 1600 Icelandic individuals with hypertriglyceridemia (>85th percentile in serum fasting triglycerides), and over 4000 of their first degree relatives, have been collected and genotyped for this study. Comprehensive phenotypic information, including the presence of other known cardiovascular risk factors, fasting serum lipids, body mass index, waist-and hip circumference, bioimpedance, serum glucose, liver function tests and blood pressure measurements were obtained for all participants. An encrypted genealogy database that covers the entire Icelandic nation was used to cluster 1584 hypertriglyceridemia patients into families. A genome wide scan, using over 1000 microsatellite markers, was performed both on the cohort as a whole and after stratifying the patients on covariates such as sex and BMI. A linkage analysis on 212 non-obese (BMI < 30) male patients uncovered a locus with a lod score of 3.7 on chr 10p. In addition, loci suggestive of linkage (i.e., lod scores 2.2-3.5) were observed on chr 3q, 7q, 8q(a), 8q(b), and 17q. We conclude that we have mapped a gene for hypertriglyceridemia on chr10p and identified multiple loci demonstrating suggestive linkage to the various sub-phenotypes of hyperlipidemia.

**Fine mapping of the Schnyder's Crystalline Corneal Dystrophy.** *V.P. Theendakara<sup>1</sup>, G. Tromp<sup>1</sup>, H. Kuivaniemi<sup>1, 2</sup>, P.S. White<sup>5, 6</sup>, S. Panchal<sup>1, 3, 4</sup>, R.S. Winters<sup>5</sup>, P. Riebeling<sup>7</sup>, F. Tost<sup>7</sup>, M. Hoeltzenbein<sup>8</sup>, T. Tervo<sup>9</sup>, J.S. Weiss<sup>3, 4</sup>.* 1) Center for Molecular Medicine and Genetics, Wayne State University School of Medicine, Detroit, MI; 2) Department of Surgery, Wayne State University School of Medicine, Detroit, MI; 3) Department of Ophthalmology, Wayne State University School of Medicine, Detroit, MI; 4) Kresge Eye Institute, Wayne State University School of Medicine, Detroit, MI; 5) Division of Oncology, Children's Hospital of Philadelphia, University of Pennsylvania, PA; 6) Department of Pediatrics, University of Pennsylvania, PA; 7) Augenklinik der Universität Greifswald, Germany; 8) Max-Planck-Institut für Molekulare Genetik, Berlin, Germany; 9) Helsinki University Eye Hospital, Helsinki, Finland.

Schnyder's crystalline corneal dystrophy (SCCD) is a rare autosomal dominant eye disease characterized by corneal clouding, and arcus lipoides, crystalline cholesterol deposition in the anterior corneal stroma, or both. The abnormal deposition of cholesterol in the cornea is postulated to result from a local abnormality of lipid metabolism. A genome-wide scan with 2 large Swede-Finn families previously mapped the SCCD locus to 1p34-p36 (Shearman et al. *Hum Mol Genet* 5:1667-1672, 1996). We recruited 9 new families and carried out fine mapping of the region by analyzing additional markers. Somatic cell hybrids of affected individuals were generated to aid in constructing haplotypes. Haplotype analysis based on recombination refined the candidate interval to a 2.9 Mbp region between markers D1S1612 and D1S1635. The region contains many genes relevant to lipid metabolism and those expressed in the anterior segment of the eye, such as ENO1, PGD, PEX14, KIF1B, SSB1, CLSTN1 and DFF1. We plan to investigate these loci as positional candidates for SCCD.

Program Nr: 1813 from 2003 ASHG Annual Meeting

**High density SNP linkage panel for human genetic studies.** *S.H. Shaw, R. Shen, C. McBride, M. Chee, A. Oliphant, M. Hansen.* Illumina, Inc., San Diego, CA.

The use of single nucleotide polymorphisms (SNPs) in genetic studies is advantageous because of their abundance in the genome and the ability to use highly automated, high throughput technologies for genotyping. We have developed a high throughput SNP genotyping system based on miniaturized arrays of beads located on the ends of optical fiber bundles. The throughput of the system is about 1 million genotypes per day, and is scalable to higher levels. The assay is highly multiplexed, and genotyping calls are made automatically. Each call is assigned a quantitative score that reflects quality.

We have constructed a panel of SNPs for genome-wide linkage studies. Loci for the linkage panel were selected based on high minor allele frequency, uniform distribution throughout the genome, assay validation on our genotyping platform, and high confidence in genotyping calls. The linkage panel is comprised of approximately 4600 loci. The average minor allele frequency (MAF) for these SNPs in a Caucasian population was 0.39 with all loci having a MAF >0.10 and >80% of all loci having a MAF >0.30. The mean physical distance between each locus was 624 kb. We have constructed a genetic map using genotype data from a series of 28 CEPH pedigrees (504 meioses). All loci have consistent map order with the physical map (build 33 genome assembly). Of the approximately 4600 loci, 53% mapped to unique positions on the genetic map, and 79% of the unique map intervals were mapped with high confidence (>1000:1). The mean genetic map interval is 1.4 cM. In addition, relative information content was computed using a subset of 8 CEPH reference pedigrees for comparison to other widely used simple tandem repeat (STR) marker panels. The average information content for all autosomes was 0.95 (range: 0.81-0.99) and is higher than the 5- and 10-cM STR marker panels tested (ABI v2.5 5- and 10-cM, Marshfield v10 10-cM). This SNP linkage panel provides rapid, accurate, and highly informative genetic data for genome-wide linkage studies.

**Search for Finnish prostate cancer predisposition loci - Fine-mapping of chromosome 3p25-p26 and 11q14.** A. Rokman<sup>1</sup>, A. Baffoe-Bonnie<sup>2,3</sup>, E. Gillanders<sup>3</sup>, K.D. Gibbs Jr.<sup>3</sup>, T. Ikonen<sup>1</sup>, M.P. Jones<sup>3</sup>, D. Gildea<sup>3</sup>, D. Freas-Lutz<sup>3</sup>, C. Markey<sup>3</sup>, M.P. Matikainen<sup>4</sup>, P.A. Koivisto<sup>5</sup>, T.L.J. Tammela<sup>4</sup>, O.P. Kallioniemi<sup>6</sup>, J. Trent<sup>7</sup>, J.E. Bailey-Wilson<sup>3</sup>, J. Schleutker<sup>1</sup>. 1) Lab. of Cancer Genetics, Inst. of Medical Technology, Univ. of Tampere and Tampere Univ. Hospital, Tampere, Finland; 2) Div. of Population Science, Fox Chase Cancer Center, Philadelphia, PA 19111, USA; 3) National Human Genome Research Inst., National Inst. of Health, Bethesda, MD 20892, USA; 4) Div. of Urology, Tampere Univ. Hospital, Tampere, Finland; 6) Medical Biotechnology Group, VTT- State Technology Research Center, Turku, Finland; 7) Translational Genomics Research Inst., Phoenix, AZ 85004, USA.

Only a few genes have been identified in the search for prostate cancer (PRCA) susceptibility genes probably due to difficulties raised by the late age at onset, heterogeneity and common nature of the disease. Such a complex disease can be more effectively studied in a homogenous population like in Finland. Recently, a genome wide linkage analysis based on ten multiplex Finnish PRCA families using 413 microsatellite markers was conducted. In that study, positivity was not found in the previously published PRCA predisposing loci. Instead, previously undescribed loci on 3p25-p26 and 11q14, seemed to be most important, with corresponding two-point LOD scores of 2.63 (= 0.01) and 2.99 (= 0.0), and non-parametric NPL scores of 2.27 (p = 0.02) and 2.66 (p = 0.008), respectively. In this study we proceeded to the fine-mapping phase using 39 markers (17 for chromosome 3 and 22 for chromosome 11), which covered the critical areas with 0.1-1.0 cM intervals. Six additional families were included in the analyses, making the total number of families 16. All families were defined as having three or more affected members with at least two sampled affected cases. Altogether 238 DNA samples, including 49 affected cases, were genotyped. The preliminary results strengthen the role of these two chromosomal regions in the PRCA predisposition in Finland.

**Coarse face, dysostosis multiplex, progressive laryngeal obstruction, and severe psychomotor retardation - a new type of autosomal recessive storage-like disease maps to chromosome 1q32.3.** *R. Shenhav<sup>1</sup>, V. Drasinover<sup>1,2</sup>, N. Magal<sup>1,2</sup>, A. Raas-Rothschild<sup>3</sup>, L. Basel-Vanagaite<sup>1</sup>, G.J. Halpern<sup>1</sup>, T. Shohat<sup>4</sup>, M. Shohat<sup>1,2,5</sup>.* 1) Medical Genetics, Rabin Med Center, Petah Tikva, Israel; 2) Felsenstein Medical Research Center, Petah Tikva, Israel; 3) Human Genetics, Hadassah University Hospital, Ein Kerem, Jerusalem, Israel; 4) Israel Center for Disease Control, Ministry of Health, Tel Hashomer, Israel; 5) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

We describe an extended multiply consanguineous Israeli Arab family. Two of the couples had together five affected daughters, all of whom had similar clinical features including coarse facies, macroglossia, short stature, dysostosis multiplex, severe psychomotor retardation, and a variable degree of progressive upper airway obstruction. The phenotypic appearance of these children and many of the clinical features suggest a storage disease, although the absence of organomegaly, mucopolysacchariduria, oligosacchariduria and other specific biochemical and ultrastructural findings rules out the known storage diseases. Based on the pedigree it seems that this family represents a new type of storage-like disease transmitted by autosomal recessive inheritance. We performed a genomewide linkage study in this family. Our data provide evidence for the existence of a disease-causing gene locus on chromosome 1q32.3. Analysis of haplotypes and recombination events suggested that the disease locus is flanked by markers D1S213 and D1S413. Analysis of additional markers in this region narrowed down the critical region to ~1.4 Mb between markers D1S2703 and D1S419 and provided evidence of homozygosity with marker D1S2646. ( $Z_{\max} = 4.45$  at  $\alpha_{\max} = 0.001$ ). The underlying pathogenesis of this autosomal recessive storage-like disease is unknown, and it is hoped that identification of the predisposing gene will allow an insight into and better understanding of the fundamental defect and the mechanisms involved.

**Search for quantitative trait loci for bone mineral density and predisposition to osteoporosis by genome wide linkage analysis.** *K. Sol-Church<sup>1</sup>, L.D. Spotila<sup>2</sup>, D.L. Stabley<sup>1</sup>, C. McKay<sup>1</sup>, H.H. Li<sup>1</sup>, K.F. Wang<sup>1</sup>, G.N. Picerno<sup>1</sup>, J. Korkko<sup>3</sup>, D. Prockop<sup>3</sup>, A. Tenenhouse<sup>4</sup>, M. Devoto<sup>1</sup>.* 1) Dept. Biomedical Research, Nemours Children's Clinic, Wilmington DE; 2) Drexel University, Philadelphia PA; 3) Tulane University, New Orleans LA; 4) McGill University, Montreal Canada.

Osteoporosis is a common condition characterized by reduced skeletal strength and increased susceptibility to fracture. The single major risk factor for osteoporosis is low bone mineral density (BMD) and strong evidence exists that genetic factors are in part responsible for an individual's BMD. In our laboratory, we seek to elucidate the underlying genetic mechanisms for low BMD and predisposition to osteoporosis by means of linkage analysis in a whole genome scan in families of individuals with low BMD. A cohort of 42 multiplex Caucasian families selected through a proband with osteoporosis, comprising a total of 254 individuals, was genotyped for microsatellite markers spaced at an average 10 cM density and Mendelian errors were detected by mean of the Pedmanager software. Linkage to femoral neck and spine BMD was analyzed using the SOLAR package that implemented a variance components approach and association was tested by means of the transmission disequilibrium test using the QTDT software. Several loci with positive support for linkage ( $Z_{\max} > 1$ ) were identified on chromosomes 1, 2, 3, 6, 12, 16, 18 and 22. The positive linkage on chromosomes 2 and 6 was observed for both spine and femoral neck BMD, while the other chromosomes were positive for either one or the other of the two traits. The highest lod-scores were observed between markers located in 1pter-p36.2 and femoral neck BMD ( $Z_{\max} = 2.85$  at marker D1S214). Variance components analysis suggested that a substantial fraction of the total genetic variation was explained by this locus. QTDT analysis also suggested the presence of linkage disequilibrium with two microsatellite markers, D1S489 ( $p=0.0012$ ) and D1S2660 ( $p=0.0098$ ), in the same region. These studies will help identify candidate genes included in the region of linkage, which may be used to identify individuals at risk of developing the disease who may benefit from early prevention therapy.

**IL4 receptor alpha Gene: Linkage and Association analysis of five polymorphisms in Italian families with atopic asthma.** *C. Patuzzo<sup>1</sup>, C. Migliaccio<sup>1</sup>, G. Malerba<sup>1</sup>, E. Trabetti<sup>1</sup>, R. Galavotti<sup>1</sup>, L. Pescollderung<sup>2</sup>, A.L. Boner<sup>3</sup>, P.F. Pignatti<sup>1</sup>.* 1) Sect Biol & Genetics, Mother-Child, Biol & Genetics, University of Verona, Verona, Italy; 2) Division of Pediatrics, Hospital of Bolzano, Italy; 3) Sect of Pediatrics, Mother-Child, Biol & Genetics, University of Verona, Verona, Italy.

Although IL4 and its receptor (IL4RA) mediate pivotal pro-inflammatory functions in asthma there are conflicting reports regarding the involvement of IL4RA variants in the pathogenesis of asthma. In this study we present linkage and association analysis of five polymorphisms (I50V, E375A, C406R, S478P, Q551R) of the IL4RA gene in a large series of well characterized individuals from North-East Italy. All the 823 individuals from 182 families with atopic asthmatic children were tested for clinical asthma, total serum IgE level, Skin Prick Test positivity to common aeroallergens, and bronchial hyper responsiveness to methacholine. The five polymorphisms were genotyped with restriction analysis, RG-PCR and ARMS-PCR and the accuracy of detection was checked by direct sequencing. Non-parametric linkage analysis and transmission disequilibrium test (TDT) were performed with the computer programs GENEHUNTER 2.1 and TRANSMIT respectively. We did not observe linkage or transmission disequilibrium in the families for any polymorphism with any of the phenotypes investigated. A multipoint analysis did not show association between any multipoint haplotype and any phenotype. The conflicting reports may be due to interactions with other factors and population differences. In conclusion, the IL4RA gene does not seem to play an important role in genetic predisposition to atopic asthma in the population tested.

**Genomic Screen for adult-onset primary open angle glaucoma: Follow-up studies suggest loci on 14q11 and 15q.**

*J.L. Wiggs<sup>1</sup>, R.R. Allingham<sup>2</sup>, J. Augustine<sup>1</sup>, J.R. Shi<sup>4</sup>, K. LaRocque-Abramson<sup>3</sup>, M. Hauser<sup>3</sup>, E. DelBono<sup>1</sup>, F.L. Graham<sup>3</sup>, M. Pericak-Vance<sup>3</sup>, J.L. Haines<sup>4</sup>.* 1) Dept Ophthalmology, Harvard Medical Sch, MEEI, Boston, MA; 2) Dept Ophthalmology, Duke Medical Center, Durham, NC; 3) Center for Human Genetics, Duke Medical Center, Durham, NC; 4) Program in Human Genetics, Vanderbilt University School of Medicine, Nashville, TN.

Glaucoma is a leading cause of blindness worldwide. The disease is characterized by degeneration of the optic nerve usually associated with elevated intraocular pressure. The most common form of glaucoma is adult onset primary open angle glaucoma which is inherited as a complex trait. We have previously completed an initial genome screen to identify the chromosomal locations of POAG susceptibility genes. The initial study identified 16 chromosomal regions that demonstrated interesting results, and after the addition of a second pedigree set, further evidence for POAG loci on chromosomes 2, 4, 14, 15, 17 and 19 was obtained. To refine these regions we have added to the analysis: a third group of sibling pairs (195 sibling pairs total), unaffected pedigree members to help establish IBD, and additional markers in the regions of interest. We have analyzed the data using four different methods: parametric analysis using an autosomal dominant model and assuming genetic heterogeneity (Hetlods), nonparametric analysis allowing for complex pedigree structure (LOD\*), nonparametric analysis using all sibpairs (MLS) and ordered subset analysis (OSA) stratifying the pedigree set by age of onset. With the current data set, all four approaches provide evidence for POAG susceptibility loci on chromosome 14q11 (Hetlod 2.5 marker D14S264; LOD\* 1.9; MLS 3.2; OSA lod score 3.68) and 15q (Hetlod 1.4 marker GABRB3; LOD\* 2.06; MLS 3.03; OSA lod 3.19). These results suggest that these two loci likely represent a substantial portion of the genetic effect in POAG. Evaluation of candidate genes located within these genomic regions is currently underway.

**Refinement of the Chronic Distal Spinal Muscular Atrophy (Chronic DSMA) locus on chromosome 11q13.3 and evidence of a founder haplotype in the European population.** *L. Viollet<sup>1</sup>, M. Zarhrate<sup>1</sup>, I. Maystadt<sup>1,2,3</sup>, A. Munnich<sup>1</sup>.* 1) INSERM U-393, Hopital Necker, Paris, France; 2) Department of Human Genetics, Catholic University of Louvain, Brussel, Belgium; 3) FNRS, Brussel, Belgium.

Chronic Distal Spinal Muscular Atrophy (Chronic DSMA) is an autosomal recessive neuromuscular disorder characterized by progressive anterior horn cell degeneration, leading to motor weakness and muscular atrophy predominating in the distal part of the limbs. In a previous study, we mapped the disease gene to a 15.16 cM interval on chromosome 11q13-q21, between markers D11S4076 and D11S1321 in a large Arabian pedigree. We report here additional linkage data resulting from the analysis of eleven unrelated European Chronic DSMA families. All patients presented an identical pattern of muscle wasting, beginning in the lower limbs, with onset extending from 6 months to 10 years. For genetic analysis, we used polymorphic markers from the Genethon map and we generated an additional microsatellite marker (called DSM4), located in the 11q13.3 region. A significant linkage (Lod score up to 5 at  $\theta = 0.00$ ) was obtained at the DSM4 locus. A recombination event with the marker locus D11S4136 was observed in two independent inbred families at the centromeric side of the region. At the telomeric side, a recombination event with the marker locus D11S1314 allowed to place the Chronic DSMA gene in a 3 cM interval between loci D11S4136 and D11S1314 on chromosome 11q13.3. In addition, the analysis of markers at loci D11S4184, DSM4 and D11S1369 revealed that the affected individuals harbored a shared haplotype (4-3-2) in 7/11 pedigrees. Interestingly, most of these families originated from Italy or Southern of France. These data suggest that, in the European population, mutant Chronic DSMA chromosomes may derive from a single founder chromosome. The genetic refinement of Chronic DSMA locus allowed us to exclude the IGHMBP2 gene, which mutations have been reported in an early severe DSMA phenotype (SMARD1), and to search for mutations in the candidate genes of the region. Direct sequencing of the coding sequences is currently carried out and will hopefully allow to identify the gene responsible for Chronic DSMA.

**Mapping of an autosomal dominant cataract (ADC) Chilean family to a unique locus.** *L. Richter*<sup>1</sup>, *J.L. Turner*<sup>1</sup>, *F.R. Barra von Bischhoffshausen*<sup>2</sup>, *P. Flodman*<sup>3</sup>, *M.A. Spence*<sup>3</sup>, *J.B. Bateman*<sup>1</sup>. 1) Department of Ophthalmology, Rocky Mountain Lions Eye Institute, University of Colorado, Aurora, CO; 2) Departamento de Oftalmología, Universidad de Concepcion, Concepcion, Chile; 3) Department of Pediatrics, University of California Irvine, Orange, CA.

**Purpose:** To map and identify the gene for ADC in a large Chilean family.

**Methods:** ADC 52 is a four generation Chilean family consisting of 14 individuals with seven affected individuals. Clinically, all the affected patients had the cataract removed except one and the one patient with the lens had a plaque on the posterior capsule of the lens. SIMLINK analysis was used to estimate the power to detect linkage of ADC 52. We have created a panel of markers for the twenty-five known ADC loci based on linkage analysis and identification of gene mutations. We screened the family with our panel using PCR amplifications performed separately for each primer set. The products were resolved on an ABI 373 using Genescan 2.1 software (Applied Biosystems). Two point LOD scores were calculated using LIPED.

**Results:** For a tightly linked marker, we estimated that linkage analysis in the chosen subset of this family will have 70% power to detect a LOD greater than 3; the maximum LOD score achieved over 1000 simulations was 3.25. We calculated LOD scores between the ADC 52 locus and markers on chromosomes 1, 2, 3, 10, 11, 12, 15, 16, 17, 19, 20, 21, and 22 and excluded all loci.

**Conclusions:** Using our ADC screening panel, we excluded linkage in this family with all markers known to be linked to human ADC. Therefore, ADC 52 represents a novel ADC locus. We are conducting a genome-wide scan of this family to determine this locus.

Work supported by NEI Grant 5 R01 EY08282-11.

**Mapping of autosomal dominant retinitis pigmentosa: evidence for a novel disease locus.** *M. Papaioannou<sup>1</sup>, Q. Prescott<sup>1</sup>, R. Koenekoop<sup>2</sup>, M. Loyer<sup>2</sup>, S. Bhattacharya<sup>1</sup>*. 1) Molecular Genetics, Institute of Ophthalmology, UCL, London, UK; 2) McGill Ocular Genetics Laboratory, Montreal Children's Hospital Research Institute, Montreal, Canada.

Retinitis pigmentosa (RP) is a highly heterogeneous group of genetic disorders of the retina that cause night blindness and progressive loss of peripheral vision. RP affects approximately 1:5000 people and can be inherited in an autosomal dominant (adRP), recessive (arRP) or X-linked (XLRP) pattern. Eleven loci have been described for adRP on chromosomes 1q, 3q, 6p, 7p, 7q, 8cen, 11q, 14q, 17p, 17q and 19q, and the respective genes have been cloned except for the 17q locus.

We have recruited a four generation family with adRP after full clinical examination and we have genotyped 26 of its members (of which 9 are affected) with ~200 fluorescently labeled microsatellite markers. After analysis excluded linkage to the eleven known adRP loci, a genome-wide search was undertaken and twelve chromosomes were excluded in their entirety. Additional family members are also being recruited in order to strengthen these results.

In an effort to map novel disease-causing adRP genes we provide evidence for a novel disease locus for adRP. This is supportive of previously published data indicating the existence of additional adRP loci in the human genome. Once linkage is established, candidate genes from the corresponding genetic interval will be characterised and screened for mutations in affected members of the adRP family.

**A two-stage genome-wide scan identifies a new susceptibility locus for autosomal dominant keratoconus in a large Caucasian pedigree.** *Y. Tang<sup>1</sup>, K.D. Taylor<sup>1, 2</sup>, X. Li<sup>1</sup>, Y. Picornell<sup>1</sup>, Y.S. Rabinowitz<sup>1, 2</sup>, H. Yang<sup>1</sup>, Genetic Epidemiology.* 1) Dept Medical Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA 90048; 2) Dept Pediatrics, Cedars-Sinai Medical Ctr, Los Angeles, CA 90048.

Keratoconus (KC) is a corneal dystrophy with an incidence of 1 in 2,000. It is a major cause of visual disability worldwide and a leading cause for cornea transplantation in Western developed countries. The etiology of KC is unknown, but heterogeneous genetic determination in the pathogenesis of KC is supported by familial aggregation, twin concordance, and linkage studies. We previously conducted a linkage study on candidate chromosome 21 because of keratoconus' known association with Down's syndrome and we observed a region of suggestive linkage (LOD = 2.5) near the marker D21S1240. To further investigate genetic contributions in the development of KC, we extended the linkage analysis to the whole genome. We studied a five-generation autosomal dominant pedigree, consisting of 39 members, 14 of whom were affected with keratoconus (diagnosed both clinically and with videokeratography). We performed linkage analysis with 343 microsatellite markers along the 22 autosomal chromosomes at ~10 cM density. For those regions with suggestive linkage, fine mapping at ~2 cM density was carried out. Model-based multipoint linkage analysis was performed using GeneHunter2. Under the dominant model with a penetrance of 0.8, evidence of suggestive linkage from the initial scan was observed at 83-115 cM region on chromosome 5 with a maximum lod score (LOD) of 3.17 near marker D5S644. Further fine mapping was performed by testing additional 8 microsatellite markers at 2-3 cM intervals in a 30 cM area, revealing a similar, but narrower, peak (99-112 cM) with maximum LOD 3.03 near marker D5S484. These results indicate a promising new locus for keratoconus at D5S484 in this pedigree. Because of the heterogeneous nature of keratoconus, this locus may be specific to familial dominant keratoconus, and may not play an important role in sporadic KC. Nevertheless, the identification of this locus may provide new insights into the pathogenesis of keratoconus.

**Age-related maculopathy: A third genome-wide scan with continued evidence of susceptibility loci within the 1q31 and 17q25 regions.** *D.E. Weeks<sup>1</sup>, Y.P. Conley<sup>1</sup>, H.-J. Tsai<sup>1</sup>, T.S. Mah<sup>1</sup>, S. Schmidt<sup>2</sup>, M.A. Pericak-Vance<sup>2</sup>, J.L. Haines<sup>3</sup>, E. Postel<sup>2</sup>, P.J. Rosenfeld<sup>4</sup>, T.O. Paul<sup>5</sup>, A.W. Eller<sup>1</sup>, L.S. Morse<sup>6</sup>, J.P. Dailey<sup>7</sup>, R.E. Ferrell<sup>1</sup>, M.B. Gorin<sup>1</sup>.* 1) Univ Pittsburgh, Pittsburgh, PA; 2) Duke Univ Med Ctr, Durham, NC; 3) Vanderbilt Univ Med Ctr, Nashville, TN; 4) Univ. of Miami, Bascom Palmer Eye Inst., Miami, FL; 5) Smith-Kettlewell Eye Research Institute, San Francisco, CA; 6) University of California Davis, Davis, CA; 7) Case Western Reserve, Cleveland, OH.

Age-related maculopathy (ARM) or age-related macular degeneration is one of the most common causes of visual impairment in the elderly within developed nations. In a combined analysis of two previous genome-wide scans that included 391 families containing up to 452 affected sib pairs, we found evidence of linkage in four regions, 1q31, 9p13, 10q26, and 17q25. We now have added a third set of families, and have carried out an integrated analysis incorporating 530 families and up to 736 affected sib pairs. Using three diagnostic models, we have conducted linkage analyses using parametric (heterogeneity lod scores [HLOD] under an autosomal dominant model) and non parametric ( $S_{all}$  statistic) methods. There is ongoing evidence of susceptibility loci within the 1q31 and 17q25 regions. Within the 1q31 region, we observed an HLOD of 2.72 under our least stringent diagnostic model, while the 17q25 region contained a maximal HLOD of 3.53 under our intermediate diagnostic model. We have evaluated our results with respect to those from several new independent genome-wide linkage studies, and also have completed ordered subset analyses using ApoE alleles, smoking history, and age-of-onset as stratifying covariates.

**Genetic study of the Bardet-Biedl syndrome in Tunisia.** *N. Smaoui*<sup>1,2</sup>, *S. Li*<sup>1</sup>, *M. Chaabouni*<sup>2</sup>, *R. Mrad*<sup>2</sup>, *H. Kallel*<sup>3</sup>, *F. Maazoul*<sup>2</sup>, *E. Nouiri*<sup>2</sup>, *H. Chaabouni*<sup>2</sup>, *J.F. Hejtmancik*<sup>1</sup>. 1) Dept OGVFB, National Eye Inst, NIH, Bethesda, MD; 2) Genetic Department, Faculty of Medicine, Tunis, Tunisia; 3) Pediatric Department, Ras Jebel hospital, Bizerte, Tunisia.

Bardet-Biedl syndrome (BBS) is a clinically and genetically heterogeneous syndrome characterized by obesity, polydactyly, mental retardation, and retinitis pigmentosa. It is caused by mutations at least seven known loci including 11q23 (BBS1), 16q21 (BBS2), 3p13-p12 (BBS3, gene unknown), 15q22.3-q23 (BBS4), 2q31 (BBS5, gene unknown), 20p12 (BBS6) and 4q27 (BBS7). We carried out a linkage study of 9 consanguineous Tunisian families with microsatellite markers flanking each of the 7 BBS loci. One family shows linkage to D4S402 near the BBS7 locus with a maximum lod score of 5.42 at  $\theta = 0$ . Affected individuals in three families show homozygosity for microsatellite markers, one family each to markers flanking the BBS1, BBS2 and BBS6 loci. Sequencing of the corresponding candidate gene coding sequences is in progress. In family 57009 all 7 known loci for BBS have been excluded and a genome wide scan is underway with this family to identify the putative new Bardet-Biedl locus.

Program Nr: 1825 from 2003 ASHG Annual Meeting

**Possible digenic inheritance for limb girdle muscular dystrophy.** *A. Starling, F. De Paula, R. Pavanello, M. Vainzof, M. Zatz.* Dept Biologia, Inst de Biociencias, Sao Paulo, Brazil.

Limb Girdle Muscular Dystrophy (LGMD) is a neuromuscular disorder characterized by a great genetic heterogeneity. At least 15 LGMD-causing genes have been mapped so far, 5 with autosomal dominant (LGMD1A-E) and 10 with autosomal recessive inheritance (LGMD2A-J). We have ascertained a family with 5 affected brothers presenting proximal muscle weakness but with a variable course and preferential muscle involvement. They have 5 normal sibs (3 brothers and 2 sisters). All affected patients have grossly elevated serum CK (50-100 fold). A muscle biopsy performed in two of them showed normal results for dystrophin and 7 other analyzed proteins (dysferlin, calpain, the four sarcoglycans and telethonin). Linkage analysis excluded all known autosomal dominant and recessive LGMD genes. Interestingly, all five affected brothers inherited the 2362AG>TCATCT CAPN3 mutation in one allele but linkage analysis confirmed that the second allele does not carry a mutation in the CAPN3 gene. In order to find out if the disease is caused by tri-allelic inheritance (with the CAPN3 mutation acting as a modifier gene) or di-allelic inheritance we are currently performing a genome scan. The analysis of 450 markers (ABI Prism Linkage Mapping Set Version 2) excluded recessive inheritance for a novel LGMD gene and therefore tri-allelic inheritance. We are currently looking for a common allele in the affected brothers that may interact with the CAPN-3 mutation causing the LGMD phenotype. If confirmed, this will be the first LGMD family showing a digenic mechanism of inheritance. Supported by FAPESP-CEPID, PRONEX, CNPq.

**Linkage analysis of LRP5 gene with bone mass density.** *E. Petrelli<sup>1</sup>, A. Sangalli<sup>1</sup>, G. Malerba<sup>1</sup>, L. Xumerle<sup>1</sup>, V. Braga<sup>2</sup>, S. Adami<sup>2</sup>, P.F. Pignatti<sup>1</sup>, M. Mottes<sup>1</sup>.* 1) Mother & Child, Biol & Gen, Univ. Verona, Verona, Verona, Italy; 2) Dept of Rheumatology, Valeggio S/M, University of Verona, Italy.

In recent years several studies have reported mutations in the Lipoprotein Receptor-related Protein 5 gene (LRP5) associated to either increased or decreased bone density conditions. We are performing a linkage analysis in a sample of Italian osteoporotic families to investigate the possible involvement of the LRP5 gene with bone density in osteoporosis. Families (119) were recruited through an osteoporotic/osteopenic proband for a total of 563 individuals genotyped. The individuals were characterised for bone density at spine and femoral sites and for lipid levels. The allele frequency of 8 intragenic SNPs (Q89R, V1119V, IVS17-30, V1330A, D1363D, N740N, IVS10+6, TSCO178416) was estimated on 118 family founders. The SNP TSCO178416 (from SNP Consortium Database) was found not to be polymorphic. Bone density has been treated both as quantitative and qualitative trait. Non parametric linkage analysis for markers V1119V and V1330A did not show suggestive results with bone density at any of the densitometric sites studied. These preliminary results suggest that the LRP5 gene is not a major genetic factor for bone mass loss in osteoporosis.

**A Genome Scan for Asthma and a Combined Analysis of Two Asthma Collections.** *N.J. White<sup>1</sup>, M. Chiano<sup>1</sup>, S. Pillai<sup>2</sup>, R. Lam<sup>2</sup>, S. Brewster<sup>1</sup>, M. Ehm<sup>2</sup>, D. Burns<sup>2</sup>, M. Wagner<sup>2</sup>, J.H. Riley<sup>1</sup>, T. GAIN Investigators<sup>3</sup>, T. Progenitor Investigators<sup>3</sup>.* 1) GlaxoSmithKline, Medicines Research Centre, Molecular Genetics, Gunnels Wood Rd, Stevenage, Hertfordshire, UK; 2) 5 Moore Drive, RTP, North Carolina, USA; 3) See Acknowledgements.

Asthma is one of the most frequent, chronic diseases with a prevalence of up to 10%. It is a common disease, with contributions from both genetic and environmental factors. The asthma genetics program at GSK was launched in 1998 with a study termed GAIN (Genetics of Asthma International Network). The aim of this study was to collect 1000 families with Asthma. In 1998 GSK obtained a second asthma collection from a company called Progenitor. This collection contained approximately 300 families from Minnesota and Denmark. We have carried out a genome scan on the GAIN collection and reported the data last year at ASHG. We have recently carried out a genome scan and performed linkage analysis on the Progenitor families and will present this. Finally we have carried out a combined analysis of the two datasets and will present this analysis also. The Progenitor genome scan analysis was of four asthma sub-phenotypes, physicians diagnosed asthma (PDA), atopic asthma, strict asthma and bronchial hyper-responsiveness (BHR). The analysis was carried out separately in each of the Danish and Minnesota populations and a combined analysis of them both. A total of 8 peaks with a LOD greater than 1.0 were observed in the combined Minnesota, Denmark analysis with 2 of these peaks with LODs greater than 2.0. The GAIN scan had a total of 12 peaks with a LOD score greater than 1.0 in one or more phenotypes and 2 with LODs greater than 2. When the collections were combined and the four phenotypes analysed we had 5 loci with a LOD greater than 2.0 and 11 loci with a LOD greater than 1.0. We will discuss the additive nature of some of these chromosomal loci and how we will use this to prioritise the next stage of our analysis.

**A Genome-wide Linkage Scan for Schizophrenia in Veterans Affairs Cooperative Study Families.** *A.D. Skol<sup>1</sup>, S.V. Faraone<sup>2</sup>, D.W. Tsuang<sup>3</sup>, S. Bingham<sup>4</sup>, K.A. Young<sup>4</sup>, S.L. Haverstock<sup>4</sup>, F. Mena<sup>4</sup>, A.S. Menon<sup>4</sup>, F. Sautter<sup>4</sup>, J.L. Vanden Eng<sup>1</sup>, T. Keith<sup>5</sup>, M. Boehnke<sup>1</sup>, M.T. Tsuang<sup>6,7</sup>, G.D. Schellenberg<sup>8</sup>.* 1) Dept. of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Harvard Medical School Department of Psychiatry at the Massachusetts General Hospital, Boston, MA; 3) Veterans Affairs Puget Sound Health Care System, Mental Illness, Research, Education and Clinical Center, Seattle, Washington; 4) Veterans Affairs Medical Center; 5) Genome Therapeutics, Inc., Waltham, MA; 6) Harvard Institute of Psychiatric Genetics, Boston, MA; 7) Harvard Department of Psychiatry at the Massachusetts Mental Health Center, Boston, MA; 8) Veterans Affairs Puget Sound Health Care System, Geriatric Research, Education and Clinical Center, Seattle, WA.

Schizophrenia is a serious psychiatric disease that affects around 1% of the population and has a known genetic component. We have nearly completed a genome scan using 166 families recruited from seven Veterans Affairs Medical Centers. The sample consists of 392 subjects affected by either schizophrenia (91.8%) or schizoaffective disorder, depressed (8.2%). Half of the families are northern European-American and half are African-American, representing one of the largest African-American samples analyzed to date.

In our preliminary findings, chromosome 18 contains the most significant result with a maximum LOD score of 3.68 located on the p-terminus, a previously unreported region of interest. When considered in concert with current literature our data suggests a number of other interesting results. These include a LOD score of 1.34 close to chromosome 11q23.3-24 which was found to be significantly linked with schizophrenia by Gurling et al. (2001), suggestive confirmation of Brzustowicz et al. (1999) chromosome 13q32 finding, a linkage peak on chromosome 15 (LOD = 0.67) only 1cM from the -7 nicotinic receptor subunit gene which was previously found associated with P50 auditory evoked potential gating deficits (Freedman et al., 2001), and suggestive confirmation of association between the NOTCH4 gene and schizophrenia found by Wei and Hemmings (2000.) The results from all chromosomes will be presented.

**Mapping of an X linked mental retardation (MRX) gene to a 9 Mb interval at Xq12.11.** *M. Frydman*<sup>1,2</sup>, *R. Attia*<sup>1</sup>, *E. Levy-Nissenbaum*<sup>1</sup>, *H. Reznik-Wolf*<sup>d</sup>, *M. Berkenstadt*<sup>1</sup>, *N. Schlaff*<sup>d</sup>, *E. Pras*<sup>1,2</sup>. 1) Danek Gertner Institute of Human Genetics, Haim Sheba Medical Centre, Tel Hashomer 52621, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

**Purpose:** Linkage mapping of an X linked mental retardation (XLMR) gene in a new 3 generation family. **Clinical details:** 4 male patients had mild mental retardation and some facial similarity. One patient had atypical sensory motor neuropathy, hypertension, hyperlipidemia, and diabetes. Another patient had gynecomastia, and two patients had short ring-finger nails. **Results:** Linkage studies confined the disease gene into a 9 Mb interval on Xq12.11, between marker DXS8107 and a polymorphic site on clone AL009047. Two point LOD score of 3.52 at theta=0 was obtained with polymorphic sites on clones AC004386 and AL137013. This localization sets the new locus apart from the more centromeric OPHN1 and the telomeric FAFL4 genes. Since the interval is tangential to MRX22, telomeric to MRX1, MRX17, MRX55 and centromeric to MRX40, it defines a new locus for XLMR, which is partially or completely crossed only by MRX4, 5, 8, 13, 20, 26, 31, 52, 65, 69 and MRX77. Sequencing of ATR-X, NLGN3, CDX, SNX12, GPR23, NAP12 and GJB1 genes did not reveal any significant changes. Non random X inactivation pattern was found in all carrier females. Synteny of the inactive allele of the androgen receptor (AR) gene and the disease-linked haplotype was observed in all the carrier females. We suggest to classify XLMR conditions with skewed X inactivation as a separate class of non-specific mental retardation (MRX), since they present a subtle but central syndromic feature. Such classification may allow further refinement of the MRX phenotype. Determination of the inactivation pattern may be important for genetic counseling in female carriers who are not informative, and facilitate gene mapping in families which are too small to be studied based on male phenotype alone.

**Transcriptional map of the dominant intermediate Charcot-Marie-Tooth neuropathy locus on chromosome 19p12-p13.2.** *M.L. Kennerson<sup>1,2</sup>, D. Zhu<sup>1</sup>, G. Walizada<sup>1</sup>, G.A. Nicholson<sup>1,2</sup>*. 1) Neurobiology Laboratory, ANZAC Research Institute, Concord, Australia; 2) Molecular Medicine Laboratory, Concord Hospital, Concord, Australia.

Charcot-Marie-Tooth (CMT) neuropathy is one of the most common hereditary disorders of the human peripheral nervous system. Dominant intermediate CMT (CMTDI1) is a form of CMT with intermediate median motor nerve conduction velocities. We previously reported linkage of CMTDI1 to a 16.8-cM interval on chromosome 19p12-p13.2 in a large Australian kindred (1). Extended haplotype analysis of additional family members and the report of a second family (2) linked to this locus enabled us to narrow the candidate region to a 6-cM interval flanked by D19S558 and D19S432 (3). This region corresponds to a 2.5-Mb physical distance and is amenable to positional cloning strategies. We have employed resources of the Human Genome Project (HGP) to construct a sequence ready contig of BAC clones that span the CMTDI1 critical region. Both bioinformatic tools and laboratory techniques have been employed to annotate the DNA sequence and generate a comprehensive transcript map. Expression profiles in neural tissues (brain, spinal cord and peripheral nerve) have identified potential candidate genes that are being screened by direct sequencing. 1.Kennerson et al. *Am. J. Hum. Genet* (2001) 69:883-888. 2.Speer et al. *Neurogenetics* (2002) 4:83-85. 3.Zhu et al. *Neurogenetics* (2003) Epub ahead of print.

**Mapping of the Infantile Bilateral Striatal Necrosis gene in the chromosomal region 19q13.32-q13.41. M.**

*Shohat*<sup>1,2</sup>, *R. Straussberg*<sup>2,3</sup>, *H. Ovadia*<sup>4</sup>, *A. Kaplan*<sup>4</sup>, *N. Magal*<sup>2,4</sup>, *Z. Shorer*<sup>5</sup>, *H. Shalev*<sup>6</sup>, *C.A. Walsh*<sup>7</sup>, *L. Basel-Vanagaite*<sup>1,3</sup>. 1) Dept Medical Genetics, Rabin Medical Ctr, Petah Tikva, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv; 3) Neurogenetics Clinic and Department of Pediatrics, Schneider Childrens Medical Center of Israel, Petah Tikva; 4) Felsenstein Medical Research Center, Petah Tikva; 5) Department of Child Neurology, Soroka Medical Center, Ben Gurion University, Beersheba; 6) Pediatrics Department, Soroka Medical Center, Beersheba, Israel; 7) Division of Neurogenetics and Howard Hughes Medical Institute, Beth Israel Deaconess Medical Center, and Department of Neurology, Harvard Medical School, Boston, Massachusetts, USA.

Background: Infantile bilateral striatal necrosis (IBSN) encompasses several syndromes of bilateral symmetrical degeneration of the caudate nucleus, putamen, and globus pallidus. Autosomal recessive infantile bilateral striatal necrosis (IBSN) is characterized clinically by developmental arrest beginning at the age of 7 to 15 months, dysphagia, choreoathetosis, pendular nystagmus and optic atrophy and severe progressive atrophy of the basal ganglia on MRI. Objective: To map the gene causing autosomal recessive IBSN. Methods: A 10-cM genomewide linkage scan was initially performed on 5 affected and 5 unaffected individuals. The extended family was included in the analysis to narrow the candidate region. LOD score was calculated using the SUPERLINK program. Results: Linkage to the chromosomal region 19q13.32-13.41 was established ( $Z_{max} = 6.27$  at  $\theta = 0.02$  at locus D19S412). Recombination events and a common disease-bearing haplotype defined a critical region of 1.2 Mb between the loci D19S596 proximally and D19S867 distally. Conclusion: Autosomal recessive IBSN maps to the chromosomal region 19q13.32-13.41. The presence of a common haplotype in all the patients suggests that the disease is caused by a single mutation derived from a single ancestral founder in all the families.

**QTL mapping for hypercalciuria in a rat model of kidney stone disease.** *S.J. Scheinman<sup>1</sup>, S. Sen<sup>2</sup>, R. Reid<sup>1</sup>, R.V. Thakker<sup>3</sup>, D.A. Bushinsky<sup>4</sup>, R.R. Hoopes, Jr<sup>1</sup>*. 1) Department of Medicine, SUNY Upstate Medical University, Syracuse, NY; 2) Department of Epidemiology and Biostatistics, University of California at San Francisco; 3) MRC Molecular Genetics Unit, University of Oxford, UK; 4) Department of Medicine, University of Rochester, Rochester NY.

The genetic hypercalciuric stone-forming (GHS) rat model was developed by selective breeding for hypercalciuria from Sprague-Dawley progenitors. Calcium excretion progressively increased for the first 30 generations, consistent with multiple loci contributing to hypercalciuria; the strain is now in its 64th generation of inbreeding. The GHS rat has been extensively characterized. The complex physiology of hypercalciuria in these rats involves increased intestinal calcium absorption, enhanced bone resorption, and impaired renal calcium reabsorption. The vitamin D receptor is overexpressed in these rats. Thus, the GHS rat model reproduces the human phenotype of idiopathic hypercalciuria, which is the most common risk factor for kidney stones. We studied an F2 generation of 234 rats bred from GHS females and normocalciuric WKY males. Ca excretion is 6- to 10-fold higher in the GHS than in the WKY progenitors. We performed quantitative trait locus (QTL) analysis on Ca excretion using the F2 rats and Pseudomarker QTL mapping methods designed to detect multiple, possibly linked or interacting, loci. After adjusting for the additive effects of sex and cross batch, we found significant evidence for five QTL, two of them linked. The loci were on chromosome 3 (2 peaks with LOD 4.92 and 3.50), 5 (LOD 4.08), 1 (LOD 3.75) and 14 (LOD 3.57). Further analysis indicated a sex effect for the QTL on chromosomes 5 and 14 ( $p < 0.01$ ). For the chromosome 5 locus the GHS allele is recessive for males, but dominant for females. We have bred N10F1 congenic rats preserving the GHS alleles for the chromosome 1 QTL on a WKY background, and these congenics are now available for study. More refined mapping using congenic strains will be needed to identify the genes at these loci contributing to hypercalciuria in rats and, potentially, in humans.

**DBH as a model of haplotype block utility in linkage disequilibrium mapping.** *C.P. Zabetian<sup>1</sup>, C.W. Wilkinson<sup>2, 3</sup>, A. Samii<sup>1</sup>, G.D. Schellenberg<sup>1, 2</sup>.* 1) Dept of Neurology; 2) GRECC; 3) Dept of Psychiatry; Univ of Washington and VAPSHCS, Seattle, WA.

Although recent findings suggest that much of the human genome is organized in blocks of low haplotype diversity, the utility of such blocks in identifying genes influencing common traits is not yet known and must ultimately be tested empirically using real data. One approach is to fine-map genes already known to affect common traits and determine if a prior knowledge of LD structure might have facilitated gene identification using marker densities appropriate for large scale studies. The DBH gene is well suited as a simple model for this purpose as it contains a putative functional single nucleotide polymorphism (SNP; -1021C>T) in the 5' upstream region that accounts for half of the total variance in plasma DBH activity levels in European-Americans (EAs). A recent study of 12 SNPs at DBH (Zabetian et al., *Am. J. Hum. Genet.* 2003; 72:1389-1400) identified a single 10 kb haplotype block that contained -1021C>T and found that only one of six markers located outside of this block was highly associated with phenotype. Here we present data from a map of 30 SNPs in a new group of EA subjects that replicate and extend these findings as follows: 1) Additional markers typed within the previously defined block-boundaries all conformed to block structure, and all intra-block markers were strongly associated with plasma DBH activity. One such marker, IVS5+192C>T (TaqI site), is of special interest because it is also associated with ADHD. 2) Most markers located outside the block containing -1021C>T showed little or no association to phenotype. 3) The remainder of the DBH gene contained several short haplotype blocks of 3 kb or less in length. Thus, if one had attempted to map quantitative trait loci for plasma DBH activity on a genomewide basis without prior knowledge of candidate regions and not included (by chance) markers within the block containing -1021C>T, the DBH locus might have been missed entirely. These results provide a direct example of the potential value of constructing a haplotype map of the human genome prior to embarking on large-scale association studies.

**Haplotype architecture of the norepinephrine transporter gene [*SLC6A2*] in four populations.** *I. Belfer*<sup>1</sup>, *G. Phillips*<sup>1</sup>, *J. Taubman*<sup>2</sup>, *M.B. Max*<sup>1</sup>, *D. Goldman*<sup>2</sup>. 1) Pain and Neurosensory Mechanisms Branch, NIDCR, NIH, Rockville, MD; 2) Laboratory of Neurogenetics, NIAAA, NIH, Bethesda, MD.

The norepinephrine transporter (NET) is a transmembrane protein responsible for norepinephrine reuptake. The *SLC6A2* missense substitution Ala457Pro alters transporter function in vitro. A synonymous substitution, G1247C has been used in a series of association studies to norepinephrine-related phenotypes including hypertension and mood disorders. However, these studies have in general been negative or equivocal. A haplotype approach combining missense polymorphisms with loci chosen for haplotype informativeness offers the potential for detection of unknown alleles of moderate abundance and effect. To elucidate *SLC6A2* haplotype block structure and SNP panel informativeness, a panel of 27 SNP markers including G1247C and Ala457Pro was selected across the 46 KB *SLC6A2* region and genotyped by the 5 nuclease method in 96 unrelated individuals from each of four ethnic populations: Finnish Caucasians, U. S. Caucasians, Plains Indians and African Americans. Genotyping error rate was directly determined and was <0.005. Genotype completion rate was 94%. Within *SLC6A2*, three conserved blocks [I: 13.6 Kb, II: 12.5 Kb, III: 25 Kb] showed evidence for little historical recombination except for some disruption of LD within Block II and shortening of Block III in African Americans. Within blocks, pairwise LD [D] was generally >0.9 for all locus pairs. For the three haplotype blocks, the numbers of SNPs were: U.S. Caucasians, Finns, and Plains Indians: 8, 8, and 9, and African Americans: 8, 8, and 8. The number of common [>0.05] haplotypes in these groups were: block I - 4, 5, 3, 6; block II - 5, 5, 4, 5, and block III - 4, 5, 5, 6, for the four populations as just listed. The 7 SNPs in block II without G1247C, the marker most extensively used in linkage studies, capture 99% of the information content of Block II when G1247 is included. The *SLC6A2* haplotype map and marker panel is a surrogate for unknown, but moderately abundant and functionally effective, *SLC6A2* alleles.

Program Nr: 1835 from 2003 ASHG Annual Meeting

**SNP Genotyping Production for the WICGR Hap Map Project.** *J.M. Moore<sup>1</sup>, B. Blumenstiel<sup>1</sup>, R. Chanoux<sup>1</sup>, M. Defelice<sup>1</sup>, M. Faggart<sup>1</sup>, M. Goyette<sup>1</sup>, A. Lochner<sup>1</sup>, H. Nguyen<sup>1</sup>, E. Stahl<sup>1</sup>, E. Winchester<sup>1</sup>, L. Ziaugra<sup>1</sup>, D. Altshuler<sup>1,2</sup>, S.B. Gabriel<sup>1</sup>.* 1) Ctr Genome Res, Whitehead Inst, Cambridge, MA; 2) Departments of Genetics and Medicine, Harvard Medical School; Department of Molecular Biology and Diabetes Unit, Massachusetts General Hospital, Boston, MA.

Our goal as part of the International Haplotype Map Consortium is to genotype a high density of markers across four chromosomal regions: 4q, 7q, 18p, and Y. We are currently in production level genotyping on the Sequenom MassArray platform. At the outset of the project, we scaled the SNP genotyping process over five-fold, enabling us to genotype >1,100 SNPs per day (per panel of 96 samples). The success rate of assay design using the Sequenom platform is >80% and the conversion rate to successful genotyping assays is 84% for the first 17,000 SNPs attempted. To select SNPs for production genotyping, we use a strategy which calls for genotyping "double-hit" SNPs preferentially to avoid genotyping of false positive from SNP discovery and to increase the yield of common SNPs. We find that 89% of candidate SNPs are validated in the CEPH DNA panel (120 chromosomes) and 72% of SNPs have a minor allele frequency > 10%. Genotyping accuracy is critical in the analysis that will generate the ultimate product of the Hap Map. Therefore, we continually monitor accuracy of production genotyping by checking for consistent segregation within families and concordance of duplicate genotypes. Overall our accuracy rate is approximately 99.8%.

**Microtape: an alternative to microtiter plates for high throughput genotyping and other applications.** A. Yu, T. Rusch, W. Dickinson, K. Fieweger, J. Chudyk, D. David, J. Weber. Center for Medical Genetics, Marshfield Medical Research Foundation, Marshfield, WI.

Microtiter plates are used today in nearly all genetics labs for genotyping, sequencing and other reactions. Microtape is a series of arrays of wells on a continuous thin strip of plastic. Microtape is cheaper to manufacture, easier to design, and more readily processed by automated instruments than individual microtiter plates. Two series of indexing holes that run along either edge of the microtape allow the tape to be automatically fed through various instruments. Many different well shapes and sizes can be created. Array geometries are also easily modified. Currently we are using 384-well arrays with the same geometry as 384-well plates and with brim well volume of about 1 l. We have developed a series of instruments to handle the tape and to carry out an allele-specific PCR genotyping assay. A 384-tip positive displacement pipetting instrument was built to transfer DNA (or PCR primers) from a reservoir plate to the arrays. Typically, the DNA or primers are dried at the bottoms of the wells. A solenoid micro-valve aspirating and jetting unit was developed for dispensing a common reaction mix into the wells. This instrument will dispense volumes ranging from about 25-2000 nl into each of 384 wells in about 1 min. Arrays are sealed using another custom built device with two closely spaced rollers, one of which is heated. After PCR within a waterbath-based thermal cycler, the arrays are scanned using an epi-fluorescence detection unit designed to read Fam and Joe fluorescent dyes. The resulting images are processed using software written in-house. In calendar year 2003 we will generate about 1 million diallelic polymorphism genotypes using the microtape. Current reaction volumes are 600 nl and dropping. At these low reaction volumes, reagent costs per genotype are only about 2. Recent genotyping completeness values in the microtape have ranged from 94%-98%, with error rates from 0.06%-0.35%. Microtape also can be applied to amplification of multiallelic polymorphisms and to other reactions.

**Large Scale SNP Genotyping with Molecular Inversion Probe (MIP) Technology.** *T. Willis<sup>1</sup>, P. Hardenbol<sup>1</sup>, O. Iartchouk<sup>1</sup>, C. Bruckner<sup>1</sup>, M. Moorhead<sup>1</sup>, E. Namsaraev<sup>1</sup>, G. Karlin-Neumann<sup>1</sup>, M. Jain<sup>1</sup>, F. Yu<sup>2</sup>, X. Lu<sup>2</sup>, S. Pasternak<sup>2</sup>, S. Ghose<sup>2</sup>, A. Perez<sup>2</sup>, D. Steffen<sup>2</sup>, S. Leal<sup>2</sup>, G. Scott<sup>2</sup>, J. Belmont<sup>2</sup>, R. Gibbs<sup>2</sup>.* 1) ParAllele BioScience, So San Francisco, CA; 2) Baylor College of Medicine, Human Genome Sequencing Center, One Baylor Plaza, Houston, Texas.

The challenge of inexpensively generating hundreds of thousands of genotypes is being met at the BCM-HGSC by the use of Molecular Inversion Probe, (MIP) technology as developed at ParAllele BioScience. MIPs are padlock probes that hybridize directly to genomic DNA and undergo a unimolecular rearrangement, or inversion, through the action of several enzymes. Inversion transforms a probe incapable of amplification into one that can - dependent on the genetic information of the SNP target. After inversion, probes are amplified by PCR using common primers and analyzed via universal sequence tag DNA microarrays. Several selective enzymatic steps in the process allow multiplexing to over 10,000 probes per assay and ensure highly accurate genotypes (99.8%). This technology has been successfully transferred to the BCM-HGSC, and is working robustly and routinely in a high throughput, production scale environment. The BCM-HGSC is responsible for genotyping, and ultimately developing a high quality Haplotype Map for Chromosome 12. By mid June 2003, the MIP technology had already yielded in excess of one million genotypes on 30 CEPH trios, with an impressive 90.49% assay success rate, a 96.3% genotype call rate, and an 80% conversion rate (randomly chosen unique SNPs in dbSNP). The average repeatability and Mendelian consistency were 99.77% and 99.69% respectively. Given that the size of Chromosome 12 is about 133 Mb an average density of one SNP per 12.6 kb has already been achieved. Early haplotype results of chromosome 12 indicate that haplotype blocks, as determined by linkage disequilibrium of at least 4 SNPs per block, currently cover 22% of the chromosome with a median block size of 40kb at the current average density of 1 marker per 8kb. Taken as a whole, early results from the high throughput use of this MIP genotyping technology are highly encouraging and demonstrate the strong utility of this multiplexed genotyping assay.

**Association of calsequestrin 1 on 1q21 with type 2 diabetes mellitus (T2DM) in the Old Order Amish.** *M. Fu<sup>1</sup>, C. Damcott<sup>1</sup>, M. Sabra<sup>1</sup>, S. Ott<sup>1</sup>, J. Lee<sup>1</sup>, T.I. Pollin<sup>1</sup>, M. Garant<sup>1</sup>, J. O'Connell<sup>1</sup>, B.D. Mitchell<sup>1</sup>, A.R. Shuldiner<sup>1, 2</sup>.* 1) Dept Med, Div Endocrinology, Univ Maryland, Baltimore, MD; 2) Geriatrics Research and Education Clinical Center, Baltimore Veterans Administration Medical Center, Baltimore, MD.

We have previously detected linkage of T2DM to chromosome 1q21-q24, a region to which linkage has been demonstrated in several other populations. Calsequestrin 1 (CASQ1), a key storage protein of luminal Ca(2+) in the sarcoplasmic reticulum of muscle, is an attractive candidate gene in this region. We hypothesized that variation in CASQ1 may affect insulin action on glucose uptake and glycogen synthesis in skeletal muscle, thus increasing susceptibility to type 2 diabetes. We screened the 11 exons, -the surrounding intronic sequences, and the proximal regulatory region of CASQ1 in 20 Amish samples. We detected four novel SNPs in CASQ, including a C593T silent mutation in exon 3 (E3; Genbank accession number: NM\_001231), AG at 1470 bp upstream of the start codon (SPF1), del C at 1456 bp upstream of the start codon (SPF2), and del C at 1366 bp upstream of the start codon (SPF3). These SNPs as well as 12 other CASQ1 SNPs from dbSNP were genotyped in Amish subjects with T2DM (n = 150), impaired glucose homeostasis (IGH)(n = 148), and normal glucose tolerant (NGT) controls (n = 385), and association analyses were performed. 5 of the 16 SNPs genotyped showed significant association with T2DM, including rs3747623 in intron 2 (P=0.0257), E3 (P=0.0261), rs227503 in intron 4 (P= 0.0015), rs822450 in intron 7 (P=0.0481) and rs688015 (P=0.0240). Furthermore, all of five of these SNPs were genotyped in an expanded set of 1200 Amish subjects and showed significant association with post challenge glucose levels (736 Amish subjects have post-challenge glucose traits available). These SNPs define at least three distinct haplotype blocks, suggesting allelic heterogeneity. We conclude that variation in CASQ1 is associated with T2DM. Further studies of the role of CASQ1 in glucose homeostasis and the functional consequences of common variations in CASQ1 are warranted.

Program Nr: 1839 from 2003 ASHG Annual Meeting

**Bimodal distribution of sensitivity to the savory taste of monosodium glutamate (MSG) and polymorphisms of known glutamate taste receptors.** *P.A.S. Breslin, D.R. Reed, R.S.J. Keast, C.D. Tharp, S. Lui, O.M. Ohmed.* Monell Chemical Senses Ctr, 3500 Market St., Philadelphia, PA. 19104.

Monosodium glutamate (MSG), when placed in the mouth, conveys a unique taste quality, often labeled savory, brothy, or 'umami'. This quality is thought to underlie the protein and amino acid tastes, which convey a highly preferred flavor in many foods, e.g., soups. But not all of the population at large can clearly taste the savory component of MSG. A small subset of the population (~6%) is insensitive to this unique taste quality. Our subjects were screened for their ability to distinguish the tastes of 29 mM NaCl vs 29 mM MSG in a forced-choice triangle test. The few subjects who could not discriminate these stimuli also demonstrated an absolute insensitivity to glutamate on a concentration-intensity scaling task. Furthermore, the synergy of savory taste that occurs for most subjects when MSG is mixed with 5' ribonucleotides, such as GMP or IMP, is lacking in selected individuals, especially with regard to IMP. This specific lack of taste synergy can occur despite normal sensitivity to MSG savoriness. Therefore, there are semi-independent mechanisms underlying sensitivity to MSG and its interactions with IMP and GMP. At present, there are two putative savory taste metabotropic receptors identified: human taste GRM4 [6p21.3] and the receptor dimer human TAS1R1-TAS1R3 [1p36.23; 1p36.33]. Taste GRM4 (an orally located splice variant of the CNS GRM4, the group III inhibitory glutamate receptor) was sequenced and several identified exonic polymorphisms were not correlated with savory taster status. Similarly, the common polymorphism in TAS1R3 (A5T) was also not correlated with savory taster status. Less common polymorphisms, however, as well as a splice variant are being examined in our laboratory. TAS1R1 remains a likely location for a polymorphism that could determine MSG taster status. Four splice variants of TAS1R1 also hold promise as possible determinants of the MSG phenotypes under investigation. These studies have the potential to definitively determine the receptors responsible for this quality of taste in humans. This research was funded by DC02995. breslin@monell.org.

**Linkage and Association of polymorphisms in The SMOC2 Gene with Pulmonary Function: The Framingham Heart Study.** *S. Karamohamed*<sup>1</sup>, *J.B. Wilk*<sup>1</sup>, *C.M. Shoemaker*<sup>1</sup>, *J. Liu*<sup>1</sup>, *R.H. Myers*<sup>1</sup>, *D.J. Gottlieb*<sup>2</sup>. 1) Dept Neurology, Boston Univ Sch Medicine, Boston, MA; 2) The Pulmonary Center, R304, Boston University School of Medicine, Boston, MA.

Chronic obstructive respiratory disease is a significant cause of mortality and morbidity in the American population. To identify genes that affect lung function, we followed up linkage results on chromosome 6 in 191 families from the Framingham Heart Study using FEV1 and FVC as quantitative traits. We found linkage to FEV1 (LOD 5.0) and FVC (LOD 1.76) at 184.5 cM. To further refine the locus influencing FEV1 and FVC, we typed 25 single nucleotide polymorphisms (SNPs) covering a 1.5 Mb region in 1811 unrelated individuals. The SNPs data were analyzed using multiple linear regression models incorporating gender, age, body mass index (kg/m<sup>2</sup>), height, and smoking history as covariates. SNP 11 was associated in non-smokers with measures of FEV1 (p<0.001) and FVC (p<0.001). SNP 16, about 12 Kb 5'-distal to SNP 11, also showed similar but less significant association in non-smokers with FEV1 (p<0.08) and FVC (p<0.05) levels. SNPs 11 and 16 lie in two different haplotype blocks. Haplotype analysis using Haplo.score with SNP 11 and 16 revealed an association with FEV1 (p<0.009) and FVC (p<0.013) for non-smokers. The GT haplotype (76.6%) was associated with reduction of about 100 mL for FEV1 (p<0.004) and about 135 mL for FVC (p<0.002). Adjustment for SNP 11 in linkage models in the 191 families reduced the LOD score by one LOD unit. SNPs 11 and 16 lie within the SPARC related modular calcium binding 2 (SMOC2) gene. Further studies of SMOC2 are underway to define its role in lung and airway development.

**Quantitative trait locus analysis reveals two intragenic sites that influence O<sup>6</sup>-alkylguanine-DNA**

**alkyltransferase activity in peripheral blood mononuclear cells.** *M.F. Santibanez Korej<sup>d</sup>, J. Heighway<sup>2</sup>, G. McGown<sup>3</sup>, M.R. Thorncroft<sup>3</sup>, K.L. Harrison<sup>4</sup>, A.J. Watson<sup>3</sup>, P.V. Barber<sup>5</sup>, P.N. O'Donnell<sup>5</sup>, S.J. Lewis<sup>4</sup>, A.C. Povey<sup>4</sup>, G.P. Margison<sup>3</sup>.* 1) Institute of Human Genetics, University of Newcastle, Newcastle upon Tyne, United Kingdom; 2) Roy Castle International Centre for Lung Cancer Research, Liverpool, United Kingdom; 3) Paterson Institute for Cancer Research, Christie Hospital NHS Trust, Manchester, United Kingdom; 4) Centre for Occupational and Environmental Health, University of Manchester, Manchester, United Kingdom; 5) North West Lung Cancer Centre, Wythenshawe Hospital, Manchester, United Kingdom.

The DNA repair protein, O<sup>6</sup>-alkylguanine-DNA alkyltransferase (MGMT) is a major determinant of resistance to the mutagenic and toxic effects of certain classes of alkylating agents. The levels of expression of this protein are therefore of interest in relation to the prevention and treatment of cancer in man. They vary widely between individuals, and the basis of this variation is not understood. Here we demonstrate that in peripheral blood mononuclear cells (PBMC), the two MGMT alleles are frequently expressed at different levels, suggesting that there is a genetic component to inter-individual variation of MGMT levels and that at least some of the basis of this variation maps close to or within the MGMT locus. Next, we show by quantitative trait locus analysis using single nucleotide polymorphisms spanning the locus that there are at least two sites influencing interindividual variation in MGMT activity in PBMC. Characterisation of the relationship between alleles at these sites and expression levels allows to infer protein activity in specific individuals. Initial results from a case-control series suggest a link between MGMT activity and lung cancer risk.

***TNF-* is associated with joint pain in Hereditary Haemochromatosis.** *E.J. Walker*<sup>1</sup>, *S.R. Wilson*<sup>2</sup>, *H.R. Rodgers*<sup>3</sup>, *M.L. Bassett*<sup>3</sup>, *J.A. Cavanaugh*<sup>3</sup>. 1) Molecular Biosciences, JCSMR, ANU, ACT, Australia; 2) Centre for Mathematics and its Applications, ANU, ACT, Australia; 3) The Canberra Hospital, ACT, Australia.

**INTRODUCTION:** Hereditary haemochromatosis (HH) is an autosomal recessive disorder leading to excess iron storage<sup>1</sup>. Symptoms include joint pain, lethargy and loss of libido. The disorder results primarily from mutations in the *HFE* gene<sup>2-3</sup>. A previous study has suggested the -308 *TNF-* promoter polymorphism may have a role in the severity of clinical presentation<sup>4</sup>. **METHODS:** A total of 117 control DNA samples and 80 HH probands (defined by clinical presentation and genotype) were genotyped for the -308 *TNF-* polymorphism by PCR-RFLP<sup>5</sup>. HH Patients reported the presence or absence of joint pain via survey. Allele frequencies were compared by counting (<sup>2</sup> Test or Fisher's Exact Test as appropriate). Serum ferritin results were compared by the Mann-Whitney test. **RESULTS:** We compare allele frequencies for controls to HH patients (G allele 0.77 vs 0.86; p0.025), and HH patients with and without joint pain (G allele 0.75 vs 0.88; p0.05). We also compare mean serum ferritin levels (g/L) in HH patients (GG-1572.8; GA-1586.7; AA-720) according to *TNF-* genotype (not significant). **CONCLUSION:** The -308 *TNF-* polymorphism is associated with level of *TNF-* expression<sup>6</sup>. We found the allele frequency at this SNP to be significantly different in controls vs. HH probands. Within the HH group we also observed a significant difference in allele frequency between patients who experienced joint pain and those who did not. This difference was not a result of differences in serum ferritin (data not shown). No other symptom showed a significant correlation with the polymorphism. It has previously been suggested that lower serum ferritin levels in HH may correlate with this polymorphism<sup>4</sup>, however we failed to demonstrate a statistically significant difference in serum ferritin levels related to the -308 *TNF-* genotype. **REFERENCES:** 1. FAP is an autosomal dominant disorder associated with mutations in the transthyretin (TTR) gene. Variability in penetrance and age of onset among carriers of the same mutation suggests that non-allelic genetic variations contribute to disease phenotype. To identify possible genetic modifiers in FAP we examined *HSPG2* (perlecan), *APCS* (serum amyloid P-component), *APOE* (apolipoprotein E), *SAAI*, *SAA2* (serum amyloid A) and *RBP4* (retinol binding protein) genes for associations with disease onset and/or susceptibility in subsets of mutant gene carriers representing classical- (under 40) and late- (over 50) onset cases. These genes encode non-fibrillar components of TTR amyloid deposits, or interact with TTR. Polymorphisms at these loci were analyzed for single- and multiple-locus effects in a Portuguese sample of V30M carriers and unrelated controls. Single-locus analyses revealed that polymorphisms in *APCS* and haplotypes assembled for *APCS* and *RBP4* were significantly more common in V30M carriers than in the control subjects. When we tested for multiple-locus associations (linkage disequilibrium), there were no significant deviations from random in the controls (6 expected by chance alone). However we identified 25 significant combinations among the late-onset patients, while only 4 were seen in the classical-onset subset. Multifactor dimensionality reduction (MDR) indicated that the best genetic model for classical onset vs. controls resided predominantly in the *APCS* gene, while for the late onset cases *APCS* and *RBP4* were involved. The results indicate that genetic interactions among multiple loci, rather than single-locus effects, are likely to govern the age of onset in FAP V30M.

**Association of RGS4 polymorphisms with schizophrenia: interactions with gender.** *M.E. Talkowski<sup>1</sup>, K.V. Chowdari<sup>1</sup>, J.A. Wood<sup>1</sup>, J.W. Ceilley<sup>1</sup>, R.E. Ferrell<sup>1</sup>, K. Mirnics<sup>1</sup>, D.A. Lewis<sup>1</sup>, P. Levitt<sup>1</sup>, B. Devlin<sup>1</sup>, N. Williams<sup>2</sup>, M.J. Owen<sup>2</sup>, G. Kirov<sup>2</sup>, M.C. O'Donovan<sup>2</sup>, V.L. Nimgaonkar<sup>1</sup>.* 1) Psychiatry, Human Genetics, Neuroscience, and Neurobiology, University of Pittsburgh, Pittsburgh, PA; 2) Psychological Medicine, University of Wales College of Medicine, Cardiff, UK.

Gene expression and mapping studies have recently implicated the regulator of G-protein signaling 4 (RGS4) in the pathogenesis of schizophrenia (SCZ). We previously reported on evidence supporting association and linkage of a haplotype encompassing four SNPs at RGS4 (SNPs 1, 4, 7, 18) (Chowdari et al, 2002). Here, we report on interactions between this locus and gender in four independently ascertained case-parent samples. Exploratory analyses of clinical sub-groups in a sample from Pittsburgh revealed significant allele frequency differences between male and female patients for all four SNPs composing the associated haplotype (n=91). Increased homozygosity for the G allele was detected among female patients for each of these four SNPs. Significant gender differences were not evident for RGS4 SNPs not associated with SCZ, nor were they observed for the RGS4 SNPs among population-based controls, parents of the cases, or patients with Bipolar I disorder. The gender effects thus appeared to be specific, motivating analysis of samples ascertained by other groups. We found significant increases in homozygosity of SNP1 in female patients of a SCZ sample ascertained by the NIMH Collaborative Genetics Initiative (n=36). A similar trend was obtained in a sample of Indian patients (n=239), but such trends were not evident in a sample from Cardiff, UK (n=677). The results of analyses from UPITT, NIMH, and Indian samples suggest an interaction of gender with RGS4 in the pathogenesis of SCZ. However, analysis of samples obtained from Cardiff may imply that these gender related effects were chance observations. Alternatively, they may reflect a primary association with a variable correlated with gender. Our preliminary analyses suggest that the increased homozygosity is restricted to women with an early age at onset. Thus, further investigations are being conducted to probe other variables associated with disease severity in SCZ.

**Neurogenin 3 contributes to the linkage to T2DM on chromosome 10q23 in Italians.** *C. Gragnoli*<sup>1,2,4</sup>, *J.F. Brittman*<sup>1</sup>, *G. Menzinger von Preussenthal*<sup>4</sup>, *J.F. Habener*<sup>1,2,3</sup>. 1) Molecular Endocrinology, MGH, Boston, MA; 2) Med. Sch., Harvard Univer., Boston, MA; 3) HHMI, Boston, MA; 4) Univ. Tor Vergata di Roma, Italy.

Our goal is to identify the genes responsible for the linkage to type 2 diabetes mellitus (T2DM) on chromosome 10q23 in the Italian population. We genotyped chromosome 10 in 148 Italian late-onset T2DM sibs. Multipoint non-parametric linkage analysis (Merlin 2000-2002/decode map) shows a peak at d10s1213. Analysis of 105 affected sibs (conditional for d10s1213) show peaks at d10s556 and d10s1665. The D10s1665 marker is physically close to neurogenin 3 (*ngn3*), essential for pancreatic endocrine cell differentiation. We genotyped at d10s1665 129 late-onset sibs/22 early-onset T2DM families and obtained a 1.08 np score. (in only 22 early-onset T2DM families, np 1.64 score). We screened *ngn3* gene in 86 single T2DM patients/101 Italian controls and identified several variants: a new -152ntC/G, delCA44-45nt, Gly167Arg, Phe199Ser SNPs and two new promoter variations (-nt498GT/nt364CT). DelCA44-45/Phe199Ser variants, Gly167Arg/Phe199Ser, show significant LD (HPPlus software). The 152nt variation does not cosegregate with disease, and is not conserved in other species. Therefore, we suggest it is not causing T2DM. DelCA44-45, located at transcription factor binding sites, is not significantly associated with T2DM. Gly167Gly is conserved among species, allele A coding for 167Arg shows an association trend toward T2DM in 61 patients linked to d10s1665 (p-value=0.07/C.I.0.92-4.6) and allele G seems to protect from disease (p-value=0.07/C.I.0.22-1.09). A insC167 mutation present in one patient is shared by 2/3 diabetic family members and is absent from the controls. Phe199Phe is conserved among species, and CC/TC199 together with GA/AA167 show an association trend towards disease (p-value=0.12/C.I.0.83-4.28). Non-parametric linkage analysis within the *ngn3* gene variants in 6 early-onset T2DM families shows a np score=3.32/p-value=0.0005. Therefore *ngn3* variations in these 6 families are in linkage with T2DM. In our study GA/AA167 genotypes contribute with an OR=2.01 (C.I.0.93-4.35/p-value=0.07) to T2DM in our population.

**Localization of Novel Loci involved in Ocular and Cutaneous Melanoma.** *E. Gillanders<sup>1</sup>, S. Juo<sup>2</sup>, M. Jones<sup>1</sup>, C. Markey<sup>1</sup>, E. Holland<sup>4</sup>, N. Gruis<sup>6</sup>, B. Bressac-de Paillerets<sup>8</sup>, A. Goldstein<sup>5</sup>, M. Tucker<sup>5</sup>, G. Mann<sup>4</sup>, J. Bailey-Wilson<sup>2</sup>, J. Trent<sup>9</sup>.* 1) Cancer Genetics Branch/NHGRI/NIH, Bethesda, MD; 2) Inherited Disease Research Branch/NHGRI/NIH, Baltimore, MD; 3) Queensland Institute of Medical Research Unit, Brisbane, Australia; 4) Westmead Institute for Cancer Research, University of Sydney at Westmead Millennium Institute, Sydney, Australia; 5) Genetic Epidemiology Branch/NCI/NIH, Bethesda, MD; 6) Department of Dermatology and Center for Human and Clinical Genetics, LUMC, Leiden, The Netherlands; 7) Institut Curie, Paris, France; 8) Institut Gustave Rousy, Villejuif, France; 9) Translational Genomics Research Institute, Phoenix, AZ.

Over the past 20 years, the incidence of cutaneous malignant melanoma (CMM) has increased dramatically worldwide. A positive family history of the disease is among the most established risk factors for CMM; it is estimated that 10% of melanoma cases result from an inherited predisposition. Although mutations in two genes, CDKN2A and CDK4, have been shown to confer an increased risk of CMM, they account for only 20%-25% of families with multiple cases of CMM. Therefore, to localize additional loci involved in melanoma susceptibility, we have performed a genome-wide scan for linkage in 49 Australian pedigrees containing at least three CMM cases, in which CDKN2A and CDK4 involvement has been excluded. In order to minimize genetic heterogeneity we explored subset analyses based on a clinical presentation of both cutaneous and ocular melanoma. Follow up analyses of 2 regions with LOD scores greater than 2 will be presented.

**Association of an orexin 1 receptor 408Val variant with polydipsia-hyponatremia in schizophrenics. J.M.**

*Meerabux<sup>1</sup>, Y. Y Iwayama-Shigeno<sup>1</sup>, H. Ohba<sup>1</sup>, T. Toyota<sup>1,2</sup>, K. Yamada<sup>1</sup>, H. Shimizu<sup>3</sup>, K. Yoshitsugu<sup>1</sup>, K. Ohta<sup>4</sup>, T. Yoshikawa<sup>1</sup>.* 1) Molecular Psychiatry, Brain Science Institute, Riken, Saitama, Japan; 2) Department of Neuropsychiatry, Tokyo Medical and Dental University, Tokyo 113-8519, Japan; 3) Hokushin General Hospital, Nakano, Nagano 383-8505, Japan; 4) Onda-daini Hospital, Matsudo, Chiba 270-2251, Japan.

Polydipsia is a common and often life threatening complication in patients with chronic psychoses, particularly schizophrenia<sup>1</sup>. Research into the genetic etiology of polydipsia is limited and the pathogenesis of the disease remains poorly understood. One contributory factor is thought to be dopamine dysregulation caused by prolonged treatment with neuroleptics<sup>2</sup>. In this study, we put forward role for orexin (also known as hypocretin) signalling in the development of polydipsia. This is based on orexins physiological effect of promoting water intake in experimental animals<sup>3</sup> and the close anatomical and functional link between orexin neurons and the dopaminergic system<sup>4</sup>. We performed mutation screening on the genes for prepro-orexin and orexin receptors 1 (HCRTR1) and 2, and identified six polymorphisms. One mutation, a 408Ile-to-Val variant of HCRTR1 showed significant association with polydipsic-hyponatremic schizophrenics (P = 0.0138). The accumulation of this mutation was more pronounced in polydipsic compared to non-polydipsic schizophrenics (P = 0.0005; odds ratio = 1.83 [95% CI = 1.19 2.80]). These results suggest that individuals carrying the 408Val variant may show an increased risk for polydipsia-hyponatremia after chronic treatment with neuroleptics.

**Strong pattern of association with AD in a 210 kb region on chromosome 12.** *P. Nowotny<sup>1</sup>, Y. Li<sup>2</sup>, P. Holmans<sup>3</sup>, S. Smemo<sup>1</sup>, K. Tacey<sup>2</sup>, L. Doil<sup>2</sup>, K. Lau<sup>2</sup>, J. Catanese<sup>2</sup>, V. Garcia<sup>2</sup>, A. Myers<sup>4</sup>, V. Wavrant-DeVrieze<sup>4</sup>, S. Lovestone<sup>7</sup>, L. Thal<sup>5</sup>, L. Jones<sup>6</sup>, J. Williams<sup>6</sup>, M. Owen<sup>6</sup>, J. Hardy<sup>4</sup>, A. Goate<sup>1</sup>, A. Grupe<sup>2</sup>.* 1) Dept Psychiatry, Washington Univ Sch Medicine, St Louis, MO; 2) Celera Diagnostics, Alameda, CA, USA; 3) MRC Biostatistics Unit, Cambridge, UK; 4) NIA, Bethesda, MD, USA; 5) Dept of Neuroscience, UCSD, San Diego, CA, USA; 6) Dept of Psychological Medicine, Cardiff, UK; 7) Dept Neuroscience, Institute of Psychiatry, London, UK.

Several studies, including our own, have reported linkage to markers on chromosome 12 in late onset Alzheimer's disease (LOAD) families. The linkage signal comes predominantly from individuals with no APOE4 alleles. To follow up these results we have genotyped 473 SNPs in positional candidate genes on chromosome 12. The SNPs were initially tested in a case-control sample of 419 cases and 375 controls. Significant SNPs ( $p < 0.05$ ) were followed up in two other case-control sets (1428 samples total) and in the sample used for the linkage screen. The exploratory study revealed a strong pattern of association in a 210kb region in the whole set ( $p = 0.00002$ ) and the APOE4 negative subgroup ( $p = 0.0003$ ). Based on these initial results, 37 markers from this region were genotyped in the other case-control sets; results were summarized in a meta analysis of all samples. Pair wise inter marker LD patterns between cases and controls and across sample sets were very similar. In the meta analysis, 10 markers within the interval show significant association with  $p$ -values between 0.004 and 0.041 in the APOE4 negative subgroup. 7 SNPs, which define over 80% of the haplotype diversity in this region were genotyped in cases from the linkage sample and unrelated controls and a multilocus genotypic analysis was performed. Analysis of 6 SNPs simultaneously replicated the initial observation in the case control series ( $\chi^2 = 18.61(6df)$ ,  $p = 0.0049$ ). However the best-fitting model was achieved by using 4 loci ( $\chi^2 = 17.39(4df)$ ,  $p = 0.0016$ ). These results strongly suggest that an AD susceptibility allele is located within this region of chromosome 12.

**Functional SNPs in the lymphotoxin- gene that are associated with susceptibility to myocardial infarction.** K. Ozaki<sup>1</sup>, Y. Ohnishi<sup>1</sup>, A. Iida<sup>1</sup>, R. Yamada<sup>1</sup>, T. Tsunoda<sup>1</sup>, A. Sekine<sup>1</sup>, H. Sato<sup>2</sup>, H. Sato<sup>2</sup>, M. Hori<sup>2</sup>, Y. Nakamura<sup>1, 3</sup>, T. Tanaka<sup>1</sup>. 1) SNP Research Center, RIKEN, Tokyo, Japan; 2) Osaka University Graduate School of Medicine, Shita, Japan; 3) Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

By means of a large-scale, case control association study using 92,788 gene-based single nucleotide polymorphism (SNP) markers, we identified a candidate locus on chromosome 6p21 associated with susceptibility to myocardial infarction. Subsequent linkage-disequilibrium (LD) mapping and analyses of haplotype structure showed significant associations between myocardial infarction and a single 50 kb haplotype comprised of five SNPs in *LTA* (encoding lymphotoxin-), *NFKBIL1* (encoding nuclear factor of light polypeptide gene enhancer in B cells, inhibitor-like 1) and *BAT1* (encoding HLA-B associated transcript 1). Homozygosity with respect to each of the two SNPs in *LTA* was significantly associated with increased risk for myocardial infarction (odds ratio=1.78,  $\chi^2=21.6$ ,  $P=0.0000033$ ; 1,133 affected individuals versus 1,006 controls). *In vitro* functional analyses indicated that one SNP in the coding region of *LTA*, which changed an amino-acid residue from threonine to asparagine (Thr26Asn), effected a twofold increase in induction of several cell-adhesion molecules, including VCAM1, in vascular smooth-muscle cells of human coronary artery. Moreover, the SNP, intron 1 of *LTA*, enhanced the transcriptional level of *LTA*. These results indicate that variants in the *LTA* are risk factors for myocardial infarction and implicate *LTA* in the pathogenesis of the disorder.

**Association and linkage disequilibrium between synapsin 2 and complexin 2 gene and Korean schizophrenia.** *H.J. Lee<sup>1,2, 5</sup>, J.W. Kim<sup>2</sup>, M.K. Kim<sup>3</sup>, S.J. Kim<sup>2</sup>, S.Y. Jin<sup>1</sup>, M.S. Hong<sup>1,2</sup>, H.J. Park<sup>2</sup>, D.H. Shin<sup>4</sup>, J. Chung<sup>1,2</sup>, H. Shibata<sup>5</sup>, Y. Fukumaki<sup>5</sup>.* 1) Department of Pharmacology, College of Medicine, Kyung Hee University, Seoul, Republic of Korea; 2) Kohwang Medical Research Institute, College of Medicine, Kyung Hee University, Seoul, Republic of Korea; 3) Seoul National Mental Hospital, Seoul, Republic of Korea; 4) Department of Preventive School of Medicine, Medicine, Keimyung University, Degeu, Republic of Korea; 5) Division of Disease Genes Research Center for Genetic Information, Medical Institute for Bioregulation, Kyushu University, Fukuoka, Japan.

One of the pathophysiologic hypotheses of schizophrenia is aberrant functional connectivity. Recent studies reported that level of synapsin 2 (SYN2) and complexin 2 (CPLX2) mRNA in sections of brain from schizophrenia patients was decreased. In the current study, we analyzed several variants in both genes and made intermarker linkage disequilibrium (LD) maps. Correlation between  $D'$  and physical distance was observed between variants for less than 50kb at SYN2 and less than 10kb at CPLX2. Also, we performed association analysis of SYN2 and CPLX2 between 170 normal healthy controls and 158 schizophrenia patients. First, our results indicated general LD map in SYN2 and CPLX2. Second, there were several significant differences between controls and schizophrenia group in both SYN2 and CPLX2 by pairwise association analysis. ( $p < 0.05$ ) These results provide a potential value of constructing haplotype map and suggest that both SYN2 and CPLX2 polymorphisms may confer increased susceptibility to schizophrenia in Korean.

**Identification of a gene causing the limb malformation using a mouse model, Dominant hemimelia(Dh).** *S.K. Koo<sup>1</sup>, H.S. Jang<sup>1</sup>, J.Y. Heo<sup>1</sup>, S.C. Jung<sup>1</sup>, B. Oh<sup>2</sup>.* 1) Division of Genetic Diseases, Department of Biomedical Science, National Institute of Health, Korea, Seoul, South Korea; 2) Division of Epidemiology and Bioinformation, National Genome Research Institute, National Institute of Health, Korea, Seoul, South Korea.

To understand the pathogenesis of limb malformation, the polydactyly mouse, Dominant hemimelia (Dh) has been studied. We characterized the phenotype of Dh, and identified the causative gene of Dh by the methods of positional cloning. The Dh mouse is characterized by tibial hemimelia, oligo or polydactyly of the hindlimbs, asplenia, and urogenital abnormality including imperforate vagina and hydropic kidney. To identify the location of the semi-dominant mutation of Dh, positional cloning method was used. From the linkage analysis, we found that the Dh gene is positioned between D1Mit310 and D1Mit389. Using the conservation of gene order between human and mouse, the 10 candidate genes of Dh were extracted from human genome map. The RT-PCR analysis of candidate genes shows that the mRNA level of one candidate gene is changed. Sequence analysis was performed in the causative gene and its regulatory region from mutant and normal mice and the mutation was identified.

**Genome-wide association study of human narcolepsy; the first and second screening.** *M. Kawashima<sup>1</sup>, T. Ikuta<sup>2</sup>, G. Tamiya<sup>2</sup>, H. Hohjoh<sup>1</sup>, T. Juji<sup>3</sup>, Y. Honda<sup>4</sup>, H. Inoko<sup>2</sup>, K. Tokunaga<sup>1</sup>.* 1) Department of Human Genetics, Graduate School of medicine, University of Tokyo, Tokyo, Japan; 2) Department of Molecular Life Science, Tokai University school of medicine, Kanagawa, Japan; 3) Japanese Red Cross Central Blood Center, Tokyo, Japan; 4) Sleep Disorder Clinic of Seiwa Hospital, Tokyo, Japan.

Narcolepsy is considered to be a sleep disorder involving multiple genetic and environmental factors. A genetic factor strongly associated with the disorder has been found in the human leukocyte antigen (HLA) region: HLA-DRB1\*1501 - DQB1\*0602 haplotype confers strong predisposition to narcolepsy. We performed the genome-wide association study using about 25,000 of microsatellite markers as a tool for identifying disease susceptibility regions. The subjects investigated in this study were all Japanese living in the Tokyo area. One hundred and five narcoleptic patients were pooled for the 1st set and the other 110 samples were pooled for the 2nd set. Similarly, 210 unrelated healthy individuals as controls were pooled for the 1st set and the other 210 samples were pooled for the 2nd set. We used the 1st set pooled DNAs for the primary screening of microsatellite markers and the 2nd set for the second screening to avoid false positive associations. Allele frequencies were estimated from heights of the peaks detected by an automated sequencer (ABI 3700) with GeneScan software. Then, we performed Fishers exact test using 2 x 2 or 2 x m (m; allele number) tables. After the analysis, five markers showed the significant differences in both screenings (p<0.001). These markers again showed strong associations with the disorder in the following analysis using all individual samples. Three candidate regions are now subjected to SNP analysis to further narrow down the susceptibility regions of narcolepsy.

**A genome wide scan in a family with Meckel syndrome suggesting a putative novel locus for MKS, MKS4.** *M.M. Kyttala<sup>1,2</sup>, R. Salonen<sup>3</sup>, R. Karikoski<sup>4</sup>, T. Varilo<sup>1</sup>, M. Kestila<sup>1</sup>, L. Peltonen<sup>1,2</sup>.* 1) Molecular medicine, National Public Health Institute, Helsinki, Finland; 2) Department of Human Genetics, University of California Los Angeles, USA; 3) Prenatal Genetics, Department of Obstetrics and Gynecology, Helsinki University Hospital; 4) Department of Paediatric Pathology, Helsinki University Hospital, Finland.

Meckel Syndrome (MKS) is a lethal autosomal recessive malformation syndrome. In the most typical cases occipital encephalocele with microcephaly, polycystic kidneys, fibrotic changes of liver and postaxial polydactyly are seen. MKS affects 1:9000 births in the Finnish population and was mapped in a Finnish study sample to chr17q23 named as MKS1 (OMIM 249000). 70% of the known Finnish MKS families have been linked to this chromosomal region and most patients share the same haplotype suggesting a common founder mutation in this isolated population. Two other genetic loci for MKS have been identified on chr11q13, MKS2 (OMIM 603194) in Northern African and Middle Eastern populations and on 8q24, MKS3 (OMIM 607361) in consanguineous families from Pakistan and Northern India. We report here a Finnish family with two affected with MKS and two healthy children. Both affected children fulfil the strict diagnosis criteria for MKS and the diagnosis was also confirmed by histological examination of liver. A genealogical study of the family showed evidence of the mothers mothers of both parents originating from the same rare family name on 18th century, and are most likely remote relatives. A linkage analysis excluded the three known MKS loci in the family and therefore we performed a genome wide scan. In two point analysis we obtained the maximum lod scores with supporting p-values ( $p < 0.02$ ) on five chromosomal locations, other than the already known MKS loci. At the moment we are fine mapping and analysing these putative novel genetic loci to confirm the linkage to the genuine MKS4 locus found in this family. This study may provide essential new information about the genetics of MKS and it may also facilitate the identification the disease genes on the other MKS loci, which still remain unidentified.

**Hydrolethalus Syndrome is Caused by a Missense Mutation in a Novel Gene Coding For a Cytoplasmic Protein.**

*L. Lanyi*<sup>1</sup>, *J. Vesa*<sup>1</sup>, *S. Finnila*<sup>1</sup>, *I. Visapaa*<sup>1,2</sup>, *K. Hovanes*<sup>1</sup>, *J. Lee*<sup>1</sup>, *R. Salonen*<sup>3</sup>, *L. Peltonen*<sup>1,2</sup>. 1) Dept Human Genetics, David Geffen School of Medicine at Univ California, Los Angeles, Los Angeles, CA; 2) Dept. of Molecular Medicine, National Public Health Institute and Dept. of Medical Genetics, University of Helsinki, Finland;; 3) Dept. of Obstetrics and Gynecology, Helsinki University Central Hospital.

Hydrolethalus Syndrome (HLS) is an autosomal recessive lethal malformation syndrome characterized by developmental defects in multiple fetal tissues. The disease is enriched in the Finnish population with an incidence of at least 1:20,000. We earlier mapped and restricted the region to a critical 1cM interval on 11q23-25 using linkage disequilibrium (LD) and shared ancestral haplotype analysis. Here we have utilized LD and haplotype analysis of single nucleotide polymorphism (SNP) markers to further restrict the locus to 470 kb between the gene PREP2 and marker D11S975. A disease associated nucleotide change was identified in one of the predicted transcripts (Celera:hCG1644899, NCBI:FLJ32915) referred to as the HLS gene. This A to G transition in this novel gene (FLJ32915: nucleotide1168) results in an Asp211Gly change in the predicted 299 amino acid polypeptide with no known functional domains. The carrier frequency of the mutation was 2.5% in Eastern Finland, 1.1% in Western Finland, and no carriers were found in the mixed European control panel. The HLS gene shows alternative splicing and is ubiquitously expressed. Wild- type (WT) polypeptides expressed from the cDNA in vitro resulted in diffuse staining of cytoplasm whereas immunostaining of the polypeptides synthesized from mutated cDNA revealed distinct nuclear vesicles. This would imply defective cellular targeting of mutant protein also in vivo.

Program Nr: 1855 from 2003 ASHG Annual Meeting

**Association between schizophrenia and the syntaxin 1a gene.** *A.H.C. Wong<sup>1,3,4</sup>, J. Trakalo<sup>4</sup>, O. Likhodi<sup>4</sup>, M. Yusuf<sup>4</sup>, A. Macedo<sup>5</sup>, M.-H. Azevedo<sup>5</sup>, T. Klemper<sup>3</sup>, M.T. Pato<sup>6</sup>, W.G. Honer<sup>7</sup>, C.N. Pato<sup>6</sup>, H.H.M. Van Tol<sup>1,2,3,4</sup>, J.L. Kennedy<sup>1,3,4</sup>.* 1) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 2) Department of Pharmacology, University of Toronto, Toronto, Ontario, Canada; 3) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 4) Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 5) Department of Psychiatry, University of Coimbra, Portugal; 6) State University of New York, Syracuse, NY; 7) Centre for Complex Disorders, University of British Columbia, Vancouver, BC, Canada.

**Background:** Both microarray and candidate molecule studies have demonstrated that protein and mRNA expression of syntaxin and other genes involved in synaptic function are altered in the cerebral cortex of patients with schizophrenia. **Methods:** DNA from 186 nuclear families with a schizophrenia proband was genotyped for the syntaxin 1a gene at two single-nucleotide polymorphisms, one located in exon 3 and the other in intron 7. Genetic association was analyzed using the transmission disequilibrium test (TDT). **Results:** A significant association was found between schizophrenia and the intron 7 polymorphism ( $p=0.015$ ) and with a haplotype consisting of the two polymorphisms ( $p=0.0069$ ). **Conclusions:** This is the first report of a genetic association between schizophrenia and the STX1a gene in a family-based sample. Combined with gene expression data, this genetic finding strengthens the hypothesis that STX1a is involved in schizophrenia.

**Haplotype tag SNPs in exclusion of the candidate gene, *CBLB*, as a common factor in susceptibility to the complex autoimmune disease, type 1 diabetes.** *F. Payne, H. Rance, B. Barratt, J.A. Todd.* JDRF/WT, DIL, CIMR, Univ of Cambridge, WT/MRC Building, Addenbrooke's Hospital, Cambridge. CB2 2XY.

The Komeda diabetes prone (KDP) rat is a spontaneous animal model of human autoimmune, T-lymphocyte-associated type 1 diabetes (T1D), in which the majority of the disease susceptibility can be attributed to two unlinked loci, the *Iddm/kdp1* locus on rat chromosome 11 and the Major Histocompatibility Complex. Previously, *kdp1* was identified as a nonsense mutation in the T lymphocyte regulatory gene, *Cblb*, which had been identified as an essential negative regulator of T lymphocyte activation. Following the strategy for examining the human orthologues of susceptibility genes identified in animal models for association with T1D, we harvested 35 polymorphisms (30 single nucleotide polymorphisms (SNPs) and five indels) from 11.8 kb of *CBLB* covering exons and 2.5 kb of 5 and 3 sequence, by re-sequencing of PCR products from 96 type 1 diabetic subjects. No non-synonymous variants were observed, nor any obvious candidate for a variant that could change *CBLB* function or expression. From the 21 polymorphisms with allele frequencies 3 %, we selected nine haplotype tag SNPs (htSNPs) that captured the allelic variation of the untyped SNPs with a minimum  $r^2$  of 0.8. These htSNPs were then genotyped in 753 T1D affected sib-pair families from the UK and USA, and the results used to calculate a global multi-locus transmission/disequilibrium test (TDT) that jointly tests the association of all of the variants in the region simultaneously. From the htSNP genotypes and patterns of linkage disequilibrium, genotype data were also imputed for each of the untyped markers and single locus TDT performed. The global multi-locus TDT test gave a *P*-value of 0.69, whereas the smallest single locus TDT *P*-value was 0.06. Although these data suggest that *CBLB* is not a major susceptibility locus in human T1D, the application of htSNPs has enabled the rapid and efficient evaluation of this gene with a 70 % saving in genotyping costs.

Program Nr: 1857 from 2003 ASHG Annual Meeting

**Ankyrin and SOCS box containing gene 2 (ASB2) in a linked region on 14q32 is associated with asthma and bronchial hyperresponsiveness (BHR) in the Hutterites.** *Z. Tan, D. Schneider, D. Newman, R. Stanaker, C. Ober.* Department of Human Genetics, The University of Chicago, Chicago, IL.

A broad region on chromosome 14q24-q32 was linked to asthma in at least 4 different populations, including the Hutterites (Ober et al., 2000; *Am J Hum Genet* 67:1154) and families in the Collaborative Study on the Genetics of Asthma (CSGA) (Xu et al., 2001; *Am J Hum Genet* 68:1437). In these two populations, there was evidence for linkage at D14S749 at 97.7 cM from p-ter (Marshfield Map). We searched the public databases for gene(s) near D14s749 and identified ASB2, which has a Suppressor of Cytokine Signaling (SOCS) box and is involved in cell growth and differentiation, as an excellent candidate. We genotyped 693 members of a large Hutterite pedigree for 3 SNPs located approximately 7 kb apart, in intron 4, intron 5, and the 3'UTR (minor allele frequency 0.33, 0.32, 0.32, respectively). We tested each SNP and pairwise combinations of the SNPs for association by the TDT. Significant overtransmission at each of the three loci ( $P=0.005-0.011$ ) was observed for individuals with asthma (defined by the presence of BHR and symptoms). Pairwise combinations of SNPs spanning the gene were also significantly over- and undertransmitted to individuals with BHR ( $P<0.01$ ), suggesting that an ASB2 haplotype or multiple SNPs within the gene contribute to susceptibility. Additional genotyping of variation in ASB2 as well as in neighboring genes is underway. Nonetheless, these data suggest that variation in ASB2, or variation in linkage disequilibrium with an ASB2 haplotype, is associated with asthma and may account for some of the linkage to 14q32 that was observed in the Hutterites. Supported by HL56399.

Program Nr: 1858 from 2003 ASHG Annual Meeting

**A SNP map of human chromosome 20q12-13.1.** *J.L. Bento, J.C. Mychaleckyj, B. Roh, P. Hicks, B.I. Freedman, D.W. Bowden.* The Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC.

Human chromosome 20q12-13.1 is linked to type 2 diabetes mellitus (T2DM) in multiple studies. To identify T2DM susceptibility gene(s) in this region, a SNP fine map has been constructed across a 6 Mb region (41.6-47.5 Mb), containing the candidate diabetogenic genes, adenosine deaminase (ADA), hepatocyte nuclear factor 4 alpha (HNF-4) and glucose transporter 10 (GLUT-10). Verified SNPs from the NCBI dbSNP database, with minor allele frequency greater than 0.20, were placed on the map at an average density of 1 SNP per 25 kb. A total of 116 SNPs were genotyped on 310 Caucasian controls and 300 Caucasian cases with T2DM and end stage renal disease, using the Sequenom MassArray genotyping system. SnpAnalyzer, a web-based, enhanced version of the SnpAnalysis package was used to test each SNP for Hardy-Weinberg equilibrium, and to calculate inter-SNP linkage disequilibrium. Within regions of high LD ( $D > 0.70$ ), haplotypes were reconstructed using PHASE and parametric and non-parametric tests for association with T2DM performed using Excel and Clump.

Currently, 1.142 Mb of the region falls into 9 haplotype blocks of high inter-SNP LD (range=64-223 kb, mean=127 kb) but there are also extensive regions that lie outside the blocks, the largest being 259 kb. An additional set of SNPs is being genotyped in regions of low SNP density. Seven SNPs show evidence of allelic association with T2DM ( $p < 0.05$ ), with the strongest association centered on an intronic SNP in the gene cadherin-like 22 (CDH22,  $p = 0.00146$ ). Each SNP was also genotyped on 40 CEPH trios, and showed similar LD results and haplotype structures to the Caucasian population of unrelateds. These results indicate that the haplotype structure of the CEPH individuals is comparable to our Caucasian population, and therefore the CEPH trios offer a powerful independent method to confirm or predict block structure, with the benefit of inheritance-based ambiguous phase resolution. In conclusion, this SNP map will provide a framework for our on-going T2DM susceptibility gene association study, and for other diseases that map to this region.

Program Nr: 1859 from 2003 ASHG Annual Meeting

**Linkage Disequilibrium Surrounding the *CDKN1A* Gene.** *L. Geller, G.P. Larson, C. Ouyang, T.G. Krontiris.*  
Division of Molecular Medicine, Beckman Research Institute of the City of Hope, Duarte, CA, 91010.

We analyzed genetic variation in a 28-kb region surrounding the *CDKN1A* gene, located at 6p21. *CDKN1A* encodes a 21-kd cyclin dependent kinase inhibitor p21<sup>*Waf1/Cip1*</sup>, which is believed to be a major downstream effector of p53 in cell cycle regulation. Although polymorphisms within the coding region are rare (we have found only the Codon-31<sub>SerArg</sub> variant), we identified 87 SNPs, insertions, and deletions upstream of the gene and within the promoter, introns, and 3' UTR. These polymorphisms are distributed over at least 20 haplotypes apparently resulting from crossovers and gene conversions. Some of these SNPs and haplotypes maybe associated with cancer risk. This region is characterized by high levels of extended, overlapping linkage disequilibrium (LD) that is distributed over several haplotypic backgrounds and includes two complex microsatellite markers downstream. Meiotic recombination at potential recombination hotspots near *CDKN1A* is currently under investigation.

**Linkage disequilibrium and haplotype mapping of the human cytoplasmic dynein heavy chain 1 gene on chromosome 14q32.** A. Ahmad-Annuar<sup>1</sup>, P. Shah<sup>1</sup>, M. Hafezparast<sup>1</sup>, D.B. Goldstein<sup>2</sup>, E.M.C. Fisher<sup>1</sup>. 1) Department of Neurodegenerative Disease, Institute of Neurology, London, United Kingdom; 2) Department of Biology, University College London, United Kingdom.

Cytoplasmic dynein heavy chain 1 (*Dnchc1*) has recently been shown to be the causal gene in a mouse model of motor neuron degeneration, Legs at Odd Angles (*Loa*). The *Loa* mouse displays progressive locomotor deficits and pathological features similar to aspects of human motor neuron disease, including loss of anterior horn cells and presence of inclusion bodies positive for SOD1, ubiquitin, CDK5 and neurofilaments. *Dnchc1* is part of the dynein-dynactin pathway which is integral in maintaining retrograde transport in neurons and microtubule-associated activities, and these functions have been shown to be perturbed in the *Loa* mice. The human homologue for the mouse *Dnchc1* lies on chromosome 14q32. We have defined the structure of the human *DNCHC1* and found it to be a large gene with 78 exons spanning 86kb. Mutational analysis of *DNCHC1* in patients with motor neuron disease, of the exon known to be mutated in *Loa* mouse, did not reveal any changes associated with the disease. Due to the size of *DNCHC1*, we have undertaken the haplotype mapping approach to facilitate the study of the gene. Statistical haplotyping of 16 single nucleotide polymorphisms (SNPs) within the human *DNCHC1* locus in 32 CEPH trios was performed to elucidate the haplotype block structure across this region. Linkage disequilibrium was estimated using  $D'$  values and revealed a pattern of two distinct haplotype blocks across *DNCHC1*. Haplotype diversity was found to be distinguishable by three tagging SNPs, however *DNCHC1* demonstrated lower haplotype diversity in the CEPH population than expected. Future work involves analysing the *DNCHC1* locus in other populations for comparison against the CEPH haplotypes as well as screening a large collection of patients with motor neuron disease to find an association between haplotype and phenotype.

**No support for association of the DTNBP1 (dysbindin) gene with schizophrenia in large samples from Germany, Poland, and Sweden.** *S. Cichon*<sup>1</sup>, *A. Van Den Bogaert*<sup>1</sup>, *A.C.J. Otte*<sup>2</sup>, *T.G. Schulze*<sup>3</sup>, *J. Schumacher*<sup>2</sup>, *S. Ohlraun*<sup>3</sup>, *P. Czerski*<sup>4</sup>, *J. Hauser*<sup>4</sup>, *E. Jönsson*<sup>5</sup>, *W. Maier*<sup>6</sup>, *P. Propping*<sup>2</sup>, *M. Rietschel*<sup>3</sup>, *M.M. Nöthen*<sup>1</sup>. 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Inst Human Genetics, Univ Bonn, Bonn, Germany; 3) Central Inst Mental Health, Mannheim, Germany; 4) Dept Psychiatry, Univ Poznan, Poznan, Poland; 5) Dept Clinical Neuroscience, Psychiatry Section, Karolinska Inst, Stockholm, Sweden; 6) Dept Psychiatry, Univ Bonn, Bonn, Germany.

Recently, Straub et al. (2002) identified significant associations between single nucleotide polymorphisms (SNPs) within the positional candidate gene DTNBP1 (dystrobrevin-binding protein 1, or dysbindin) on 6p22.3 and schizophrenia in the Irish population. In a subsequent replication study, Schwab et al. (2003) tested six SNPs in two independent parent-offspring trio samples from Germany and obtained confirmatory evidence for association. A second replication study by Morris et al. (2003) investigated a case-control sample of schizophrenia from the Irish population. No evidence was found to suggest an association between the dysbindin gene and schizophrenia in their sample. The major difference between their study and the reports by Straub et al. (2002) and Schwab et al. (2003) was that the case-control sample used by Morris et al. (2003) was not selected for familiarity. We have performed an independent replication study in a large sample of 418 schizophrenic cases from Germany that were not selected for familiarity and 284 controls using SNPs in the dysbindin gene. Two other, smaller case-control samples were tested, one from Sweden (158 cases/292 controls) and one from Poland (296/115). No significant p-values were observed in single-marker and haplotype analyses. Likewise, no significant p-values were observed in a separate analysis of the subsamples with a positive family history of schizophrenia and other psychiatric disorders. Our results are in line with the finding by Morris et al. (2003) and might reflect different genetic mechanisms underlying individuals derived from high-density families and cases coming from families less heavily loaded with schizophrenia.

**SNP map and haplotype analysis of the beta-globin gene region in beta<sup>0</sup>-thal/HbE patients.** *K.J. Abel<sup>1</sup>, J. Whitacre<sup>1</sup>, O. Sripichai<sup>2</sup>, P. Erlich<sup>3</sup>, L. Farrer<sup>3</sup>, A. Braun<sup>1</sup>, S. Fucharoen<sup>2</sup>.* 1) SEQUENOM, Inc., San Diego, CA; 2) TRC, Mahidol University, Nakornpathom, Thailand; 3) Boston University, Boston, MA.

Beta-thalassemias are extremely common in SouthEast Asia, and due to recent worldwide migrations these abnormal alleles and associated disorders are becoming more common in other regions. Many genetic defects responsible for beta thalassemias have been described. The mutant HbE allele encodes a Glu to Lys amino acid substitution at codon 26, plus the potential for alternative mRNA splicing leading to a frame shift mutation. A puzzling feature of patients compound heterozygous for beta<sup>0</sup>-thalassemia/HbE is the variable disease presentation, ranging from nearly asymptomatic to severe, transfusion-dependent disease. The need exists to identify the modifying genetic factors, representing either novel therapeutic targets or the focus of new diagnostics to identify at-risk individuals for early intervention.

Using an automated, chip-based platform for genetic analysis based on mass spectrometry (MassARRAY), we are examining the extent to which genetic variation within the beta globin gene complex may contribute to thalassemia disease severity in Thai/Chinese patients with beta<sup>0</sup>-thalassemia/ HbE disease. Toward this goal a map of single nucleotide polymorphisms (SNPs) has been constructed spanning more than 80 Kb, including all beta-like genes and extending into the locus control region (LCR). Assays were designed for >130 putative SNPs obtained from targeted resequencing efforts and from the public domain, and are being tested in individuals from different ethnic groups. Also included are assays for polymorphic sites reported to influence globin gene expression (XmnI<sup>+/-</sup> and BP1-binding sites upstream of  $\alpha$ - and  $\beta$ -globin, respectively). SNPs having minor allele frequencies >0.15 are being selected at spacings of roughly 2-3 Kb. Multiplexed assays are being used in haplotype analyses for association with disease severity. These efforts will be complemented by a genome scan for other modifier alleles, comparing up to 100,000 gene-based SNP frequencies in pooled DNAs from mild and severe disease patients.

**Haplotype structure of *ESRI* and association studies with complex traits.** *J. Butler*<sup>1</sup>, *P. Bretsky*<sup>2</sup>, *C. Haiman*<sup>2</sup>, *D.O. Stram*<sup>2</sup>, *M.C. Pike*<sup>2</sup>, *K.L. Lunetta*<sup>3</sup>, *K.G. Ardlie*<sup>3</sup>, *B.E. Henderson*<sup>2</sup>, *M.J. Daly*<sup>4</sup>, *D. Altshuler*<sup>4,5</sup>, *J.N. Hirschhorn*<sup>1,4</sup>. 1) Genetics, Children's Hospital/Harvard Med School, Boston, MA; 2) Norris Comprehensive Cancer Center/Keck School of Med, USC, Los Angeles, CA; 3) Genomics Collaborative, Cambridge, MA; 4) Whitehead/MIT Center for Genome Research, Cambridge, MA; 5) Genetics/Medicine, Mass General Hospital/Harvard Med School, Boston, MA.

In haplotype-based association studies, single nucleotide polymorphisms (SNPs) are used to determine the particular patterns of alleles (haplotypes) that are common in the population. A set of haplotype-tagging SNPs (htSNPs) is chosen to assay the common haplotypes and the variants carried on these haplotypes, allowing more efficient and comprehensive studies. We are applying this approach to studies of *ESRI*, encoding estrogen receptor. We chose to study *ESRI* because it is an excellent candidate for two traits of interest to us, breast cancer and stature, and is in a region that we and others have linked to stature (6q24-25).

To determine common haplotypes (>5% frequency) within blocks in *ESRI*, we genotyped SNPs in 349 unrelated individuals from 5 self-described ethnic groups: African-American, White, Hawaiian, Japanese, and Latino. Within blocks of strong linkage disequilibrium (LD), custom software packages were used to reconstruct haplotypes and select htSNPs.

We successfully genotyped 140 SNPs in 480 kb encompassing *ESRI* and its known promoters. Consistent with previous studies, we observed blocks of strong LD with generally low haplotype diversity (3-6 common haplotypes/block). We identified a set of approximately 60 htSNPs for the non-African-derived populations. At least 20 additional htSNPs were required to capture the common haplotypes in African-Americans. By genotyping the htSNPs in 1500 people from each end of the stature distribution, and in a large (n = 3936) case-control study for breast cancer, we are testing *ESRI* for a role in these complex traits. The htSNPs we identified should also be useful in studies of *ESRI* with other complex traits and in a wide variety of ethnic groups.

**Identification of framework haplotypes defining blocks of linkage disequilibrium conserved across ethnic populations.** *C. Ouyang, T.G. Krontiris.* Division of Molecular Medicine, Beckman Research Institute of the City of Hope, Duarte, CA.

The recent discovery of a block-like haplotype structure of linkage disequilibrium (LD) throughout the human genome has sparked hope for the future success of genome-wide disease mapping studies. In a study designed to determine the required single nucleotide polymorphism (SNP) density to uncover major underlying haplotypes within LD blocks, we analyzed the haplotype diversity of 13 genes distributed across the length of the long arm of chromosome 5 and spanning 247 kb at single-base resolution. We found that haplotype diversity could generally be simplified into one to three frameworks by using highly structured SNPs conserved across different human populations. These framework SNPs could generally be easily identified as having allele frequencies greater than 15%; and pairwise  $r$  near 1. Our analyses suggested that such framework haplotypes were likely to be the common ancestral backgrounds upon which more recent mutations were superimposed. Nucleotide diversity across a given region was directly correlated with the number of framework haplotypes. At some loci, we observed a reduction of frameworks in individuals of European descent when compared to individuals of African descent, supporting the out-of-Africa scenario. Preliminary studies at 6 other loci not on chromosome 5 revealed the same patterns. We discuss the advantages using our framework haplotype analysis to define the boundaries of LD blocks and to simplify haplotype diversity for genome-wide association studies.

**SNP frequency, haplotype structure and linkage disequilibrium in human FBN1-gene.** *C. Kraus, M. Krumbiegel, A. Reis.* Institute of Human Genetics, University of Erlangen, Germany.

The fibrillin gene (FBN1) is a relatively large (approximately 100kb) and highly fragmented (65 exons) gene. Mutations in the FBN1 cause Marfan syndrome and autosomal dominant Weill-Marchesani syndrome. Moreover, it is a candidate for association studies in complex disease. To determine the SNP frequency and haplotypes structure of the human FBN1 gene we analyzed a total of 28 single-nucleotide polymorphisms (SNPs) spanning the entire 110kb locus. 17 of these 28 SNPs were initially identified as sequence variants in Marfan patients, of which 8 were already published in the database. Additionally, 11 SNPs were selected from the genome SNP database (dbSNP), whereas heterozygosity of 0.3 was the major criteria. SNPs were genotyped on 96 unrelated individuals from Caucasian origin by sequencing the corresponding fragments. For the analysis for the linkage disequilibrium (LD) and haplotypes structure of the region we chose those SNPs, which showed a minor allele frequency of at least 9% in our control group. Only 18 of the 28 SNPs analyzed fulfilled this criteria. Of the published 11 SNPs with a given heterozygosity of 0.3, 3 were not detected in our control samples and two were found only twice. LD was calculated with *ldmax* using an expectation-maximization algorithm and visualized with *GOLD*. SNPs in a region of 110kb covering the entire FBN1 locus are in a significant pair wise LD. Haplotypes and their frequencies were estimated using the *PHASE* program. Within this region 5 common haplotypes were observed accounting for 91% of chromosomes. The most frequent one was found in 64% of the control samples. All but two of the rare haplotypes can be reconstructed from the 3 most common by changing only one site. To review the quantity of chromosomes which are necessary for definition of LD and haplotypes structure of the FBN1 locus, calculation were repeated with 48 control persons. Repeated calculation with only 48 control persons demonstrated the same LD and haplotype structure.

**Linkage disequilibrium analysis of single nucleotide polymorphisms of the glutamate receptor 6 gene and schizophrenia.** *M. Martinez*<sup>1</sup>, *A.R. Sanders*<sup>2</sup>, *L. Martinolich*<sup>2</sup>, *E.B. Carpenter*<sup>2</sup>, *J. Duan*<sup>2</sup>, *B.J. Mowry*<sup>3</sup>, *D.F. Levinson*<sup>4</sup>, *R.R. Crowe*<sup>5</sup>, *J.M. Silverman*<sup>6</sup>, *P.V. Gejman*<sup>2</sup>. 1) INSERM EMI 00-06, Evry, France; 2) Schizophrenia Genetics Research Program Univ of Chicago, Chicago, IL; 3) Center for Schizophrenia Research, Univ of Queensland, Brisbane, Australia; 4) Dept of Psychiatry, Univ of Pennsylvania School of Medicine, PA; 5) Dept of Psychiatry, Univ of Iowa, Iowa City, IA; 6) Dept of Psychiatry, Mount Sinai School of Med, New York, NY.

The chromosome 6q13-q26 region has been implicated as harboring a schizophrenia susceptibility gene (SCZD5) in multiple independent family collections. Interestingly, the 6q21 region has also been described as a candidate region for autism. A positive association has recently been reported with the glutamate receptor 6 (GRIK2) gene and this syndrome. Glutamate is the principal excitatory neurotransmitter in the brain and is directly involved in cognitive functions such as memory and learning. We report here on a linkage disequilibrium analysis of 13 GRIK2-SNPs in a sample of 146 schizophrenia pedigrees (>750 subjects with DNA). Using family-based tests in the FBAT program, each SNP was tested for association with SZ individually and by multilocus analysis. No significant association was found. The most significant results were observed with G-14810e2A and G-2710e14T (p=0.20). Altogether, our results do not indicate that GRIK2 gene is a strong candidate gene for SZ.

**Simulating a Coalescent Process with Disease Ascertainment Bias.** *Y. Wang, B. Rannala.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

There is currently much interest in the possibility of using population linkage disequilibrium (LD) to identify and localize disease-associated mutations on chromosomes. One approach to evaluating the potential power and feasibility of these LD mapping methods is to simulate population samples of chromosomes carrying linked genetic markers to examine the expected extent of LD. To do so, new simulation methods are needed that take account of genetic and population demographic processes as well as the sample ascertainment bias present in case-control studies of genetic diseases. A new method is presented for use in simulating samples of disease and normal chromosomes bearing multiple linked genetic markers under a neutral model of mutation, genetic drift, and recombination. The basic strategy is to simulate the sample path (over time) of the population frequency of a disease allele, using a diffusion approximation, and then to simulate the coalescent of a sample of chromosomes conditional on the sample path of the allele frequency. The method is implemented in a computer program. We evaluated the simulation method by comparing the results with a real data set used to positionally clone the diastrophic dysplasia (DTD) gene. The pattern of LD is similar between the DTD data and the simulated data. We also applied the simulation program to study the general effects of disease mutation age (frequency), marker allele polymorphism cutoff level, and sample size, on the pairwise LD. It is shown that the levels of LD between markers and a disease mutation is lower for older, or more prevalent, disease mutations. The marker polymorphism level also has an important effect on LD. The results suggest that selecting marker loci with higher polymorphism levels may increase the power of LD mapping. This effect decreases with an increasing the map distance of the marker from the disease mutation. The level of LD may be biased upward with small sample sizes. If more chromosomes are sampled (more than 100), the average LD changes little.

**Investigation of recombination hotspots and blocks of linkage disequilibrium within the human *PGMI* gene: An allelic association and mapping approach.** *N.A Rana*<sup>1, 2</sup>, *N.D. Ebenezer*<sup>1</sup>, *A.R. Webster*<sup>1</sup>, *D.B. Whitehouse*<sup>2</sup>, *S. Povey*<sup>2</sup>, *A.J. Hardcastle*<sup>1</sup>. 1) Inst.of Ophthalmology, UCL, UK; 2) The Galton Laboratory, UCL, UK.

The distribution of linkage disequilibrium (LD) in the human genome has important consequences for the design of experiments that infer susceptibility genes for complex disease using association studies. Recent studies have shown a non-random distribution of human meiotic recombination associated with intervening tracts of LD. This phenomenon can be better understood by the continual dissection and fine structure analysis of several genomic regions. Here, we report clustered hotspot activity with intervening blocks of LD within the human *PGMI* gene (1p31) using data derived from comparative mapping, meiotic and population studies. Earlier work has suggested a high recombination rate in two regions within the *PGMI* gene; Site A (exons 4 to 8) and Site B (exons 1A to 4). Site A has been previously studied, Site B is the subject of this current study. CRIMAP was used to construct a genetic map of the region using locally typed intragenic *PGMI* markers and previously typed CEPH markers. Integration of this map with physical data revealed the *PGMI* recombination rate to be 50 times higher than the genomic average. Specific recombination events in CEPH families and large multi-generation families were sought and further refined. The recombination rate across *PGMI* was estimated at 37.8 cM/Mb showing an excess of male recombinants (12.6 cM/Mb female, 63.1 cM/Mb male,  $p=0.10$  two-tailed). Sequencing of 8 individuals across 6 Kb of targeted regions in Site B identified 18 informative SNPs. Individuals from three distinct populations, Caucasian ( $n=264$ ), Chinese ( $n=222$ ) and Vietnamese ( $n=187$ ) were genotyped, and haplotypes determined using EH, Idmax and Arlequin. Allelic association and haplotype analysis in these samples revealed variable recombination rates in the region, demonstrating the presence of, (i) at least two hotspots and, (ii) two haplotype blocks. The spatial arrangement of haplotype blocks was identical in all three populations. Fine mapping of recombination events placed these at the regions of LD collapse. Sequence motifs associated with recombination will also be presented.

**Marker-dependent background disequilibrium on human chromosome 11p.** *L. Rodríguez<sup>1</sup>, J. Hermida<sup>1</sup>, E. Sande<sup>1</sup>, S. Rodríguez<sup>1</sup>, C. Nuñez<sup>1</sup>, C. Louro<sup>1</sup>, C. Martín<sup>2</sup>, C. Zapata<sup>1</sup>.* 1) Departamento de Genética, Universidad de Santiago, 15782 Santiago de Compostela, Spain; 2) Departamento de Dermatología y Otorrinolaringología, Universidad de Santiago, 15782 Santiago de Compostela, Spain.

Information on the amount and distribution of gametic disequilibrium across human genome (background disequilibrium) is relevant to successful localization of disease genes by disequilibrium. Background disequilibrium over large anonymous regions of human chromosomes has been evaluated using genetic markers with very different evolutionary dynamics, such as microsatellites and SNPs. It follows that quantification of the amount of background disequilibrium can be seriously confounded by the occurrence of marker-dependent disequilibrium. Here, we report a study aimed at assessing the influence of different genetic markers on the quantification on background disequilibrium across an extensive anonymous region of human genome. Specifically, disequilibria between microsatellites and SNPs distributed along the human chromosome 11p were compared, from two independent large samples of the Galician population (northwest Spain). Our observations show that the amount of disequilibria is similar for these two genetic markers but their patterns of distribution along 11p differ markedly. Notably, disequilibria between microsatellites extend over wider regions than disequilibria between SNPs. In addition, a significant negative correlation was detected between the strength of disequilibrium between SNPs and recombination frequency. In contrast, the strength of disequilibrium between microsatellite pairs does not appear to be correlated with recombination frequency. Our findings suggest that the occurrence of marker-dependent background disequilibrium is a relevant factor for designing and interpreting experiments of localization of disease genes by disequilibrium mapping.

**Characterization and comparison of multiple pair wise linkage disequilibrium indices and definitions of haplotype blocks using simulated SNPs data.** *A. Takahashi<sup>1</sup>, R. Yamada<sup>2</sup>, T. Tsunoda<sup>1</sup>*. 1) Laboratory for Medical Informatics, SNP Research Center, The Institute of Physical and Chemical Research(RIKEN); 2) Laboratory for Rheumatic Diseases, SNP Research Center, The Institute of Physical and Chemical Research(RIKEN).

It is well recognized that linkage disequilibrium (LD) mapping and haplotype block analysis using SNPs are promising. There are, however, multiple indices for quantification of pair wise LD and definitions of haplotype blocks are also multiple. These indices of LD and definitions of haplotype blocks have been used in various studies without good characterization of them from the standpoint of genome-wide evaluation with SNPs. It seems necessary that relationship between different LD indices and haplotype blocks by different methods should be investigated to offer basic data for various genetic studies. For this purpose, we created simulation data of haplotypes consisted of SNPs by considering recombinations, genetic drifts and mutations and characterized LD indices and haplotype blocks as well as relationship between LD indices and haplotype blocks.

**Evaluation of different haplotype block definition methods and characterisation of the genomic architecture of human chromosome 17q.** *E. Zeggini*<sup>1</sup>, *A. Barton*<sup>2</sup>, *S. Eyre*<sup>2</sup>, *D. Ward*<sup>2</sup>, *J. Worthington*<sup>1,2</sup>, *S. John*<sup>1</sup>. 1) CIGMR, University of Manchester, Manchester, UK; 2) arc Epidemiology Unit, University of Manchester, Manchester, UK.

The finding of mosaic patterns of linkage disequilibrium (LD) in the human genome have instigated attempts to characterise the distribution of haplotype blocks as a useful tool in association studies. Several recent reports have focused on determining the genomic architecture of different chromosomal segments, each by applying distinct haplotype block definitions based on LD measures or haplotype diversity. The effect that different haplotype block definition methods have on association studies, however, remains unclear. A proposed strategy to utilise blocks in association studies is to initially select haplotype tagging single nucleotide polymorphisms (htSNPs) in the region of interest. We have applied various sets of criteria in characterising blocks in a 6.1Mb region of human chromosome 17q. One hundred eighty nine unrelated healthy individuals were genotyped for 137 SNPs, at a median spacing of 15.5 kb. Haplotype block maps of the region were constructed using diverse methods, including those employed by Gabriel et al., 2002, Daly et al., 2001, Wang et al., 2002, and novel methods we have developed. HtSNPs were identified for each map. Blocks were generally found to be shorter (16464 to 28410 bp) and coverage of the region limited (5% to 12.7%) with definitions based on LD measures, compared to methods based on haplotype diversity (42024 to 130678 bp and 26.2% to 85.8%). Although the distribution of blocks was highly variable, the number of htSNPs was consistent, indicating that, for the marker spacing used in this study, choice of haplotype block definition is not important when used as an initial screen of the region to identify htSNPs. However, methods based on haplotype diversity may have greater utility when used in association studies due to greater coverage of the region, maximising the chances of detecting an association within the boundaries of a block.

**Linkage disequilibrium analysis of G72 in Canadian families with schizophrenia.** *B. Xu*<sup>1</sup>, *E.W.C. Chow*<sup>2</sup>, *A.S. Bassett*<sup>2</sup>, *L.M. Brzustowicz*<sup>1,3</sup>. 1) Dept. of Genetics, Rutgers University, Piscataway, NJ; 2) Dept of Psychiatry, University of Toronto, and Schizophrenia Research Program, Queen Street Division, Centre for Addiction and Mental Health, Toronto, Ontario; 3) Dept of Psychiatry, UMDNJ, Robert Wood Johnson Medical School, Piscataway, NJ.

A number of studies have suggested the existence of a schizophrenia-susceptibility gene on 13q22-34. We have previously described a significant linkage signal on 13q32 in a sample of 22 medium-sized Canadian families selected for study because multiple relatives were clinically diagnosed with schizophrenia or schizoaffective disorder (Brzustowicz et al 2000). Families were analyzed under autosomal dominant and recessive models, with broad and narrow definitions of schizophrenia. All models produced positive LOD scores with markers on 13q. Chumkov et al (2002) have reported linkage disequilibrium between markers in the gene G72, located on chromosome 13q33, and schizophrenia, suggesting this as a candidate gene for schizophrenia susceptibility. In order to investigate if linkage disequilibrium to G72 exists in our sample exhibiting linkage to 13q32, we tested 5 single-nucleotide polymorphism (SNPs) that span the G72 gene, described by Chumkov et al. The original 22 families plus two new families were genotyped by pyrosequencing at these 5 SNPs (rs3916965, rs3916967, rs778293, rs3918342, rs1421292). Evidence for LD was first assessed using the program PSEUDOMARKER which, in contrast to popular TDT-based programs, explicitly separates the evidence for linkage and LD in families with multiple affecteds. Genotypes were analyzed under dominant and recessive pseudomarker models, using both the narrow and broad diagnostic classification. Only one marker, rs3918342, produced evidence for linkage disequilibrium at  $p < 0.05$  ( $p = 0.011$  under broad recessive model), although it is not clear that this result should be considered significant given the multiple markers and models tested. Analysis of 5-marker haplotypes using the program TRANSMIT also failed to identify significant genetic association to schizophrenia. These results suggest that G72 is not the chromosome 13q schizophrenia susceptibility locus acting in these families.

**Large Scale SNP Genotyping at the BCM-HGSC with Molecular Inversion Probe (MIP) Technology.** *F. Yu<sup>1</sup>, G. Scott<sup>1</sup>, X. Lu<sup>1</sup>, D. Nelson<sup>1</sup>, J. Belmont<sup>1</sup>, D. Steffen<sup>1</sup>, S. Leal<sup>1</sup>, P. Hardenbol<sup>2</sup>, M. Thomas<sup>2</sup>, M. Jain<sup>2</sup>, M. Faham<sup>2</sup>, T. Willis<sup>2</sup>, R. Gibbs<sup>1</sup>.* 1) Human Genome Sequencing Center, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX77030; 2) ParAllele Bioscience, 384 Oyster Point Blvd, Suite 8, South San Francisco, California, 94080.

Linkage strategies that have worked well for single-gene Mendelian disorders lack power to map polygenic susceptibility loci. Thus, little is known about the genetic basis of the complex human diseases, such as diabetes, cancer, stroke, Alzheimer's disease, Parkinson's disease, psychiatric disorders, alcoholism, heart disease, deafness, arthritis, and asthma. The goal of this International HapMap Project is to develop a genome-wide haplotype map by identifying the haplotype blocks and the common haplotypes in the human genome, and to define a set of tag SNPs, using the population samples collected from the Yorubas in Nigeria, Japanese, Han Chinese and U. S. residents with ancestry from northern and western Europe. This effort aims at speeding the discovery of genes related to common complex illnesses. In Collaboration with ParAllele, the Human Genome Sequencing Center (HGSC) at BCM in particular is responsible for genotyping the single nucleotide polymorphisms (SNPs) and generating the haplotype map of chromosome 12. We will carry out 60,000 SNP genotyping on 288 individuals in two years. The highly multiplexed genotyping technology, Molecular Inversion Probe (MIP) technology, invented by the scientists at ParAllele is used to perform SNP genotyping. The oligonucleotide probe in this process undergoes a unimolecular rearrangement from a molecule that cannot be amplified into a molecule that can be amplified. HGSC has already generated 1,091,697 genotypes on the 30 CEPH trios.

**Fine Mapping a Gene For Severe Pediatric Gastroesophageal Reflux On Human Chromosome 13q14.** *J. Donfack, F.Z. Hu, A. Amed, R. Dopico, J.C. Post, G.D. Ehrlich, R.A. Preston.* Center for Genomic Sciences, Allegheny General Hospital, Pittsburgh, PA.

A genome-wide screen was used to establish linkage in multiple families between severe pediatric gastroesophageal reflux disease (GERD) and a locus (GERD I) on Chromosome 13q14 (Hu et al., 2000a). Initial refinement of this locus identified a 9 cM interval flanked by the markers CAGR1 (MAB21L1) and D13S263 (Hu et al. 2000b). In a further attempt to reduce the size of the GERD I locus, we have performed linkage disequilibrium (LD) analyses using two sets of DNA specimens. The first study was performed as case/control association study in which we analyzed 73 individual cases and 93 controls, all of white European ancestry. In the second study we performed transmission disequilibrium testing on 22 small families. In both studies all individual were genotyped for forty-one single nucleotide polymorphisms (SNPs) which were selected from among 164 SNPs we had previously identified as part of our ongoing effort to identify the causative mutation for GERD in the five families that were originally used for our linkage study. In the current analyses, we used Chi-Square and the Fischer Exact Tests for the case/control association studies and LD was estimated using the Transmission Disequilibrium Test (TDT) in the family samples. In the family samples TDT analyses revealed preferential transmission of SNP142 ( $3.0 \times 10^{-3}$ ) and the two-marker haplotype SNP160-SNP142 to affected children ( $8.05 \times 10^{-6}$ ). The case/control samples showed significant difference with SNP180 ( $1.0 \times 10^{-3}$ ) and haplotypes SNP32-SNP160 and SNP5-SNP180 ( $4.0 \times 10^{-4}$ ). The combined results from the familial and case/control association tests suggest that the GERD I gene is most likely located between SNP160 and SNP180, a region of about 1.5 Mb.

**Fine linkage mapping and haplotype association localize a susceptibility gene for prostate cancer to a chromosome 3 region bearing the FHIT gene.** *Y. Ding<sup>1</sup>, G.P. Larson<sup>1</sup>, L. Cheng<sup>2</sup>, C. Lundberg<sup>1</sup>, V. Gagalang<sup>1</sup>, G. Rivas<sup>1</sup>, C. Ouyang<sup>1</sup>, L. Geller<sup>1</sup>, T.G. Krontiris<sup>1</sup>, The ECOG E1Y97 Study Group.* 1) Molecular Medicine and; 2) Information Sciences, Beckman Res Inst City of Hope, Duarte, CA.

We performed a candidate gene-based linkage study on 228 affected brother pairs (200 families) to detect susceptibility loci for prostate cancer. Evidence of linkage was initially identified for two candidate genes, CDC25a and FHIT, on chromosome 3. Subsequent fine mapping yielded a maximum LOD score of 3.17 at D3S1234 using LODPAL (S.A.G.E 4.2). For a subset of 38 families (66 pairs), in which three or more affected brothers were reported, the LOD score was elevated to 3.83 at D3S1234. The linkage was also confirmed using MERLIN (Maximum Zmean = 2.94,  $p = 0.002$  at D3S2420). In the subgroup, although maximum linkage peaks produced using S.A.G.E and MERLIN were 10 cM apart, both programs generated maximum sharing of 2 IBD = 0.49 and minimum sharing of 1 IBD = 0.27 at D3S1234, suggestive of a recessive model. We then genotyped 12 SNPs spanning approximately 400 kb surrounding D3S1234 for 162 cases of European descent (one case from each family) and 120 unrelated European-descent controls. We predicted SNP pair-wise haplotypes combining cases and controls using PHASE. We found significant evidence for association between case status and haplotype at SNP pair rs760317/rs722070 (Pearson's  $\chi^2 = 10.76$ ,  $df = 3$ ,  $P = 0.013$ ). The association was particularly strong for a subset of cases (61) that shared 2 alleles IBD with one or more affected brothers. In this subset, haplotype 2/1 was elevated at 56.6% (69/122), compared to 50.3% (163/324) in all cases and 43% (102/240;  $\chi^2 = 9.53$ ,  $df = 3$ ,  $P = 0.023$ ) in controls. Consistent with a recessive inheritance, the frequency of 2/1 homozygotes was 32.8% (20/61) in the 2 IBD subset, compared to 25.7% (26/101) in the remaining cases and only 16.7% (20/120;  $\chi^2 = 6.105$ ,  $df = 1$ ,  $P = 0.014$ ) in controls. Our results strongly suggest a new locus related to prostate cancer risk on chromosome 3p14.2, a region frequently involved in chromosomal instability in many types of cancer. These findings warrant further confirmation through extended linkage and association studies.

**Mapping of an Autosomal Recessive Congenital Cataract Locus To Chromosome 9q.** *T. Forshew<sup>1</sup>, CA. Johnson<sup>1</sup>, C. Willis<sup>2</sup>, AT. Moore<sup>2</sup>, ER. Maher<sup>1</sup>.* 1) Paediatrics and Child Health, The University of Birmingham, Birmingham, B15 2TG, UK; 2) Institute of Ophthalmology, University College London, England, UK.

Cataracts are a major cause of blindness affecting approximately 16 million individuals worldwide. The genetics of human cataracts are complex, with examples of syndromic and non-syndromic, autosomal dominant, autosomal recessive and X-linked forms described. At least 20 loci for autosomal dominant cataracts have been reported, but only a few non-syndromic recessive loci have been mapped. In order to investigate the molecular basis for recessive cataracts, we investigated two consanguineous families of Pakistani origin. Linkage to candidate genes and loci at 3p, 19q13.4 (*LIM2*), 21q22.3 (*CRYAA*) and the i- blood group locus was excluded (using the criterion of heterozygosity at microsatellite markers) in the largest family. Subsequently we have identified an extensive (20cM) region of homozygosity at 9q21.12-9q22. This region overlaps with the ARPC locus associated with autosomal recessive later-onset pulverulent cataracts. We then demonstrated linkage to 9q in the second family. The maximum cumulative two-point LOD score [ $Z_{\max}$ ] for the two families was 3.378 at  $\theta=0$  for marker D9S303. These findings suggest that congenital and later onset autosomal recessive cataracts may result from allelic heterogeneity at a 9q21.12-q22 locus.

**Candidate regions to Richieri-Costa-Pereira syndrome.** *R.L.L. Ferreira de Lima*<sup>1</sup>, *R. Schultz*<sup>2</sup>, *M. Marazita*<sup>3</sup>, *D. Moretti-Ferreira*<sup>1,4</sup>, *A. Richieri-Costa*<sup>4</sup>, *J.C. Murray*<sup>2</sup>. 1) Departamento de Genética, Universidade Estadual Paulista UNESP, Botucatu, SP, Brazil; 2) University of Iowa, IA, USA; 3) University of Pittsburg; 4) Universidade de São Paulo USP, Bauru, SP, Brazil.

The Richieri-Costa-Pereira syndrome is a rare autosomal recessive disorder characterized by short stature, Robin sequence, cleft mandible, pre/postaxial anomalies and clubfoot (Richieri-Costa and Pereira, 1992). This syndrome was described almost exclusively in Brazil, appearing just one case in French, suggesting this condition represents a rare mutation and founder effects (Richieri-Costa and Pereira, 1993). We have collected fifteen affected from 14 apparently unrelated families with this unique syndrome. In the initial phase of research, DNA from affected individuals were excluded of 497 possible candidate regions and PAX9, MSX1, PITX1, DLX5, DLX6, PITX2, TBX4, TBX5, LIMH1, CLIMB2 and FGF8 as candidate genes (Ferreira de Lima et al., in press). In complementary analysis we typed 387 markers in all families and found evidence for allele sharing in one family with two typed affected. The most positive multipoint LOD results were found under recessive model for chromosomes 9 (LOD=1.49 and TDT p-value=0.08) and 13 (LOD=1.53) given the agreement between the LOD and TDT results, the chromosome 9 regions seems like the most likely to target for the gene. The linkage approaches are done only in the single family and the TDT association approach is done over all families. We will now proceed to high resolution SNP mapping of the two strong candidate regions to look for a block of allele sharing that can focus candidate gene evaluation.

**Linkage analysis using the TSC SNP map.** *B.L. Browning, M.G. Ehm, M.J. Wagner.* Population Genetics, GlaxoSmithKline, Research Triangle Park, NC.

With the recent publication of The SNP Consortium's SNP linkage map there has been increasing attention focused on using clusters of tightly linked single nucleotide polymorphism (SNP) markers for linkage analysis. Although individual SNPs are relatively uninformative, clusters of tightly linked SNPs can be as informative as microsatellite markers. However, SNPs within clusters will typically be in linkage disequilibrium, and the estimates of genetic distances between SNPs in a cluster may exhibit considerable relative error. We evaluated the TSC SNP map to determine the effect of the intracluster LD and intracluster map error on linkage analysis.

We genotyped 83 markers from the TSC linkage map in 3 regions covering 190 cM previously scanned with microsatellite markers and found to be linked to type 2 diabetes (Ehm et al 2000). We found that due to the low intracluster linkage disequilibrium in the TSC SNP map, satisfactory results were obtained from analyzing the TSC markers with existing multipoint linkage analysis software (e.g. GENEHUNTER, MERLIN) provided that the intracluster genetic distances were set to a reasonable small positive distance (e.g. 0.03 cM). We found that the linkage signals were relatively insensitive to changes in estimates of intracluster genetic distances.

22% of the TSC SNP markers in the 3 regions failed to validate on a multiplexed, single base chain extension genotyping platform. For the 83 validated markers, we found the information content and LOD score profiles were similar to a microsatellite map with a 10 cM average spacing. There was comparable evidence for linkage in 2 of 3 regions, and the TSC map yielded weaker evidence for linkage in a region where the TSC map has poor marker coverage.

We recommend that the TSC SNP map be supplemented with additional markers in regions of poor marker coverage, and we suggest that regions showing evidence for linkage be reviewed for possibly error due to intracluster linkage disequilibrium and poorly estimated intracluster genetic distances before proceeding with association studies.

**Replication of a parent of origin effect and genome-wide significant linkage on chromosome 10 for late onset**

**Alzheimer's disease.** *D. Avramopoulos*<sup>1</sup>, *M.D. Fallin*<sup>2</sup>, *R.T. Perry*<sup>3</sup>, *H. Wiener*<sup>3</sup>, *B. Watson*<sup>3</sup>, *R.C.P. Go*<sup>3</sup>, *S.S. Bassett*<sup>1</sup>.

1) Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Epidemiology, Johns Hopkins University, Baltimore, MD; 3) Epidemiology, University of Alabama at Birmingham, Birmingham, AL.

Of all the regions that have been detected in genome scans for late onset Alzheimer's disease (LOAD), only a few have consistently provided positive findings. One such region is on chromosome 10, 60 to 90 cM from the p-telomere. Clinical and epidemiological studies have suggested excess maternal transmission of Alzheimer's disease (AD). Genetic imprinting has been suspected in AD because of parental age effects. Differential chromosome sensitivity to 5-azacytidine in AD has been described suggesting differences in methylation patterns. In a recent paper we reported evidence of linkage in our subset of the NIMH genetics initiative pedigrees, approaching genome-wide significance (non-parametric LOD score = 3.27), when only families with maternal disease origin were analyzed (N=49). This parental origin effect was shown to be statistically significant by multiple random stratifications. We have now acquired parent of origin information for an independent subset of the NIMH genetics initiative pedigrees, those collected by the University of Alabama (UAB). Like in our sample, maternal pedigrees from the UAB set (N=21) show significantly increased linkage in the chromosome 10 region. Combining all maternal pedigrees (N=21+49=70) we acquire a non-parametric LOD score of 4.93 in the same region, which exceeds the conservative threshold for genome wide significant linkage (3.6). These findings add to our previous report in two ways: 1. Replication of the parent of origin effect and 2. Detection of highly significant linkage in a region reported by many investigators. We conclude that this region on chromosome 10 very likely harbors a gene for LOAD, and that mechanisms involving a parent of origin effect, like genomic imprinting, need to be examined.

**Screening validated SNPs for the development of a human genome linkage marker resource.** *K. Doheny<sup>1</sup>, P. Boyce<sup>1</sup>, D. Witmer<sup>1</sup>, D. Hayden<sup>1</sup>, J. Pettengill<sup>1</sup>, Y. Tsai<sup>1</sup>, E. Pugh<sup>1</sup>, E. Luong<sup>2</sup>, R. Nussbaum<sup>2</sup>.* 1) Center for Inherited Disease Research, IGM, JHUSOM, Baltimore, MD; 2) IDR, NHGRI, NIH, Bethesda, MD.

Methods of reducing cost and increasing genotyping throughput are required in order to utilize SNP markers in linkage and association studies. Multiplexing genotyping reactions at both the PCR and detection level is one solution. We are developing a linkage marker resource with the aim of providing quality markers capable of multiplex processing using Sequenom's Homogeneous Mass Extend assay, which discriminates genotypes through MALDI-TOF Mass Spectrometry (Bruker Autoflex). The development process began with a set of 4,524 publicly available SNPs (SNP Consortium, Orchid set) with minor allele frequencies >0.25. Single Base Extension (SBE) assays were designed for these SNPs and multiplexed by their primer, pause, and extension products resulting in 1900 assays grouped into 380 five-plex panels. The assays were screened for utility, 5-plexing at both the PCR and detection level, by genotyping 23 Polymorphism Discovery Resource samples (Coriell). The median genotype call rate was 75%. 965 SNPs were above the median. Genotype reproducibility was tested by typing 50 assays on the 23 samples 16 times each. 8 errors were observed out of 11,664 genotypes (0.07%). Additional results addressing contributing factors to call rates and errors such as multiplex levels and genomic DNA concentration will also be presented. The set of 965 SNPs is distributed across all chromosomes, has an average minor allele frequency of 0.33 and a median inter-marker physical distance of 3.3 Mb. Our reagent costs per genotype using 96 spot chips are currently 5-plex \$0.08, 3-plex \$0.13, 1-plex \$0.40.

**Fine mapping of the apolipoprotein B regulator gene 2 (*Abrg2*) on mouse chromosome 4.** G.P. Ables, B. Reid, A.L. Lin, H. Leung, L.-S. Huang. Medicine, Columbia University, New York, NY.

Elevated plasma levels of apolipoprotein B (apo B) and low density lipoprotein (LDL) are associated with a higher risk for atherosclerotic coronary heart disease (CHD). Using a human apo B transgenic mouse (HuBTg) model, we identified two novel quantitative trait loci (QTL), *Abrg1* and *Abrg2*, with major effects on plasma human apo B levels in crosses between C57BL/6 (B6) and 129/Sv (129). The *Abrg2* is within an interval on chromosome 4 defined by D4Mit27 and D4Mit204 (42.5-61.9 cM) with peak LOD score on D4Mit204 (LOD=8.4) in male mice. Male congenic mice (n=10) heterozygous for the interval (derived from the 129 genome) had significantly lower plasma apo B levels compared to male B6 HuBTg mice (n=193) (769 vs. 9017 mg/dl, p=0.002). Data from subcongenic lines generated between the markers D4Mit164 and D4Mit204 (28.6-61.9 cM) show the low-apo B phenotype. Subcongenic lines generated between D4Mit164 and D4Mit187 (28.6-49.6 cM) had the high-apo B phenotype. These data predict that the *Abrg2* is located in a 12-cM interval between markers D4Mit187 and D4Mit204 (49.6-61.9 cM). However, mean plasma apo B levels of the lines generated within the area of D4Mit164 and D4Mit334 (28.6-57.0cM) were intermediate between levels for B6 HuBTg mice and the other subcongenic lines with a low-apo B phenotype. These data suggest that at least two genes (or gene clusters) are required for a full effect on plasma apo B levels. One of the genes is located between D4Mit187 and D4Mit334 and the other one is located between D4Mit334 and D4Mit204. Our data also showed that the *Abrg2* is located within an interval syntenic to a human chromosome segment associated with a QTL for familial combined hyperlipidemia (FCHL), a very prevalent disorder in general populations. Overall, our data suggest that the *Abrg2* QTL consists of more than one gene or gene clusters and it is strong candidate gene for a human FCHL locus.

**Fine Mapping on Chromosome 6q in the NIMH Genetics Initiative Bipolar Pedigrees.** *S. Buervenich<sup>1</sup>, S.D. Detera-Wadleigh<sup>1</sup>, N. Akula<sup>1</sup>, C.J.M. Thomas<sup>1</sup>, L. Kassem<sup>1</sup>, A. Rezvani<sup>1</sup>, W.R. Corona<sup>1</sup>, W. Berrettini<sup>2</sup>, W. Byerley<sup>2</sup>, W. Coryell<sup>2</sup>, J.R. DePaulo Jr<sup>2</sup>, E.S. Gershon<sup>2</sup>, J. Kelsoe<sup>2</sup>, M.G. McInnis<sup>2</sup>, D.L. Murphy<sup>2</sup>, J.I. Nurnberger Jr<sup>2</sup>, T. Reich<sup>2</sup>, W. Scheftner<sup>2</sup>, F.J. McMahon<sup>1</sup>.* 1) National Institute of Mental Health Intramural Research Program, Bethesda, MD; 2) The NIMH Genetics Initiative for Bipolar Disorder (Coordinating Center: Indiana University School of Medicine, Indianapolis, IN).

Whole-genome scans in 2 successive collections of NIMH Genetics Initiative bipolar disorder pedigrees have led to identification of two linkage signals on the long arm of chromosome 6. Both sets of samples were collected using the same ascertainment criteria and diagnostic tools. However, the first signal peaked at marker D6S311 (6q24.3), while in the second sample the strongest linkage was at D6S1021 (6q16.3). Based on these results, we have selected 31 markers from the Decode map, with a 3cM average spacing on 6q, for genotyping in the complete NIMH bipolar disorder pedigree series (n=2000). With about 70% of the genotypes finished, we have so far not observed any substantial change in the magnitude or resolution of the linkage signals on 6q. However, alleles of 2 markers near positional candidate genes on 6q have shown preliminary evidence of association with bipolar disorder in both pedigree samples by the family-based association test (FBAT): D6S1642, located within the GRIK2 gene that encodes a kainic acid-type glutamate receptor, and D6S1009, located close to the interleukin-20 receptor alpha gene (IL20RA) at the intersection of the 2 linkage peaks. There is also some evidence that the associated alleles of D6S1009 partition the linkage evidence on 6q in the NIMH3 sample: the 90 families harboring at least one of the associated alleles produced a significantly higher non-parametric lod-score than the 160 families that did not carry any associated alleles (1.73 vs. 0.573, p=0.02). Based on these findings, IL20RA and GRIK2 are considered high-priority candidate genes for association studies using dense sets of SNPs, alongside other positional candidates PREP, NR2E1, FOXO3A, and APOGL5, which have been prioritized for study on neurobiological grounds.

**Fine-mapping and further localization of schizophrenia susceptibility loci from a genome-wide linkage scan among Ashkenazi Jewish families.** *M. Fallin*<sup>1</sup>, *V.K. Lasseter*<sup>2</sup>, *P.S. Wolynec*<sup>2</sup>, *J.A. McGrath*<sup>2</sup>, *G. Nestadt*<sup>2</sup>, *D. Valle*<sup>3,4,5</sup>, *KY. Liang*<sup>6</sup>, *A.E. Pulver*<sup>2</sup>. 1) Dept Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 2) Department of Psychiatry & Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD; 3) Departments of Pediatrics and Molecular Biology, Johns Hopkins School of Medicine, Baltimore, MD; 4) Institute for Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 5) Howard Hughes Medical Institute; 6) Dept Biostatistics, Johns Hopkins School of Public Health, Baltimore, MD.

Previous linkage studies in schizophrenia have been discouraging due to inconsistent findings and weak signals. Genetic heterogeneity has been cited as one of the primary culprits for such inconsistencies. We have performed a 10cM autosomal genome-wide linkage scan for schizophrenia susceptibility regions using 29 multiplex families of Ashkenazi Jewish descent, in hopes of reducing genetic heterogeneity among families and increasing the detectable effects of any particular locus. We pursued both allele-sharing and parametric linkage analyses as implemented in Genehunter V2.0. We found 7 regions with NPL scores greater than 2.00 (chromosomes 1p32.2, 4q34.3, 6p21.31, 7p15.2, 10q22.3, 15q11.2 and 21q21.2). Our strongest signal was achieved on chromosome 10, with a nonparametric linkage score (NPL) of 3.35 (genome-wide empirical p-value=0.035) and a dominant heterogeneity lod score (HLOD) of 3.14. We have now followed up the regions on chromosomes 6, 10, and 21 to achieve a 1Mb density, and have increased marker content on chromosomes 4, 7, and 15 as well. We present results of fine-mapping for each of these 6 chromosomes, highlighting our encouraging findings on chromosome 10, where the peak NPL score increased to 4.27 (D10S1774; empirical p-value = 0.00002), and a 95% confidence interval of 12.2 Mb for the location of the trait locus was delineated (D10S1677 to D10S1753).

**A genome scan of specific language impairment loci in families from the United States.** *C.W. Bartlett<sup>1</sup>, J.F. Flax<sup>2</sup>, W. Li<sup>1</sup>, T. Reaple-Bonilla<sup>2</sup>, J. Hayter<sup>1</sup>, L.S. Hirsch<sup>2</sup>, M.W. Logue<sup>3</sup>, R. Zimmerman<sup>1</sup>, V.J. Vieland<sup>3</sup>, P. Tallal<sup>2</sup>, L.M. Brzustowicz<sup>1,4</sup>.* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ; 3) Dept of Biostatistics, Division of Statistical Genetics, College of Public Health and Dept of Psychiatry, College of Medicine, University of Iowa, Iowa City; 4) Dept of Psychiatry, UMDNJ, Robert Wood Johnson Medical School, Piscataway.

Specific language impairment (SLI), affecting ~ 7% of children entering school, is defined as a failure to develop language normally in the absence of other explanatory factors such as hearing loss, autism or mental retardation. Children with SLI typically have difficulty on a wide range of phonologically based reading and language tasks, and many later develop dyslexia (DYX). We have conducted a genome-scan for language impairment susceptibility genes on 22 multiplex nuclear and extended pedigrees ascertained in the United States. Families were analyzed using three diagnostic categories: language impairment (language score > 1 SD below population mean), reading impairment (single nonword reading > 1 SD below nonverbal IQ) and clinical impairment (residual language difficulties defined as either language or reading difficulties). Microsatellite markers were genotyped at ~10 cM resolution. Two-point linkage analysis using MLINK assuming reduced penetrance under both dominant and recessive modes of inheritance was performed. For the clinical impairment diagnosis, HLOD scores > 2 were obtained on 18p11 (dominant MOI) and 1q31 (recessive). The peak on 18p11 is ~30 cM away from the peak of the DYX6 locus. The reading impairment diagnosis yielded HLOD scores > 2 on 7q11 (dominant) and 6p21 (recessive). The result on 6p21 is within the DYX2 region. Previous genome scans for SLI susceptibility indicated loci on 13q, 16q and 19q (Bartlett et al 2002, SLIC 2002). This sample produced HLOD scores > 1 on both 13q and 19q. The locus on 19q was positive for multiple traits and models, perhaps indicating pleiotropy. Our results indicate a genetic overlap of SLI and dyslexia on 6p21, show several loci are unique to SLI, and may replicate linkage of SLI to 13q and 19q.

**Examination of multilocus association of the GABAA receptor subunit genes in multiplex autism families.** *A.E. Ashley-Koch, E.R. Martin, J. Jaworski, M.M. Menold, C.A. Haynes, M.L. Cuccaro, J.R. Gilbert, M.A. Pericak-Vance.*  
Duke University Medical Center, Durham, NC.

We have previously shown both linkage and association to the GABA receptor subunit GABRB3 on chromosome 15q11-q13 in autism. Given that the GABAA receptor genes, GABRA5 and GABRG3, are located in a cluster with GABRB3 on 15q11-q13 and are functionally related to GABRB3, it is possible that an intergenic combination, or combinations of alleles in this family of genes may influence susceptibility to autism. We examined 210 multiplex families with autism (including 99 from the Autism Genetic Exchange) using a novel statistical method, the multilocus geno-PDT, to detect multilocus associations in these three genes. The two SNPs genotyped in GABRB3 were located in intron 6 and the 3UTR. For GABRA5, three SNPs were genotyped in exon 8 and introns 7 and 9. For GABRG3, two SNPs were genotyped in exon 8 and the 5UTR. Global p-values and p-values for individual genotype combinations were computed. Significant association was detected between GABRA5 exon 8 and GABRG3 5UTR (global  $p=0.04$ , max indiv  $p=0.02$ ). Marginal results were found for GABRA5 intron 9 and GABRG3 exon 8 (global  $p=0.08$ , max indiv  $p=0.01$ ), GABRA5 intron 9 and GABRG3 5UTR (global  $p=0.09$ , max indiv  $p=0.04$ ), as well as GABRB3 intron 6 and GABRG3 5UTR (global  $p=0.09$ , max indiv  $p=0.01$ ). Most of these multilocus associations were explained by significant single locus geno-PDT results. However the GABRA5 intron 9/GABRG3 exon 8 association was not detected by single locus results and may represent gene-gene interactions between these loci in autism etiology. We are currently genotyping our sporadic autism families for these SNPs to further examine the possibility of multilocus associations within the GABAA receptor genes clustered on chromosome 15 as a mechanism for autism etiology.

**Linkage Analysis of C-peptide Concentrations in a Cohort of Siblings with Type 2 Diabetes from West Africa.** *G. Chen, J. Zhou, H. Daniel, Y. Chen, C. Rotimi.* Natl Human Genome Ctr, Howard Univ, Washington, DC.

C-peptide is a substance that the pancreas releases into the circulation in equimolar amounts to insulin. It has been considered to be biologically inactive, general view that C-peptide serves a spacer during the biosynthesis of insulin to promote efficient translocation and folding of pro-insulin. Recently, C-peptide has been demonstrated important physiological effects of the C-peptide itself which relate to the vascular field, in particular to the microcirculation. For log transformation of C-peptide, additive genetic heritability is 0.79 (0.11) ( $P < 0.0000001$ ), Kurtosis is 0.39 in our African American Diabetes Mellitus (AADM) study. To identify genes contributing to C-peptide variation, we conducted a genome wide scan in an average 9cM genome map of 373 type-2 diabetes affective sib-pairs in 343 pedigrees (10.52% involved the treatment of insulin). Using variance components approach in SOLAR package, we obtained LOD Score = 3.42 in chromosome 18 (7cM, between markers C18S1781 and D18S976), a LOD Score = 3.10 (33cM, D4S2639) in chromosome 4, a LOD Score = 1.41 in chromosome 10 (107cM, between markers D10S2327 and D10S2470) and a LOD = 2.20 in chromosome 15 (43cM, D15S659). In conclusion, since C-peptide is along with insulin in bloodstream and has some amount as insulin, the finding of linkage regions for C-peptide is as same as finding of linkage regions for insulin and also studies have been demonstrated physiological effects of C-peptide involving renal and never function in diabetes. Our findings provided the significant linkage evidences in 18p11 and 4p15 regions and suggestive linkage evidences in 15q12 and 10q22 in a cohort of siblings with type 2 diabetes from West Africa.

**Reduction in the minimal candidate region of cerebral cavernous malformations type 3 (CCM3) on chromosome 3q26.31-27.3.** C.L. Liquori<sup>1</sup>, V. Maglione<sup>2</sup>, F. Balogun<sup>1</sup>, M. Cannella<sup>2</sup>, E. Huang<sup>1</sup>, L. Hughes<sup>1</sup>, T. Leedom<sup>1</sup>, F. Squitieri<sup>2</sup>, D.A. Marchuk<sup>1</sup>. 1) Dept. Mol. Genet. and Microbiol., Duke University, Durham, NC; 2) Dept. Mol. Pathology, Mediterranean Neurological Institute, Pozzilli, Italy.

Cerebral cavernous malformations (CCMs) are vascular abnormalities of the brain that can result in a variety of neurological disabilities, including hemorrhagic stroke and seizures. CCMs can be sporadic or inherited in an autosomal dominant fashion. There are three known loci that are responsible for familial CCM. The gene responsible for CCM1 is *KRIT1*. The genes responsible for CCM2 and CCM3 have not yet been identified, and their loci map to chromosome bands 7p15-13 and 3q25.2-27, respectively. In order to identify potential CCM2 and CCM3 families, we have collected CCM families and have excluded those with mutations within *KRIT1* by sequence analysis. We ran a panel of markers for both the CCM2 and CCM3 loci on these families, including the previously published family CAV02 (Squitieri, *et al.*, *Neurol Sci* 21:129-34.). In the CAV02 family, the affected parent passed on one haplotype to both affected children and the other haplotype to the unaffected (MRI negative, 3 times over 8 years) child for the CCM3 region, indicating that the CAV02 family has CCM3. In addition, we identified a recombination event in one of the affected siblings. By designing several new polymorphic markers, we were able to define the site of recombination to a 55.2 kb region. Previously published studies (Craig, *et al.*, *Hum Mol Genet* 7: 1851-8.) only established lod-1 and lod-3 support intervals for both the CCM2 and CCM3 loci. The CAV02 recombination event establishes a definitive centromeric border for the CCM3 locus. It also reduces the size of the critical region by 1.5 Mb (based on using the markers defining the lod-1 support interval to arbitrarily define the CCM3 locus boundaries). This recombination event also excludes 7 genes from consideration as candidate genes. In addition, we have sequenced 13 candidate genes and did not identify any mutations in these genes. By reducing the size of the critical region and excluding several candidate genes, we have made progress towards the identification of the CCM3 gene.

**A genome-wide screen for myopia susceptibility loci in twins, including a replicate sample.** *C.J. Hammond, T. Andrew, M.J. Barber, T.D. Spector.* Twin Research & Genetic Epidemiology Unit, St Thomas' Hospital, London, UK.

**Purpose:** Myopia has been shown to be under strong genetic control with a heritability based on twin studies of around 85%. Susceptibility loci have been identified in families with AD high myopia. The purpose of this genetic epidemiological study was to identify regions of the genome that contain quantitative trait loci (QTL) for refractive error, as no loci have been identified to date in population samples.

**Methods:** Refractive error in 221 unselected female dizygotic twin pairs from the St Thomas' Adult Twin Registry was obtained using a Humphrey 670 autorefractor, and the spherical equivalent obtained for each sib-pair. A genome-wide screen using around 400 markers was performed. Non-parametric multipoint linkage analyses were undertaken, using optimal Haseman-Elston methods implemented in a generalised linear model (gamma regression) and using the square of sib phenotypic differences. A replicate sample of different twins, whose refractive error was obtained by postal questionnaire, was similarly analysed.

**Results:** Maximum evidence of linkage in the autorefracted twins was observed at chromosome 11p13 (LOD 6.1), with further loci at chromosomes 3q26 (LOD 3.7) and 4q12 (LOD 3.3) and 8p23 (LOD 4.1). Evidence for these loci remained or became stronger after checking model fit diagnostics and removing unduly influential outliers. Weaker evidence of linkage ( $1.0 < \text{LOD} < 3.0$ ) was also obtained for several other regions. Possible replication was produced at the 3q26 locus for 170 twin pairs returning questionnaires. Additional twins are being recruited, to increase the power to replicate these results.

**Conclusions:** These results, if confirmed in our ongoing replicate sample and in other studies, provide strong evidence of possible susceptibility loci for refractive error, and warrant characterization of QTLs and candidates responsible.

**Linkage Analysis in Families with Joubert Syndrome plus Oculo-Renal Involvement Identifies the CORS2 Locus on Chromosome 11p12-q13.3.** *L.C. Keeler<sup>1</sup>, S.E. Marsh<sup>1</sup>, C.G. Woods<sup>2</sup>, A. Gururaj<sup>3</sup>, L. Al-Gazali<sup>3</sup>, L. Sztriha<sup>3</sup>, J.G. Gleeson<sup>1</sup>.* 1) Neurogenetics Laboratory Division of Pediatric Neurology Department of Neurosciences University of California, San Diego, CA ; 2) Molecular Medicine Unit and Yorkshire Clinical Genetics Service St James's University Hospital Leeds, UK; 3) Department of Pediatrics Faculty of Medicine and Health Sciences United Emirates University Al Ain, United Arab Emirates.

Joubert syndrome (JS) is an autosomal recessive developmental brain condition characterized by hypoplasia/dysplasia of the cerebellar vermis and by ataxia, hypotonia, oculomotor apraxia, and neonatal breathing dysregulation. A form of JS that includes retinal dysplasia and cystic dysplastic kidneys has been differentiated from other forms of JS, called either JS type B or Cerebello-Oculo-Renal syndrome (CORS), but the genetic basis of this condition is unknown. Here we describe three consanguineous families that display CORS. Linkage analysis defines a novel locus on chromosome 11p12-q13.3, with a maximum two-point LOD score of  $Z = +5.2$  at the marker D11S1915. Therefore, the cerebello-oculo-renal form of JS is a distinct genetic entity from the previously described Joubert Syndrome 1 (JBTS1) locus, in which there is minimal involvement of retina or kidney. We suggest the term CORS2 for this new locus. Several additional families fail to map to either JBTS1 or CORS2, indicating further genetic heterogeneity.

**Autosomal dominant Retinitis Pigmentosa: evidence for a novel disease-causing gene.** *L. Jiang<sup>1, 2</sup>, M. Payne<sup>1, 2</sup>, N. Faulkner<sup>1, 2</sup>, M. Machan<sup>1, 2</sup>, S. Sims<sup>1, 2</sup>, K. Hart<sup>1, 2</sup>, X. Li<sup>1, 2</sup>, P. Bernstein<sup>1, 2</sup>, Z. Yang<sup>1, 2</sup>, K. Zhang<sup>1, 2</sup>.* 1) Department of Ophthalmology and Visual Science, University of Utah Health Science Center, Salt Lake City, UT80132; 2) Programme in Human Molecular Biology and Genetics, University of Utah Health Science Center, Salt Lake City, UT80132.

**Purpose:** Retinitis pigmentosa (RP) is a type of inherited retinal degenerations characterized by progressive night blindness and loss of peripheral vision, with eventual loss of central vision. RP is the most prevalent group of inherited retinopathies, affecting approximately 1 in 3,500 persons. RP is genetically heterogeneous and may present as an adRP, autosomal recessive, or X-linked recessive trait. To date, at least 13 autosomal dominant genes/loci have been localized and 12 genes have been identified (RetNet [www.sph.uth.tmc.edu/RetNet/](http://www.sph.uth.tmc.edu/RetNet/)). Loci include RP1, RP4(Rhodopsin), RP7(RDS/Peripherin), RP18(HPRP3), RP9(PIM1K), RP10(IMPDH1), RP11(PRP31), RP13(PRPC8), RP17, RP27(NRL), ROM1, Fascin, CRX. **Methods:** A large Mormon kindred with a total of 144 members (20 members affected by RP) was studied. Of 46 individuals who participated in the study, 12 were found to be affected. The disease gene is transmitted as an autosomal dominant trait. Linkage analysis to all known adRP loci and mutational screening of PIM1K, RDS/Peripherin, NRL, CRX, ROM1, and Fascin were performed. **Results:** Affected individuals showed night blindness, and constriction of peripheral visual fields, with loss of central vision in the advanced stage of the disease. Fundus examinations revealed retinal and RPE atrophy, bone spicule pigmentation, arterial attenuation in affected individuals. Linkage analysis using short-tandem repeat polymorphic markers encompassing candidate loci showed that none of above described loci was linked to the phenotype in this kindred. Direct sequencing of RDS/peripherin, RP9, NRL, CRX, ROM1 and Fascin showed no mutation in any of the affected individuals. **Conclusions:** We identified a large Mormon family with an autosomal dominant RP. Linkage analysis and candidate gene sequencing have excluded known genes. A genome-wide scan is underway to identify a potentially novel RP locus in this kindred.

**A genome scan for modifiers of age at onset in Huntington's disease: The HD MAPS study.** *J.L. Li<sup>1,2</sup>, M. Hayden<sup>3</sup>, E.W. Almqvist<sup>3</sup>, A. Durr<sup>3</sup>, C. Dod<sup>3</sup>, P.J. Morrison<sup>3</sup>, O. Suchowersky<sup>3</sup>, C.A. Ross<sup>3</sup>, R.L. Margolis<sup>3</sup>, E. Gmez-Tortosa<sup>3</sup>, D. Mayo<sup>3</sup>, A. Novelletto<sup>3</sup>, M. Nance<sup>3</sup>, R.J.A. Trent<sup>3</sup>, A. Zanko<sup>3</sup>, R.K. Abramson<sup>3</sup>, A.L. Russ<sup>1</sup>, J.F. Gusella<sup>4</sup>, M.E. MacDonald<sup>4</sup>, R.H. Myers<sup>1,2</sup>.* 1) Neurology, Boston University School of Medicine, Boston, MA; 2) Bioinformatics Program, Boston University, Boston, MA; 3) The HD MAPS Study Group; 4) Molecular Neurogenetics Unit, Massachusetts General Hospital, Boston, MA.

Huntington's disease (HD) is caused by the expansion of a CAG repeat within the coding region of a novel gene on 4p16.3. While the variation in age at onset is partly explained by the size of the expanded repeat, the remaining variation in onset age is strongly heritable ( $h^2 = 0.56$ ) suggesting that other genes modify the onset age of HD. To identify these modifier loci, we performed a 10-cM density genome-wide scan in 629 affected sibling pairs (295 pedigrees and 695 individuals). Ages at onset were adjusted by linear regression for the effects of the expanded CAG repeat length, the normal repeat size and an interaction term of these two factors, and standardized residuals were generated for linkage analysis. The obtained residuals were normally distributed. Because all those studied were HD affected, estimates of allele sharing identical by descent at and around the HD locus were adjusted by a positionally weighted method to correct for the increased allele sharing at 4p. Suggestive evidence for linkage was found at 4p16 (LOD=1.93), 6p21-23 (LOD=2.29), and 6q24-26 (LOD=2.28). These regions may be useful for investigation of genes that modify age at onset of HD.

**Genome-wide scan of obesity-related traits in Mexican American coronary artery disease families.** *X. Li<sup>1</sup>, M.J. Quiñones<sup>2</sup>, D. Wang<sup>1</sup>, I. Enriquez<sup>2</sup>, X. Jimenez<sup>2</sup>, G. Hernandez<sup>2</sup>, R. De La Rosa<sup>2</sup>, W.A. Hsueh<sup>2</sup>, J.I. Rotter<sup>1</sup>, H. Yang<sup>1</sup>.*  
1) Cedars-Sinai Medical Center, Los Angeles, CA; 2) UCLA, Los Angeles, CA.

Obesity is an independent risk factor for coronary artery disease (CAD). To identify the genetic determinants of obesity, we performed a genome-wide linkage analysis of obesity-related traits using data from 101 Mexican American nuclear families ascertained via a parent (proband) with documented CAD. The available obesity traits include body mass index (BMI), body surface area (BSA), waist-to-hip ratio (WHR), fat mass as percent of body weight (FM%), and percent truncal fat (FM-T%). These traits were measured in adult offspring and offspring spouses (n=438). 568 adult offspring and their parents were genotyped for 408 microsatellite markers along the genome at ~10cM density. Heritability estimates and multipoint linkage analysis was performed using a variance components procedure implemented in SOLAR. After taking into account age and gender effects, the heritability estimates were 0.62 for BMI, 0.73 for BSA, 0.40 for WHR, 0.39 for FM% and 0.38 for FM-T% (all  $P < 0.001$ ). Evidence for linkage was observed at 252~267cM on chromosome 2 for four obesity-related traits (except for WHR). The maximum LOD scores (LOD) were 2.35 for BMI, 3.16 for BSA, 2.80 for FM% and 2.62 for FM-T%. We also observed suggestive linkage for BMI and BSA on chromosomes 5 (BMI: LOD = 2.18 at 167 cM; BSA: LOD=2.06 at 163 cM). Additional linkage signals were observed for BMI on chromosome 4 (LOD = 1.42 at 204 cM), for BSA on chromosome 8 (LOD=2.25 at 119 cM), for FM-T% on chromosome 11 (LOD=1.41 at 123 cM) and chromosome 16 (LOD = 1.48 at 51 cM). These results indicate that 1) there is a strong genetic influence on obesity in CAD families, and 2) the greatest evidence for linkage is observed for a group of obesity-related traits at approximately the same locus on chromosome 2q.

**A genome wide search for Kawasaki Disease susceptibility genes.** *Y. Onouchi<sup>1</sup>, S. Onoue<sup>1</sup>, M. Tamari<sup>2</sup>, K. Wakui<sup>3</sup>, Y. Fukushima<sup>3</sup>, M. Yashiro<sup>4</sup>, Y. Nakamura<sup>4</sup>, H. Yanagawa<sup>5</sup>, T. Kawasaki<sup>6</sup>, Y. Nakamura<sup>7,8</sup>, A. Hata<sup>1,9</sup>.* 1) Lab Gastrointestinal Diseases; 2) Lab. Genetics of Allergic Diseases, SNP Research Center RIKEN, Yokohama, Japan; 3) Dept. Preventive Medicine, Shinshu Univ. School of Medicine, Matsumoto, Japan; 4) Dept Public Health, Jichi Medical School, Tochigi, Japan; 5) Saitama Prefectural Univ, Koshigaya, Japan; 6) Japan Kawasaki Disease Research Center, Tokyo, Japan; 7) Lab. Molecular Medicine, Human Genome Center, Inst. Medical Science, the University of Tokyo, Tokyo, Japan; 8) Research Group for Personalized Medicine, SNP Research Center, RIKEN, Yokohama, Japan; 9) Dept. Public Health, Graduate School of Medicine, Chiba Univ, Chiba, Japan.

Kawasaki disease (KD), mucocutaneous lymphnode syndrome (MCLS), is an acute systemic vasculitis syndrome of young children. Although initially thought to be a benign illness, it is now known that coronary artery abnormalities develop in approximately 15 to 25% of children with untreated KD. KD is a leading cause of acquired heart diseases of children in the developed countries. Based on clinical and epidemiological features, it had been thought that some infectious agents trigger the activation of immune system and cause the KD phenotype, but the etiology remains unknown. The high incidence of KD in the population of Japanese ancestry, high relative recurrent risk for siblings ( $s=10$ ) and male predominacy suggest that there exist genetic factors. Here we performed genome wide search using 81 Japanese affected sib pairs to identify genes determining susceptibility for KD. 399 microsatellite markers were genotyped for these sib pairs, if available, their parents and unaffected siblings. Multipoint linkage analysis using MAPMAKER/SIBS program, and single point analysis using SIBPAL program was conducted. 8 chromosomal region showed supportive evidence of linkage of  $MLS=1.0$  or higher. In 12q24, 7p15, 19q13.3, relatively high LOD score ( $MLS=3.1, 2.9, 2.2$  respectively) was observed after additive markers were analyzed. It was suggested that major susceptibility genes for KD lie within these regions and now case control association study with SNPs in the candidate genes is in progress.

**Dense genome scan for rheumatoid arthritis (RA).** *J. Osorio y Fortea*<sup>1</sup>, *H. Bukulmez*<sup>2</sup>, *E. Petit*<sup>1</sup>, *L. Michou*<sup>1</sup>, *C. Pierlot*<sup>1</sup>, *S. Cailleau*<sup>1</sup>, *S. Lasbleiz*<sup>3</sup>, *T. Bardin*<sup>4</sup>, *B. Prum*<sup>3</sup>, *J. Olson*<sup>2</sup>, *F. Cornelis*<sup>1,2</sup>. 1) GenHotel/Laboratoire de recherche Europeen pour la polyarthrite rhumatoide, Universite d'Evry, Evry, France; 2) Department of epidemiology and biostatistics, Case Western Reserve University, Cleveland, Ohio; 3) Unite genetique clinique, hopital Lariboisiere, Paris, France; 4) Laboratoire statistique et genome, genopole, tour Evry2, Evry, France.

**Background** RA is the most frequent autoimmune disorder (1% prevalence). It is a complex disease ( $s = 2 - 10$ ), with HLA locus accounting for 1/3 of the familiarity. The European Consortium on RA Families reported in 1998 a 12 cM scan, suggesting 26 non-HLA loci ( $P < 0.05$ )

**Aim** Produce a 4 cM scan and 10000 simulations to refine the analysis

**Methods** 88 French affected sibling pair families were studied with 1088 markers. Linkage analysis was performed with Allegro1.1. Assessment of the statistical significance was performed with 10000 simulations

**Results** The average marker density was 3.3 cM. HLA linkage was found ( $P = 6.2 \cdot 10^{-5}$ ) and 19 regions were suggested at the 5% significance level, on chromosomes 1 to 6, 12, 13, 16, 18, 20, 22 and X. The probability of observing  $\geq 19$  non-HLA hits by chance was  $P < 0.05$ , suggesting the existence of RA loci. The average number of false positives was 11, suggesting 8 true linkages (19 observed - 11 expected). From the 26 regions suggested in 1998, only 9 remained and 11 were new. No region was found to overlap with all RA scans reported, by the Japanese, North American and English groups, presumably for linkage power and marker density issues. Some regions overlapped with those found for other autoimmune diseases and animal model scans, suggesting the existence of shared autoimmune genes

**Conclusion** We report a 3.3 cM genome scan for RA, suggesting the existence of non-HLA RA loci ( $P < 0.05$ ). Such a dense genome scan permitted to refine the description of candidate RA loci, some of which might be autoimmune loci. Simulations were consistent with an estimation of 8 genuine RA loci.

**Genome scan of cleft lip with or without cleft palate (CL/P): Part II: Broadening the phenotype to include velopharyngeal incompetence (VPI).** *K. Neiswanger<sup>1</sup>, M.D. Ford<sup>2</sup>, M.E. Cooper<sup>1</sup>, T.H. Goldstein<sup>1</sup>, S.S. Petiprin<sup>1</sup>, K.M. Bardi<sup>1</sup>, C.A. Brandon<sup>1</sup>, R.F. Giles<sup>1</sup>, M.L. Marazita<sup>1</sup>.* 1) Center for Craniofacial and Dental Genetics, Univ Pittsburgh Sch Dent Med, Pittsburgh, PA; 2) Cleft Palate-Craniofacial Center, Univ Pittsburgh Sch Dent Med, Pittsburgh, PA.

Nonsyndromic CL/P is a common birth defect with a complex, multifactorial etiology. Individuals with CL/P have a variable range of speech deficits, including anatomical and/or functional problems with their velopharyngeal (VP) mechanism. The purpose of this study is to seek genetic regions that may be important in the VP portion of the CL/P phenotype. We used the University of Pittsburgh Weighted Values for Speech Symptoms Associated with VPI scale to assess the VP status of 36 CL/P and 86 unaffected family members in 23 multiplex, nonsyndromic CL/P Caucasian families ascertained through the University of Pittsburgh Cleft Palate-Craniofacial Center. Scores of 0 on this assessment are considered VP competent (unaffected), and scores of 1 or higher are considered VPI (affected). We performed a genome scan using 392 anonymous markers spaced an average of 9 cM apart (from CIDR). Single-point and multipoint parametric and nonparametric linkage analyses were performed. We calculated the results twice--first using CL/P as the affected phenotype, and then repeating the analysis with a broad definition that added 19 non-CL/P family members with VPI scores > 0. The highest single-point LOD scores using the broad definition of affection status were +1.95, +1.74, and +1.74 for markers on chromosomes 5, 1 and 7, respectively. None of these scores occurred within 30 cM of the highest LOD scores on each chromosome under the narrow definition. These results suggest that the genes predisposing to VPI are not the same set of genes as the primary CL/P genes. Instead, they may modify the expression of primary CL/P genes, or act to alter the VP mechanism independently of clefting. Supported by NIH grants DE13076 & RR00084; genotyping grant from the Center for Inherited Disease Research.

**Significant linkage of attention-deficit/hyperactivity disorder (ADHD) to three genomic regions: 5p13, 6p12, and 17p11.** *M.N. Ogdie<sup>1</sup>, S.E. Fisher<sup>4</sup>, S.K. Loo<sup>2,3</sup>, M. Yang<sup>2</sup>, J.J. McGough<sup>3</sup>, J.T. McCracken<sup>3</sup>, A.P. Monaco<sup>4</sup>, S.L. Smalley<sup>2,3</sup>, S.F. Nelson<sup>1,2,3</sup>.* 1) Dept Human Genetics, UCLA, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 3) Department of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA; 4) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, UK.

A previous genome-wide scan in 270 ADHD affected sibling pairs (ASPs) identified 5 novel independent regions of linkage (Ogdie et al. 2003). We have fine-mapped all 5 candidate regions in an extended population sample comprising 230 multiplex families and 306 ASPs. Parents and siblings were genotyped at 2cM density and maximum-LOD score (MLS) analysis was performed in Genehunter v. 2.1. MLS analysis yielded three regions with significant linkage to a broad definition of ADHD: 5p13 (MLS 3.60,  $P = 2.3 \times 10^{-5}$ ), 6p12 (MLS 3.93,  $P = 1.0 \times 10^{-5}$ ), and 17p11 (MLS 3.62,  $P = 2.2 \times 10^{-5}$ ). Simulations within the specific parameters of this data set indicate that all three regions present MLS values above the threshold for significance. 10,000 replicates of each chromosome under the null hypothesis produced the following approximations of the empirical p-values: 5p13 ( $P = 0.0016$ ), 6p12 ( $P = 0.0012$ ), and 17p11 ( $P = 0.0016$ ). Estimates for sibling relative risk ratios (s), derived from sharing parameters, indicate s values of approximately 1.4 to 1.5 for all three regions. Thus, all three genomic intervals constitute candidate regions for susceptibility loci of moderate effect size.

**A genome-wide search for angiotensin-I converting enzyme (ACE) quantitative trait loci in Nigerian families.**

*C.A. McKenzie<sup>1</sup>, A. Adeyemo<sup>2</sup>, X. Zhu<sup>3</sup>, N. Bouzekri<sup>4</sup>, T. Forrester<sup>1</sup>, R.S. Cooper<sup>3</sup>.* 1) Tropical Metabolism Research Unit, University of the West Indies, Kingston, Jamaica; 2) Dept. of Pediatrics/Institute for Child Health, University of Ibadan, Ibadan, Nigeria; 3) Dept. of Preventive Medicine and Epidemiology, Loyola University Medical Center, Maywood, IL; 4) Institute of Biological Anthropology, University of Oxford, Oxford, UK.

Angiotensin I-converting enzyme (ACE) appears to play a critical role in the maintenance of cardiovascular homeostasis. There is well-characterised evidence from measured haplotype and other analyses conducted in different ethnic groups that circulating ACE levels are influenced by one or more quantitative trait loci (QTLs) either within or near to the ACE gene on chromosome 17. In several of these studies there are residual familial correlations, after accounting for the ACE-linked QTL, which are compatible with the presence of unlinked genetic factor(s) - no such loci have been identified as yet. The high heritability of circulating ACE suggests that the prospects for mapping ACE QTLs may be evaluated in samples of relatively modest size.

As part of a larger study of hypertension in the African diaspora, a genome-wide panel of microsatellite markers has been typed in 2 Nigerian family panels in which circulating ACE levels were also available. In a subset of these families single nucleotide polymorphisms (SNPs) in the ACE gene were also typed. In an effort to map putative QTL(s) unlinked to the ACE gene, we have analysed these marker and phenotype data using FASTLINK. Single locus models with fixed parameters were used to compute lod scores for linkage to ACE; several markers in both family sets showed modest evidence of linkage (i.e. lod scores > 1.5) including a marker on chromosome 17 with a lod score > 3.0. We also explore analyses of linkage to ACE levels and to ACE levels adjusted for the effects of ACE gene markers by computing lod scores with fixed parameters or by maximising the likelihood over theta and the QTL parameters joint.

Program Nr: 1898 from 2003 ASHG Annual Meeting

**A comprehensive human genetic map using all currently available CEPH markers.** *M. Jirout, C.C. Abney, N.J. Schork.* Dept of Psychiatry, UCSD School of Medicine, La Jolla, CA.

We have developed a comprehensive genetic map using all available marker data in the CEPH repository. This map consists of over 14,000 microsatellite, SNP, RFLP and in/del variations. We compared our new recombination frequency data to available physical map information. In addition, we have compared recombination frequencies obtained from the CEPH data to recombination rates observed in syntenic regions in the mouse and rat genomes.

**Parkinsonism Linked to Chromosome 2 and 18 in an Extended Amish Family.** *S. Lee*<sup>1</sup>, *Y. Bradford*<sup>2</sup>, *A. Crunk*<sup>2</sup>, *E. Bratton*<sup>1</sup>, *M. Allen*<sup>2</sup>, *J. Haines*<sup>2</sup>. 1) Dept Neurology, Vanderbilt Univ, Nashville, TN; 2) Dept. Molecular Physiology and Biophysics, Program in Human Genetics, Vanderbilt Univ, Nashville, TN.

Causative gene mutations identified in familial Parkinson disease (PD) have yielded insights into the pathogenesis of this neurodegenerative disorder. We previously reported an Amish population in Ohio with parkinsonism and dementia whose clinical features include typical idiopathic PD as well as progressive supranuclear palsy. Given the complex nature of the pedigree, we used SIMWALK 2.0 in a genomic screen with approximately 350 microsatellite markers at less than 20 cM resolution and identified several markers on chromosomes 1, 2, 5, 17, and 18. Using a more stringent requirement of lod score greater than 1.0 in parametric testing and a P value less than 0.5 in a nonparametric test, markers on chromosomes 2 and 18 were identified. The strongest result was with marker D2s2968 (252 cM sex-averaged) in a region near the recently identified region on chromosome 2q36-37 that was recently identified in a genomic screen of sibling pairs with a strong family history. This data suggests that at least one novel locus for PD exists in the Amish population.

**A genome-wide scan for age-related cortical cataracts in a sample from the Beaver Dam Eye Study (BDES) shows evidence of linkage on chromosome 1.** *J.H. Schick<sup>1</sup>, S.K. Iyengar<sup>1</sup>, K. Reading<sup>1</sup>, R. Liptak<sup>1</sup>, C. Millard<sup>1</sup>, K.E. Lee<sup>2</sup>, E.L. Moore<sup>2</sup>, G. Jun<sup>1</sup>, R. Klein<sup>2</sup>, R.C. Elston<sup>1</sup>, B.E. Klein<sup>2</sup>.* 1) Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison, WI.

Age-related cortical cataract is a common complex disorder with a multifactorial etiology. The importance of genetics in its etiology has been demonstrated by population, family and twin studies. Although genes for the Mendelian forms of cataracts have been identified, no genome scans or linkage studies have been conducted for age related cataracts. We performed genome-wide linkage scans for cortical cataracts and their rate of change in a selected sample from Beaver Dam, Wisconsin. The Beaver Dam Eye Study (BDES) is a longitudinal study to evaluate risk factors for age related macular degeneration and lens opacities. We genotyped 353 autosomal markers in 325 participants (N = 257 sib pairs). Second stage mapping was conducted in regions that demonstrated marginal evidence of linkage (P 0.01). Multipoint linkage analysis was performed using SIBPAL (S.A.G.E. 4.3) to identify regions linked to this age-related disease. The trait of interest was a quasi-continuous 12-category severity score determined using continuous gradings of duplicate Neitz photographs that included nine segments of the lens of the eye. Prior to conducting the linkage analysis, we adjusted this quasi-quantitative trait for age, age<sup>2</sup>, sex, age x sex interaction and vitamin usage. There was empirical evidence of linkage along a 58 cM region of chromosome 1p at a threshold significance level of 0.01 or less that includes markers D1S1597 (P = 0.0137), GATA29A05 (P = 0.0012), D1S552 (P = 0.0010), and D1S1622 (P = 0.0009). We also found suggestive evidence of genetic linkage for the rate of change over time for this disease along a 12 cM region of 1q21-35 containing markers D1S518 (P = 0.0288), D1S202 (P = 0.0288) and D1S2525 (P = 0.0396). Our analysis suggests that one or more genes for cortical cataract development may exist on chromosome 1, the first step in positional cloning.

**Using genomic convergence to identify susceptibility genes for age-related macular degeneration (AMD).** S.

*Schmidt<sup>1</sup>, E.A. Postel<sup>1</sup>, A. Agarwal<sup>2</sup>, J.R. Gilbert<sup>1</sup>, M.B. Gorin<sup>3</sup>, C. Bowes Rickman<sup>1</sup>, J.L. Haines<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Duke Univ Med Ctr, Durham, NC; 2) Vanderbilt Univ Med Ctr, Nashville, TN; 3) Univ Pittsburgh School of Med, Pittsburgh, PA.

We have completed a genomic screen of 62 affected sib-pair families with AMD, on whom 389 microsatellite markers were genotyped. Data on 12 follow-up markers are available on an additional 34 multiplex families. We have identified four chromosomal regions of interest: (i) chr 16p11-12 with a non-parametric MLS of 3.5 on in a subset of 14 obese families (average BMI of affected siblings >28.5), which overlaps the linkage region from an independent report; (ii) chr 10q26 with an MLS of 1.6, also consistent with a previous study; (iii) chr 9p24 with an MLS of 1.4 in a subset of 76 non-APOE4 families (APOE4 may be protective for AMD); (iv) chr 1q25-31 with an MLS of 1.3, also consistent with previous reports. To prioritize positional candidate genes within these regions, we are combining our linkage data with independently generated gene expression data. To this end, we have developed a human cDNA microarray database with regional neural retina expression levels for over 9000 genes. The retina expression profiles were generated by differentially screening arrays with two distinct neural retina cDNA probes derived from 4mm trephine punches of pooled (28-66 year old) human neural macula and mid-peripheral retina. 165 genes in the four regions of interest are detected on the array and are hence expressed in the neural retina. 92 of them show elevated expression in the macula. We are analyzing SNP genotype data for identified candidate genes in our current data set of over 650 multiplex and singleton AMD patients, and over 170 unrelated controls with documented absence of AMD. Parallel to our genotyping efforts, we will verify macular expression of these genes by real-time quantitative RT-PCR. Our approach illustrates the emerging paradigm of genomic convergence for dissecting the genetic basis of complex disorders.

**A GENOME-WIDE SCAN FOR LINKAGE IN 42 ANDALUSIAN MULTIPLEX FAMILIES WITH BIPOLAR AFFECTIVE DISORDER.** *J. Schumacher*<sup>1</sup>, *R. Abou Jamra*<sup>1</sup>, *O. Diaz*<sup>2</sup>, *F. Rivas*<sup>2</sup>, *S. Ohlraun*<sup>3, 4</sup>, *R. Kaneva*<sup>5</sup>, *C. Windemuth-Kieselbach*<sup>6</sup>, *E. Gay*<sup>2</sup>, *S. Sans*<sup>2</sup>, *M.J. Gonzalez*<sup>2</sup>, *S. Gil*<sup>2</sup>, *F. Cabaleiro*<sup>2</sup>, *T.F. Wienker*<sup>6</sup>, *P. Nrnberg*<sup>7</sup>, *Y.A. Lee*<sup>7</sup>, *S. Cichon*<sup>8</sup>, *P. Propping*<sup>1</sup>, *M. Rietschel*<sup>3, 4</sup>, *M.M. Nthen*<sup>8</sup>. 1) Inst. of Human Genetics, Univ. of Bonn, Germany; 2) Civil Hosp. Carlos Haya, Mlaga, Spain; 3) Central Inst. of Mental Health, Mannheim, Germany; 4) Dept. of Psychiatry, Univ. of Bonn, Germany; 5) Lab. of Mol. Pathology, Med. Univ., Sofia, Bulgaria; 6) Inst. of Med. Biometry, Informatics and Epidemiology, Univ. of Bonn, Germany; 7) MDC, Berlin, Germany; 8) Dept. of Medical Genetics, Univ. of Antwerp, Belgium.

In order to identify chromosomal regions containing genes that might play a role in determining susceptibility to bipolar affective disorder, we have performed a genome wide screen with 413 STRs in a sample of 42 multiplex families consisting of 357 individuals recruited in Andalusia, Spain. Parametric and non-parametric affecteds-only linkage analyses were carried out under three affection status models: a narrow model which included only individuals with bipolar I (103 affecteds), an intermediate model which included also individuals with bipolar II and schizoaffective disorder (144 affecteds) and a broad model which also comprised individuals with recurrent unipolar depression (209 affecteds). Suggestive evidence for linkage in the non parametric analysis (NPL) were observed in chromosomal regions 1p36, 2p22, 4q31, 6q23-q24, 11q13, and 13p13. Parametric two-point-analysis revealed suggestive LOD-scores on chromosomes 1p36, 4q31, 8p22, 13q13, and 19p13. We are currently performing fine mapping with dense sets of STR markers on chromosomal regions 1, 2, 4, 6 and 13. These regions have previously been described in independent genome screens of BPAD. Our fine mapping sample also includes 66 German families with BPAD because this series of families provided evidence for linkage to these chromosomal regions in a previous genome scan conducted by our group.

**Leber Congenital Amaurosis: evidence for a novel disease-causing gene in a Greek family.** Z. Yang<sup>1, 2</sup>, M.B. Ptersen<sup>3</sup>, N. Faulkner<sup>1, 2</sup>, M. Payne<sup>1, 2</sup>, M. Machan<sup>1, 2</sup>, S. Sims<sup>1, 2</sup>, L. Jiang<sup>1, 2</sup>, X. Li<sup>1, 2</sup>, J. Hu<sup>1, 2</sup>, G. Aperis<sup>3</sup>, M. Grigoriadou<sup>3</sup>, K. Zhang<sup>1, 2</sup>. 1) Department of Ophthalmology and Visual Science, University of Utah Health Science Center, Salt Lake City, UT 80132; 2) Program in Human Molecular Biology and Genetics, University of Utah Health Science Center, Salt Lake City, UT 80132; 3) Department of Genetics, Institute of Child Health, Athens, Greece.

**Purpose:** Leber Congenital Amaurosis (LCA) is a group of autosomal recessive retinal dystrophies representing one of the most severe visual impairments in infants and children. Known Loci/genes for this disorder include 17p13.1 (LCA1, GUCY2D), 1p31 (LCA2, RPE65), 14q24 (LCA3), 17p13.1 (LCA4, AIPL1), 6q11-q16 (LCA5), 14q11 (LCA6, RPGRIP1), 1q31-q32.1 (RP12, CRB1), and 19q13.3 (CRX). We report an eight-generation kindred with recessive Leber Congenital Amaurosis (LCA) without linkage to any of the known loci or associated mutations in previously reported LCA genes. **Methods:** Ophthalmic examination was performed, and genomic DNA was obtained from blood samples after informed consent. Linkage analysis using short-tandem repeat polymorphic markers encompassing known LCA loci and mutational screening of the reported genes for LCA by direct DNA sequence were performed. **Results:** An eight-generation Greek family with a total of 38 members (5 members affected by LCA) was studied. The disease gene was transmitted as an autosomal recessive trait. Of 25 individuals who participated in the study, 5 were found to be affected. Affected individuals showed light perception vision and nystagmus. Fundus examinations revealed diffuse pigmentary changes throughout the retina. Linkage analysis showed that none of the known LCA loci was associated with the phenotype in this kindred. Direct sequencing of GUCY2D, RPE65, AIPL1, CRB1, and CRX revealed no mutations in any of the affected individuals. **Conclusions:** We have identified a large Greek family with LCA. Linkage analysis and candidate gene sequencing have excluded known loci/genes. A genome-wide scan is underway to identify the potentially novel locus associated with LCA in this kindred.

Program Nr: 1904 from 2003 ASHG Annual Meeting

**A nonsense mutation in the I-branching -1,6-N-acetylglucosaminyl-transferase (IGnT) gene, causes autosomal recessive congenital cataract.** *E. Pras, N. Smaoui, JF. Hejtmancik.* OGVFB, National Eye Institute, NIH, Bethesda, MD.

**Purpose:** To identify the genetic defect causing autosomal recessive congenital cataract in 4 Arab Muslim families.

**Methods:** Genotyping was performed using the ABI Prism linkage mapping set (MD10). Two-point lod scores were calculated using MLINK of the LINKAGE Program Package. Mutation analysis of the IGnT gene was performed by direct sequencing of PCR amplified exons.

**Results:** The cataract locus was mapped to a 10.5 cM interval on Chr. 6p24 in between D6S470 and D6S289. Maximum two point lod scores of 7.986 at  $\alpha=0.019$  was obtained for the marker D6S470. Sequencing exons of the IGnT gene, mutation of which have been associated with cataracts and the i blood group phenotype, of these families revealed a homozygous GA substitution in base 58 of exon-2, resulting in the formation of a premature stop codon W328X, W326X and W328X, of the IGnTA,B and C isoforms, respectively. Subsequent blood typing of affected family members confirmed the possession of the rare adult i blood group phenotype.

**Conclusions:** A nonsense mutation in the IGnT gene isoforms causes autosomal recessive congenital cataract in 4 Arab Muslim families. These findings provide further insight into the dual role of the I-branching -1,6-N-acetylglucosaminyl-transferase in the lens and reticulocytes.

Program Nr: 1905 from 2003 ASHG Annual Meeting

**Genetic studies of stuttering in inbred Pakistani families.** *N. Riaz*<sup>1</sup>, *J. Ahmad*<sup>2</sup>, *B. Raza*<sup>2</sup>, *S. Riazuddin*<sup>2</sup>, *N. Cox*<sup>3</sup>, *D. Drayna*<sup>1</sup>. 1) NIDCD/NIH, Rockville, MD; 2) CEMB, University of the Punjab, Lahore, Pakistan; 3) Department of Human Genetics, University of Chicago, Chicago, IL.

Stuttering is a communication disorder that affects speech fluency, and is diagnosed by the presence of syllable repetitions, syllable prolongations, and by interruptions in the smooth flow of speech known as blocks. Many types of evidence suggest genetic factors contribute to stuttering. Because the genetics of stuttering is complex, we have sought specialized populations to give added power to linkage studies. One hundred consanguineous stuttering families were identified from the city of Lahore and surrounding villages in Punjab Province, Pakistan. Blood and diagnostic speech samples were collected from 55 families where there were more than 3 stuttering individuals. These families contain an average of three inbreeding loops containing affected individuals, and 90% of the individuals genotyped are the offspring of either first or second cousin matings. Diagnosis was performed using Stuttering Severity Instrument, and quantitative measures of affection status were obtained. We are undertaking genetic linkage studies using a total of 405 markers from the Weber/Marshfield set 9. A total of 250 individuals have been genotyped, and non-parametric linkage analysis methods are being performed.

Program Nr: 1906 from 2003 ASHG Annual Meeting

**Genome-Wide Scan for Adult Height in a Cohort of Type 2 Diabetes Patients from West Africa.** *J. Zhou, G. chen, Y. chen, H. Daniel, C. Rotimi.* Natl Human Genome Ctr, Howard Univ, Washington, DC.

A linkage analysis was performed for adult height in a cohort of diabetes patients from five centers in West Africa (Ghana: Accra and Kumasi; Nigeria: Enugu, Ibadan and Lagos). Using the variance component approach in SOLAR package, we searched for informative genomic regions for adult height (cm) in 341 families including 691 diabetes cases. Kurtosis for adult height in this cohort was 1.7. The strongest evidence of multipoint linkage analysis was obtained at 112cM (marker D3S4529) on chromosome 3 (LOD = 2.74, P-value = 0.00019). Follow by a LOD = 2.23 (P-value = 0.00068) at 53cM (marker D6S2427) and a LOD score = 1.84 (P-value = 0.0018) at 155cM (marker D6S2436) on chromosome 6, a LOD score = 1.82 (P-value = 0.0019) at 140cM (marker D8S1128) on chromosome 8, and a LOD score = 2.11 (P-value = 0.00092) at 88cM (marker D16S2624) on chromosome 16. All analyses were adjusted for gender ( $P < 0.0000001$ ) and age ( $p = 0.0000041$ ). The linkage signals lie in regions that have been reported in several previous studies conducted in multiple populations and ethnic groups. In conclusion, we replicated linkage evidence for adult height in chromosomes 3, 6, 8, and 16 in a cohort of diabetes patients from West Africa one of the ancestral populations of African Americans.

**A genome-wide scan for endometriosis loci in a Finnish study sample.** *O. Saranen*<sup>1,2</sup>, *M. Perola*<sup>2,3</sup>, *L. Heinonen*<sup>2</sup>, *K. Pelli*<sup>2</sup>, *J. Papp*<sup>2</sup>, *M. Ryyanen*<sup>1</sup>, *L. Peltonen*<sup>2,3</sup>. 1) Department of Obstetrics and Gynecology, University of Oulu, Oulu, Finland; 2) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, USA; 3) Department of Molecular Medicine, National Public Health Institute, and Department of Medical Genetics, University of Helsinki, Helsinki, Finland.

Endometriosis is a common gynecological disorder among fertile women with a prevalence of 10-15 %. Several twin studies have shown evidence for a genetic trait in this disease, with genetic risk ratios similar (2-3) to other complex disorders such as asthma or diabetes. However, no significant linkage evidence for any chromosomal region has been reported so far. Here we describe a genome-wide linkage study of endometriosis in nuclear families originating from the genetically isolated Finnish population. We have performed a two-stage genome-wide scan in a Finnish endometriosis study sample consisting of 31 core families, each with multiple affected subjects (178 individuals, 83 are affected women). All diagnoses were confirmed via laparoscopy or laparotomy and unaffected individuals were used only for phase information. In stage I we genotyped 323 markers (Weber 9 screening set) and in stage II the regions of interest were covered with denser marker maps. Further, 9 additional core families were included in the study in stage II. We identified suggestive linkage evidence for loci on chromosomes 7q ( $Z=1.98$ ), 8q ( $Z=2.35$ ) and 1p ( $Z=2.57$ ). These regions are currently being studied in the set of families ascertained for their geographical region of origin or shared genealogical roots to maximize the potential for shared genetic background in the subisolates of Finland.

**Genetic heterogeneity in familial chordoma.** *R.X. Yang<sup>1</sup>, M.J. Kelley<sup>2</sup>, M. McMaster<sup>1</sup>, N.J. Liebsch<sup>3</sup>, A.W. Bergen<sup>4</sup>, M. Beerman<sup>4</sup>, K. Haque<sup>4</sup>, A.M. Goldstein<sup>1</sup>, D.M. Parry<sup>1</sup>.* 1) Dept DCEG, NCI, NIH, DHHS, Rockville, MD; 2) Dept. of Medicine, Duke Univ., Durham, NC; 3) Dept. of Radiation Oncology, Mass. General Hospital, Boston, MA; 4) CGF, NCI, NIH, DHHS, Gaithersburg, MD.

Chordoma is a rare tumor originating from notochordal remnants. Five chordoma families with two or more affected individuals have been described, suggesting a genetic predisposition. The pattern of inheritance in these chordoma families is compatible with an autosomal dominant trait. Previously, we performed a whole genome scan on three unrelated chordoma kindreds (16 patients with chordoma) and reported significant evidence for linkage to chromosome 7q33 ( $Z_{\max} = 4.78$ ) with a minimal disease locus region of 11 cM. In the present study, a new chordoma family from Italy was clinically evaluated and genotyped for microsatellite markers on chromosome 7q. The father had nasopharyngeal chordoma at age 9 that was treated with radiation therapy. The tumor recurred at age 42 and he died at age 47 from tumor progression. One daughter was diagnosed with skull base chordoma at age 7, the second daughter had multicentric chordoma diagnosed at age 25, and the third daughter was diagnosed with a cervical astrocytoma at age 12. The three daughters and their mother were genotyped for 16 chromosome 7q markers from the chordoma locus region previously identified. The two daughters with chordoma did not share the same paternal haplotype for these 7q markers, suggesting the possibility of genetic heterogeneity. We cannot exclude the possibility that one of the affected daughters had a sporadic chordoma. However, since chordoma is such a rare tumor, this is highly unlikely. To further investigate the evidence for linkage and genetic heterogeneity in this region, we genotyped these four chordoma families for 120 SNP markers on chromosome 7. Examination of these SNP markers in conjunction with the microsatellite markers should help resolve the question of genetic heterogeneity of familial chordoma.

Program Nr: 1909 from 2003 ASHG Annual Meeting

**A Genomic Screen of Essential Tremor.** *F. Zhang, J. Stajich, S. West, R. Smith, J. Vance, M. Pericak-Vance, A. Ashley-Koch, J. John.* Duke Univ Medical Ctr, Durham, NC.

Essential tremor (ET), the most common movement disorder in adults, is clinically and genetically heterogeneous. ET is characterized by postural and intention tremor primarily affecting the arms and hands, although the head, voice, and legs may also be affected. Segregation analysis has suggested that the inheritance of ET is autosomal dominant and that the penetrance is nearly complete by the age of 65 (Bain et al, 1994). To date, three ET loci have been reported on chromosomes 2, 3 and 4. Evidence from our own dataset and that of Kovach et al (2001) has suggested that additional, unidentified ET loci exist. To that end, we have performed a 12 cM microsatellite genomic screen of a large ET family comprised of 36 sampled individuals, 9 of whom are affected. Two-point linkage analysis was performed with the VITESSE software package. Based on these results, high-priority regions on chromosomes 5, 8, 15, 16 and 20 have been defined, the two-maximum two-point LOD scores are respectively 1.76, 1.89, 1.63, 1.35, and 1.25. With additional markers genotyped in a 15 cM region on Chromosome 5, we conducted multipoint analysis. The highest LOD in Chromosome 5 is 2.64. We are currently genotyping additional markers in the rest of high-priority regions for pursuing fine-mapping and multipoint analysis. To assist in localization and fine-mapping of both novel and existing ET loci, we have amassed a collection of over 25 multiplex families. These families will be critical for identifying and isolating ET genes, which will advance therapeutic interventions for this major public health concern.

**Linkage confirmation of renal disease in systemic lupus erythematosus.** *A.I. Quintero-Del-Rio<sup>1,2</sup>, J.A. Kelly<sup>1</sup>, C.P. Garriott<sup>1</sup>, J.B. Harley<sup>1,2,3</sup>*. 1) Oklahoma Medical Research Foundation; 2) University of Oklahoma; 3) VA Hospital, Oklahoma City, OK, United States.

Renal disease occurs in 40-75% of systemic lupus erythematosus (SLE) patients, contributing to much of the morbidity and mortality of SLE. We have previously reported the results of two pedigree stratification strategies that explored the impact of the ACR renal criterion (cellular casts or proteinuria) for SLE classification upon genetic linkage. A multipoint sib-pair regression algorithm (SIBPAL2) produced  $p = 0.0000008$  in European-American (EA) pedigrees at 10q22.3 (SLEN1) and  $p = 0.000001$  in African-American (AA) pedigrees at 2q34-35 (SLEN2). To confirm these previously identified linkage effects, we collected an additional 144 pedigrees multiplex for SLE, 89 of which contained at least one SLE affected with the SLE renal criterion (27 AA, 43 EA, and 19 Hispanic (HI) pedigrees). SIBPAL results confirmed the previously identified SLE susceptibility locus (SLEN2) in the AA pedigrees ( $p=0.002$ ). When both independent sets of pedigrees were analyzed together, a  $p=0.0000006$  was obtained. The SLEN1 effect at 10q22.3 was highly supported by the additional set of pedigrees with a  $p=0.001$  in the same region. In addition, an effect at 5p16.3 is now significant in the AA pedigrees and is seen in both independent groups of pedigrees ( $p=0.00002$  in the initial pedigrees,  $p=0.001$  in the confirmatory pedigrees and  $p=0.0005$  in the combined set). All of the effects found dominated in either the AA or EA and were less impressive in the combined group. Multiple genetic linkages are related to renal criterion in SLE. Confirmations and additionally support of these identified genetic linkages will hopefully lead to the identification of the genes that predispose a lupus patient to develop renal disease.

**Replication of linkage on 2p for chronic mucocutaneous candidiasis and thyroid disease using two different high-density SNP genome scan technologies.** *Y. Tsai<sup>1</sup>, E.W. Pugh<sup>1</sup>, P. Boyce<sup>1</sup>, K.F. Doherty<sup>1</sup>, Y.T. Fan<sup>1</sup>, A.F. Scott<sup>2</sup>, M.St. Hansen<sup>3</sup>, A. Oliphant<sup>3</sup>, H. Loi<sup>4</sup>, R. Mei<sup>4</sup>, J.M. Puck<sup>5</sup>.* 1) CIDR, IGM, JHUSOM, Baltimore, MD; 2) IGM, JHUSOM, Baltimore, MD; 3) Illumina, San Diego, CA; 4) Affymetrix, Inc. Santa Clara, CA; 5) GMBB, NHGRI, NIH, Bethesda, MD.

Previously Atkinson et al. (AJHG 69:791-803) identified a candidate linkage region on chromosome 2p using a 10 cM microsatellite genome scan in a family with a combination of chronic mucocutaneous candidiasis and thyroid disease. We attempted to replicate this linkage result using single nucleotide polymorphism (SNP) markers and two different detection technologies, Illumina's BeadArray™ platform Linkage Panel Version 1 and Affymetrix GeneChip Human Mapping 10K Array Xba 130 (Early Access version). Data from 18 samples from this family was received from Affymetrix and Illumina. The overall missing data rate for this family was 0.022% using Illumina 2,245 SNPs, and 3.72% for Affymetrix 8,803 SNPs. The Mendelian inconsistency rate was 0.03% for both technologies. Genehunter was used for nonparametric linkage analysis. Due to this program's constraints, a trimmed version of the pedigree containing 20 individuals and 11 genotyped individuals was used. Genetic locations were approximated based on the physical map. For multipoint analysis we excluded non-informative markers (two point NPL scores between -0.05 and 0.05). The highest two point NPL score on chromosome 2 using Illumina assay (193 SNPs) was 0.56 (p=0.076) at position 45.29 cM and using Affymetrix assay (717 SNPs), was 0.81 (p=0.05) at positions 70.84 and 74.33 cM. Among the 190 informative Illumina SNPs, multipoint NPL scores reached 2.17 (p=0.035) in the 56.92-80.33 cM region on chromosome 2. For the 392 informative Affymetrix SNPs, multipoint NPL scores reached 9.41 (p=0.0078) in the 44.21-58.16 cM region. Original results using microsatellite markers reported parametric two point LOD scores greater than 1.0 at 5 consecutive markers in the 38.33-73.61 cM region. In this family, our results from both SNP technologies were comparable to that of the original microsatellite genome scan. Additional results using Illumina Linkage Panel Version 3 will be provided.

**Evidence for linkage to chromosome 19 in autism.** *M.A. Pericak-Vance<sup>1</sup>, R. Rabionet<sup>1</sup>, D. Skaar<sup>1</sup>, R.K. Abramson<sup>2</sup>, H.H. Wright<sup>2</sup>, G.R. DeLong<sup>1</sup>, M.L. Cuccaro<sup>1</sup>, J.R. Gilbert<sup>1</sup>.* 1) Duke University Medical Center, Durham, NC; 2) University of South Carolina, Columbia, SC.

Previous genome-wide screens for autism have provided suggestive evidence for linkage to Chromosome 19, including our own, in which 99 multiplex families were analyzed (multipoint maximum LOD score (MLS)=1.21). In an effort to confirm and expand these findings we conducted a follow-up analysis of the region of observed linkage in 210 multiplex families. The families were ascertained through the Collaborative Autism Team (CAT) (N=111) and through the Autism Genetics Exchange (AGRE) (N=99) and met ADI and ADOS criteria for the diagnosis of autism. Five microsatellite markers spanning a region of chromosome 19 from 45.5cM to 58.6cM (d19S593, d19S407, d19S407, d19S49, d19S433) were analyzed. The most significant result was for marker d19s593 with a maximized parametric lod score allowing for heterogeneity (MLOD) of 2.5 (recessive model), and an MLS of 2.0 in the overall dataset. Stratifying the families by ascertainment source (CAT vs. AGRE), however, resulted in a significant result in the AGRE subset (MLOD=4.1 and an MLS=3.2) for D19S593. D19S407 located 3cM distal was also positive with MLOD=1.0. These results continue to strongly implicate this region of chromosome 19 as containing an autism susceptibility gene and suggest that family source is an important stratification variable to consider in analysis. High resolution SNP mapping of the region is ongoing and will be presented.

**Identifying modifier loci in existing data.** *E.W. Daw, S. Shete.* Dept Epidemiology, UT MD Anderson Cancer Center, Houston, TX.

In many disorders where a primary disease-causing locus has been identified, evidence for additional trait variation due to genetic factors has been found. These findings have led to several studies in which secondary modifier loci are being sought. Identification of such modifier loci provides additional insight into disease mechanisms and may provide additional treatment targets. We believe that some modifier loci can be identified by re-analysis of genome screen data while controlling for the effects of the primary locus. To test this hypothesis, we simulated multiple replicates of typical genome screening data on to two real family structures that were used to identify a genetic mutation that causes hypertrophic cardiomyopathy. Along with the marker data, we simulated a trait with characteristics similar to one measure of hypertrophic cardiomyopathy. This trait was influenced by a primary gene, a secondary modifier gene, and a third very small effect gene. We examined the power and false positive rates to map the secondary locus while controlling for the effect of the primary locus with three types of analyses. First, we examined the L-scores produced by the Monte Carlo Markov chain (MCMC) combined segregation and linkage analysis package, Loki. These L-scores are Bayes Factors for linkage computed in 1cM intervals, with a score 1 suggesting linkage and 1 suggesting no linkage. Second, we examined an alternate scoring method for MCMC linkage analysis, the LOP (Daw et. Al., Genetic Epidemiology 24:181-190), which is the log of the posterior probability of linkage to the real chromosome divided by that to an unlinked pseudochromosome. Third, we calculated lod scores using an individual-specific liability class based on the quantitative trait value. We found that all three methods produced scores that are significant on a genome-wide level in some replicates. Our results indicate that a re-analysis that accounts for the effect of an identified gene may localize modifier genes. In view of the relatively low cost of such analysis, we recommend re-analysis of exiting genome screen data as a first step in hunting for modifier genes. Support: HL68884.

**How useful is fine mapping complex trait linkage scan peaks ?** *S. Wiltshire, A. Morris, M. McCarthy, L.R. Cardon.*  
Wellcome Trust Ctr Human Gen, Univ Oxford, Oxford, United Kingdom.

Genotyping additional markers under linkage peaks in primary genome scans is a near universal practice. Strongly implicit inferences regarding the true or false nature of a linkage result are often made on the basis of the behaviour of the peak upon fine mapping: if the peak increases, it is thought to be a true positive; if it decreases, it is regarded as a possible false positive. We have quantified the statistical inferences that can be made from such exercises by simulation. With completely genotyped data and no gene effects (ie., the null hypothesis of no linkage), increased support for a false positive linkage from a primary analysis occurs 54.2% of the time upon fine mapping with a LOD threshold 1.18. With a threshold of LOD2.08, such a peak increases 48.6% of the time. With a real gene in the linkage region (eg., with  $\lambda_S=1.25$ ), increased evidence for a true positive linkage result occurs 74.7% of the time with a fine mapping LOD threshold 1.18, and 70.1% of the time with LOD threshold 2.08. Given the simple instance of a 5% prior probability for linkage to a causative gene, the posterior probabilities of a true positive before fine mapping are 0.18 (LOD1.18) and 0.49 (LOD2.08). If the peak increases on fine mapping, these posterior probabilities increase to 0.24 (LOD1.18) and 0.58 (LOD2.08; if it decreases on fine mapping, these drop to 0.11 (LOD1.18) and 0.36 (for LOD2.08). As  $\lambda_S$  increases, these posteriors increase as the linkage peak increases and decrease as the peak shrinks, on fine mapping. When both the priors and the LOD threshold for fine mapping increase, both posteriors increase. Similar results are obtained under different data configurations (i.e. absence of parents, and/or otherwise incomplete genotypes). In summary, there are only modest increases in the probability that a linkage peak reflects a real gene when LOD scores increase, and modest decreases when the peak shrinks, upon fine mapping. Peak behaviour upon finemapping would therefore appear to add little to determining whether a linkage peak is a true or a false positive, the principal determinant of which remains the magnitude of the primary LOD score.

Program Nr: 1915 from 2003 ASHG Annual Meeting

**Representing Quantitative Trait Loci in the Mouse Genome Informatics (MGI) Database.** *D.W. Bradt, I. Lu, J.T. Eppig, C.J. Bult, Mouse Genome Informatics Staff.* Bioinformatics, The Jackson Laboratory, Bar Harbor, ME.

The Mouse Genome Informatics (MGI) database is a community database that provides integrated access to data on the genetics, genomics, and biology of the laboratory mouse. MGI is freely available on the Web at <http://www.informatics.jax.org/>. Mapping information in MGI is obtained from primary research data collected reported in scientific publications as well as electronically submitted data. Genetic linkage data specify parental genotypes and progeny segregants. Mapping data includes representation of Quantitative Trait Loci (QTL) derived from published literature. Information about each QTL is available as free text and includes the genetic marker with the peak statistical association score. If available in the associated publication, the information about flanking markers and candidate genes are described. Progenitor strain polymorphisms underlying the mapping of the QTLs are also detailed. Genetic map positions for QTLs expressed as cM positions based on the marker with which the QTL has the highest reported linkage. Information on approximately 1,400 QTLs are included within MGI currently. QTL from MGI have been integrated with the public mouse genome sequence. The QTLs displayed in their genomic context can be observed via the Ensemble genome browser, the UCSC Genome Browser, and NCBI's Map Viewer. The integration of QTL data from MGI with the annotated mouse genome serves as a useful framework for in silico positional candidate gene analysis.

**Genome-screen of a healthy cohort of twin pairs reveals linkage for bone metabolism markers to chromosomes 1, 12, 17 and 19.** *T. Andrew<sup>1</sup>, M.J. Barber<sup>1</sup>, R. Swaminathan<sup>2</sup>, M. Langdown<sup>3</sup>, S.G. Wilson<sup>4</sup>, T.D. Spector<sup>1</sup>.* 1) *Twin Research & Genetic Epidemiology Unit, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH;* 2) *Department of Chemical pathology, St.Thomas' Hospital;* 3) *Sequenom Inc., 3595 John Hopkins Ct, San Diego, CA 92121;* 4) *Endocrinology & Diabetes, Sir Charles Gairdner Hospital, Western Australia 6009.*

**Purpose:** Osteoporosis is a disease characterized by low bone mass, architectural deterioration of bone tissue and abnormalities in bone turnover. In this study we have conducted a genome-wide scan for bone turnover markers previously reported to have high heritabilities.

**Methods:** Five genome-wide screens were conducted using upto 932 dizygous caucasian female twin pairs aged between 18 and 80 years. Levels of blood serum total and bone specific alkaline phosphatase were used as distal measures of bone formation; Urinary deoxypyridinoline crosslinks (DPD) for bone formation; and serum parathyroid hormone and serum 25-hydroxyvitamin D (25(OH)D) for bone calcium and vitamin D regulation, respectively. Multipoint linkage analyses were performed using optimal Haseman and Elston methods implemented in Stata as a Generalised Linear Model. Regression diagnostics were used to help identify poor fitting linkage models and hence artefactual results.

**Results:** Linkage peaks were observed for 25(OH)D at chr1p21-31 (LOD 3.1-4.2), chr17q21-24 (LOD 2.2-4.5) and chr19q13.4 (LOD 5.4-7.1); DPD peaked at chr12q24.3 (LOD 4.3-4.7).

**Conclusion:** Preliminary evidence for bone markers linked to chromosomes 1, 12, 17 and 19 highlight these regions as potentially important for studies of genes that regulate bone.

**Findings in an independent sample support association between bipolar affective disorder and the G72/G30 locus on chromosome 13q33.** *Y.-S. Chen<sup>1</sup>, N. Akula<sup>2</sup>, S.D. Detera-Wadleigh<sup>2</sup>, T.G. Schulze<sup>3</sup>, J. Thomas<sup>2</sup>, J.R. DePaulo<sup>4</sup>, M.G. McInnis<sup>4</sup>, N.J. Cox<sup>1</sup>, F.J. McMahon<sup>2</sup>.* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Mood and Anxiety Program, National Institute of Mental Health Intramural Research Program, National Institutes of Health, Dept. of Health and Human Services, Bethesda, MD; 3) Division of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, Mannheim, Germany; 4) Dept. of Psychiatry and Behavioral Sciences, The Johns Hopkins University School of Medicine, Baltimore, MD.

Markers near the genes G72 and G30 on chromosome 13q33 have been implicated in the etiology of schizophrenia and, recently, bipolar affective disorder (BPAD). Hattori et al (2003) reported that single-nucleotide polymorphisms (SNPs) near the G72/G30 locus were associated with BPAD in a small pedigree sample and that SNP haplotypes were associated in a second, larger sample of triads. The present study attempts to replicate this finding in an independent case-control sample. Eight SNPs near the G72/G30 locus, including the most strongly associated markers in the previous study, were genotyped in 139 cases and 113 ethnically-matched controls. Significant association was detected between BPAD and 2 adjacent SNPs (smallest  $p = 0.007$ ; global  $p=0.024$ ). Haplotype analysis produced additional support for association (smallest  $p = 0.004$ ; global  $p=0.004$ ), although the associated haplotypes differ from those previously reported. These results support the previous findings and provide further evidence, in an independent sample, for an association between BPAD and genetic variation in the vicinity of the genes G72 and G30.

**Quantitative Trait Loci for steady-state platelet count in mice.** *M. Buckley*<sup>1,2</sup>, *C. Cheung*<sup>1,2</sup>, *I. Martin*<sup>3</sup>, *K. Zenger*<sup>4</sup>, *J. Donald*<sup>4</sup>, *P. Thompson*<sup>3</sup>, *C. Moran*<sup>3</sup>. 1) Centre for Vascular Research, University of New South Wales, Sydney, Australia; 2) Molecular & Cytogenetics Unit, South Eastern Area Laboratory Services, Sydney, Australia; 3) Centre for Advanced Technologies in Animal Genetics and Reproduction, University of Sydney, Australia; 4) Department of Biological Sciences, Macquarie University, Sydney, Australia.

Approximately 85 percent of the inter-individual variance in human platelet numbers can be attributed to genetic factors. As part of a project to identify novel factors that regulate platelet count, we identified two inbred mouse strains, CBA/CaH and IQS5, with substantial differences in platelet count (mean values of 581 vs. 1062 x 10<sup>9</sup>/L). An F2 intercross resource of 1,126 animals was bred for a genome-wide scan for quantitative trait loci (QTL) for platelet count. QTL were identified on MMU 1 (LOD 6.8, p<0.0005) and MMU 11 (LOD 11.2, p<0.0005) by selectively genotyping animals from the extremes of the F2 platelet count distribution. Three other QTL of borderline significance were also detected. It is noteworthy that no QTL was detected in the vicinity of the genes encoding thrombopoietin (Tpo), and its receptor (c-Mpl), both known to influence platelet production. These results represent the first published use of a genetic linkage based approach to the identification of genetic factors that regulate platelet count.

**Refinement of the 6p21.3 QTL influencing dyslexia through linkage and association analysis.** *K.E. Deffenbacher<sup>1</sup>, J.B. Kenyon<sup>1</sup>, D.M. Hoover<sup>1</sup>, R.K. Olson<sup>3</sup>, B.F. Pennington<sup>2</sup>, J.C. DeFries<sup>3</sup>, S.D. Smith<sup>1</sup>*. 1) Dept Molec Genetics, Univ Nebraska Med Ctr, Omaha, NE; 2) Univ of Denver, Denver, CO; 3) Institute for Behavioral Genetics, Univ of Colorado, Boulder, CO.

Reading disability (RD), also known as dyslexia, is the most common learning disability with a prevalence rate of ~5-10% in school age children. RD is known to be highly heritable with evidence of a neurobiological origin. A quantitative trait locus (QTL) for RD has been reported on chromosome 6p21.3, spanning a 16.4Mb (13.8cM) interval from D6S109-D6S291 (Fisher and DeFries 2002). In this study, we performed sib pair linkage analyses using Haseman-Elston and DeFries-Fulker methods to define more accurately the QTL interval. An extended sample of 349 nuclear families were genotyped for 22 microsatellite markers spanning ~22Mb of the 6p21-22 region. Linkage was assessed using five quantitative phenotypes, including a composite measure of reading performance and 4 component phenotypes. When probands were selected for severe scores, single and multipoint analysis showed suggestive linkage with 3 of our phenotypes, converging over an ~3.4Mb interval spanning D6S1597-D6S1571. Multipoint analysis suggested a peak of linkage for the composite measure of reading ability near D6S1663, with 2 of the component phenotypes showing a peak near D6S1571. Out of the twelve genes in the linkage interval, ten cluster within ~680kb, and were selected for association analysis based on CNS expression and putative function. 31 SNPs spanning these 10 genes were genotyped in 114 family trios. Marker-trait associations were assessed using QTDT and FBAT, and haplotype analysis was done using Genehunter TDT in conjunction with 1 of the 3 linked phenotypes. Marker associations were detected in four of the ten genes, results that were corroborated by our haplotype TDT analysis. The results of the association study have thereby allowed us to significantly reduce the number of possible candidate genes, as well as prioritize genes for further mutation screening. This work was supported in part by NICHD Center Grant HD-27802.

**A genome-wide scan for loci contributing to population variation in adult height.** J.A. Ellis, Z.Y.H. Wong, S.B. Harrap. Dept Physiology, Univ Melbourne, Melbourne, Australia.

Adult height is widely regarded as the complex human trait most amenable to genetic dissection. It shows a high degree of heritability (between 55%<sup>1</sup> and 90%), and can be easily and accurately measured. Investigation of this trait therefore has the potential to shape strategies for genomic discovery. Identification of genes controlling height will also enhance our understanding of the fundamental biological processes of bone growth. Several genome-wide linkage analyses of height have recently been published, however few loci have been consistently identified across studies. We have performed a multipoint quantitative genome-wide linkage analysis for height in the Victorian Family Heart Study (VFHS)<sup>1</sup>, a population survey of 2959 healthy Caucasian individuals from 783 adult families. A total of 275 sibling pairs aged 18-31 yrs were genotyped using the ABI Linkage Mapping Set v2 that defines a human index map of ~10 cM intervals. Data was analysed using GENEHUNTER 2. Six promising linkage peaks were observed, including Chromosomes 3 (50-80 cM, Z=3.2), 2 (155-185cM, Z=2.7) and X (170cM-tel, Z=2.2). The identified regions have not been reported previously in other genome-wide analyses. However, a number of candidate genes exist in our regions. On chromosome 3, these include the genes encoding parathyroid hormone receptor 1 (*PTHRI*) that was recently associated with height in women<sup>2</sup>, and tetranectin (*TNA*), an extracellular matrix protein produced by osteoblasts. The X-chromosome region contains biglycan (*BGN*), a proteoglycan synthesised by osteoblasts. The next step is to undertake a thorough association analysis of single nucleotide polymorphisms (SNPs) in and around candidate genes, and if necessary, throughout identified regions to elucidate the causative variants. It will not be until such comprehensive investigations of the results of genome-wide scans of complex traits are carried out that we will begin to fully understand the accuracy and reliability of such methods to detect contributing loci, and the basis for the between-study discrepancies. <sup>1</sup> Harrap SB, et al. Am J Epidemiol 152:704-15,2000. <sup>2</sup> Minagawa M, et al. J Clin Endocrinol Metab 87:1791-6,2002.

**A genomewide scan for the susceptibility gene loci to ankylosing spondylitis in Chinese Han population.** *M. Gu*<sup>1</sup>, *W. Yuan*<sup>2</sup>, *J. Yang*<sup>3</sup>, *J. Zhang*<sup>2</sup>, *F. Yao*<sup>3</sup>, *Z. Wang*<sup>1</sup>, *L. Jin*<sup>2,4</sup>, *W. Huang*<sup>2</sup>, *L. Fan*<sup>3</sup>. 1) Department of Medical Genetics, Shanghai 2nd Med. University, Shanghai, China; 2) Chinese National Human Genome Center at Shanghai, Shanghai, China; 3) Shanghai Second Medical University and Shanghai Institute of Immunology, Shanghai China; 4) Center for Genome Information, Department of Environmental Health, University of Cincinnati.

Ankylosing spondylitis (AS) is a common arthritis, with a prevalence of 1/1000-3/1000 in Caucasian and 2/1000 in Chinese population. Genomewide scans showed that some affected-sibling-pair families with AS not only demonstrated strong linkage to the MHC locus, but also identified other regions with suggestive or strong linkage on chromosomes 1p, 2q, 9q, 10q, 16q, and 19q. In order to localize the regions containing genes that determine susceptibility to AS in Chinese, we performed a genome-wide scan in nine Chinese families with AS, including 29 affected individuals. LINKAGE and GNEHUNTER packages were used for parametric (LOD) and non-parametric (NPL) analyses. The significant two-point LOD score value with D6S276 (at 44.9cM from the 6p telomere) was 3.8782 in parametric analysis. Fine mapping showed LOD scores of D6S1691 (at 42.7cM) and D6S1618 (at 47.6cM) around D6S276 were 1.5717 and 2.0056, respectively. Single point NPL score of D6S276, D6S1691 and D6S1618 were 2.6053, 2.7490, 2.0202, respectively, and minimum P value were 0.0072, 0.0047, and 0.0265, respectively. Using multipoint NPL, the maximum LOD score values, NPL score and minimum P value obtained near D6S276 were 5.0623, 3.7561, and 0.000233, respectively. The haplotype analysis showed that the regions from D6S1691 to D6S1618 associated with AS. As a result, the strong linkage of the D6S276 with AS was found, the region of D6S1691-D6S276-D6S1618 exist a susceptibility gene of AS. In addition, we identified 3 regions with suggestive linkage on D3S1292, D4S1535 and D18S64.

**A Leu184Val polymorphism in PCK1 gene is associated with type 2 diabetes in Chinese population.** *Y. Dong*<sup>1,2</sup>, *G. Li*<sup>2</sup>, *G. Wu*<sup>2</sup>, *L. Jin*<sup>1</sup>, *Y. Shen*<sup>1</sup>, *T. Luo*<sup>2</sup>, *M. Luo*<sup>2</sup>, *W. Huang*<sup>1</sup>. 1) Chinese National Human Genome Center at Shanghai, Shanghai, China; 2) Shanghai Institute of Endocrinology, Ruijin Hospital, Shanghai Second Medical University.

Type 2 diabetes mellitus is a multifactorial, heterogeneous metabolic disease with environmental and genetic components. In the previous study, we performed a genome-wide linkage study in Chinese pedigrees with type 2 diabetes and gave a suggestive evidence for linkage to type 2 diabetes, which is on chromosome 20q13. PCK1 gene, as one potential candidate gene within this linked area, is a regulated enzyme catalyzing the conversion of oxalacetate to phosphoenolpyruvate in gluconeogenesis. In this study, we detected the single nucleotide polymorphisms (SNPs) in the coding and regulating regions of the PCK1 gene by direct sequencing and eight SNPs were detected in PCK1 gene, among which one SNP (Leu184Val) was a missense variant. The frequency of the Leu184Val polymorphism was further evaluated in a case-control study (195 type 2 diabetes patients and 188 controls). The allelic frequency of the Leu184Val polymorphism in the cases and controls was 75.6% and 83.2% respectively ( $P=0.009$ ). The odds ratio for the frequency of the mutation allele is 1.6 (the 95%- confidence interval: 1.121~ 2.284). Our data implicated that the Leu184Val polymorphism in PCK1 gene was significantly associated with the pathogenesis of type 2 diabetes in the Chinese population.

Program Nr: 1923 from 2003 ASHG Annual Meeting

**Evidence for linkage but not association to the GABRB3 region of chromosome 15 in a subset of primary open angle glaucoma (POAG) families.** *F.L. Graham<sup>1</sup>, R.R. Allingham<sup>1</sup>, M. Hauser<sup>1</sup>, K. LaRocque-Abramson<sup>1</sup>, C.M. Santiago<sup>1</sup>, A. Ventura<sup>1</sup>, E. DelBono<sup>2</sup>, J.R. Shi<sup>3</sup>, J.L. Haines<sup>3</sup>, J.L. Wiggs<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Medicine, Duke University Medical Center, Durham, NC; 2) Massachusetts Eye and ear Infirmary, Boston, MA; 3) Vanderbilt University, Nashville, TN.

Previously, we employed Ordered Subset Analysis (OSA) to identify a homogenous subset of POAG families linked to chromosome 15q in order to refine our candidate region for analysis (Allingham, et al, ASHG 2002). We used *age at diagnosis* as a surrogate for age of onset as a covariate in the analysis. The peak OSA lod score reached a maximal value of 3.05 in a subset of 15 families with a family specific mean age at diagnosis 49 years of age at the GABRB3 locus (12.4 cM) ( $p = 0.011$  by permutation test). Within this region are located three GABA receptor genes, GABRA5, GABRB3 and GABRG3. These genes are all expressed in the retina making them good candidate susceptibility genes. Using the 15 families (92 individuals) that were identified by OSA as being a homogeneous subset of the POAG data set, we analyzed 21 single nucleotide polymorphisms (SNPs) within the GABRB3 gene and in the region located beyond the 3' end of the gene. Seven of the twenty-one SNPs showed positive linkage with a peak LOD score of 1.63 for SNP SNPEX1A-2. Allelic association analysis was not significant for any of the SNPs using the Pedigree Disequilibrium Test (PDT) ( $p < 0.05$ ). The full coding region of all three genes were sequenced and no coding variants were found. We are testing other candidate genes as well as additional SNPs in the GABRB3 gene region. Support: The Glaucoma Research Foundation, Barkhouser Glaucoma Research Fund, and NIH Grant EY 10886.

**Genetic variation in a haplotype block spanning IDE has a major impact upon clinical features of Alzheimer's Disease.** *A.J. Brookes, L. Feuk, J. Prince.* Center for Genomics and Bioinformatics, Karolinska Institute, Stockholm, Sweden.

Linkage studies have identified a large (> 60 Mb) region on chromosome 10q that segregates with Alzheimers Disease (AD), but the causative gene in this region remains elusive. In fact, different linkage peak localizations suggest that more than one gene in the region may influence the disease. One candidate gene for which a good biological case could be made is that for insulin degrading enzyme (IDE), which acts to degrade both the extracellular beta-amyloid protein constituent of amyloid plaques and the intracellular domain of APP that is released by gamma-secretase processing. To evaluate IDE in AD, we undertook extensive SNP association analysis in its vicinity (480kb surrounding the gene). Estimations of linkage disequilibrium amongst 26 tested SNPs revealed a major 276kb haplotype block that extends across three genes (IDE, KNSL1, and HHEX). We evaluated this block further by scoring 3 haplotype-tagging SNPs. Experiments employed multiple independent sets of clinical materials comprising early- and late-onset AD individuals (collaborations with Kaj Blennow, University of Gteborg; Boo Johansson, University of Gteborg ; Margaret Gatz, University of Southern California; Nancy Pedersen, Karolinska Institute), and we focused our analyses upon case-control status as well as various quantitative traits that are pertinent to AD diagnosis and severity (MMSE scores, Tau protein levels in CSF, and age-at-onset). Significant evidence of AD association was found, entailing consistent risk and protective haplotypes present in most of the investigated populations (p-values ranging from 0.05 to  $<1 \times 10^{-9}$ ). Thus, strong association was found between features of AD and a haplotype block that spans IDE. The signal patterns seen in our studies, and in collaborative replications of our work (Steven Younkin, Mayo Clinic; Rudi Tanzi, Harvard University) indicate that many allelic variants pathogenic for AD probably exist in and around this genomic domain. Deciphering the etiology of AD encoded by this portion of chromosome 10q will probably require extensive and detailed further study of this challenging genomic region.

**Strong linkage evidence for a locus influencing sensitivity to *Chlamydia pneumoniae* infection on chromosome 21.**

H.H.H. Göring<sup>1</sup>, J.T. Williams<sup>1</sup>, L. Almasy<sup>1</sup>, M.C. Mahaney<sup>1</sup>, S.A. Cole<sup>1</sup>, M.P. Stern<sup>2</sup>, J.W. MacCluer<sup>1</sup>, J. Blangero<sup>1</sup>. 1) Dept. of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Div. of Clinical Epidemiology, Dept. of Medicine, University of Texas Health Science Center, San Antonio, TX.

For many years, it has been speculated that chronic disease of old age may in part be a result of hidden, long-term infection. The infectious agent(s) may be causing disease directly, or disease may be a consequence of inflammation caused by the host's immune reaction to the pathogen(s). An intriguing candidate is *Chlamydia pneumoniae*, to which accumulating evidence points as potentially being partly responsible for atherosclerosis.

We have conducted a genome-wide linkage screen on seropositivity to *C. pneumoniae* in 591 individuals belonging to 23 large, randomly ascertained pedigrees of Mexican Americans, who are participants in the San Antonio Family Heart Study. Seropositivity was assessed by IgA and IgG ELISA tests on blood serum. Genome-wide variance components-based linkage analysis was conducted using a quantitative liability model for the dichotomous trait seropositivity. The significance was assessed empirically by simulation.

66 % of individuals were found to be seropositive, indicating current infection with *C. pneumoniae*. The additive heritability to infection, after adjusting for sex and age, was estimated as 0.38 +/- 0.14. A (empirical) lod score of 3.2 was obtained on chromosome 21p. No other lod scores over 2 were observed. To our knowledge, this is the first study to demonstrate that sensitivity to *C. pneumoniae* infection is heritable and to localize an underlying genetic factor.

**MULTIDISEQ: Computer software for multipoint linkage analysis of complex traits allowing for marker-marker LD (Linkage Disequilibrium).** *T. Hiekkalinna*<sup>1</sup>, *L. Peltonen*<sup>1,2</sup>, *J.D. Terwilliger*<sup>3,4</sup>. 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) Department of Psychiatry and Columbia Genome Center, Columbia University, NY, USA; 4) New York State Psychiatric Institute, NY, USA.

The current trend in mapping complex traits is use of dense SNP and/or microsatellite marker maps which are in some or complete LD with each other and hypothesized predisposing variant(s). Currently available multipoint linkage analysis software are not well suited for analyzing such marker maps. If the marker-marker LD (i.e., marker-locus haplotype frequencies) is not counted for in multipoint analysis, it results in false positive evidence and significant overestimation of linkage and LD. Consequently it is important to use such multipoint analysis software which can accommodate the marker-marker LD. Here we introduce a new multipoint linkage analysis software MULTIDISEQ, which can accommodate the observed intermarker LD. The program uses a special version of ILINK program of the FASTLINK4.1P package to maximize the likelihood over the marker-marker haplotype frequencies with the presence of LD. Next the program performs the multipoint linkage analysis with maximized haplotype frequencies using the LINKMAP program of the FASTLINK4.1P package. We have applied this method to the actual data of the markers showing tight LD and have been able to exclude false positive results from further analyses. We think this robust method is helpful and user-friendly in current and future linkage studies extracting information from dense set of markers. Software is available from <http://www.helsinki.fi/~tsjuntun/multidiseq/index.html>.

**Fine mapping of susceptibility loci for preeclampsia on chromosomes 2p25, 4q23 and 9p13-p21.** *E. Kerkelä<sup>1</sup>, H. Laivuori<sup>1</sup>, H. Jiao<sup>1</sup>, V.-V. Mäkelä<sup>1</sup>, R. Kaaja<sup>2</sup>, O. Ylikorkala<sup>2</sup>, J. Kere<sup>1</sup>.* 1) Department of Biosciences, Karolinska Institute/Novum, Huddinge, Sweden; 2) Department of Obstetrics and Gynaecology, University of Helsinki, Finland.

Preeclampsia is a common (3%) hypertensive disorder of pregnancy, and one of the leading causes of maternal mortality. It also increases perinatal mortality five-fold. The pathogenesis of this heterogeneous disorder is incompletely understood, but it has a familial component suggesting that one or more common alleles may act as susceptibility genes. We have previously mapped three candidate susceptibility loci for preeclampsia on chromosomes 2p25, 4q32 and 9p13-p21 in 15 Finnish families, recruited predominantly from the Kainuu province (Laivuori et al. *AJHG* 72:168-177, 2003). We increased the marker density in these loci by adding 34 microsatellites at approximately 1 cM intervals. Linkage was assessed by the affecteds-only non-parametric multipoint linkage (NPL) analysis method. We were able to narrow down the candidate area on chromosome 2 with the highest peak showing significant linkage (NPL score 4.09,  $p=0,00036$ ). Instead, NPL scores for two other loci showed only suggestive linkage with no apparent improvement to the previous scan. To study if the overall haplotype distribution in the loci differs among the chromosomes of the affected vs. non-affected individuals, haplotype association analysis using the HPM algorithm (Toivonen et al. *AJHG* 72:168-177, 2003) was done, including testing of significance by permutation tests. Empirically significant associations were observed, supporting and refining considerably the linkage results. We are currently narrowing the associated haplotype further by fine mapping using high-density SNP genotyping.

**Dutch genome-wide scan for preeclampsia revisited.** *A.M.A. Lachmeijer<sup>1</sup>, G. Pals<sup>1</sup>, M. Grippeling<sup>1</sup>, G.A. Dekker<sup>2</sup>, L.P. ten Kate<sup>1</sup>.* 1) Dept Clinical Genetics and Human Genetics, VU University Medical Center, Amsterdam, The Netherlands; 2) Dept Obstetrics and Gynecology, NW Adelaide Health Service, Adelaide, Australia.

Preeclampsia, de novo hypertension and proteinuria in pregnancy, and its more severe form HELLP-syndrome, are among the most common obstetrical disorders and have a familial tendency. Our genome-wide scan in 67 affected sib-pair families (Lachmeijer et al. *EJHG* 2001) showed a maximum lod score of 1.99 on chromosome 12q. The subgroup of preeclamptic families showed suggestive lod scores on 22q and 10q. In the subgroup of HELLP-families the lod score peak on 12q increased to 2.1 whereas it disappeared in the preeclampsia subgroup. Our data did not fit loci found in three previous genome scans from Australia (4q; Harrison et al. *AJHG* 1997), Iceland (2p13; Arngrmsson et al. *Hum Mol Genet* 1999) and Australia/New Zealand (2p,2q; Moses et al. *AJHG* 2000), although two smaller peaks on chromosome 3p and 15q overlapped with peaks in the Icelandic scan. In contrast to our families, the families in the other scans comprised also affected women with a milder phenotype; non-proteinuric hypertension. To assess whether inclusion of the mild phenotype would alter our previous data we performed additional marker analysis at the loci on chromosome 2p13, 2q, 3p, 4q, 10q and 15q in all our 150 sib-pair families comprising 99 women with the mild phenotype. The non-parametric multipoint lod score on 2p13 increased from 0.0058 to 0.87, suggesting a role for this locus in the susceptibility for the mild-phenotype subgroup in part of our families. Lod scores at the other loci did not change substantially. Finding an increase of the lod score of 1.14 to 1.64 at the 10q locus after analysing the data, omitting the families linking to the 2p13 locus, may be another illustration of preeclampsia's presumed genetic heterogeneity.

**A genome-wide scan for the susceptibility loci to cholelithiasis in Chinese population.** *T. Han<sup>1</sup>, W. Yuan<sup>1</sup>, J. Qin<sup>1,2</sup>, J. Fei<sup>2</sup>, Z. Jiang<sup>2</sup>, L. Jin<sup>1,3</sup>, S. Zhang<sup>2</sup>, W. Huang<sup>1</sup>.* 1) Chinese National Human Genome Center at Shanghai, Shanghai, China; 2) Department of Surgery, Ruijin Hospital, Shanghai Second Medical University, Shanghai Institute of Digestive Surgery; 3) Center for Genome Information, Department of Environmental Health, University of Cincinnati.

Cholelithiasis is the presence of gallstones with strong family predisposition among which cholesterol stones are most common. The supersaturation of cholesterol in bile leads to its crystallization and formation of a nidus for stone. The incidence of cholelithiasis in China is about 7%-10%. We collected twelve cholelithiasis pedigrees in Shanghai China including 95 members, among which there are 63 patients with gallbladder stone diseases. We performed a genome-wide scan combined with both parametric and non-parametric linkage analyses for the susceptibility loci to cholelithiasis in these pedigrees. The result indicated that three loci, D3S1266, D9S1682 and D11S902 were shown suggestive evidence for linkage. Non-parametric linkage (NPL) scores at D3S1266 and D9S1682 were 0.94 and 1.92 with P value of 0.17 and 0.04, respectively. The corresponding LOD scores at both loci were 1.35 and 2.07, respectively. A rise of LOD score of D9S1682 from 2.07 to 2.40 was found when we only carried out the linkage analysis in pedigrees with cholelithiasis combined by hypertriglyceridemia. Transmitted disequilibrium test for D11S902 showed a P value of 0.0027. It was found that there was a maximum LOD scores of 1.35 and 2.07 respectively when fine-mapping study was done around both D3S1266 and D9S1682. Therefore, not only the suggestive results from the genome-wide scan were confirmed but also a fine map from 51.4 cM to 8.6 cM for D3S1266 and from 16.9 cM to 5.8 cM for D9S1682 were achieved. It was suggested that genes on chromosome 3, 9 and 11 might be associated with Chinese cholelithiasis pedigrees, and D9S1682 may contain susceptible genes linked to gallbladder stone diseases with hypertriglyceridemia.

**A genome wide scan using 400 non-synonymous SNP markers in DNA pools identifies genes associated with language impairment in children.** *E. Meaburn, L. Schalkwyk, I. Craig, R. Plomin.* SGDP, Institute of Psychiatry, London, United Kingdom.

Language impairment is a common problem of childhood that occurs despite adequate environmental stimulation and in the absence of sensory or neurological deficits. Twin studies have consistently demonstrated a substantial genetic component in its aetiology, which is thought to be due to the combined action of many genes, or quantitative trait loci (QTLs). In order to increase the power to detect genes associated with language impairment, we have used a direct association strategy based on nonsynonymous SNP (nsSNPs) markers, DNA pooling and large sample sizes. Using public databases we identified 400 nsSNPs with common variants in genes that are expressed in the brain. These were then genotyped using SNaPshot primer extension methodology in triplicate DNA pools consisting of 302 language-impaired children and 1000 representative controls. Relative allele frequencies for the case and control pools were compared, and following corrections for variance in the triplicate pools, 24 nsSNPs were significantly different ( $p < .05$ ), when 20 significant differences would be expected on the basis of chance. In order to avoid false positive results, these nsSNPs showing positive associations with language impairment are currently being tested for their association with the entire distribution of general language quantitative trait scores, using DNA sub-pools representing quintiles of the normal distribution derived from the 1000 controls. The QTL theory assumes that an association at the extremes of a quantitative trait will affect the trait throughout the distribution. This constructive replication indicates whether the QTL association replicates just for the extremes or whether the association operates throughout the distribution as predicted by QTL theory. nsSNPs that replicate in the normal distribution will be individually genotyped. The present nsSNP strategy combined with DNA pooling and large samples represents a step towards identifying genes associated with complex traits in the postgenomic era when all functional polymorphisms are known.

**Association analysis of the VR22 locus in late-onset Alzheimer disease.** *E. Martin<sup>1</sup>, P. Bronson<sup>1</sup>, J. Mitchell<sup>1</sup>, D. Schmechel<sup>1</sup>, G. Small<sup>2</sup>, A. Saunders<sup>3</sup>, A. Roses<sup>3</sup>, P-T. Xu<sup>1</sup>, Y-J. Li<sup>1</sup>, J. Vance<sup>1</sup>, J. Haines<sup>4</sup>, J. Gilbert<sup>1</sup>, M. Pericak-Vance<sup>1</sup>.* 1) Duke Univ Medical Center, Durham, NC; 2) UCLA, Los Angeles, CA; 3) GlaxoSmithKline, RTP, NC; 4) Vanderbilt Univ, Nashville, TN.

Regions on chromosome 10q have been linked to both risk and age at onset (AAO) genes in late-onset Alzheimer disease (AD). Younkin et al. (2002) reported association with single nucleotide polymorphisms (SNPs) in the VR22 gene lying in the region of linkage with plasma A42 levels in a small set of families with AD. They also demonstrated association with the AD phenotype in a set of sib pairs with late-onset AD. The VR22 gene codes for the alpha-catenin-like protein, which is believed to be involved in cell adhesion. Association with A42 levels and AD in sibships suggests that this gene may be involved with AD susceptibility. To test this hypothesis, we genotyped two SNPs in a large set of AD families, unrelated cases and age-matched controls. Both family-based and case-control analyses were used to test for association between the SNPs and AD disease status as well as AAO. No association was found with either SNP in the overall set of 276 families (with 936 discordant sib pairs-DSPs) using the pedigree disequilibrium test (PDT) or in the unrelated cases (N=1568) and controls (N=682) using a chi-square test. However, we did find significant association ( $p=0.009$ ) with one SNP using the PDT in the subset of 50 families (with 131 DSPs) having the oldest AAO (mean AAO>75 years). The significance of the association was even greater ( $p=0.007$ ) in families in this subset containing at least one affected individual without an APOE-4 allele (26 families with 81 DSPs). This suggests that the VR22 locus, or one in linkage disequilibrium with this VR22 polymorphism, could explain some risk for AD in families with the latest onset. However, the same association could not be found in the unrelated cases and controls when stratified by AAO and APOE genotype. Nor could we demonstrate association between the SNPs and AAO in the overall samples. Though it is possible that this locus contributes to AD in some families with late-onset AD, the VR22 locus does not appear to have a broad impact on AD risk or AAO.

**Additional support for a Type 2 diabetes susceptibility locus on chromosome 14.** *I. Kovac<sup>1</sup>, R.J. Havlik<sup>2</sup>, D. Foley<sup>2</sup>, R. Peila<sup>2</sup>, A. Singleton<sup>2</sup>, J. Hardy<sup>2</sup>, J. Egan<sup>3</sup>, D. Taub<sup>3</sup>, B. Rodriguez<sup>4</sup>, K. Masaki<sup>4</sup>, D. Curb<sup>4</sup>, W. Fujimoto<sup>5</sup>, A.F. Wilson<sup>1</sup>.* 1) Dept Genometrics, NHGRI, Baltimore, MD; 2) NIA, Bethesda, MD; 3) NIA, Baltimore, MD; 4) Univ. of Hawaii, Honolulu, HI; 5) Univ. of Washington, Seattle, WA.

Type 2 diabetes is a common genetically influenced multifactorial disorder, affecting an estimated 8.6 million Americans over age 60 alone. Our objective was to evaluate candidate regions for potential replication of previous results suggestive of linkage (GENNID study supported by ADA, and scan results provided by GlaxoSmithKline) in an independent sample. The data were derived from a sample of older Japanese Americans with a high prevalence of diabetes living in Hawaii, and included 529 siblings from 175 families. Model-independent sib-pair linkage analyses were performed on markers D14S297, D14S1040, D14S1032, D1S2657, D1S3721 and D1S1616, with SIBPAL (SAGE 4.3). The affected phenotype was either a diagnosis of diabetes or impaired glucose homeostasis; covariates included age and sex. Evidence of decreased proportion of sib-pairs sharing 2 alleles IBD (.19) was observed at the marker D14S297 in 107 discordant sib-pairs ( $p < .02$ ). The test for mean proportion of alleles shared IBD in these 107 sib-pairs (.46) was marginally significant ( $p < .06$ ). Tests of association were performed at this marker only, with FBAT. A chi-square test of the genotypic frequency distributions between affected ( $N=412$ ) and unaffected ( $N=50$ ) subjects was significant ( $p < 0.000014$ ). Because sparseness of the genotypic contingency table can influence chi-square statistics, Monte Carlo simulation for Fisher's exact test (SAS) was also used. The difference in frequency distribution of D14S297 genotypes was significant at the .05 level ( $p \leq .016$ , 99% CI=.013-.019). Absence of allelic association with diabetes, in both FBAT and SAS analyses, may relate to high degree of polymorphism at the marker locus. The present study was limited by the relatively small sample size. Nevertheless, our results suggest additional support for the hypothesis that a susceptibility gene for Type 2 diabetes may reside in a region around the D14S297 marker on chromosome 14.

**Significant linkage on chromosome 15q in recurrent early-onset major depression.** *D.F. Levinson<sup>1</sup>, G.S. Zubenko<sup>2</sup>, R.R. Crowe<sup>3</sup>, J.R. DePaulo<sup>4</sup>, W.S. Scheftner<sup>5</sup>, M.M. Weissman<sup>6,7</sup>, W.N. Zubenko<sup>2</sup>, S. Boutelle<sup>3</sup>, K. Murphy-Eberenz<sup>1</sup>, D. MacKinnon<sup>4</sup>, M.G. Mcinnis<sup>4</sup>, D.H. Marta<sup>5</sup>, P. Adams<sup>6,7</sup>, J.A. Knowles<sup>6,7</sup>, M.G. Alexander<sup>1</sup>, J. Thomas<sup>4</sup>, P. Holmans<sup>8,9</sup>.*  
1) Dept Psychiatry, Univ Pennsylvania, Philadelphia, PA; 2) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 3) Dept Psychiatry, Univ Iowa, Iowa City, IA; 4) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 5) Dept Psychiatry, Rush-Presbyterian Med Ctr, Chicago, IL; 6) Dept Psychiatry, Coll Physicians & Surgeons, Columbia Univ, NY, NY; 7) NY State Psychiatric Inst, NY, NY; 8) MRC-BSU, Cambridge, UK; 9) Dept Psychological Med, Univ Wales Coll Medicine, Cardiff, UK.

The Genetics of Recurrent Early-Onset Depression (GenRED) project will collect about 650 families (950 independent affected sib pairs) for the NIMH Cell Repository by 9/03. Preliminary genome scan results are presented for the first 297 families. Proband had recurrent major depressive disorder (MDD-R) with onset before age 31, with at least one sibling (and sometimes additional relatives) with MDD-R and onset before 41. The Center for Inherited Disease Research genotyped 392 microsatellite markers in 1,057 individuals, including 819 affected cases (415 independent ASPs, 660 total affected pairs). Multipoint allele-sharing analysis of all affected pairs was carried out using ALLEGRO (exponential model), and P-values computed by simulation. Preliminary analyses demonstrate genome-wide significant linkage on chromosome 15q ( $Z_{lr} = 4.14$ , empirical genome-wide  $P=0.016$ ). No other locus produced significant or suggestive evidence for linkage. Power would be >80% to detect significant linkage for a locus associated with population-wide  $sibs$  (RR) of about 1.8 in this preliminary sample, or 1.3 for the full sample. Secondary logistic regression analyses considered the effects of covariates including sex (MM, MF, FF pairs), age at onset (AAO), comorbid substance use and anxiety disorders. Accounting for sex increased the evidence for linkage on chromosome 15q, and also on three chromosomes without genome-wide significant linkage (6, 8 and 17); accounting for AAO increased the evidence for linkage on chromosomes 8 and 18.

**Linkage analyses of myostatin pathway genes in human muscle mass: the Leuven Genes for Muscular Strength project.** *M.A. Thomis<sup>1</sup>, W. Huygens<sup>1</sup>, R. Janssen<sup>2</sup>, M. Peeters<sup>1</sup>, R. Vlietinck<sup>2,3</sup>, G. Beunen<sup>1</sup>.* 1) Fac. Physical Education and Physiotherapy, Katholieke Univ. Leuven, Leuven, Belgium; 2) Division of Genetics and Molecular Cell Biology, University Maastricht, The Netherlands; 3) Center for Human Genetics, Faculty of Medicine, Katholieke Univ. Leuven, Belgium.

Myostatin (GDF8) is a transforming growth factor- family member that clearly acts as a negative regulator of skeletal muscle mass in animals. This preliminary study investigated evidence for linkage of 11 microsatellite markers near or within 11 candidate genes of the myostatin pathway in humans as putative QTLs for variation in human muscle mass. Muscle mass indicators (circumferences, estimated muscle+bone cross-sectional areas and volumes) and body composition (fat and fat-free mass) were assessed in 748 male Caucasian sibs from 335 families in the Leuven Genes for Muscular Strength project. Upper-limit heritabilities ranged from 0.57 in adipose tissue measures to 0.90 for several muscle mass indicators. Single-point linkage analysis was performed using Merlin software (Abecasis et al., *Nat Genet* 30:97-101, 2002) and combined identity by descent allele sharing and phenotypic information was analyzed using the implemented regression-based QTL-analysis approach (Sham et al., *Am J Hum Genet* 71:238-253, 2002) as well as variance component analysis in a subset of 108 paired observations. Four phenotypes showed suggestive evidence for linkage with D2S118 (GDF8). Highest LOD scores (1.176,  $P=0.01$ ) were found for muscle+bone area of the mid-thigh and muscle area of the quadriceps. Percent body fat and fat free mass showed less pronounced LOD scores (0.76,  $P=0.03$  and 0.61,  $P=0.05$ ). Suggestive signals for linkage were observed for percentage body fat and sum of 10 subcutaneous skinfolds with markers D12S326, D12S1708 (MYF5, MYF6: 0.68LOD1.6) and to a lesser extent with D12S1030 (IGF-1). Multi-point QTL linkage analyses results on a larger set of siblings will be reported.

**MCMC analysis of complex traits caused by multiallelic loci.** *E.A. Rosenthal*<sup>1</sup>, *E.M. Wijsman*<sup>1,2</sup>. 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Division of Medical Genetics, University of Washington, Seattle, WA.

Complex traits are affected by multiple loci. While analytic methods used in the analysis of complex traits are often based on a diallelic trait model, many traits are known or suspected to be multiallelic. For example, APOE, a triallelic locus, plays a role in Alzheimer's disease and cardiovascular disease. Multiallelism is problematic when alleles are common, in which case more than one risk allele may be segregating in a family. Analyses of complex traits are further complicated by the lack of information concerning the number of underlying loci and the number of alleles at each trait locus. In order to study common complex traits, linkage analyses may need to allow for multiple underlying loci each with multiple alleles. Loki is a program that uses reversible jump MCMC, which allows the number of quantitative trait loci (QTL) to be a variable in a multipoint linkage analysis of a quantitative trait. However, an underlying assumption is that each QTL is diallelic. This assumption may reduce the ability to detect and localize underlying multiallelic QTL. We test Loki's performance when a trait is caused by a triallelic locus. Traits are simulated using a real data set consisting of multilocus marker data from chromosome 19 on four large pedigrees, ranging in size from 48 to 87 individuals. By grouping marker alleles for one locus into a three allele system and simulating quantitative traits based on this system, we can incorporate the complexities of multilocus transmission inherent in real data while maintaining investigative control over the trait model. Analysis results vary depending on the amount of dominance and heritability ( $h^2$ ) of the linked trait locus. For example, as  $h^2$  increases from 0.4 to 0.9, the localization bias decreases from 38.3 to 3.7 cM in a purely additive model. In the case of dominance, when the broad sense heritability ( $H^2$ ) ranges from 0.2 ( $h^2 = .2$ ) to 0.8 ( $h^2 = 0.7$ ), the localization bias decreases from 9.7 to 7.7 cM. Furthermore, in some cases, Loki appears to compensate for the diallelic assumption by fitting two or more loci near the true location. Potential remedies will be discussed. Supported by NIH HG00035 and GM46255.

**A genome-wide scan for age-related macular degeneration susceptibility loci.** *Y. Zhao*<sup>1</sup>, *BM. Yashar*<sup>2,3</sup>, *GR. Goncalo*<sup>1</sup>, *S. Zarepari*<sup>2</sup>, *E. Trager*<sup>2</sup>, *K. Branham*<sup>2</sup>, *A. Reddick*<sup>2</sup>, *J. Richards*<sup>2</sup>, *A. Swaroop*<sup>2,3</sup>, *AMD Clinical Study Group*. 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Department of Ophthalmology and Visual Sciences, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Age related macular degeneration (AMD), one of the leading causes of irreversible vision loss among the elderly, is a clinically complex disease that is characterized by a variety of retinal pathologies. Family history is one of the strongest risk factors for the development of AMD, underscoring the importance of genetic loci in the development of disease. Here we report the results of a genome-wide search for these loci. We examined 781 microsatellite markers (average spacing 4.7, standard deviation 2.6 cM) from Marshfield Clinic in 333 affected individuals and 93 unaffected relatives in 116 families. Probands were identified from ophthalmic clinics in the U-M Health Care System. Retinal findings in all participants were evaluated in accordance with the AMD International Grading System. The average age of diagnosis for affected individuals was 70.4 years, and slightly lower at 68.8 years for individuals with geographic atrophy (GA). Disease in probands was biased towards terminal forms; greater than 80% were affected with either GA or neovascular AMD. We performed an affected relative pair analysis using non-parametric methods. We identified 2 loci linked to geographic atrophy on chromosome 1 (NPL LOD score 2.01) and chromosome 5 (NPL LOD score 2.65) and three loci linked to neovascular disease on chromosome 2 (NPL LOD score 1.96), chromosome 9 (NPL LOD score 1.64) and chromosome 22 (NPL LOD score 1.87). Two of these loci also showed substantial evidence for linkage among all AMD cases. Our results are in good agreement with previous studies, support the importance of genetic risk factors in the development of disease and suggest that distinct genetic pathways influence variations in clinical manifestations.

**A genome-wide screen for autism susceptibility loci identifies significant linkage on 19p.** *J.S. Sutcliffe<sup>1</sup>, L.M. Olson<sup>1</sup>, J.L. McCauley<sup>1</sup>, M. Dowd<sup>2</sup>, B. Winkloski<sup>2</sup>, B. Rosen-Sheidley<sup>2</sup>, G. Crockett<sup>1</sup>, S.E. Folstein<sup>2</sup>, J.L. Haines<sup>1</sup>.* 1) Program in Human Genetics, Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 2) Department of Psychiatry, Tufts University-New England Medical Center, Boston, MA.

Autism is a complex genetic neuropsychiatric condition characterized by deficits in social interaction and language and patterns of repetitive or stereotyped behaviors and restricted interests. Several genomic screens in autism families have been performed, and these have identified loci on 7q and 2q as being consistently replicated in most studies. We report a second-generation, 10 cM genomic screen of multiplex autism families, including 81 families recruited from New England and 80 well-characterized families from the AGRE collection. Two-point and multipoint heterogeneity LOD (HLOD) scores were calculated for both dominant and recessive models, and nonparametric allele-sharing was calculated using Allegro. One locus mapping to ~40 cM on chromosome 19p achieved genome-wide significance, with a multipoint HLOD of >3. Other suggestive signals (HLODs > 1.6) were detected on 17q, 6q, 16p and 12p, and of these, all but the 12p site represents a replication of suggestive linkage identified by other autism genomic screens. To homogenize our dataset for these studies and to relate particular loci to phenotypic domains in autism, we subdivided our families according to genetically-relevant ADI-based subsets. While no appreciable effect was evident on the 19p locus, other regions showed significantly increased linkage in specific subsets, supporting the utility of this approach. These results highlight the locus and phenotypic heterogeneity in autism and point to chromosomal positions likely to harbor autism susceptibility genes.

**A genome-wide scan in familial ankylosing spondylitis susceptibility.** *J.D. Reveille<sup>1</sup>, J. Bruckel<sup>2</sup>, R. Inman<sup>3</sup>, M. Mahowald<sup>4</sup>, M. Weisman<sup>5</sup>, H.R. Schumacher<sup>6</sup>, M.A. Khan<sup>7</sup>, W.P. Maksymowych<sup>8</sup>, D.T.Y. Yu<sup>5</sup>, M. Stone<sup>3</sup>, J. Lee<sup>9</sup>, L. Jin<sup>9</sup>.* 1) Division of Rheumatology, University of Texas - Houston, Houston, TX; 2) Spondylitis Association of America, Sherman Oaks, CA; 3) University of Toronto, Toronto, ON; 4) University of Minnesota, Minneapolis, MN; 5) University of California-Los Angeles, Los Angeles, CA; 6) University of Pennsylvania, Philadelphia, PA; 7) Case-Western Reserve, Cleveland, OH; 8) University of Alberta, Edmonton, AB, Canada; 9) Center for Genome Information, University of Cincinnati, Cincinnati, OH.

Although the MHC is likely the primary mediator of genetic susceptibility to ankylosing spondylitis (AS), it accounts for less than 50% of the total genetic risk. In order to define the genetic basis of susceptibility to AS, 269 affected sibpairs of primarily European ancestry concordant for AS by modified New York criteria with available sacroiliac radiographs from 121 pedigrees were genotyped for 400 markers in ABI PRISM Linkage Map. Two point and multi-point non-parametric linkage analyses were conducted using the NPL statistic. The linkage of MHC region was supported by both two-point and multi-point analyses with the strongest peak at 44.41 cM (D6S276,  $p = 3.5 \times 10^{-4}$ ) and at 48.37 cM ( $p = 7.3 \times 10^{-10}$ ), respectively. A second region was found to have positive linkage at the q arm of chromosome 6 (D6S441) in two-point analysis supported by a 29 cM region (148.47-177.33 cM) in multi-point analysis with the smallest  $p$  ( $3.0 \times 10^{-3}$ ) at 162.25 cM. Another broad region was found on chromosome 11q positively linked to AS separated by two single markers (D11S908 and D11S4151) supported by multi-point analysis spanning 68 cM continuously from 88.89 cM to 156.86 cM with the strongest peak at 125.84 cM ( $p = 1.2 \times 10^{-3}$ ). Weaker evidence of linkage was found on chromosome 1q, as well as chromosomes 5q and 19q, the latter two having been also seen in another scan (Laval et al. 2001). Thus this genome-wide scan implicates, in addition to the MHC, regions outside the MHC in AS susceptibility, especially on chromosomes 6q and 11q.

**A genome-wide linkage scan for QTL influencing the skeletal maturation of healthy children in the Fels Longitudinal Study.** *B. Towne<sup>1</sup>, J. Blangero<sup>2</sup>, J.S. Parks<sup>3</sup>, T. Dyer<sup>2</sup>, S.A. Cole<sup>2</sup>, M.R. Brown<sup>3</sup>, D.L. Duren<sup>1</sup>, A.F. Roche<sup>1</sup>, R.M. Siervogel<sup>1</sup>.* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Emory University School of Medicine, Atlanta, GA.

Most current knowledge of genetic influences on skeletal development comes from studies of monogenic disorders. Few studies have examined genetic influences on normal variation in skeletal development. During childhood, the skeletal age (SA) of a normal child can vary up to 3 years from that child's chronological age. In this study, we present initial findings from linkage analyses of the SA of children assessed at chronological ages 1 to 17 years. SA data were obtained from 9,865 hand-wrist radiographs taken between 1931 and 2002 of 1,069 children from 220 families in the Fels Longitudinal Study (Roche, 1991). Estimates of SA were made using the FELS method (Roche et al., 1988), a maximum likelihood approach that uses measured and graded indicators of skeletal development appropriate for a given chronological age. An initial set of 478 subjects was genotyped for 377 autosomal markers spaced approximately every 10 cM. A variance components-based linkage analysis method (SOLAR; Almasy and Blangero, 1998) was used to obtain multipoint LOD scores. Significant LOD scores ( $> 3.0$ ) were found for SA during middle childhood - a LOD of 3.37 for linkage of SA at chronological age 8 to a QTL on chromosome 8 at 122 cM (between markers D8S270 and D8S1784), and a LOD of 3.40 for linkage of SA at chronological age 10 to a QTL on chromosome 3 at 44 cM (between markers D3S2338 and D3S1266). Nine suggestive LOD scores ( $> 1.9$ ) were found for SA at chronological ages 1, 2, 4, 7, 11, and 13 years. These results indicate the existence of genes on chromosomes 3 and 8 that influence the tempo of normal skeletal maturation during middle childhood, and suggest other genes that influence skeletal maturation at other childhood ages. Future work will seek to identify specific genes that influence particular aspects of skeletal maturation at different stages of childhood development. Supported by NIH grants R01HD36342, R01HD12252, and R01MH59490.

**A new locus for disseminated superficial actinic porokeratosis at Chromosome 17q24-25.1.** Z. Zhang<sup>1,2</sup>, W. Yuan<sup>1</sup>, J. Zhang<sup>1</sup>, F. Jiang<sup>2</sup>, Z. Niu<sup>1</sup>, J. Zhao<sup>2</sup>, W. Liu<sup>2</sup>, W. Huang<sup>1</sup>. 1) Chinese National Human Genome Center at Shanghai, Shanghai, China; 2) Institute of Dermatology, Chinese Academy of Medical Sciences, Peking Union Medical College, Nanjing, China.

Disseminated superficial actinic porokeratosis (DSAP) is an autosomal dominant localized skin keratinization disorder, characterized by multiple superficial keratotic lesions surrounded by a slightly raised keratotic border. The susceptible loci for DSAP have been previously mapped to chromosomes 12q23.2-24.1 and 15q25.1-26.1, respectively. However, no gene for DSAP has been identified and the genetic basis and pathogenesis for this disorder are still unclear to date. To identify the causative gene in a four-generation Chinese DSAP family, we initially performed linkage analysis with microsatellite markers located on 12q23.2-24.1 and 15q25.1-26.1 and failed to confirm the linkage to these regions. Therefore, a genome wide scan with 382 microsatellite markers from the autosomes was performed and two-point linkage analysis of the members in this family showed supportive lod score for markers D17S949 ( $Z_{\max} = 2.30$ , at  $\alpha = 0.00$ ). The fine mapping with 8 polymorphic microsatellite markers between D17S944 and D17S785 were further tested and the haplotype analysis showed that the susceptible gene for DSAP in this family lies in an 13.0-cM interval between D17S944 and D17S1351. Our data suggest DSAP is a genetic heterogeneous disorder. It is conceivable that the underlying genes for 12q23.2-24.1, 15q25.1-26.1 and 17q24-25.1 loci are involved in the same biochemical pathway.

**Identification of the cylindromatosis tumor-suppressor gene responsible for multiple familial trichoepithelioma.**

*X. Zhang<sup>1</sup>, Y. Liang<sup>1,2</sup>, P. He<sup>1,2</sup>, S. Yang<sup>1</sup>, Y. Shen<sup>2</sup>, Y. Yuan<sup>2</sup>, Y. Cui<sup>1</sup>, W. Huang<sup>2</sup>.* 1) Institute of Dermatology, Anhui Medical University, Hefei, Anhui, China; 2) Chinese National Human Genome Center at Shanghai, Shanghai, China.

Multiple familial trichoepithelioma is an autosomal dominant skin disease characterized by the presence of many small tumors predominantly on the face. The first locus has been previously mapped to chromosome 9p21, but no gene for multiple familial trichoepithelioma has been identified to date. To identify the causative gene in a large Chinese family, we initially performed linkage analysis with microsatellite markers located on 9p21 and failed to confirm the linkage to this region. Previous publications showed multiple familial trichoepithelioma and hereditary cylindromatosis could occur within one family and in a single person. Therefore we speculated the CYLD1 gene is responsible for hereditary cylindromatosis, which may be related with the pathogenesis of multiple familial trichoepithelioma. Consequently, we genotyped all available individuals using 11 microsatellite markers spanning the CYLD1 gene at 16q12-13. We identified the linkage of multiple familial trichoepithelioma to this region. Through mutation analysis in the CYLD1 gene by sequencing, we detected a frameshift mutation, designated 5-8 delCAGA in the exon 18. The study firstly identified the CYLD1 gene responsible for multiple familial trichoepithelioma and showed that different mutations of the CYLD1 gene can give rise to distinct clinical and histological expression such as hereditary cylindromatosis and multiple familial trichoepithelioma.

**A genome-wide linkage scan for Photoparoxysmal Response.** *D. Pinto*<sup>1,2</sup>, *B. Westland*<sup>2</sup>, *G-J. de Haan*<sup>1</sup>, *J. Parra*<sup>1</sup>, *D.G. Kasteleijn-Nolst-Trenite*<sup>1</sup>, *G. Rudolf*<sup>1</sup>, *B. Neubauer*<sup>1</sup>, *U. Stephani*<sup>1</sup>, *A.M. da Silva*<sup>1</sup>, *B. Pedersen*<sup>1</sup>, *D. Parain*<sup>1</sup>, *H. Stroink*<sup>1</sup>, *L. Lagae*<sup>1</sup>, *M. Piccioli*<sup>1</sup>, *M. Brinciotti*<sup>1</sup>, *M.L. Friis*<sup>1</sup>, *P. Bonnani*<sup>1</sup>, *T. Covanis*<sup>1</sup>, *D. Lindhout*<sup>1,2</sup>, *B.P.C. Koeleman*<sup>1,2</sup>. 1) European Consortium on Genetic Analysis of Photosensitivity and Visual Sensitive Epilepsies; 2) Department of Medical Genetics, Univ Medical Center Utrecht, Utrecht, Netherlands.

Photosensitivity is defined as the occurrence of a photoparoxysmal response (PPR) on the EEG during intermittent photic stimulation. PPR is a major finding across several Idiopathic Generalized Epilepsies (IGEs), especially Juvenile Myoclonic Epilepsy (JME). Segregation studies suggest that PPR is an autosomal dominant trait with age-related reduced penetrance, in which case standard linkage analysis is expected to have relative high power to detect the underlying disease locus. In order to identify the susceptibility locus for PPR, a European Consortium has been formed which aims at collecting PPR-families and performing a joined genome-wide linkage scan. Through this collaborative action we have collected 39 multiplex pedigrees from Dutch, French and German origin, ascertained by the presence of 2 or more individuals with photosensitivity in the EEG. All patients were diagnosed by standardized IPS protocol and classification system. A first-stage genome scan was done using 427 microsatellite markers with inter-marker distance of <10 cM in which 274 family members were genotyped. Parametric and Non-Parametric multipoint Linkage (NPL) analyses using the Genehunter program were performed. NPL analysis provided four interesting chromosomal regions that met our initial criteria of a P value < 0.05. These promising regions are currently being followed-up. Identification of the PPR gene(s) will help resolving the genetic background of the common IGEs and may clarify the effect of the PPR gene in the polygenic background of JME.

**Genome-Wide Search for QTL traits of Schizophrenia Reveals a Locus for Verbal Learning and Memory on 4q and for Visual Working Memory on 2q.** *T. Paunio*<sup>1, 2</sup>, *AM. Tuulio-Henriksson*<sup>1</sup>, *T. Hiekkalinna*<sup>1</sup>, *M. Perola*<sup>1</sup>, *T. Varilo*<sup>1</sup>, *T. Partonen*<sup>1</sup>, *T. Cannon*<sup>3</sup>, *J. Lonngqvist*<sup>1</sup>, *L. Peltonen*<sup>1, 3</sup>. 1) National Public Health Institute, Finland; 2) Helsinki University Hospital, Finland; 3) UCLA, USA.

In the light of the current linkage studies and numerous tentatively identified associated loci we can conclude that genetic background of schizophrenia seems extremely heterogeneous. Further, the clinical end state diagnosis most probably does not provide the ideal phenotype for the identification of involved genes. In our population-wide study sample of Finnish schizophrenia families the best evidence for linkage, using dichotomized phenotype classification, has been obtained for markers on 1q and 5q (Paunio et al. 2001). Here we have used a set of quantifiable variables derived from neuropsychological test data in a genome-wide variance component-based linkage analysis (SOLAR) in 168 Finnish families ascertained for schizophrenia. All the analyzed QTLs are closely associated with vulnerability to the disorder. Our major findings were a locus for functions related to verbal learning and memory on 4q, for visual working memory on 2q and for recognition memory on 10p. Many variables measuring verbal learning and memory showed linkage to 4q. The best individual two-point lod score was obtained for long-term memory on 4q ( $Z = 3.01$ ). Among the measures assessing attention and working memory, the best evidence of linkage was obtained for visual working memory on 2q ( $Z = 2.80$ ). For recognition memory the best two point lod score was obtained for 10p ( $Z = 2.27$ ). Interestingly, when families were ascertained for the linkage of schizophrenia to either 1q or 5q, the evidence of linkage of long-term memory to 4q increased in those families not linked to 5q ( $Z = 4.87$ ). In contrast, this did not occur with linkage of visual working memory to 2q. This provides some initial evidence of negative interaction between the schizophrenia locus on 5q31 and the QT locus on 4q. The results confirm and extend previous linkage findings on 4q and 2q and demonstrate the benefits of using measurable quantitative trait components, instead of clinical diagnosis, in search for genes involved in susceptibility to schizophrenia.

**Linkage analyses using autoantibody traits as intermediate phenotypes in lupus pedigrees.** *P.S. Ramos<sup>1</sup>, J.A. Kelly<sup>2</sup>, C.M. Meyer<sup>1</sup>, A.N. Leiran<sup>1</sup>, W.A. Ortmann<sup>1</sup>, K.J. Espe<sup>1</sup>, G.R. Bruner<sup>2</sup>, J.M. Olson<sup>3</sup>, J.B. Harley<sup>2</sup>, K.L. Moser<sup>1</sup>.*  
1) Dept Medicine, Univ Minnesota, Minneapolis, MN; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) Case Western Reserve University, Cleveland, OH.

Numerous studies have suggested that various autoimmune phenotypes may share underlying genetic components. Given the higher incidence of autoimmune diseases and serologic abnormalities in family members of systemic lupus erythematosus (SLE) probands, we hypothesized that redefining phenotypes of individuals in SLE pedigrees with a propensity for autoimmunity may provide a useful intermediate phenotype for unraveling the complexity of SLE and possibly other autoimmune diseases. We have characterized lupus-related autoantibody profiles of 1668 total subjects in 229 families multiplex for SLE. Based on the presence of specific autoantibodies commonly associated with SLE we have defined a novel phenotype for lupus-related autoimmunity (LRA). We also used measures of association between siblings and familial correlations for each autoantibody to determine which specificities were most likely to aggregate in families and provide potentially useful information for subsequent linkage analyses. We identified evidence of familial aggregation for La/SSB ( $p=0.001$ ,  $OR=4.4$ ), nRNP ( $p=0.009$ ,  $OR=2.5$ ), and Sm ( $p=0.04$ ,  $OR=3.0$ ). Genome wide linkage analyses were performed using both the revised Haseman-Elston algorithm (SIBPAL) and an affected relative pairs approach (LODPAL) to identify chromosomal regions of increased allele sharing. Significant evidence for linkage ( $p<0.00005$ ) was found using La/SSB autoantibodies as the trait for 8 loci: 6p23, 10q23, 11p15, 12q24, 15q22, 16q23, 17q25, and 19p13. Several additional loci with suggestive evidence for linkage ( $p<0.002$ ) were identified using various other autoantibody traits. These results demonstrate that using autoantibody traits as intermediate phenotypes may increase the power to detect linkage, and provide evidence of the presence and locations of genes that are involved in the development of lupus-related humoral autoimmunity. Identification of these genes is likely to help further unravel the complexity of SLE as well as other autoimmune diseases.

**Linkage of biochemical and molecular traits related to obesity in the Old-Order Amish.** *G.J. Papanicolaou<sup>1</sup>, P. Platte<sup>2</sup>, E.W. Pugh<sup>3</sup>, K. Doheny<sup>3</sup>, K.M. Pirke<sup>4</sup>, M.-H. Roy-Gagnon<sup>1,5</sup>, A.J. Stunkard<sup>6</sup>, C. Francomano<sup>7</sup>, A.F. Wilson<sup>1</sup>.*

Trier, Germany; 5) Dept. Epidemiology, JHSPH, Balt., MD; 6) Dept. Psychiatry, U. PA, Phila., PA; 7) NIA, NIH, Balt., MD.

The gradual increase in overweight in the U.S., first observed in the 1960s, has increased significantly in the past decade; today nearly two-thirds of the population is overweight and over thirty percent are obese. As part of an ongoing study of traits related to obesity in the Old-Order Amish, seven two- and three- generation families totaling 157 individuals (with a mean sibship of 7.2) were assessed for 21 obesity related traits, including diastolic and systolic blood pressure, and levels of guanine nucleotide-binding protein, beta-3 (GNB3), glucose, insulin, leptin, triiodothyronine (t3), thyroxin (t4), thyroid stimulating hormone (tsh), and uncoupling protein 3 (UCP3). Although families were ascertained on a surrogate measure of obesity, the families were normotensive and did not exhibit signs of diabetes. Genotyping was performed at the Center for Inherited Disease Research (Baltimore, MD) with a modified Marshfield Genetics 8 marker set consisting of 384 short tandem repeat markers with an average distance of 9 cM. Model-independent linkage analysis identified candidate regions for diastolic b.p., glucose, insulin, leptin, t3, t4, and tsh. Traits GNB3 and UCP3 were mapped to respective known locations, providing both an internal control for the analysis as well as an estimation of Type I error.

**A genome-wide scan for age-related macular degeneration provides evidence for linkage to several chromosomal regions, including significant linkage to chromosomes 2, 3, 6, and 8.** *S.L. Santangelo*<sup>1,2,3</sup>, *K. Book*<sup>4</sup>, *C-H. Yen*<sup>1</sup>, *J.M. Seddon*<sup>2,3,4</sup>. 1) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Charlestown, MA; 2) Harvard Medical School, Boston, MA; 3) Harvard School of Public Health, Boston, MA; 4) Ophthalmology/Epidemiology, Massachusetts Eye and Ear Infirmary, Boston, MA.

We report the results of a genome-wide linkage scan for age-related macular degeneration (AMD) in 158 multiplex families. AMD classification was based on fundus photography and was assigned a grade ranging from 1 (no disease) to 5 (exudative disease) according to a modified grading system used in the Age-Related Eye Disease Study (AREDS Research group, 2001). Genotyping was performed by the NHLBI Mammalian Genotyping Service at Marshfield (404 short tandem repeat markers, Weber Screening Set 10). The sample included 158 families with 2 or more siblings with AMD, 490 affected individuals (grade 3 or higher), 101 unaffected (grades 1 or 2 over age 60), and 38 whose affection status was unknown (grades 1 or 2, under age 60). Relative pairs included 511 affected sibling, 28 avuncular, 53 cousin, 7 grandparent-grandchild, and 9 grand avuncular pairs. Two-point parametric and multipoint parametric and nonparametric analyses were performed.

Maximum 2-point LOD scores ranging from 1.0-2.0 were found for markers on chromosomes 1,2,8,10,14,15 and 22. Multipoint analyses were consistent with 2-point results for chromosomes 1,2,8,10 and 22 and provided evidence for additional linkage regions on chromosomes 3,6,8,12,16 and X. Our signals on chromosomes 1q, 6p, and 10q are consistent with previously published results (e.g., Klein et al. 1998; Weeks et al. 2000; 2001; Schick et al. 2003). Our strongest evidence for linkage was found on chromosomes 2 (1 marker), 3 (2 adjacent markers), 6 (2 adjacent markers), and 8 (7 contiguous markers); these multipoint signals were statistically significant, with empirical p-values = 0.00001. However, we identified several additional regions on chromosomes 1,10,12,16, and 22 that warrant further study because of internally consistent evidence and/or consistency with other published AMD scans.

**Linkage and association studies of the controversial locus 6p21 in idiopathic generalized epilepsies (IGE).** P.A.O. Ribeiro<sup>1</sup>, V.D.B. Pascoal<sup>1</sup>, L.E. Betting<sup>2</sup>, N.F. Santos<sup>1</sup>, R. Secolin<sup>1</sup>, S.B. Mory<sup>2</sup>, C.A.M. Guerreiro<sup>2</sup>, M.M. Guerreiro<sup>2</sup>, F. Cendes<sup>2</sup>, I. Lopes-Cendes<sup>1</sup>. 1) Department of Medical Genetics, UNICAMP, Campinas, Brazil; 2) Department of Neurology, UNICAMP, Campinas, Brazil.

**Purpose:** The first *locus* for IGE was mapped on chromosome (ch) 6p21 (the HLA region), in families segregating juvenile myoclonic epilepsy (JME), a common type of IGE. Additional linkage and association studies were performed in many IGE families leading to conflicting results. One hypothesis to explain these is the presence of genetic heterogeneity, which may be related to differences in ethnic origin of the families studied. The aim of the present study was to investigate linkage and/or association between the gene(s) predisposing to IGE and the candidate *locus* on ch 6p21 in Brazilian patients. **Methods:** We performed linkage analysis of 6 unrelated families, with at least 2 IGE cases. For the association study we analyzed 44 unrelated patients with IGE and 54 normal controls. For both studies we genotyped 3 microsatellite markers flanking the HLA region on ch 6p21: tel. D6S276, D6S265 and D6S291 cent. Two-point and multipoint lod-scores were calculated using the software LINKAGE. For the association studies we used chi-square and Fishers exact test. **Results:** Linkage simulation analysis of the 6 families combined yield a  $Z_{max} = 5.09$ . Lod-scores were negative for all 3 markers genotyped (for = 0: D6S276,  $Z = -7.22$ ; D6S265,  $Z = -4.16$ ; D6S291,  $Z = -1.23$ ), excluding the entire HLA region. There was no significant association between any allele of 2 microsatellites genotyped (D6S276 and D6S265,  $p$  ranging between 0,09 and 1,0). However, allele 1 of the D6S291 marker occurred more frequently in controls as compared to patients ( $p = 0,04$ ). **Conclusion:** Linkage results excluded the presence of a major *locus* predisposing to IGE in ch 6p21. However, the association study indicate the presence of a modifier *locus*, that could be involved in protection against IGE. These results confirm the hypothesis of genetic heterogeneity among IGE and points to the presence of complex inheritance in this disorder.

**Haplotype associations between ADAM33 and childhood asthma.** *B. Raby*<sup>1</sup>, *E.K. Silverman*<sup>1</sup>, *C. Lange*<sup>2</sup>, *R. Lazarus*<sup>1</sup>, *D.J. Kwiatkowski*<sup>3,4</sup>, *S.T. Weiss*<sup>1,4</sup>. 1) Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 3) Hematology Division, Brigham and Womens Hospital, Boston, MA; 4) Harvard Partners Center for Genetics and Genomics, Boston, MA.

ADAM33 (chr.20p13) has been implicated as an asthma-susceptibility gene using a positional cloning approach (Nature 2002). However, genetic linkage of asthma phenotypes to chr.20p13 has not been observed in most asthma genome scans, and it is unclear whether these associations with ADAM33 are broadly generalizable. We performed a family-based association study of ADAM33 using parent-child trios ascertained through the Childhood Asthma Management Program (CAMP). CAMP is a multi-centered, randomized placebo-controlled clinical trial comparing the efficacy of long-term inhaled anti-inflammatory medication use in improvement of lung function. Of the 1041 children enrolled in the clinical trial, DNA was available for 968, as well as 1518 of their parents. In total, 652 parent-child trios were available for analysis. 17 SNPs (including 9 associated with asthma in the initial report) were genotyped using the Sequenom mass spectrometry platform. All 17 SNPs were in Hardy-Weinberg Equilibrium among the parents. Among Caucasians, 11 haplotypes with frequency of at least 1% were observed. Single-SNP and haplotype association analysis was performed using the FBAT program for both the asthma diagnosis phenotype and four quantitative phenotypes (percent predicted forced expiratory volume in one second, airways responsiveness, total serum immunoglobulin E levels [IgE], and total serum eosinophil counts). No single-SNP association was observed, regardless of genetic model specification. However, a common haplotype (frequency 14.6%) was associated with asthma ( $p=0.03$ ), FEV1 ( $p=0.04$ ), IgE ( $p=0.07$ ), and serum eosinophils ( $p=0.02$ ). These data provide support for an asthma locus in the ADAM33 genomic region. However, the magnitudes of the observed associations are modest, and suggest that either the gene has only modest effects or that the true asthma locus is located near, but not at, ADAM33. Further SNP mapping of this region is needed.

**Linkage of Speech Sound Disorder to Dyslexia candidate regions.** *S.D. Smith*<sup>1</sup>, *K.E. Deffenbacher*<sup>1</sup>, *R. Boada*<sup>2</sup>, *N. Raitano*<sup>2</sup>, *R. Tunick*<sup>2</sup>, *B.F. Pennington*<sup>2</sup>. 1) Pediatrics, Univ Nebraska Med Ctr, Omaha, NE; 2) Psychology, Univ. Denver, Denver, CO.

Speech Sound Disorder (SSD) is a developmental disability in learning to produce intelligible speech, noted in the preschool years. In contrast, specific reading disability (dyslexia) is diagnosed at school age and involves difficulty learning to read and spell. SSD has been conceptualized as primarily a motor disorder, while in the majority of cases the core deficit of dyslexia is in the ability to recognize phonemes of language and map them on to letters. Despite these apparent differences, it has been observed that SSD and dyslexia cosegregate, suggesting that they may have common cognitive and genetic etiologies. Sixty-nine families were identified with at least one child between the ages of 5-6 years with a history of moderate to severe SSD, and one sib between the ages of 5-8 years who could be evaluated. Five phenotypes were used, 4 quantitative variables assessing speech sound and phonologic abilities and one categorical phenotype that assigned affection status based on clinical history. Sib-pair linkage analysis was done with markers from 3 chromosomal regions previously linked with dyslexia: 1p36, 6p21.3, and 15q21. Single point analysis was done with SIBPAL (SAGE 4.4), with GENEHUNTER2 and QMS2 used for multipoint analysis. All three regions showed some indication of linkage with SSD phenotypes. The strongest results were for single point analysis of the categorical phenotype and 6p21.3, with highest significance at D6S1571 ( $p=0.00051$ ). Multipoint analyses (QMS2) were suggestive for 3 of the quantitative phenotypes ( $p$  values ranging from 0.02-0.004). For chromosome 15, suggestive results were found for markers including and distal to D15S143, with maximum significance of 0.004 at D15S117 for single point analysis of a standardized articulation test. Suggestive multipoint results (GENEHUNTER2) were also found on chromosome 1 for a nonword repetition test, with a maximum NPL of 1.07 at D1S199. These results support the hypothesis that both dyslexia and SSD share common genetic mechanisms involving phonologic processing. Supported by NIH-NICHD 2 R01 MH38820 to BFP.

**Linkage and Association of Systemic Lupus Erythematosus (SLE) on 1q23.3.** *H. Wu<sup>1</sup>, R.M. Cantor<sup>2</sup>, J.M. Grossman<sup>1</sup>, A.A. Rumbin<sup>1</sup>, N. Shen<sup>3</sup>, C.S. Lau<sup>4</sup>, D.J. Wallace<sup>5</sup>, F.C. Arnett<sup>6</sup>, H.M. Badsha<sup>7</sup>, H.H. Chng<sup>7</sup>, B.H. Hahn<sup>1</sup>, B.P. Tsao<sup>1</sup>.* 1) Medicine,UCLA,LA,CA; 2) Human Genetics and Pediatrics,UCLA,LA,CA; 3) Renji Hosp.,Shanghai,China; 4) Queen Mary Hosp.,Hong Kong; 5) Cedars-Sinai Research Institute,LA,CA; 6) Univ. of Texas,Houston,TX; 7) Tan Tock Seng Hosp.,Singapore.

SLE is a complex, multifactorial autoimmune disease, and twin and family studies indicate that genetic factors play a key role in its pathogenesis. Evidence of SLE linkage to 1q22-24 has been reported in independent cohorts. We fine-mapped this region to provide additional support for linkage and localize the putative SLE susceptibility gene(s). Ten markers spanning 33cM of 1q22-25 were typed and analyzed by model-free, multipoint linkage analysis. Linkage to 1q23 peaked at D1S2675 (NPL 3.51,  $P = 0.0002$ ) in 115 multiethnic families with 143 affected sibpairs (ASP). When the sample was stratified by ethnicity, 76 non-Caucasian (NC) ASP linkage peaked at D1S2675 (170.8cM, NPL 3.41,  $P = 0.0003$ ), while in 67 Caucasian ASP linkage peaked at D1S1677 (175.6cM, NPL 2.44,  $P = 0.008$ ). Using a drop of one NPL score as a guide, we focused on 11cM of the linked region. Association was assessed for 11 markers in the region using the ETDT program. Overall of skewing allele transmission at D1S2844 (175.0cM,  $P = 0.0009$ ) and D1S1677 (175.6cM,  $P = 0.01$ ) was observed in 160 Caucasian trios, and at D1S484 (169.7cM,  $P = 0.008$ ) and D1S2878 (177.9cM,  $P = 0.02$ ) in 125 NC trios. Preferential transmission of FCGR2A-131R/H alleles was not observed when this sample augmented by an additional cohort of simplex families was stratified into 152 Caucasian and 133 NC simplex families. The two markers associated in NC are 8cM apart, suggesting the possibility of multiple susceptibility genes in that ethnic group. The region between the two markers associated in Caucasian contains novel positional candidate genes including RGS4 (regulator of G-protein signaling 4), RGS5 and CDCA1 (cell division cycle associated 1) that we are testing. FCGR2A-131R/H, an important candidate gene at 170.8cM was typed and tested for association. It appears not to be an SLE risk factor in this multiethnic cohort.

**Chromosome 7q linkage in autism: No evidence for strengthened signal by including parental information or stratification based on language delay.** *S.J. Spence, S.H. Kim, D.H. Geschwind, M. Alarcón, AGRE.* UCLA Psychiatry, Pediatrics, Neurology, LA, CA.

Results of whole genome scans of autism have implicated several regions on chromosome 7 as putative sites for autism susceptibility loci. Stratifying affected families by language endophenotypes and including parental language history information have strengthened original linkage signals in the 7q region (Bradford et al. 2001). QTL analysis of language delay in multiplex autism families also yielded evidence of linkage on 7q (Alarcón et al. 2002). To replicate and extend these findings we obtained parental language history on a subset of 150 families from the Autism Genetic Resource Exchange (AGRE). Proband diagnosis was based on the Autism Diagnostic Interview-Revised and includes both narrow and broad spectrum. Parental language delay was defined as history of language delay and/or problems learning to read. Genotypes including 48 microsatellite markers were available for the nuclear families. A multipoint nonparametric linkage analysis was performed using the diagnosis of autism spectrum disorder with the Genehunter program. Samples were analyzed in 3 ways: all families, language delayed families (i.e., two probands with word delay-age at first word > 18 months [WD] or phrase delay-age at first phrase > 36 months [PD]), and non-delayed families (i.e., less than two probands with word [NWD] or phrase [NPD] delay). These analyses were repeated including parental language information. The strongest linkage peak to autism for chromosome 7 in all families was at 147.55 cM (NPL=2.59), and a smaller peak was at 107 cM (NPL=1.45). Stratifying families as a function of proband language delay, either in word or phrase, did not strengthen the linkage signal. For example, the peak nonparametric linkage score for PD families (n=37; NPL=1.17, 154.39 cM) was lower than the peak score for NPD families (n=113; NPL=2.73, 147.55 cM). In addition, the NPL signal did not vary due to the presence of parent language information (Z=2.55, 147.55 cM). Therefore, parental language information or stratification based on speech delay did not significantly strengthen linkage to autism in this sample.

**Young-onset hypertension in Chinese is linked to STRP marker of lipoprotein lipase (LPL) and associated with its haplotype.** *W. Pan<sup>1</sup>, P. Chen<sup>1, 4</sup>, Y. Jou<sup>2</sup>, C.S.J. Fann<sup>1</sup>, J. Chen<sup>3</sup>, C. Chung<sup>1</sup>, Y. Chen<sup>1</sup>, S. Wu<sup>4</sup>, M. Kang<sup>1</sup>, C. Lin<sup>1</sup>.*  
1) Inst Biomedical Sci, Academia Sinica, Taipei, Taiwan; 2) National Health Research Inst, Taipei, Taiwan; 3) Veteran General Hospital, Taipei, Taiwan; 4) National Defense Medical College, Taipei, Taiwan.

Young-onset hypertension is associated with moderate obesity and borderline elevation of fasting triglyceride (TG) in Chinese. Therefore, LPL, a major metabolizing enzyme of TG, has been selected as one of 18 candidates in our efforts to map hypertension genes.

Young-onset hypertension was defined as essential hypertension developed prior to age 40. Using data from 59 families, the initial ASP analysis showed a positive linkage signal for D8S1145 near *LPL*. The second stage analysis with more STRP markers showed a significant linkage (NPL score=3) and TDT-association ( $p < 10^{-5}$ ) with LPL marker located in intron 6 of *LPL*. In order to identify variants of *LPL* in Taiwanese, we sequenced 5 flanking region and exons of *LPL* for 41 subjects. Two cSNPs, a silent mutation in exon 8 and Ser447X in exon 9, were verified. By sequencing another 12 individuals, 8 new iSNPs were discovered from intron 1 to intron 3. In addition, 38 iSNPs were verified and 5 new iSNPs discovered from the exon 4 to 3 flanking region. Two major LD blocks ( $D \geq 0.8$ ) were identified within 44 SNPs with minor allele frequency 0.07. Six haplotypes, each with 2-4 SNPs, were constructed using information on LD and their locations. A haplotype consisting of two cSNPs of exon 8 and 9 and one SNPs in the intron 7 was significantly lower in its transmission to the obese hypertension probands (no. of informative trios=39). We extended the analysis to another larger sample (no. of informative trios=151) obtaining consistent results of lower transmission to young-onset hypertension ( $p < 0.05$ ) and young-onset obese hypertension ( $p < 0.0003$ ). On the other hand, the haplotype consisting of the common SNP allele in exon 8 and the common allele of Ser447X significantly increased the risk of young-onset obese hypertension ( $p = 0.007$ ). Our results suggest that *LPL* may be involved in the pathogenesis of essential hypertension.

**Increased evidence for schizophrenia linkage to 8p after stratification by *DTNBPI* high-risk haplotype.** *B.T. Webb*<sup>1, 3</sup>, *M.C. Neale*<sup>1, 2, 3</sup>, *E.J.C.G. Van den Oord*<sup>2, 3</sup>, *A.H. Fanous*<sup>2, 3</sup>, *K.S. Kendler*<sup>1, 2, 3</sup>, *B.P. Riley*<sup>1, 2, 3</sup>. 1) Departments of Human Genetics and; 2) Psychiatry; 3) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA, USA.

We have previously reported a schizophrenia linkage to 8p and more recently a highly significant association with SNPs and a high-risk haplotype in the *DTNBPI* gene on 6p using the Irish Study of High Density Schizophrenia Families (ISHDSF). The evidence for linkage on 8p was reexamined in light of the association evidence on 6p. When families containing the *DTNBPI* high-risk haplotype are removed, the evidence for linkage to 8p increases substantially and includes a maximum multipoint HLOD of 4.08 and a multipoint NPL Z-score (uncorrected) of 3.78. Conversely, the high-risk haplotype positive group has little evidence for linkage on 8p. The maximum difference in NPL Z-score between the *DTNBPI* high-risk haplotype positive and negative groups was 4.11. Monte Carlo stratification simulation showed that this pattern of results was unlikely to have occurred by chance (p-value <0.05). Null genome scan simulations were used to calculate the empirical genome-wide significance of the NPL results, which were significant (p-value 0.014, 95% C.I. 0.0077-0.02). This is the first report of genome-wide significant multipoint linkage results using the ISHDSF, currently one of the largest single study collections of schizophrenia pedigrees. These results provide further support for both a schizophrenia locus independent of *NRG1* on 8p and the *DTNBPI* high-risk haplotype association on 6p.

**Reevaluation and fine mapping of a Brazilian pedigree reveals another family with Allan-Herndon-Dudley syndrome.** *M.R. Passos-Bueno<sup>1</sup>, T.S. Zorick<sup>1</sup>, S. Kleimann<sup>2</sup>, M. Zatz<sup>1</sup>, S. Rosenberg<sup>2</sup>.* 1) CEGH, Dept Biol, Univ De Sao Paulo, Sao Paulo SP, Brazil; 2) Santa Casa Hospital, So Paulo, SP, Brazil.

Microsatellite-based fine genetic mapping of a previously published family affected by a severe form of X-linked mental retardation was performed (Passos-Bueno et al., 1993, *Am J Med Genet*, 46(2):172-175). Taking advantage of several informative recombinations, we were able to narrow down the critical region for the disease gene from 52 cM to an interval of approximately 13.4 cM (26.5MB) on the X chromosome, between the microsatellite markers DXS8080 (Xp11.2) and DXS986 (Xq13). Given that this genetic interval overlaps with that for Allan-Herndon-Dudley Syndrome (AHDS), which has been mapped to Xq12-Xq21, we performed a further neurological workup of affected members in this family. Neurological examination of patients from this family shows that from a clinical point of view, the pedigree under study is indistinguishable from AHDS. Based upon these results, we now propose that the original Brazilian pedigree actually represents another familial case of AHDS. This would restrict the candidate region for AHDS on the X chromosome to approximately 3 cM (10MB), containing at least 100 genes (NCBI). Eighteen genes mapped within this area (AR, CHIC1, CITED1, Dach2, EphrinB1, ARHGEF9, GPR23, HCA1, HCA3, ITM2A, KLHL4, NE-DLG3, NLG3, RagB, SNX12, TAF9L, ZNF261, ZNF6) were already tested by direct sequencing, however, no obvious mutations have yet been found. FAPESP, CNPq, CEPID.

Program Nr: 1955 from 2003 ASHG Annual Meeting

**Genotyping: Evaluation of inter-run sizing precision of the Applied Biosystems 3730 DNA Analyzer.** *B. Craig, M. Brehm, Y. Tsai, C. Boehm, E. Pugh, K. Doheny.* Center for Inherited Disease Research, IGM, JHUSOM, Baltimore, MD.

Microsatellite linkage studies of complex disease require the genotyping of thousands of samples. The capillary electrophoresis instrument being evaluated for use at the Center for Inherited Disease Research is the 3730 DNA Analyzer, which operates at higher efficiency and lower operating costs than the 3700 platform. The 3730 was developed with specifications of  $<0.15$  SD intra-run sizing precision, which allows for single base-pair resolution for sequencing applications. For microsatellite genotyping, inter-run variability is also a key factor because allelic sizing data is combined across multiple runs and instruments. Too much variability in inter-run sizing leads to the inability to bin data with confidence. Our experience with the 3700 platform is an inter-run variability of  $\sim 0.12$  SD using GS500-LIZ(-250) size standard and  $\sim 0.09$  SD using CIDR size standard. We first measured sizing precision of the 3730 instrument using GS500-LIZ(-250,-340) size standard, G5 installation standards, standard instrument running protocols, and unaltered lab environmental conditions over the period of a week (2 trials). The SD across 23 runs ( $n=1,104$ ) was as high as  $\sim 0.18$  SD. The variability across trial 1 was significantly higher than trial 2, with the most variation in the first 2 runs. Further tests identified key variables: temperature of the running buffer and laboratory. Preheating the 1X running buffer to 30 C immediately before starting runs significantly reduced the inter-run variability across 2 trials, to a maximum  $\sim 0.10$  SD. The additional impact of environmental temperature was tested by varying the laboratory temperature from 19 C to 23 C (while preheating 1X buffer to 30 C). Significantly lower inter-run variability were observed under the 23 C conditions ( $\sim 0.07$ SD). These findings suggest that optimal conditions of the 3730 for genotyping are pre-equilibrated 30 C running buffer in an environmental temperature of  $\sim 23$  C. Failure to control inter-run sizing for data combined across multiple runs will result in genotypes falling outside predefined allelic bins, significantly reducing the utility of automated allele calling software such as GeneMapper.

Program Nr: 1956 from 2003 ASHG Annual Meeting

**Multiplex PCR for microsatellite genotyping using an existing marker set.** *K. Hetrick, D. Hayden, B. Craig, B. Troup, J. Romm, C. Boyce, K. Doheny, C. Boehm.* Center for Inherited Disease Research (CIDR), IGM, Johns Hopkins Univ Sch of Medicine, Baltimore, MD.

CIDR uses 400 markers for a 10cM genome-wide scan. Until recently these were organized into 50 panels. With the availability of new dyes for Applied Biosystems (AB) platforms, we reorganized these markers into 38 panels (average 11 markers/panel), primarily focusing on dye color and product size. In this study, 373 markers (37 panels) were PCR'd both as a PCR reaction that combined all markers in the panel (multiplex or MP) and by themselves (singleplex or SP) using standard PCR conditions. Since there was a wide range of Tms within each panel (up to 11<sup>0</sup>C), we utilized a touch-down PCR to minimize non-specific products. Performance was evaluated on the AB 3730 DNA analyzer. Six categories were observed: Primer-pair (1) worked comparably in both reactions (217/373 = 58%); (2) had significant decrease in yield in the MP (23%); (3) worked well as a SP but failed in MP (1%); (4) worked poorly in SP, failed in MP (8%); (5) failed in both reactions (7%); and (6) unable to score (3%). Although product yield overall was lower in the MP, 24% of the markers (categories 2 and 3) showed significant decrease in MP. Despite expectation, there was not a good correlation between the G values and a primer-pairs performance. Other phenomena observed in the MPs included non-specific PCR products, a tendency for the product to fall out of the +A form (all R primers are tailed to favor the +A form), and an increase in allelic imbalance. Changing the extension temp from 72<sup>0</sup>C to 60<sup>0</sup>C eliminated many of the non-specific products. Lengthening the final extension to 90 minutes pushed products back into the +A form. We continue to investigate allelic imbalance. Primer reagent was shown to be stable at 4<sup>0</sup>C over at least 3 months. Of the 37 panels, 5 (14%) are utilized routinely now and 32 (86%) require modification of one or two primer-pairs. We believe these results indicate that high-level multiplexing will be achievable without having to redesign or replace most of our current markers.

**Refinement and Candidate Gene Screening of the Cerulean Cataract Type 1 Locus on 17q24-q25.** *M.B. Gorin<sup>1</sup>, B.W. Rigatti<sup>2</sup>, F.Y. Demirci<sup>2</sup>, S.R. Clarke<sup>2</sup>, T.S. Mah<sup>2</sup>, D.E. Weeks<sup>3</sup>, R.E. Ferrell<sup>3</sup>*. 1) Ophthalmology & Human Gen, Univ Pittsburgh, Pittsburgh, PA; 2) Ophthalmology, Univ Pittsburgh SOM; 3) Human Genetics, Univ Pittsburgh GSPH.

Cerulean cataracts (CCA) are autosomal dominant, juvenile-onset hereditary cataracts that are noteworthy for tiny blue or white opacities, predominantly in the lens cortex. There are three reported CCA loci: CCA type 1 on 17q24-q25, CCA type 2 on 22q11.2-q12.2, and CCA type 3 on 2q33-35. CCA2 and CCA3 were shown to be caused by a mutation in the -B2-crystallin gene and -D crystalline gene, respectively. The CCA1 locus was originally mapped in a single large family between microsatellite markers D17S802 and D17S836. Because of new data available since the original study, we have remapped the disorder in this family and tested several candidate genes. We used GenBank and other databases to establish a physical contig. We evaluated new microsatellite markers using ABI genotyping and SNPs using a combination of DHPLC (Transgenomic Wave), RFLP, and sequencing of the PCR products to detect alleles and refine the critical region. Potential candidate genes were evaluated for expression using the NEIBank lens cDNA database and by PCR in a human lens cDNA library and tested for mutations in exons and splice junctions by sequencing. We evaluated 7 known and 14 previously unreported microsatellite markers, as well as 16 previously reported SNPs and 6 novel SNPs within potential candidate genes spanning our critical region. In addition to the 7 known microsatellite markers, 7 of the 14 novel microsatellite markers and 16 of the 22 SNPs were informative in this family. Twelve possible candidate genes showed expression in a human lens cDNA library. Sequencing of the exons of these genes did not identify any disease-causing mutations. With the gradual completion of the Human Genome Project, this region of chromosome 17 is becoming better-defined. We have been able to further localize the CCA1 locus and establish that no known lens-specific genes are within the critical region. Elucidation of the causative gene for CCA1 has the potential of identifying a novel gene that contributes to lens biology.

**Determining phase of the poly-GT and poly-T repeat tracts in the CFTR gene by melting curve analysis of hybridization probes.** *A. Millson<sup>1</sup>, G. Pont-Kingdon<sup>1</sup>, S. Page<sup>1</sup>, E. Lyon<sup>1,2</sup>*. 1) ARUP Laboratories, Salt Lake City, UT; 2) Pathology Department, University of Utah.

Over 1000 mutations have been described in the CFTR gene. Although some of these mutations such as F508del are clearly classified as severe, the phenotype/genotype correlation of other mutations is not well established. Polymorphisms within the CFTR gene may modify the effects of some mutations. The poly-T tract located in the intronic region before exon 9 is one example. The number of Ts present, either 5,7, or 9, affects the splicing efficiency of exon 9. The combination of the R117H mutation in cis with the 5T polymorphism confers a severe CF allele, whereas R117H alone or in trans with the 5T may be mild. A tract of GT repeats immediately precedes the poly-T tract and may also influence the CF phenotype. We have developed a molecular assay to determine the chromosome phase (cis or trans) of the poly-T and poly-GT tracts at the 3' end of intron 8 (IVS-8) of the CFTR gene directly from an individual sample. The assay utilizes LightCycler melting curve analysis of a hybridization probe covering both the poly-GT and the poly-T region. The temperature at which the probe dissociates from the template is determined by the base composition between the target and the complementary probe. Distinct Tms were obtained for each combination of GT and T repeats. Bi-directional sequencing with BigDye terminator chemistry was used to confirm the polymorphisms and phase. In 90 samples screened, 7 distinct haplotypes were determined with 10, 11 and 12 GT repeats in varying combinations with the 5, 7 and 9 poly-T repeats. This assay demonstrates the ability of melting curve analysis to haplotype directly from a single individual.

**Evaluation of the Human Fas (-670 A/G) and Fas Ligand (-844 C/T) Single Nucleotide Polymorphisms in Scleroderma Patients from North America.** *Y. Zhang<sup>1</sup>, L. Wang<sup>1</sup>, B.S. Maher<sup>2</sup>, R.E. Ferrell<sup>3</sup>, P.A. Morel<sup>4</sup>, T.A. Medsger Jr.<sup>4</sup>.* 1) Dept Medicine, Div PACCM, Univ Pittsburgh Sch Med, Pittsburgh, PA; 2) Center Craniofacial Dental Genet, Univ Pittsburgh Sch Dent Med, Pittsburgh, PA; 3) Dept Human Genet. Univ Pittsburgh Grad Sch Public Health, Pittsburgh, PA; 4) Dept Medicine, Div Rheumatology, Univ Pittsburgh Sch Med, Pittsburgh, PA.

Scleroderma, or systemic sclerosis (SSc), is a group of heterogeneous disorders characterized by fibrosis of skin and internal organs. The etiology and pathogenesis of SSc is still largely unknown. The soluble Fas receptor (Fas) has been shown to be elevated in the sera of SSc patients in comparison with healthy controls, suggesting that impaired apoptosis may play roles in the development of SSc. To determine whether genetic polymorphisms in the Fas receptor and Fas ligand (FasL) genes are associated with SSc, we have evaluated the -670 A/G and -844 C/T SNPs in the promoter region of the Fas and FasL gene, respectively, in SSc patients from North America. The study cohort consists of 350 American Caucasians recruited from the University of Pittsburgh Medical Center with 224 of SSc patients and 126 of ethnicity-matched controls. The two SNPs were analyzed using TaqMan SNP method. Although it was not quite statistically significant, the frequency of AA genotype of the -670A/G SNP in the Fas gene was reduced in the SSc (23.2%) compared to normal controls (32.6%) with  $p = 0.0602$  in a Fishers exact test. Different genotype distributions of the -670 A/G SNP in the Fas gene were also detected between SSc (AA = 23.2%, AG = 54.1%, GG = 22.8%) and controls (AA=32.6%, AG=46%, GG=21.4%) with  $p = 0.156$  for the Chi-square analysis. In contrast, the allele frequency and genotype distribution for the FasL gene polymorphism (-844 C/T) are similar between the SSc and matched controls. Further characterizations of the -670 A/G polymorphism in additional SSc cohorts are essential to determine the significance of this polymorphism in the development of SSc.

**Association of Schizophrenia and a polymorphism in the 12-LOX gene.** *C. Fridman, E. P.B. Ojopi, S. P. Gregrio, H. Vallada, P. Saletti, J. Yacubian, W. Gattaz, E. Dias Neto.* Dept and Inst Psychiatry (IPq-FMUSP), Univ Sao Paulo, Brazil.

Schizophrenia (SC) is a psychiatry disorder affecting ~1% of the population. SC often develops in young adults previously normal, and is characterized by hallucinations, psychotic symptoms, inappropriate emotional responses, disordered thinking and concentration, social deterioration. The neurodevelopmental hypothesis to SC suggests that interaction between genetic and environmental events during early periods in neuronal growth may negatively influence the way by which nerve cells differentiated. Growing evidence indicates bipolar disorder (BP) and SC display considerable overlap in epidemiologic features. Family studies show that genes play an important role in the predisposition to SC, and reveal familial co-aggregation of the two disorders, suggesting a significant overlap in the genes contributing to them. SNPs are the most frequent variations found in the human genome, defined as punctual regions of DNA where nucleotides can vary among individuals, and are frequently used in studies of complex diseases. Our goal is to search non-synonymous SNPs in genes that can be associated with psychiatric diseases, and to investigate their frequencies in a series of patients. Due to the overlap among BP and SC, and to the association we recently found in BP patients for a SNP in 12-LOX gene, we test this same polymorphism to SC. The alteration is a G to A substitution that leads to a change of an Arginine to a Glutamine. We sequenced 134 SC patients and 148 control individuals, showing an increased frequency of heterozygous G/A among patients when compared to controls (35.1% in controls and 50% in cases;  $X^2 = 4.426$ ;  $P=0,035$ ) and a significant increase of allele A in individuals from this group (58.8% in controls and 70% in cases;  $X^2 = 3.952$ ;  $P=0,047$ ). This gene belongs to the lipoxygenase family, is involved in the leukotrienes pathway, is able to sensitise the nuclear membrane to be more susceptible to the release of arachidonic acid and is related to the apoptosis. Our results suggest an association of this polymorphism and SC in this Brazilian sample. Supported: FAPESP, ABADHS.

**Association of a Met/Thr Polymorphism in the Pigment Epithelium-Derived Factor Gene within a Population with Age-Related Macular Degeneration.** *B. Appukuttan<sup>1</sup>, T.J. McFarland<sup>1</sup>, B. Wilmot<sup>3</sup>, K. Rust<sup>1</sup>, Y. Zhang<sup>1</sup>, D.W. Schultz<sup>1</sup>, P. Francis<sup>1</sup>, P. Kramer<sup>2,3</sup>, M. Wirtz<sup>1</sup>, M.L. Klein<sup>1</sup>, J.T. Stout<sup>1</sup>.* 1) Casey Eye Institute; 2) Department of Neurology; 3) Department of Molecular & Medical Genetics, OHSU, Portland, OR.

Age-related macular degeneration (AMD) is common complex disorder in which progressive central retinal atrophy or hemorrhagic neovascularization result in visual loss. Pigment epithelium-derived factor (PEDF) is a retinal neurotrophic factor with antiangiogenic properties. It is thought that amino acid substitutions resulting from non-synonymous single nucleotide polymorphisms (nsSNPs) within the PEDF gene may alter the antiangiogenic potency of the protein, in turn predisposing to neovascular disease. The purpose of this study is to determine the frequency of such nsSNPs in patients with and without AMD. PCR products from 201 patients with AMD (neovascular AMD and geographic atrophy) and 172 age-matched controls were either sequenced or characterized by RFLP analysis. Nine SNPs are present within the protein coding sequence of the PEDF gene and of these, 4 result in amino acid changes. The nsSNPs are at codon 72 (Met/Thr), 132 (Pro/Arg) and 196 (Thr/Ile). All 373 individuals were homozygous for Thr-196. The nsSNP at codon 72 is highly polymorphic (49.3% heterozygous for Met/Thr-72), whereas very few individuals possess the homozygous allele coding for Arg-132. Depending on the presence of Met or Thr at codon 72 there is a gain/loss of a potential phosphorylation at Ser-93, which is situated within the putative receptor binding site. Chi-squared test was used in a test for homogeneity between AMD group and controls. AMD affected individuals were significantly more likely ( $p=0.44$ ) to carry at least one Thr-72 allele. Heterozygotes Met/Thr-72 were significantly more likely to be affected than homozygotes of either Met/Met-72 or Thr/Thr-72 ( $p=0.024$ ). Thus, there is a significant difference in the proportion of people that have the Met/Thr-72 genotype in this particular AMD population when compared to controls. Analyses are underway to characterize the precise functional implications of these changes.

**The ABCA1/G1051A polymorphism and Alzheimers disease in Whites and African Americans.** *P.P. Desai<sup>1</sup>, S.T. DeKosky<sup>1,2,3</sup>, H.C. Hendrie<sup>4</sup>, J.R. Murrell<sup>5</sup>, M.I. Kamboh<sup>1,2</sup>.* 1) Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 3) Neurology, Univ Pittsburgh, Pittsburgh, PA; 4) Psychiatry, Indiana Univ, Indianapolis, IN; 5) Pathology and Laboratory Medicine, Indiana Univ, Indianapolis, IN.

A pathological hallmark seen in the brain of all Alzheimers disease (AD) cases is the deposition of -amyloid (A) plaques. Studies in transgenic animal models of AD show that elevated cholesterol levels increase A production, while treatment with cholesterol-lowering agents decrease A levels. Among the genetic loci implicated in late-onset sporadic AD, only the E4 allele of the apolipoprotein E (APOE) gene has been consistently shown to be associated with AD. APOE is also involved in brain cholesterol metabolism, further signifying the role of cholesterol in AD pathogenesis. Among other members of the cholesterol transport pathway, ATP-binding cassette transporter 1 (ABCA1) regulates the excretion of cholesterol from tissues. In the present study, we examined the role of the ABCA1/G1051A polymorphism in modifying the risk of sporadic late-onset AD in white and African American subjects. The cohorts were comprised of 695 white AD cases and 637 age-matched controls; and 128 African American AD cases and 213 age-matched controls. Among whites, frequency of the less common 1051\*A allele was significantly higher in female AD cases (n=470) compared to female controls (n=392), and the 1051\*A allele carriers showed a significant association with AD, with age and APOE-adjusted OR 1.63 (1.20-2.22; p=0.002). No significant difference in allele or genotype frequencies was seen in white male AD cases and controls. Frequency of the 1051\*A allele was significantly higher in African American AD cases than white AD cases (56.3% vs. 29.2%; p=0.0001), and in African American controls compared to white controls (58.5% vs. 27.6%; p=0.0001). There was no significant difference in allele or genotype frequencies in African American male or female AD cases and controls. In summary, we report a gender-specific association between the ABCA1/G1051A polymorphism and AD in whites however, no significant association was seen in African Americans.

**Interleukin 9 receptor gene polymorphisms in childhood wheezing and atopy.** *E. Melen*<sup>1,2</sup>, *H. Gullsten*<sup>2,3</sup>, *A. Lindstedt*<sup>2</sup>, *M. Zucchelli*<sup>4</sup>, *F. Nyberg*<sup>1,5</sup>, *G. Pershagen*<sup>1</sup>, *M. Wickman*<sup>6</sup>, *J. Kere*<sup>2,4</sup>. 1) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Clinical Research Centre, Huddinge University Hospital, Stockholm, Sweden; 3) Department of Medical Genetics, University of Helsinki, Finland; 4) Centre for Biotechnology at Novum, Karolinska Institutet, Stockholm, Sweden; 5) AstraZeneca, Molndal, Sweden; 6) Department of Occupational and Environmental Health, Karolinska Hospital, Stockholm, Sweden.

Interleukin 9 (IL9) has many biological effects that are important for the development of allergic diseases. The IL9 receptor gene, located on the pseudoautosomal region of X and Y chromosomes, has previously been associated with asthma. Our aim was to study polymorphisms in the IL9 receptor gene and childhood allergic diseases. Infants born in Stockholm, Sweden (n=4,089), were recruited in a prospective study, BAMSE. Symptoms of allergic diseases were obtained at one, two and four years of age. Blood samples (n=2,614) were drawn at four years of age for analysis of specific IgE. Using a case-cohort design, 526 cases (wheezers) and 526 controls were selected for analyses of 26 IL9R single-nucleotide polymorphisms (SNPs). Twenty SNPs were non-polymorphic or had very low allele frequencies and 2 SNPs were excluded because they were not in Hardy-Weinberg equilibrium. The remaining 4 SNPs were found to be in strong linkage disequilibrium and within one haplotype block. Haplotype analyses with these SNPs showed significant associations with wheezing up to the age of four (most common haplotype 52.8% in controls vs 57.4% in wheezers, p=0.02 and second most common haplotype 18.9% vs 14.7%, respectively, p<0.01). The frequency of the second most common haplotype was also lower in children with specific IgE to airborne or food allergens (19.0% in non-sensitised vs 14.3% in sensitised children, p=0.02). Thus, both disease-associated and protective haplotypes were identified. Our data suggest that variations in the IL9R gene may influence susceptibility to childhood wheezing and atopy.

Program Nr: 1964 from 2003 ASHG Annual Meeting

**Family based and case-control association analysis of circadian gene polymorphisms in bipolar I disorder.** *H. Mansour, J. Wood, B. Devlin, T. Logue, K.V. Chowdari, D.J. Kupfer, V.L. Nimgaonkar.* Departments of Psychiatry and Human Genetics, University of Pittsburgh School of Medicine and Graduate School of Public Health, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania, USA.

Disruption in circadian rhythms is a hallmark of bipolar I disorder (BD1). Hence, we evaluated associations of BD1 with polymorphisms of genes mediating circadian function. We investigated 135 probands with BD1 (DSM IV criteria), as well as available parents. Cord blood samples from local live births served as unrelated, unscreened controls (n =182). The following genes are being investigated: Clock, Bmal1, Cry1, Cry 2, Per 1, Per 2, Per 3, Timeless, and CSNK1E. We have identified 45 informative SNPs from public databases and through our re-sequencing efforts. Assays for these polymorphisms have been developed and are based on multiplex PCR followed by single base extension analysis (SnaPshot assays, ABI). Out of eight SNPs genotyped at Bmal1, two showed significant transmission distortion. Significant transmission distortion of haplotypes bearing these SNPs was also present. Case-control differences reinforced these findings. Bmal1 is known to interact at the molecular level with Clock and Per 1. Remarkably, SNPs and haplotypes at these genes also displayed transmission distortion. Only one of the other six circadian genes showed any transmission distortion (Timeless). We are currently analyzing gene-gene interactions. These results suggest an etiological role for circadian genes in BD1.

**Comparison of SNP genotyping between RFLP analysis and LNA dual labelled probes for allele discrimination.**

*M.P. Johnson, L.M. Haupt, L.R. Griffiths.* Genomics Research Centre, Griffith University, Gold Coast, Queensland, Australia.

The analysis of single nucleotide polymorphisms (SNPs) can be achieved via a vast array of methodologies. More rapid and cost effective assays are sought that are as reliable as conventional genotyping efforts such as RFLP analysis. This study compared RFLP analysis and locked nucleic acid (LNA) dual labelled probes to confirm DNA pooling results obtained for several SNPs in a migraine population-based association cohort. Selected SNPs underwent initial screening using DNA pooling and the ABI Prism SNaPshot Multiplex Reaction Kit. Allele frequency estimates obtained from the DNA pools were then confirmed by individual genotyping. RFLP analysis identified a *Sau96I* restriction site for an AG SNP. Genotyping for this SNP underwent conventional PCR and restriction digest protocols prior to agarose gel electrophoresis. With no naturally occurring restriction enzyme recognition sequence for a second SNP (CT) screened by DNA pooling, a dual labelled LNA probe set was designed (Proligo LLC). SNP allelic discrimination using the LNA probe set was optimised using real-time PCR analysis and confirmed by ABI BigDye Terminator Sequencing. RFLP analysis for the AG SNP confirmed individual allele frequencies (A 57.2%; G 42.8%) to those of the estimated pooled allele frequencies (A 58.7%; G 41.3%) for the migraine group (n = 358). Similarly, individual allele frequencies (A 54.5%; G 45.5%) and estimated pooled allele frequencies (A 52.4%; G 47.6%) were replicated for the control group (n = 372) using RFLP analysis. Sequencing confirmed the SNP allelic discrimination using the LNA probe set and real-time PCR analysis for the CT SNP (n = 9, 4 CC homozygotes, 5 CT heterozygotes). Initial analysis using a dual labelled LNA probe set has proven effective in SNP genotype calling. In particular, the use of LNA probes is appropriate for target sequences containing no naturally occurring restriction enzyme recognition sequence. Considerably less time and effort to genotype individual DNA samples is involved when using LNA probe/real-time PCR analysis, with increased reliability of SNP genotype calling evident for the LNA probe/real-time PCR assay.

Program Nr: 1966 from 2003 ASHG Annual Meeting

**An association of the FBN1 gene polymorphism with tall stature.** *M. Mamada, T. Yorifuji, K. Kurokawa, M. Kawai, T. Nakahata.* Dept Pediatrics, Kyoto Univ Hosp, Kyoto, Japan.

Contribution of genetic factors for controlling stature is estimated around 80%, however the major genes have not been fully determined. In our study to identify genes controlling stature, we carried out an association study targeting subjects with tall stature. We have analyzed 3 single nucleotide polymorphisms (SNPs) in each 6 candidate genes; FBN1, GH1, GHR, SHOX, FGFR3 and LH. SNPs were genotyped in healthy Japanese men grouped into Tall Stature (TS, N=150) and Normal Stature (NS, N=150). Tall stature was defined by final height over 180 cm (over 2SD), and normal stature by final height between 165 and 175 cm (-1 SD to 1 SD). Chi-square test with Bonferroni correction was used for statistical analysis. Haplotypes were reconstructed by means of a Bayesian algorithm implemented in the program Haplotyper in order to confirm that the selected SNPs were appropriate for the analysis. We demonstrated a significant association between SNP2 (T2008C) in FBN1 and tall stature ( $p=0.012$ ). In TS group, men with CC allele were significantly taller than those with TT. On the other hand in NS group, no significant differences were found. SNPs in other 5 genes were not statistically significant. An association between FBN1 gene polymorphism and stature has not been reported before. We cannot describe the exact mechanism by which this silent mutation affect stature. To clarify this point further investigation will be needed. In conclusion, our results suggest that variation of FBN1 may be one of the important determinant of stature.

**FEB2 positional candidate screening: ion channel associated genes on c19p.** *L. Nowak*<sup>1</sup>, *T. Stoffer*<sup>1</sup>, *D. Stone*<sup>2</sup>, *E. Johnson*<sup>1</sup>. 1) Neurogenetics Research, Barrow Neurological Institute, Phoenix, AZ; 2) CuraGen Corporation, Branford, CT.

Febrile seizures are the most common form of seizure disorder. 2-5% of all children will experience a febrile convulsion (FC) before the age of 5 (up to 15% in certain Asian populations), and as many as 7% of these children will go on to develop nonfebrile seizures and epilepsy later in life. This is 2-10 times the rate in the general population and a potentially serious health risk factor.

Loci for several potential febrile convulsion genes have been documented: FEB1 on chromosome 8q in a single Australian family; FEB2 on chromosome 19p in several large families from the Midwest, the East Coast and China; FEB3 (GEFS+1) which is associated with a mutation in the sodium channel subunit, SCN1B; FEB4 (GEFS+2) identified in April of 2000 as SCN1A, the sodium channel, neuronal type I, alpha subunit; FEB5 on chromosome 5q in a number of Japanese families; and finally FEB 6, localized to 6q22-24 in a European family.

The refinement of the C19p physical map, which includes the FEB2 critical interval, is essentially completed. A number of ion channel candidate genes map to this region of 19p and are undergoing mutational analysis as potential FEB2 candidates. One positional candidate gene, coding for a protein associated with the NMDA receptor shows a particularly high level of polymorphism. The results from the screening of this positional candidate will be presented.

**Detection and characterization of human *TPH2* variants.** Z. Zhou, R. Lipsky, D. Goldman. Laboratory of Neurogenetics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, MD.

Serotonin is a neurotransmitter that is involved in a wide variety of central nervous system (CNS) functions, including sleep, mood, pain, food intake, alcohol and drug abuse, and sexual behavior. Tryptophan hydroxylase (TPH) is the rate-limiting enzyme in the biosynthesis of serotonin. TPH2 was recently identified and shown to be responsible for serotonin synthesis in brain. We screened *TPH2* for sequence variants in 95 ethnically and clinically diverse individuals using denaturing high performance liquid chromatography (DHPLC) and direct sequencing, and examined the frequencies of some of these variants across several populations. Nineteen PCR amplicons were produced, covering 4.25 kb of the promoter, coding exons and their flanking intronic regions, and 3-untranslated sequences. PCR products were screened for single nucleotide sequence polymorphisms (SNPs) by detecting heteroduplex DNAs from heterozygotes. Amplicons revealing heteroduplexes were then directly sequenced. Sixteen SNPs were detected in the 4.25 kb region. Among the 16 SNPs, three were previously reported by NCBI dbSNP and Celera. Thirteen SNPs discovered in our study were new, four of which are located in the promoter, four in the exons, two in the introns, and three in 3-untranslated region. Heterozygosities for each of the SNPs were also calculated. Six SNPs with relatively high heterozygosities were selected for large scale genotyping using a 5nuclease assay. A total of 722 individuals from three ethnic groups, consisting of 198 African American, 180 Finnish Caucasians, and 344 U.S. Caucasians, were genotyped. Four of the six SNPs showed significant differences in allele frequencies among different ethnic groups, especially between the Finns and African Americans. We are now genotyping additional SNP markers spanning the 93 kb region of *TPH2* for haplotype and linkage disequilibrium analyses.

**A data mining tool for screening and analyzing single nucleotide polymorphisms (SNPs) in the human genome.** Z. Zhao<sup>1,2</sup>. 1) Human Genetics Center, University of Texas at Houston Health Science Center, Houston, TX 77030; 2) Keck Center for Computational and Structural Biology, Houston, TX 77030.

Single nucleotide polymorphisms (SNPs) are main genetic variations in the human genome and are valuable tools for identifying disease-associated genes, understanding the molecular mechanisms of mutation, and revealing the evolutionary history of human populations. With more than four millions of single nucleotide polymorphisms (SNPs) identified in the human genome, it is difficult to manually select and analyze SNPs from a large region or from various genes. Currently, the researcher is largely restricted to perform the basic search function in the public or private SNP databases. To data mine SNPs efficiently, a SNP database was designed and implemented by MySQL and a web interface was developed to allow the user to retrieve, search, and analyze the data from millions of SNPs. Besides the basic search of SNPs or genes, the user can screen a list of genes having the highest number of SNPs or the highest SNP density in a selected genomic region, a chromosome, or the whole genome. Other utilities include the statistical analyses of the substitutions, the ratio of transition over transversion, and gene structure categories of the SNPs in a restricted region or the genome. Furthermore, using the functional criteria of the genic categories, the user can obtain a fixed (say, 5) number of functional candidate SNPs for each gene within a large genomic region, which is critical in such projects as large-scale genotyping the complex disease genes. Such utility has been applied to screen approximately 10,000 functional candidate SNPs from all the SNPs available on chromosome 19. Finally, the basic or advanced queries can be performed directly on the database by users special requirements. This application can be easily extended to other functionalities for the genetic study if more SNP-related data are included. In conclusion, it provides a useful and efficient data mining tool for the researchers who study SNP patterns or search candidate SNPs in disease-causing genes.

**Polymorphisms in the genes of interleukin 10 and its receptors in association with inflammatory bowel diseases.**

*L. Zhang*<sup>1</sup>, *D.P. McGovern*<sup>1, 2</sup>, *T. Ahmad*<sup>1</sup>, *D.P. Jewell*<sup>1</sup>. 1) Gastroenterology Unit, NDM, Oxford University, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, United Kingdom.

Interleukin 10 (IL10) is a down-regulatory cytokine that has been used in the treatment of Crohns disease (CD) and ulcerative colitis (UC). The overall response in clinical trials has been disappointing, but the clinical response might be confounded by the influence of genetic variation in the IL10 promoter or in its receptors. Analyses of polymorphisms in the IL10 gene and its receptors, IL10RA and IL10RB, might allow targeting of therapy to those patients who will respond. Furthermore, the IL10 knockout mouse is highly susceptible to the development of colitis. For these reasons the genes encoding IL10 and its receptors are attractive candidate genes for IBD. In this study, a total of 26 SNP markers have been examined: 9 located in the IL10 gene, 5 in IL10RA and 12 in the cytokine receptor cluster on chromosome 21q22.11. This cluster contains four genes that encode for IL10 RB and the subunits of the receptors for interferon-alpha, -beta and -gamma genes. Genotyping was performed with Sequenome in 376 UK Caucasians with CD, 380 with UC and 384 health controls. A strong association was seen between CD and IL10/+1812-A/A genotype ( $P = 0.0009$ , OR 6.1, 95%CI 1.8-20.8). Subanalysis showed no association with extent of disease, but this genotype was seen more commonly in those without peri-anal disease compared to patients with peri-anal disease ( $P = 0.014$ , OR 3.8, 95%CI 1.26-11.47). The wild type +1812-C/C appeared to be protective for UC ( $P = 0.0006$ , OR 0.566, 95%CI 0.4108-0.7785), but UC was associated with a coding polymorphism IL10RA/A60A-G/G ( $P = 0.005$ , OR 1.74 CI 1.184-2.56). There were very weak associations between polymorphisms of IL10 (-1387), IFNAR2 (-15843) and IFNGR2(+33543) and CD ( $P = 0.026, 0.035, 0.036$ , respectively), but no other associations were seen. These findings provide support for the role of IL10 in the pathogenesis of CD and UC. The biological significance of these mutations needs to be investigated.

Program Nr: 1971 from 2003 ASHG Annual Meeting

**Association of IL-13 -C1055T polymorphism with Asthma and Atopy in African-American patients.** *B. Chinoy, J. Moissidis, K. Yanamandra, D. Napper, T.F. Thurmon, J.A. Bocchini Jr., S. Bahna.* Dept. Pediatrics, LSU Health Sciences Center, Shreveport, LA.

Asthma and atopy are multifactorial diseases with genetic and environmental factors involved in their etiology. Several chromosomal loci have been implicated in the etiology such as chromosome 5q31-33, 12q15-24, and 11q13. Chromosomal region 5q31-33, contains several cytokine genes including IL-4, IL-5, IL-13, etc. Earlier findings have suggested a strong genetic influence of the chromosome 5q31 region in the development of allergic asthma. Immunoglobulin E synthesis is dependent on IL-4 and to lesser extent on IL-13. IL-5 induces eosinophilia. Because of their biological effects, IL-4 and IL-13, located at close proximity to 5q31, are very likely candidates in the inheritance of allergic asthma. For the first time, van der Pouw Kraan and his associates in 1999 have identified a single nucleotide polymorphism (SNP) in the promoter region of IL-13 gene, -C1055T. They have associated this SNP with increased risk of allergic asthma in the Dutch Caucasians. In the year 2000, van der Pouw Kraan et al have associated -C1055T polymorphism also with chronic obstructive pulmonary disease (COPD). Although several studies were conducted in Caucasians, there was limited literature on the association of this polymorphism with asthma or atopy in Africans or African-Americans. In the present investigation, we began the SNP studies on interleukins in the search for genetic markers in asthma and atopy patients in our local Northwest Louisiana African-Americans. We evaluated IL-13 -C1055T SNP genotyping in over 30 patients and compared the genotypes from 100 control infants. Our pilot data showed 24% -1055TT homozygotes in our patients compared to 12% in controls ( $p < 0.03$ , odds ratio 4.8). Mutant alleles also were significantly higher in patients than in controls 54.6% vs 37.9% ( $p < 0.03$ , odds ratio 2). Based on our data we believe that the 1055T mutant genotypes are a risk factor in the etiology of asthma and atopy in African-Americans. This is the first report on IL-13 C1055T in this community. Detailed data will be presented.

**Linkage and Association Analysis of COPD-related Phenotypes on Chromosome 19.** *J.C. Celedon*<sup>1,2</sup>, *B. Raby*<sup>1,2</sup>, *L. Palmer*<sup>1,2</sup>, *J. Sylvia*<sup>1</sup>, *D. Kwiatkowski*<sup>1,2</sup>, *H. Chapman*<sup>3</sup>, *M. Hernandez*<sup>1</sup>, *F. Speizer*<sup>1,2</sup>, *S. Weiss*<sup>1,2</sup>, *E.K. Silverman*<sup>1,2</sup>. 1) Channing Lab, Brigham & Women's Hosp, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) University of California at San Francisco, San Francisco, CA.

To study genetic determinants of chronic obstructive pulmonary disease (COPD), we enrolled 72 pedigrees ascertained through severe, early-onset COPD probands (FEV1 < 40% predicted [pred], age <53 yrs, without severe AAT deficiency). Results of a previously reported genome-wide linkage analysis for COPD-related traits in this population suggested that post-bronchodilator (post-BD) spirometric measures were optimal COPD-related phenotypes (Hum Mol Genet 2003;12:1199-1210). Following this genome scan, we conducted linkage analysis of 15 STR markers on chromosome (chr.) 19 (range, 33 to 68 cM) with post-BD quantitative (FEV1 and FEV1/FVC) and post-BD qualitative (mild airflow obstruction [FEV1 <80% pred and FEV1/FVC <90% pred], and moderate airflow obstruction [FEV1 <60% pred and FEV1/FVC <90% pred]) COPD-related phenotypes in 585 members of the COPD pedigrees. We used SOLAR for variance component linkage analysis of quantitative traits and the NPL all statistic (in MERLIN) for the analysis of qualitative traits. The maximum multipoint LOD scores were: 1.91 (at 63 cM) for FEV1; 1.87 (at 62 cM) for FEV1/FVC; 1.49 (at 42.3 cM) for mild airflow obstruction; and 2.41 (at 43.3 cM) for moderate airflow obstruction. To follow up on these results, we performed a family-based association analysis between four SNPs in a candidate gene in the linkage peak on chr. 19 (TGF1) and COPD-related traits using FBAT. Preliminary analyses have shown no significant association between any of the SNPs tested and qualitative COPD-related traits. Thus, we have found suggestive evidence for a COPD susceptibility locus on chr. 19, but our preliminary analyses do not support an association between TGF1 and COPD-related phenotypes. This abstract is funded by NIH Grants: HL61575 (EKS) and HL04370 (JCC).

**A first locus for isolated autosomal recessive optic atrophy (ROA1) maps to chromosome 8q.** *F. Barbet<sup>1</sup>, S. Gerber<sup>1</sup>, S. Hakiki<sup>1</sup>, I. Perrault<sup>1</sup>, S. Hanein<sup>1</sup>, D. Ducroq<sup>1</sup>, G. Tanguy<sup>1</sup>, J.-L. Dufier<sup>2</sup>, A. Munnich<sup>1</sup>, J.-M. Rozet<sup>1</sup>, J. Kaplan<sup>1</sup>.* 1) Unit de Recherches sur les Handicaps Gntiques de l'Enfant,INSERM U393, Hpital des Enfants Malades, Paris, France; 2) Service d'Ophtalmologie, Hpital des Enfants Malades, Paris, France.

In contrast to the frequent dominant optic atrophies where the neuropathy is usually an isolated event, isolated recessive optic atrophies (ROA) are very uncommon and have been described as severe congenital or early infantile conditions. To date, two loci for isolated dominant optic atrophy have been mapped, of which one was ascribed to mutations in the dynamin-like gene (OPA1). Conversely, no isolated autosomal recessive optic atrophy locus has previously been localised. Here, we report a large multiplex consanguineous family of French origin affected with an early onset but slowly progressive form of isolated optic atrophy. A genome-wide search for homozygosity allowed the mapping of the disease-causing gene to chromosome 8q21-q22 (Zmax of 3.41 at theta=0 for D8S270), in a 12 Mb interval flanked by markers D8S1702 and D8S1794. This localisation excludes allelism of the disease with isolated dominant optic atrophies and all known syndromic forms of recessive optic atrophy. This study supports the mapping of a first gene for isolated autosomal recessive optic atrophy (ROA1) to the long arm of chromosome 8.

**Expanding the genetic heterogeneity of keratoconus and posterior polymorphous dystrophy.** *N. Noordeh*<sup>1</sup>, *C.E. Willoughby*<sup>1,2,3,4</sup>, *V.E. Di Giovanni*<sup>1</sup>, *G. Billingsley*<sup>1</sup>, *S.B. Kaye*<sup>4</sup>, *E. Héon*<sup>1,2</sup>. 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept of Ophthalmology and Vision Sciences, Hospital for Sick Children, Toronto, ON, Canada; 3) Dept of Medicine, University of Liverpool, Liverpool, UK; 4) Royal Liverpool University Hospital, Liverpool, UK.

Keratoconus (MIM#148300) is the most common cause of corneal transplantation in the Western world. We previously identified mutations in the human visual system homeobox (*VSX1*;MIM#605020) gene in keratoconus and also posterior polymorphous dystrophy. *VSX1* is the only keratoconus gene identified to date, but a keratoconus locus has recently been reported on chr16q 22.3-q23.1. Posterior polymorphous dystrophy (PPD;MIM#122000) is a progressive disorder of the corneal endothelium which is normally dominantly inherited and may co-exist with keratoconus. We reported mutations in *VSX1* in patients with both PPD and keratoconus, and mutations in *COL8A2* (MIM#120252) have been described in PPD. Eleven family members (5 affected and 6 unaffected) of a three generation Caucasian family from the UK with PPD and keratoconus were recruited. All individuals had a full ocular assessment including corneal topography and pachymetry. The diagnosis in the proband was histologically proven by light microscopy and immuno-histochemistry of corneal material obtained following corneal transplantation. This family was excluded from the *VSX1* and *COL8A2* loci by haplotype and linkage analysis. Microsatellite markers for the 16q22 loci, a recently documented keratoconus locus, were selected to cover the 6cM region on chr16q22.3-q23.1 (markers D16S2624, D16S3059, D16S512, D16S3018, D16S515 and D16S3138) for genotyping. Haplotype segregation has also excluded this family from the 16q22 locus. The genetic analysis of this family further expands the genetic heterogeneity of keratoconus and PPD.

**Optineurin sequence variants do not contribute to high-tension primary open-angle glaucoma.** *J.W. Walter<sup>1</sup>, R.R. Allingham<sup>1</sup>, J.D. Flor<sup>1</sup>, K.R. Abramson<sup>1</sup>, F.L. Graham<sup>1</sup>, C.S. Cohen<sup>1</sup>, C. Santiago<sup>1</sup>, E.A. del Bono<sup>2</sup>, J. Auguste<sup>2</sup>, K. Rogers<sup>2</sup>, J.L. Haines<sup>3</sup>, M.A. Pericak-Vance<sup>1</sup>, J.L. Wiggs<sup>2</sup>, M.A. Hauser<sup>1</sup>.* 1) Duke University, Durham NC; 2) Massachusetts Eye and Ear Infirmary, Boston MA; 3) Vanderbilt University, Nashville TN.

Recent studies have suggested that sequence variants in the optineurin gene (OPTN) increase susceptibility to normal-tension glaucoma (NTG), in which patients exhibit optic nerve damage without elevated intraocular pressure (Rezaie et al., *Science* 295: 1077). Two OPTN variants have been observed in multiple probands: the disease allele E50K, and the risk-associated allele M98K. To confirm the role of the E50K variant in NTG, we screened a panel of 50 NTG patients for this allele. E50K was observed in a single NTG patient, consistent with the interpretation of E50K as a NTG disease allele. To determine whether OPTN variants contribute to the more common high-tension primary open-angle glaucoma (POAG), we performed mutation analysis on our collection of 86 POAG families. Exons 4 and 5, containing these two variants, were sequenced using the probands from these families. E50K was observed in 0 of 86 high-tension POAG probands, suggesting that this allele does not contribute to glaucoma in this clinically distinct population. M98K was observed at the same frequency in POAG, NTG, and control populations, suggesting that this allele does not confer any additional risk of glaucoma. The remaining OPTN coding exons were screened for variations using denaturing HPLC analysis. No additional coding variants were detected in our sample set. A number of intronic SNPs were detected, none of which are anticipated to cause splice defects. These findings indicate that NTG and POAG do not have significant genetic overlap, and should be considered genetically discrete disorders. Our evidence indicates that OPTN variations do not contribute to high-tension POAG. To determine the effect of ethnic background on the frequencies of OPTN polymorphisms, and their possible roles in POAG, we have collected an additional 148 POAG patients from Ghana, the ethnic background of whom is similar to African American patients enrolled in our study.

**Candidate gene polymorphisms analysis and acquired skewing of X-chromosome inactivation in an elderly female population.** *P. Chagnon, S. Provost, M. Lussier, V. Bolduc, L. Busque.* HemaX Genome, Hopital Maisonneuve-Rosemont, Montreal, Quebec, Canada.

To equalize X-linked gene dosage between XX females and XY males, mammals have developed a unique dosage compensation mechanism that inactivates one of the two X-chromosomes in every female somatic cell. Females are in theory mosaics with an equal proportion of cells with the paternal X-chromosome in the active state and the other half with the maternal X chromosome in the active state. Significant deviation from the theoretical 1:1 ratio between paternal and maternal X chromosome is rare. However, Busque et al. (1996) have discovered that blood cells present an increased incidence of skewing of X-inactivation ratio over time. In fact, ratios greater than 3 to 1, occurs in 38 to 56% of normal females over 60 years of age. The exact aetiology of this age-associated skewing of blood cells is still unknown. Several recent observations point to an X-linked genetic basis to this phenomenon. We believe that gene(s) responsible for this phenotype are probably cell growth factors that favor cells harbouring either the activated maternal or paternal X chromosome. In order to test this hypothesis, we have analyzed, by a SNPs genotyping approach, 6 different genes located on the X chromosome that could be implicated in the phenomenon of X chromosome inactivation skewing. GATA1 (globin transcription factor 1), BMX (bone marrow kinase, X-linked), CYBB (cytochrome b-245, beta polypeptide), WAS (Wiskott-Aldrich), PIGA (phosphatidylinositol glycan, class A) and BM042 (uncharacterized bone marrow protein). We have recruited for this study 850 independent women from French Canadian population. X inactivation ratio was determined by the HUMARA test. Using TaqMan technology (ABI 7000), we have genotyped 48 different SNPs in the 380 most informative women (i.e. women who are highly skewed and normal women). Statistical analysis was performed by a chi-square based association test and also by the Fishers Exact Test using genotype frequencies. The results presented here show that the 6 genes investigated are not the cause of the age-associated skewing of blood cells.

**RHD maternal-fetal genotype incompatibility and schizophrenia: extending the MFG test to include multiple siblings and birth order.** *P. Kraft*<sup>1</sup>, *C.G.S. Palmer*<sup>2,3</sup>, *J.A. Woodward*<sup>3,4</sup>, *J.A. Turunen*<sup>5,7</sup>, *S. Minassian*<sup>1</sup>, *T. Paunio*<sup>7</sup>, *J. Lönnqvist*<sup>8</sup>, *L. Peltonen*<sup>5,7</sup>, *J. Sinsheimer*<sup>1,5,6</sup>. 1) Dept Biostatistics, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Psychiatry and Behavioral Sciences, Univ California, Los Angeles, Los Angeles, CA; 3) Dept Statistics, Univ California, Los Angeles, Los Angeles, CA; 4) Dept Psychology, Univ California, Los Angeles, Los Angeles, CA; 5) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 6) Dept Biomathematics, Univ California, Los Angeles, Los Angeles, CA; 7) Dept Molecular Medicine, National Public Health Institute, Helsinki, Finland; 8) Dept Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland.

Rh incompatibility disease has been implicated as a risk factor for schizophrenia. Here we extend the maternal-fetal genotype incompatibility (MFG) test used in a previous case-parent trio study of RHD maternal-fetal genotype incompatibility in a large Finnish schizophrenia sample. We modify the MFG test to include any number of siblings. The additional subjects not only give us greater power, they also enable us to model the impact of previous RHD maternal-fetal genotype incompatible pregnancies on the relative risk of genotype incompatibility in later-born siblings. This modeling is important, because RHD maternal-fetal genotype incompatibility is a proxy for Rh incompatibility disease, and the risk of Rh incompatibility disease increases with the number of previous genotype-incompatible pregnancies. We apply the modified test to available data from the Finnish sample. The best-fitting models are consistent with the hypothesized effect that previous incompatible pregnancies increase risk of schizophrenia due to RHD maternal-fetal genotype incompatibility. There was significant evidence that the relative risk of schizophrenia in the second- and later-born RHD maternal-fetal genotype incompatible children is 1.7, consistent with earlier estimates. Our extension of the MFG test has general application to family-based studies of maternal-genotype and maternal-fetal genotype interaction effects.

**Inheritance of expression profiles in MS families: A family based microarray analysis reveals higher similarity in the expression profiles of related individuals for the genes of the linked region.** *J. Saarela<sup>1</sup>, J. Hollmen<sup>2</sup>, D. Chen<sup>3</sup>, P. Tainola<sup>1</sup>, A. Jokiahho<sup>3</sup>, A. Palotie<sup>3,4</sup>, H. Mannila<sup>5</sup>, L. Peltonen<sup>1,3</sup>.* 1) Dept Molecular Medicine, Natl Public Health Inst, Helsinki, Finland; 2) Lab of Computer and Information Science, Helsinki University of Technology, Finland; 3) Dept. of Human Genetics, UCLA, CA; 4) Finnish Genome Ctr, Univ of Helsinki, Finland; 5) Helsinki Inst. of Information Technology, Finland.

We performed a genome-wide profiling of gene expression in four pedigrees to monitor whether a familial correlation existed in expression profiles. Analyzed families represented multiplex MS families showing linkage to a locus on 17q22-q24. Peripheral blood lymphocytes of 20 individuals were fractionated to CD4 positive and CD4 negative cells. Total RNA was extracted from cell populations and analyzed using the Affymetrix U133A microarrays. For comparison of expression profiles, we used the linear correlation coefficient between the profiles as a measure of similarity. As an aggregate quantity of similarity for families, we took the average of pairwise correlations between the expression profiles. In addition, we calculated the expected frequency of shared alleles between family members from the pedigree structure and used this as additional information when weighting the correlations. The profiles of gene sets (all genes, 25 mostly expressed genes, 500 randomly selected genes, genes with highest standard deviation, HLA genes mapping to 6p, genes mapping to 17q22-q24) were used in the comparisons. To test our hypothesis of average correlation in expression being stronger for families than for any other sets, we performed a permutation test. We consistently observed higher similarity between relatives than non-relatives in the expression profiles of 17q genes, while the other sampling groups of genes showed more variable findings. According to the permutation test (estimated with 100000 randomized samples), the familial correlation was statistically significant, both between family members ( $p=0.048$ ) and when the correlations were weighted using the pedigree structure information ( $p=0.015$ ).

**Maternally inherited aminoglycoside-induced and non-syndromic deafness associated with the novel C1494T mutation in the mitochondrial 12S rRNA gene in a large Chinese family.** *M.X. Guan*<sup>1,2</sup>, *H. Zhao*<sup>1,2</sup>, *R. Li*<sup>1</sup>, *Q. Wang*<sup>2</sup>, *Q. Yan*<sup>1</sup>, *W.Y. Yang*<sup>2</sup>. 1) Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) Department of Otolaryngology, Head and Neck Surgery, Chinese PLA General Hospital, Beijing 100853, China.

Mutations in the mitochondrial 12S rRNA gene have been shown to account for the significant cases of aminoglycoside ototoxicity. We report here the clinical, molecular and biochemical characterization of a large Chinese family with maternally transmitted aminoglycoside induced and non-syndromic deafness. Maternal members of this family showed the variable severity and age-of-onset in hearing impairment. Sequence analysis of the complete mitochondrial genome in this pedigree identified a homoplasmic C-to-T transition at position 1494 (C1494T) in the 12S rRNA gene. The C1494T mutation is expected to form a novel 1494U-A1555 base-pair, which is the same position as the 1494C-G1555 pair created by deafness-linked A1555G mutation, at the highly conserved A-site of 12S rRNA. This site has been implicated for the main target of aminoglycoside toxicity. Thus, it is anticipated that this alteration in the tertiary structure of 12S rRNA may lead to the sensitivity to aminoglycosides. Here, the sensitivity to aminoglycosides paromomycin or neomycin has been analyzed in lymphoblastoid cell lines derived from four deaf individuals and two hearing individuals from this Chinese family carrying C1494T mutation and four unrelated controls. In the presence of high concentration of paromomycin or neomycin, the C1494T mutation-carrying cell lines derived from Chinese family exhibited a significant average increase in doubling time, when compared to control cell lines. Furthermore, this mutation was absent in 300 unrelated controls, suggesting specific segregation with the disorder. These data suggest that the C1494T mutation is a novel mtDNA mutation that causes a genetic predisposition to aminoglycoise-induced and non-syndromic deafness.

**Biochemical defects caused by a combination of the deafness-linked mitochondrial tRNA<sup>Ser</sup>(UCN) mutation with two mtDNA mutations lead to the high penetrance of deafness in a large African American pedigree.** *X. Li<sup>1</sup>, N. Fischel-Ghodsian<sup>2</sup>, R. Friedman<sup>3</sup>, M.X. Guan<sup>1</sup>*. 1) Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) Ahmanson Department of Pediatrics, Cedars-Sinai Medical Center, Los Angeles, California 90048; 3) House Ear Clinic and House Ear Institute, Los Angeles, California 90057.

Mutations in the mitochondrial DNA (mtDNA) have been shown to be one of important causes of deafness. Recently, an African-American family with maternally inherited nonsyndromic hearing loss has been associated with the mitochondrial tRNA<sup>Ser</sup>(UCN) T7511C mutation, which has been found in genetically unrelated pedigrees with non-syndromic deafness. In addition, the homoplasmic mutations T3308C in the ND1 gene and T5655C in the tRNA<sup>Ala</sup> gene have been found in all members of this pedigree and also in some controls. We report here an investigation of pathogenetic mechanism underlying these mtDNA mutations by analyzing three mutant and three control transformants, constructed by transferring mitochondria from lymphoblastoid cell lines derived from a deaf individual and one control individual, into human mtDNA-less (o) cells. We show that the T7511C mutation leads to the decrease (~75%) in the amount of tRNA<sup>Ser</sup>(UCN) but not co-transcribed ND6 mRNA, which in mutant cells. Furthermore, the T5655C mutation yields the reduction (~50%) in the tRNA<sup>Ala</sup> level in these mutant cells. Strikingly, the T3308C mutation causes a significant decrease both in the amount of ND1 mRNA and adjacent tRNA<sup>Leu</sup>(UUR) in mutant cell lines. A combination of these alternations leads to the significant biochemical defects in the rate of mitochondrial protein synthesis, substrate-dependent respiration and the rate of growth in medium containing galactose in mutant cell lines. These observations provide the first direct biochemical evidence that three mtDNA mutations in different genes contribute to the high penetrance of non-syndromic deafness in the African American family.

**Genomic convergence: Identification of candidate genes for Parkinson Disease (PD) using genetic linkage and gene expression in the substantia nigra.** *M.A. Hauser<sup>1</sup>, M. Nouredine<sup>1</sup>, J.W. Walter<sup>1</sup>, R.W. Walters<sup>1</sup>, C.M. Hulette<sup>1</sup>, D.E. Schmechel<sup>1</sup>, M.L. Bembe<sup>1</sup>, J.M. Stajich<sup>1</sup>, H. Xu<sup>1</sup>, E.R. Martin<sup>1</sup>, B.L. Scott<sup>1</sup>, J. Stenger<sup>1</sup>, Y.J. Li<sup>1</sup>, R. Jensen<sup>3</sup>, C. Scherzer<sup>2</sup>, S. Gullans<sup>2</sup>, J.M. Vance<sup>1</sup>.* 1) Duke Univ Medical Ctr, Durham, NC; 2) Brigham and Womens Hospital, Harvard Medical School, Boston, MA; 3) Department of Physics, Wesleyan University.

Parkinsons Disease (PD) is a progressive neurodegenerative disease characterized by the loss of dopaminergic neurons in the substantia nigra. We are investigating candidate susceptibility genes for PD using Genomic Convergence, a multifactorial approach that combines linkage, expression analysis, SNP association and other methods. We have previously reported five large genomic linkage peaks in 174 multiplex PD families. We present here gene expression profiling in the substantia nigra of 6 patients with PD, 2 with progressive supranuclear palsy (PSP), one with frontotemporal dementia with Parkinsonism (FTDP), and 5 controls. PSP and FTDP are related parkinsonisms that, like PD, show loss of dopaminergic neurons. This allows us to assess the effect of changes in cell population within the PD samples. All samples were analyzed with Affymetrix U133A microarrays, and a subset was analyzed by serial analysis of gene expression. Genes from several metabolic pathways are significantly ( $p < 0.05$ ) altered in PD patients. The two molecular chaperones HSPA1A and HSPA1B are overexpressed. Apoptosis is suppressed: levels of the pro-apoptotic mediators NGFRAP1, MOAP1, and MTCH1 are reduced, while the level of the anti-apoptotic Bcl-2 is increased. There are reductions in vesicle transport genes: 9 subunits of the vacuolar ATPase ATP6 are reduced, as are GDI1, STXB1, SYT1, and VAMP1, proteins involved in docking of secretory vesicles. A large number of nuclear encoded mitochondrial proteins are also downregulated in PD patients. These genes (and others in the same pathways) that map to regions of PD linkage are being investigated as susceptibility genes: polymorphic variants identified by sequence analysis and family-based association analysis of tightly-linked polymorphisms will be presented.

**Identification of genes important in hypothalamic regulation of body weight.** *R. Wevrick, M.A. O'Neill, J.M. Bischof.* Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Obesity is one of the major health issues facing the developed countries today. Despite years of population studies, the genetic determinants of healthy body weight are poorly understood. Likewise, although there is increased understanding of the role of the hypothalamic-pituitary-adrenal axis in obesity, the proteins implicated in the development and/or function of this organ system are not all known. Specific proteins, such as hormones and their receptors, are responsible for control of appetite and long term maintenance of body weight. An increasing number of studies rely on mapping obesity modifier loci in mice or humans, then choosing candidate genes within the mapped region for further study. Still other studies examine changes in gene expression in mice undergoing dietary challenges, or in obesity gene knockout versus wild type mice. The hypothalamus is a complex region of the brain involved in homeostatic processes including, but not limited to energy balance. We have examined the relative expression levels of an estimated 30,000 genes in the murine hypothalamus as determined by Affymetrix microarray technology and made available by the Novartis Research Foundation (<http://expression.gnf.org>). From this, we identified a set genes not previously recognized to be important in hypothalamic function, but highly and preferentially expressed in the murine hypothalamus. We used bioinformatic databases to map the selected genes to chromosomal regions in the mouse genome and human genomes. We correlated the mapped positions of selected genes with the genomic positions of published loci influencing obesity related traits. We are now experimentally determining the developmental time frame for expression in specific murine hypothalamic nuclei with distinct functions in appetite and homeostasis, using northern blot and RNA in situ hybridization. These proteins can become targets for pharmacological intervention in obese individuals. Since susceptibility to obesity is in part genetically determined, we may also determine that variations in these genes contribute to familial obesity.

**Genetic Evaluation of Protein Tyrosine Phosphatase-1B (PTP-1B) Gene Polymorphisms and Measures of Glucose Homeostasis: The IRAS Family Study.** *N.D. Palmer<sup>1</sup>, C.D. Langefeld<sup>2</sup>, W.M. Brown<sup>2</sup>, F. Hsu<sup>2</sup>, D.W. Bowden<sup>1</sup>.* 1) The Center for Human Genomics, Wake Forest University, Winston-Salem, NC; 2) Public Health Sciences, Wake Forest University, Winston-Salem, NC.

PTP-1B is a ubiquitously expressed protein that dephosphorylates proteins at tyrosyl residues and has been shown to modulate the activity of the insulin receptor and its substrates. We have evaluated 24 SNPs in a 161kb region encompassing the ten exons spanning 74kb of PTP-1B. SNPs were genotyped on 1152 Hispanic (San Antonio, TX and San Luis Valley, CO) and African American (Los Angeles, CA) participants in the Insulin Resistance Atherosclerosis Family Study. To test for association among each PTP-1B SNP and trait, a series of generalized estimating equations was computed. A sandwich estimator of the variance and exchangeable correlation was used to account for familial correlation. SNPs within a region of 86kb, containing a portion of PTP-1B, were found to be in high linkage disequilibrium ( $D > 0.7$ ). Within this LD block, multiple SNPs show statistically significant associations with measures of glucose homeostasis. In combined population analysis, significant associations were with fasting glucose, insulin sensitivity (Si), and acute insulin response (AIR) ( $P = < 0.001 - 0.045$ ). In population specific analyses, the San Antonio population showed associations to Si, disposition index, and fasting glucose ( $P = < 0.001 - 0.050$ ), the San Luis Valley population to fasting glucose and Si ( $P = < 0.001 - 0.043$ ), and the Los Angeles population to AIR ( $P = 0.003 - 0.035$ ). Measures of adiposity were also evaluated for association. In combined populations analyses, visceral and subcutaneous adipose tissue, measured by computed tomography, were significantly associated ( $P = 0.002 - 0.012$ ). In center specific analyses, the San Luis Valley and Los Angeles populations showed associations to waist and waist to hip ratio ( $P = < 0.001 - 0.050$ ). In conclusion, PTP-1B polymorphisms are associated with measures of glucose homeostasis and have moderate, but significant associations with adiposity measures in Hispanic and African American populations.

**Amino acid substitutions underlying Mendelian disease are different from those implicated in complex diseases.**  
*P.D. Thomas*<sup>1</sup>, *A. Kejariwal*<sup>1</sup>, *D.A. Gilbert*<sup>2</sup>, *J.J. Sninsky*<sup>3</sup>. 1) Protein Informatics, Celera Genomics, Foster City, CA; 2) Applied Biosystems, Foster City, CA; 3) Celera Diagnostics, Alameda, CA.

We have recently developed a method for quantifying the severity of amino acid substitutions, based on an evolutionary conservation score (Thomas *et al.*, *Genome Research*, in press). In brief, the method uses an alignment of evolutionarily-related protein sequences and statistics from Hidden Markov Models, to estimate the probability that a given substitution at a given position will affect the proteins function. In other words, whether a substitution is conservative or radical will depend not only on the amino acids involved, but *where* in the protein it occurs. We have shown that these position-specific scores are much better than amino acid difference scores, such as the Grantham scale, at distinguishing known (mostly Mendelian) disease-causing alleles from normal variation. Here, we apply this method to analyzing amino acid substitutions (cSNPs) that are believed to play causative roles in Mendelian and complex diseases. We show that Mendelian disease cSNPs have a very strong tendency to occur in the most highly conserved regions of proteins, suggesting that they generally have a severe impact on the molecular-level function of the protein. Putative causative cSNPs underlying complex diseases, however, have a significantly weaker tendency to occur at conserved sites. In fact, the distribution of evolutionary conservation scores for complex disease cSNPs is much more similar to the distribution for normal human variation, than it is to the distribution for Mendelian disease cSNPs. Although there are relatively few generally accepted cSNPs implicated in complex disease, the difference from Mendelian disease cSNPs is statistically significant with  $P < 10^{-6}$ . This suggests that caution should be exercised when using Mendelian disease as a model for complex disease, at least with respect to molecular-level effects on protein function.

**The spectrum and frequency of MEFV, TNFRSF1A, and NALP3/CIAS1/PYPAF1 mutations in patients with AA amyloidosis associated with systemic inflammation.** *E. Aganna<sup>1</sup>, P.N. Hawkins<sup>2</sup>, H.J. Lachmann<sup>2</sup>, A. Bybee<sup>2</sup>, L. Karenko<sup>3</sup>, T. Pettersson<sup>3</sup>, A. Ranki<sup>3</sup>, G.A. Hitman<sup>1</sup>, P. Woo<sup>4</sup>, M.F. McDermott<sup>1</sup>.* 1) Unit of Molecular Medicine, Barts and London, UK; 2) Centre for Amyloidosis, Royal Free, UK; 3) Dept. of Medicine, Helsinki University, Finland; 4) Rheumatology, University College, London, UK.

**Objective:** We have investigated for the presence of mutations in the MEFV, TNFRSF1A, and NALP3/CIAS1/PYPAF1 genes in patients suffering from recurrent inflammatory attacks with and without AA amyloidosis. **Methods:** Genomic DNA from 233 unrelated patients with recurrent inflammatory attacks due to variety of conditions [juvenile idiopathic arthritis (JIA), rheumatoid arthritis (RA), Crohn's disease and periodic fever syndromes] were analysed. Mutational screening was done using the Transgenomic DHPLC (WAVE) system with subsequent sequencing of samples using an ABI 3100 automated sequencer and standard restriction fragment length analysis. **Results:** Four of 67 RA patients with amyloidosis had MEFV gene variants; of these 3 had E148Q, one being homozygous and two heterozygous; the fourth FMF patient had the V726A mutation, which is one of the five common mutations in FMF. It was also notable that in a TRAPS family (4 affected members with C88Y TNFRSF1A mutation) the single patient with amyloidosis was the only individual with E148Q. Two JIA patients with amyloidosis were found to have an R92Q variant of TNFRSF1A. A novel C to G transition in exon 2 of this gene, producing a histidine to glutamine at residue 22 (H22Q), was identified in a patient with JIA without AA amyloidosis. The reduced penetrance V200M variant of NALP3/CIAS1/PYPAF1, was identified in one FMF patient with amyloidosis and in an RA patient without amyloidosis. **Conclusion:** We have identified two MEFV gene variants in 67 RA patients with amyloidosis but none in 34 RA patients without amyloidosis. The R92Q TNFRSF1A variant was found in 2 of 61 JIA patients with AA amyloidosis but not in 80 controls. Mutations in the MEFV and TNFRSF1A genes may play a role in the development of AA amyloidosis in RA and JIA patients and E148Q increases the risk of this complication in TRAPS patients.

**Association analysis of VDR, -2-Macroglobulin, TNFR11, FcR111A and ACE gene polymorphisms in South Asian Rheumatoid Arthritis patients of the East Midlands, UK.** A. Ghelani<sup>1</sup>, A. Pacynko<sup>1</sup>, A. Gilmour<sup>1</sup>, L. Goh<sup>2</sup>, A. Jones<sup>3</sup>, A. Samanta<sup>2</sup>, J.I. Robinson<sup>4</sup>, A.W. Morgan<sup>4</sup>, J.D. Isaacs<sup>5</sup>, S.S. Mastana<sup>1</sup>. 1) Human Sciences, Loughborough University, Loughborough,UK; 2) Leicester Royal Infirmary, Leicester, UK; 3) City Hospital, Nottingham,UK; 4) St. James' University Hospital, Leeds,UK; 5) University Medical School, Newcastle Upon Tyne, UK.

**Introduction:** Rheumatoid Arthritis (RA) is a polygenic disease characterised by localised joint destruction. The pathogenesis of RA is complex but genetic factors such as Vitamin D receptor (VDR) gene which regulates the bone turnover and mass, Alpha-2-macroglobulin (A2M) involved in modulation of cytokines may play a significant role. Tumor necrosis factor RII (TNFR11) is associated with tissue destruction. FcR111A is linked with the clearance of immune complexes and Angiotensin-converting enzyme (ACE) is expressed in the synovial membranes during angiogenesis. We have analysed VDR, A2M, TNFR11, FcR111A and ACE genotypes in the development of RA amongst South Asians. **Methods:** DNA samples from 132 South Asian RA patients and 142 matched controls were analysed for VDR, A2M, TNFR11, FcR111A and ACE loci. The association analysis was performed by computing Odds ratios and Chi-square values ( $P < 0.05$ ). **Results:** Our results indicate an increased frequency of BB genotype of VDR gene in patients compared to controls leading to highly significant differences ( $\chi^2 = 24.70$ , DF 2,  $P < 0.01$ ). Similarly, A2M 22 genotype was prominent in patients ( $\chi^2 = 10.61$ , DF 2,  $P < 0.01$ ). TNFR11(GG) and FcR111A (VV) genotypes were slightly higher in patients but not did attain statistical significance. The ACE I/D polymorphism was not associated with RA in the present sample. The BB genotype of VDR locus (Odds ratio = 3.89) and A2M 22 genotype (Odds ratio = 4.18) were associated with RA. **Conclusions:** Our preliminary analyses suggests that the VDR BB and A2M 22 genotypes were associated with RA among South Asians. The mechanism by which the VDR polymorphism is associated with RA is unknown, but they could be related to immuno-regulatory properties of vitamin D. A2M association may be due to cytokine binding affinity which could modulate the progression of RA.

**A Candidate Gene for Idiopathic Scoliosis.** *S. Bashiardes*<sup>1</sup>, *R. Veile*<sup>1</sup>, *C.A. Wise*<sup>2</sup>, *L. Szappanos*<sup>2</sup>, *M. Lovett*<sup>1</sup>. 1) Genetics, Washington University, St. Louis, MO; 2) Texas Scottish Rite Hospital for Children, Dallas, TX.

Idiopathic scoliosis (IS) affects approximately 1-2% of the population. The genetics of this disorder are complex and several loci have been suggested with genome-wide linkage scans. Here we describe a family in which a pericentric inversion of chromosome 8 co-segregates with idiopathic scoliosis. It is possible that scoliosis was caused by disruption of a gene at one of these breakpoints. To further characterize these regions we used fluorescent in situ hybridization (FISH) to identify cloned DNAs that span the breakpoints on both chromosomal arms. We identified a BAC of 150kb that crosses the q arm breakpoint and a BAC of 120kb that crosses the p arm breakpoint. The complete genomic DNA sequences of these BACs were analyzed to identify candidate genes and to further localize the precise breakpoint. This revealed that the p-arm breakpoint does not appear to disrupt any known gene and occurs in a region of highly repetitive sequence elements. On the q-arm, the break occurs between exons 10 and 11 of the gamma-1 syntrophin (SNTG1) gene. Syntrophins are a group of cytoplasmic peripheral membrane proteins that associate directly with dystrophin, the Duchenne muscular dystrophy gene. Dystrophin acts as a protein complex scaffold and different members of the syntrophin family bind dystrophin depending on the type of tissue. Gamma- 1 syntrophin has been shown to be a neuronal cell specific protein. Preliminary analysis of 152 sporadic IS patients revealed a 6 base deletion in exon 10 of SNTG1 in one patient and a single base pair mutation occurring in a polypyrimidine tract of intronic sequence 20 bases upstream of the SNTG1 exon 5 splice site in another patient. These changes were not seen in a screen of 240 control chromosomes. At present, it is unclear whether alterations to SNTG1 co-segregate with scoliosis in any familial cases of IS.

**Smoking status and Estrogen Receptor genotype show significant interaction with Bone Mineral Density in the Framingham Offspring Study.** A. Shearman<sup>1</sup>, D. Karasik<sup>2</sup>, L.A. Cupples<sup>3</sup>, S. Coven<sup>1</sup>, K. Gruenthal<sup>1</sup>, D.E. Housman<sup>1</sup>, D.P. Kiel<sup>2</sup>. 1) Center Cancer Res, Massachusetts Inst Technology, Cambridge, MA; 2) Hebrew Rehab Ctr for Aged & Harvard Med Sch, Boston, MA; 3) Biostatistics, BU Sch of Public Health, Boston, MA.

There are conflicting results from studies of estrogen receptor alpha (ESR1) polymorphisms and bone mineral density (BMD). Smoking affects estrogen metabolism, is associated with lower BMD and greater risk of osteoporosis, and may affect ESR1 transcription. We hypothesized that smoking might influence the association between ESR1 and BMD. We studied 732 men and 792 women (mean age 60 yrs). BMD was measured by DXA at the hip and lumbar spine. Covariates: age, height, BMI, current cigarette smoking (12% of men and 15% of women), and estrogen use in women. Six common ESR1 polymorphisms were genotyped. We used ANOVA/ANCOVA to estimate the main effects of each polymorphism, as well as haplotype probabilities derived using the expectation-maximization algorithm, on crude and covariate-adjusted BMD in each sex separately. No significant main associations between ESR1 polymorphisms and BMD were observed. In contrast, significant interactions between PvuII and XbaI genotypes, smoking, and BMD ( $p = 0.004$  to  $0.01$ ) were found in men, but not women. PvuII and XbaI are in strong LD and in men interactions were also found between smoking, common haplotypes, and BMD at the hip. A substantial additive effect of combined PvuII and XbaI genotypes was found only among men who smoked: BMD was higher in pp-xx compared to PP-XX, difference of 12% (femoral neck), 14% (trochanter), 20% (Wards area), and 9% (lumbar spine). Conclusion: common Estrogen Receptor polymorphisms are associated with BMD in men who smoke. This highlights the important role of estrogen in men, and more generally of environmental interactions and the need for studies large enough to identify them.

**Linkage of Reading Disabilities and Attention-Deficit Hyperactivity Disorder to the Chromosome 15q Region.** C.

*Barr*<sup>1,2</sup>, *Y. Feng*<sup>1</sup>, *T. Pathare*<sup>2</sup>, *B. Anderson*<sup>2</sup>, *T. Cate-Carter*<sup>2</sup>, *J. Crosbie*<sup>2</sup>, *M. Malone*<sup>2</sup>, *W. Roberts*<sup>2</sup>, *R. Tannock*<sup>2</sup>, *A. Ickowicz*<sup>2</sup>, *R. Schachar*<sup>2</sup>, *M. Lovett*<sup>2</sup>, *T. Humphries*<sup>2</sup>, *J. Kennedy*<sup>3</sup>, *K. Wigg*<sup>1</sup>. 1) Toronto Western Hospital; 2) The Hospital for Sick Children; 3) The Centre for Addiction and Mental Health, Toronto, ON, Canada.

Twin studies support an overlap in the heritabilities for specific reading disabilities (RD) and attention-deficit hyperactivity disorder (ADHD), with 95% of the overlap for inattention symptoms and RD due to common genetic influences. Linkage findings have been reported for several regions for RD (1p, 2p, 6p, 6q, 15q, 18p) with the 6p and 15q regions reported to be linked to the ADHD phenotype in families with RD. We investigated the overlap of these phenotypes in the 15q region using two samples of nuclear families, one ascertained through a proband with reading difficulties (n=118 families) and the other through a proband with ADHD (n=186 families). Based on previous studies of this region, four microsatellite markers, D15S214, D15S994, D15S146 and D15S143, were chosen to be genotyped in these families. Using the transmission disequilibrium test (TDT) we found evidence for biased transmission of alleles of the marker D15S146 in the ADHD sample for the ADHD phenotype as a categorical trait (chi-square =6.5, 1d.f., p=0.01) and in the RD sample for the categorical trait of RD (chi-square=5.4, 1 d.f., p=0.02). The D15S146 marker is located in an intron of a putative G-protein coupled receptor gene (GPR). To further investigate this region, we genotyped 3 SNPs in the GPR locus, flanking the D15S146 marker. Haplotype analysis of these markers in the ADHD sample showed one haplotype with biased transmission to affected children (chi-square=4.6, 1d.f., p=0.03). Using a quantitative approach to look at evidence for linkage to the reading phenotypes of phonological awareness, decoding, and word identification we observed evidence for linkage to one of the GPR markers in the RD sample. Our study provides evidence for a susceptibility locus contributing to both RD and ADHD in the 15q region. Further the finding of allelic association for the D15S146 and GPR markers, substantially narrows the region in which this gene resides.

**Molecular characterization of chromosome 4p inversion breakpoints in two autistic siblings.** *S. Choufani*<sup>1</sup>, *J. Vincent*<sup>1, 3</sup>, *J. Skaug*<sup>1</sup>, *M. Li*<sup>1</sup>, *D.A. Kwasnicka*<sup>1</sup>, *B.A. Fernandez*<sup>4</sup>, *P. Szatmari*<sup>5</sup>, *W. Roberts*<sup>2</sup>, *S.W. Scherer*<sup>1</sup>. 1) Department of Genetics and Genomic Biology; 2) The Child development Center, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, On; 4) Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, St. John's, Nf; 5) Canadian centre for Studies of Children at Risk, Hamilton, On, Canada.

Autism is a severe neurodevelopmental disorder, characterized by impairments in social interaction and communication skills. Chromosomal abnormalities among autistic individuals have been described, and include almost all chromosomes. We describe here two brothers diagnosed with autism and having paracentric inversion of the short arm of chromosome 4 [46, XY, inv(4) (p12-p15.3)]. It was determined that this inversion was inherited from an apparently unaffected mother. Bacterial artificial chromosome (BAC) clones spanning the breakpoints were identified by means of fluorescence in situ hybridization (FISH) analysis. The distal p15.3 breakpoint was present between D4S3036 and D4S2906. A region downstream to this (12Mb) was linked to autism at markers D4S2936 and D4S412 using ASPEX with a multipoint (MLS) of 1.55 (IMGSA, 1998). The proximal breakpoint was between D4S1536 and D4S396 in a region previously shown to be disrupted in a familiar case of autism in a girl having dup (4) p12-p13 (Sabaratnam M. et al., 2000). The proximal breakpoint (4p12) maps to a region containing a cluster of the gamma-aminobutyric acid A (GABA(A)) receptor genes. This region is of particular interest because elevated plasma GABA levels have been reported in autistic children suggesting a role for GABA as biochemical marker for autistic disorder. Furthermore, another cluster of GABA(A) receptor genes are located in the 15q11-q13 candidate autism region. Our findings provide further support for the possible involvement of the short arm of chromosome 4 in the genetic etiology of autism. We are currently assessing all candidate genes in the vicinity of the breakpoints by sequencing DNA samples from autistic multiplex families.

**GENETIC STUDY OF PARAOXONASE GENE VARIANTS IN AUTISTIC DISORDER.** *M. D'Amelio*<sup>1</sup>, *T.H. Wassink*<sup>2</sup>, *L. Muscarella*<sup>3</sup>, *V. Guarnieri*<sup>3</sup>, *L. We have described an association, replicated in at least two independent studies, between autism and long alleles of a polymorphic GGC repeat located in the 5'UTR of the gene encoding Reelin, a pivotal protein for neuronal migration during neurodevelopment. We have also found that long GGC alleles yield reduced protein translation rates, both in vitro and in vivo, and that Reelin exerts a proteolytic activity potently inhibited by organophosphates (OP), compounds routinely used as pesticides and insecticides. Within the framework of a gene-environment interactive model, genetically-vulnerable individuals producing lower amounts of Reelin, if prenatally exposed to OP during critical periods in neurodevelopment, could undergo altered neuronal migration resulting in an autistic syndrome. Paraoxonase, the enzyme responsible for OP detoxification, displays impressive 40-fold interindividual differences in humans, largely resulting from functional polymorphisms present in the paraoxonase (PON1) gene, located on human ch 7q21.3. Current studies carried out on 263 complete trios with primary autistic probands using functional SNPs located in the promoter and coding sequence of the PON1 gene yield significant linkage/association (Q192R TDT  $\chi^2 = 4.85$ , 1df,  $P < 0.05$ ) in Caucasian-American and not in Italian families, as predicted on the basis of our prior Reelin findings. Supported by Telethon-Italy (GPP02019), the Fondation Jerome Lejeune, and the CAN/AGRE.

**Ghrelin and Peptide YY Levels and Gene Expression in Prader-Willi Syndrome.** *M.G. Butler, Z. Talebizadeh, D.C. Bittel.* Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prader-Willi syndrome (PWS) is due to imprinting caused by a deficiency in expression of paternal genes on chromosome 15q11-q13 through a deletion (Del) or UPD. One of the main hallmarks of PWS is an insatiable appetite leading to early childhood obesity. An important objective of our study is to better understand the abnormalities in appetite-regulating pathways in PWS including at the gene level. Ghrelin and peptide YY are produced by the gastrointestinal system and involved with controlling appetite. We obtained fasting plasma ghrelin and peptide YY (PYY) levels in 12 PWS infants and children ranging in age from 2.5 months to 13.3 years and six healthy control subjects ranging in age from 5 to 43 years. Ghrelin levels in our PWS children and infants were similar to other PWS subjects and were significantly higher (3 to 5X) than reported in obese children without PWS. Interestingly, the PYY levels in our PWS group were lower than reported in similarly aged subjects without PWS. It is unclear why ghrelin levels are high and peptide YY levels are low in subjects with PWS. The genes for ghrelin, peptide YY and their receptors (i.e., GHS-Ra1, GHS-Rb1 and NPY2) are not localized on chromosome 15q. We performed preliminary gene expression studies using quantitative RT-PCR on 4 of these subjects [1 control (15-yrs-old male) and 1 subject from each PWS genetic subtype (1-yr-old female Del; 1.5-yrs-old female UPD; and 13-yrs-old male IC)]. Expression level of ghrelin, GHS-Ra1, GHS-Rb1, PYY and NPY2 were measured in RNA extracted from lymphoblast cell lines. GAPDH, a housekeeping gene, was used to normalize the expression data. All five genes showed higher expression levels (e.g., 2X) in the control than PWS subjects. In addition, the UPD and deletion subjects had markedly lower expression level than the PWS subject with an imprinting defect. The expression levels of these genes will be measured in additional subjects (controls and PWS). Expression studies with the five genes were also performed in frontal cortex from our 1-yr-old female Del subject and will be compared with other regions of the brain as well as brain tissue from control subjects.

**Genetic variants in a haplotype block spanning *IDE* influence plasma A42 levels and risk for Alzheimers disease.**

*N. Ertekin-Taner*<sup>1,2</sup>, *M. Allen*<sup>2</sup>, *D. Fadale*<sup>2</sup>, *L. Scanlin*<sup>2</sup>, *L. Younkin*<sup>2</sup>, *R.C. Petersen*<sup>3</sup>, *N. Graff-Radford*<sup>4</sup>, *S.G. Younkin*<sup>2</sup>.

1) Dept Neuroscience, Mayo Clinic, Rochester, MN; 2) Dept Neuroscience, Mayo Clinic, Jacksonville, FL; 3) Dept Neurology, Mayo Clinic, Rochester, MN; 4) Dept Neurology, Mayo Clinic, Jacksonville, FL.

Risk for late onset Alzheimers disease (LOAD) and plasma A42 levels, an intermediate phenotype for LOAD, show linkage to chromosome 10q. Several strong candidate genes (*VR22*, *PLAU*, *IDE*) lie within the 1-lod support interval for linkage. Two groups independently identified haplotypes in the chromosome 10q region harboring *IDE* that show highly significant association with intermediate AD phenotypes and with risk for AD. To pursue these associations, we analyzed the same haplotypes for association with plasma A42 in 24 extended LOAD families and for association with LOAD in two independent case-control series. One series (MCR, 183 age-matched case-control pairs) did not show association ( $p=0.43$ ) with the six haplotypes in the 276 kb region spanning three genes (*IDE*, *KNSL1*, and *HHEX*), previously shown to associate with LOAD. The other series (MCJ, 93 age-matched case-control pairs) showed highly significant ( $p<10^{-7}$ ) association with these haplotypes. In the MCJ series, the H4 (OR=5.1,  $p=0.001$ ) and H5(H10) haplotypes (OR=0.45,  $p=0.06$ ) had the same effects previously reported. In this series, the H8 haplotype (OR=5.3,  $p<0.001$ ) also had a significant effect as in one previous case control series but not in others. In the extended families, the H8 haplotype was associated with significantly elevated plasma A42 ( $p=0.02$ ) and the H5(H10) haplotype with reduced plasma A42 ( $p=0.007$ ). These results provide strong evidence for pathogenic variant(s) in the 276 kb region harboring *IDE* that influence intermediate AD phenotypes and risk for AD.

Using plasma amyloid protein (A42) levels as an intermediate, quantitative phenotype for late onset Alzheimers disease (LOAD), we previously obtained significant linkage at 80 centimorgans (cM) on chromosome 10. Linkage to the same region was obtained independently in a study of affected LOAD sib-pairs. Together, these two studies provide strong evidence for a novel LOAD locus on chromosome 10 that acts to increase A42. *VR22* is a large (1.7 Mb) gene located at 80 cM that encodes -T catenin, which is a binding partner of catenin. This makes *VR22* an attractive candidate gene because catenin interacts with presenilin 1, which has many mutations that elevate A42 and cause early onset familial AD. We identified two intronic *VR22* SNPs (4360 and 4783) in strong linkage disequilibrium (LD) that showed highly significant association ( $p=0.0001$  and  $0.0006$ ) with plasma A42 in 10 extended LOAD families. This association clearly contributed to the linkage at 80 cM because the lod scores decreased when linkage analysis was performed conditional upon the *VR22* association. The association was robust because it replicated in two independent sets of LOAD families. Bounding of the association region using multiple SNPs showed *VR22* to be the only confirmed gene within the region of association. These findings indicate that *VR22* has variant(s) which influence A42 and contribute to the previously reported linkage for plasma A42 in LOAD families.

**NON-ALLELIC GENETIC HETEROGENEITY IN AUTOSOMAL DOMINANT LATERAL TEMPORAL LOBE EPILEPSY AND ABSENCE OF LGI1 MUTATIONS IN FAMILIAL MESIAL TEMPORAL LOBE**

**EPILEPSY.** A. Badhwar<sup>1</sup>, L. Racacho<sup>3</sup>, D. D'Agostino<sup>1</sup>, F. Dubeau<sup>1</sup>, F. Andermann<sup>1</sup>, D. Bulman<sup>3</sup>, E. Andermann<sup>1, 2</sup>. 1) Dept Neurology & Neurosurg, Montreal Neurological Hospital and Institute, McGill Univ, Montreal, PQ, Canada; 2) Dept Human Genetics, McGill Univ; 3) Ottawa Health Research Institute, Ottawa, Ontario, Canada.

Familial temporal lobe epilepsy (FTLE) is subdivided into two groups: familial mesial temporal lobe epilepsy (FMTLE) and autosomal dominant lateral temporal lobe epilepsy (ADLTLE) with auditory features. Mutations in LGI1 (chr10q23) were identified in several ADLTLE families. Since we found occasional individuals with auditory features in FMTLE families, we evaluated 21 FTLE patients for mutations in LGI1, postulating either pleiotropy or allelic heterogeneity of these two conditions. Detailed clinical and family histories were obtained in 18 FTLE families. 21 patients (18 probands) were screened for mutations in the LGI1 gene. Each exon and the surrounding splice sites were amplified by PCR and sequenced directly. In total, 8 exons were sequenced as well as the entire intron between exons 3 and 4. Mean age of onset was 15.7 years, ranging from infancy to 52 years. 20% had a history of febrile convulsions, 13% had *deja-vu*. 40% had intractable seizures, and 13% had been operated successfully. Seizure types included simple partial, complex partial and occasional secondary generalization. Three probands were the only ones in their families with auditory hallucinations. 56% showed hippocampal atrophy and 33% had hippocampal gliosis. There was an average of 3.7 relatives with epilepsy per family, most with temporal lobe epilepsy. No mutations of the LGI1 gene were identified. We identified two known and one novel SNP. The lack of mutations in LGI1 in our families suggests that the molecular basis of FMTLE differs from that in ADLTLE. Furthermore, absence of LGI1 mutations in our patients with auditory features demonstrates non-allelic heterogeneity in ADLTLE.

**Variant in calcium-sensing receptor promoter region is associated with Alzheimer disease status.** *Y. Conley*<sup>1,2</sup>, *H. Brockway*<sup>1</sup>, *D. Finegold*<sup>2</sup>, *R. Ferrell*<sup>2</sup>. 1) Health Promotion & Development; 2) Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

The calcium-sensing receptor (CASR) is primarily involved with systemic calcium ion homeostasis, although its systemic function does not explain why it is expressed in brain tissue. We previously reported the association of an intronic CASR polymorphism with Alzheimer disease (AD) status. We believed that this polymorphism was likely to be in linkage disequilibrium with another variant in or around the CASR gene and began screening the coding region, intron/exon boundaries, and promoter region of the CASR gene for a variant that could have a functional impact on the CASR. Using dHPLC we located a previously unreported variant in the CASR promoter region. It is located in the second promoter, 176nt away from the alternative transcriptional start site. We genotyped a subset of our AD cases and controls for the variant, and detected a significant association between the variant and AD status. Genotype and allele frequencies differed significantly ( $p < 0.001$ ) between AD cases ( $n=274$ ) and age-matched, race-matched, geographically matched and non-demented controls ( $n=162$ ). Of note is that this variant is only 8nt away from a vitamin D response element. Experiments are currently in progress to assess this variant for functionality, postulating that it could alter level of expression of the CASR gene product.

**Deletion of the endogenous mouse Snca gene markedly exacerbates synucleinopathy in transgenic mice expressing Ala53->Thr.** *D.E. Cabin*<sup>1</sup>, *S. Gispert*<sup>2</sup>, *D. Murphy*<sup>3</sup>, *G. Auburger*<sup>5</sup>, *R. Myers*<sup>4</sup>, *R.L. Nussbaum*<sup>1</sup>. 1) NHGRI/GDRB, NIH, Bethesda, MD; 2) Institute for Experimental Neurobiology University Frankfurt/M, Germany; 3) National Institute for Neurological Disease and Stroke, NIH, Bethesda, MD; 4) University of California at San Diego, San Diego, CA; 5) Section Molecular Neurogenetics, Bldg 26, University Hospital, Frankfurt/M, Germany.

Mutations in  $\alpha$ -synuclein (SNCA) are known to cause Parkinsons disease in a subset of familial cases. The normal function of SNCA is unknown, but it is a component of Lewy bodies, the neuronal inclusions diagnostic for Parkinsons disease. An A53T human SNCA transgene under the control of the mouse prion promoter was crossed onto mice that lack endogenous Snca. Though the expression level of the mutant transgene is low, knockout mice expressing only the human mutant SNCA develop a fast-progressing limb weakness and paralysis with the earliest age of onset at 16 months and peaking at about 19 months of age. This is probably caused by inappropriate expression of A53T SNCA in the spinal cord, particularly in the ventral region, leading to Wallerian degeneration in the ventral roots. However, mice carrying the same transgene on a wild type background only rarely develop the neuropathy and only at a later age. This may be due to some protective effect of the mouse protein, though endogenous levels are low in the ventral spinal cord and roots. At position 53, the wild type mouse amino acid is the same as the human mutation, indicating that mice are either too short-lived to suffer ill effects from the threonine, or else have developed compensatory changes elsewhere in Snca or in other proteins. Our results shows that the best approach to generating good mouse models for Parkinsons disease will be to use human transgenes controlled by a promoter that does not drive spinal cord expression in mice that lack endogenous Snca.

**Association Study Of Dopamine D2 Receptor (DR2) and Bipolar Affective Disorder in Colombian Population.** C. Duran<sup>1</sup>, J.C. Prieto<sup>1,2</sup>, A. Ordonez<sup>1</sup>, J.F. Ortiz<sup>3</sup>, D. Patermina<sup>3</sup>, R. Tamayo<sup>3</sup>, F. Rivadeneira<sup>3</sup>, C. Gomez<sup>3</sup>. 1) Instituto de Genetica Humana, Universidad Javeriana., Bogota, Cundinamarca, Colombia; 2) Hospital la Victoria, SDS, Bogota, Colombia; 3) Hospital San Ignacio, Departamento Psiquiatria, Bogota, Colombia.

Bipolar affective disorder (BPD) is a major psychiatric disorder that affects 1% of the population worldwide and it is characterized by episodes of mania and depression. The studies suggesting the dopamine D2 receptor (DRD2) gene as a candidate gene for schizophrenia includes the correlation of the antipsychotic potency of neuroleptic drugs with their affinity for the receptor. In Japanese was found the variant Cys 311, produced by a substitution of serine with cysteine (Ser 311-Cys) at codon 311 of the receptor. The objective of this study is to investigate association of the variant Cys 311 of the dopamine D2 receptor gene. We have performed a case-control analysis in 62 cases with bipolar affective disorder and 81 control subjects. Allele frequencies for Ser311 and Cys 311 alleles were similar in the control subjects Ser311=0.975, Cys311=0.025 and cases Ser311=0.984 and Cys311=0.016. No statistically significant difference in the allele frequencies (chi square 0.241, p=0.623) was observed between cases and control likewise we found no evidence of association of this polymorphism with BPD in this sample. Our results suggest other genes involving in BPD in our population.

**Frequency of the Glucocerebrosidase N370S Mutation and Susceptibility to Parkinson's Disease in a Cohort of Ashkenazi Jewish Ethnicity.** *L.N. Clark<sup>1, 2</sup>, A. Nicolai<sup>2</sup>, J. Harris<sup>4</sup>, H. Mejia-Santana<sup>3</sup>, L.J. Cote<sup>3, 4</sup>, E.D. Louis<sup>3, 4</sup>, S. Fahn<sup>3</sup>, K. Marder<sup>1, 3, 4</sup>.* 1) Taub Institute for Research on Alzheimer's Disease and the Aging Brain; 2) Department of Pathology; 3) Gertrude H. Sergievsky Center; 4) Department of Neurology, Columbia University, New York, NY.

Mutations in the glucocerebrosidase gene located at chromosome 1q21 are associated with Gaucher Disease (MIM 230800), a glycolipid storage disorder that is clinically heterogeneous presenting with a wide spectrum of phenotypes, including neuronopathic and non-neuronopathic forms. Recent studies suggest that a deficiency in glucocerebrosidase associated with a milder form of late-onset Type I Gaucher disease may contribute to a susceptibility to Parkinson's disease. One of the most common mutations reported in Ashkenazi Jewish patients with Type I Gaucher disease is N370S with the gene frequency for this allele estimated to be 0.031 in this population. In one study, Tayebi et al (2003) showed that 82% of patients with parkinsonian symptoms had at least one N370S mutant allele (all six Ashkenazi Jewish patients included in the study had one N370S allele with 4 patients homozygous for N370S), and although brain glucosylsphingosine levels were not elevated a loss of pigmented neurons in the substantia nigra and Lewy bodies were observed in post mortem tissue available for four probands. To determine the frequency and relative genetic contribution of N370S to Parkinson's disease in patients of Ashkenazi Jewish ethnicity we have determined genotypes in a large clinically well-characterized Ashkenazi Jewish cohort of 192 PD probands that includes 59 early-onset cases (mean age at onset 43.6 years) and 133 late-onset cases (mean age at onset 65.5 years) that were ascertained independent of family history in addition to controls matched by gender, education and ethnicity. PD cases were recruited from the Center for Parkinson's Disease and Other Movement Disorders (CPD) at the College of Physicians and Surgeons at Columbia University. We report the frequency of the N370S Glucocerebrosidase mutation in both early-onset and late-onset Parkinson's disease cases of Ashkenazi Jewish ethnicity.

**Gene expression of APOE allele specific hippocampal tissues in Alzheimers disease.** *J.R. Gilbert<sup>1</sup>, Y-J. Li<sup>1</sup>, P-T. Xu<sup>1</sup>, X.J. Qin<sup>1</sup>, D. Schmechel<sup>3</sup>, C. Hulette<sup>3</sup>, A. McLaurin<sup>1</sup>, C. Sherzer<sup>4</sup>, S. Gullans<sup>4</sup>, J. Haines<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Center for Human Genetics, Duke Univ, Durham, NC; 2) PHG, Vanderbilt Univ. Nashville, TN; 3) ADRC, Duke Univ. Med, Ctr, Durham, NC; 4) Brigham and Womens Hospital, Boston, MA.

Total RNA was isolated from the hippocampi of 12 Alzheimer disease (AD) patients and 3 age matched controls. AD patients were of APOE4/4, APOE4/3, and APOE3/3 genotypes and matched for Braak and Braak (B&B) stages IV and V and post mortem delay. Controls were APOE3/3 (B&B stage I). Gene expression in these samples was assayed using Affymetrix GeneChips (U133A) microarrays containing 22,000 predicted or known human genes. Gene expression analysis showed significant differential expression between AD hippocampus and controls, and between APOE 4/4 and 3/3 AD samples, but not between B&B stage IV and V AD tissues. For analysis genes with average raw sample signal intensity of less than 500 were excluded from statistical analysis. After statistical filtering 1541 genes remained for analysis. A p value of 0.05 was used as a cut-off for significance. The methods of Benjamini and Hochberg were used to estimate the false discovery rate (FDR). A two-sample t-test identified 237 significant differentially expressed genes between AD and controls by p-values, with 124 genes showing significant results by FDR. For the comparison of B&B stages IV and V within AD samples, 48 genes demonstrated significant differential expression by p-values, but were excluded after FDR correction, implying that gene expression patterns do not significantly change between B&B stages IV and V. The APOE genotype of AD patients did have an effect on gene expression with 99 genes showing significant expression differences by the p-value and 27 genes after FDR correction between APOE 4/4 and APOE 3/3 of AD samples. This study will identify differentially expressed genes between AD and control individuals as well as significant affected pathways and potential candidate genes for further study. These data will also be integrated with our ongoing genetic mapping studies (genomic convergence) to identify high priority candidate genes for AD genetic risk.

Program Nr: 2001 from 2003 ASHG Annual Meeting

**Possible association between haplotype of the GABA-A receptor alpha 1 subunit gene (GABRA1) and mood disorders.** *Y. Horiuchi<sup>1</sup>, J. Nakayama<sup>1</sup>, H. Ishiguro<sup>1</sup>, T. Ohtsuki<sup>1</sup>, T. Toyota<sup>2</sup>, K. Yamada<sup>2</sup>, M. Nankai<sup>3</sup>, H. Shibuya<sup>4</sup>, T. Yoshikawa<sup>2</sup>, T. Arinami<sup>1</sup>.* 1) Dept Medical Genetics, Univ Tsukuba, Tsukuba, Japan; 2) Laboratory for Molecular Psychiatry, RIKEN Brain Science Institute, Wako, Saitama, Japan; 3) Tokyo Metropolitan Police Hospital, Department of Neuropsychiatry, Tokyo, Japan; 4) National Sanatorium Minami-Hanamaki Hospital, Hanamaki, Iwate, Japan.

The gamma-aminobutyric acid (GABA) neurotransmitter system has been implicated in the pathogenesis of mood disorders. The GABRA1 gene encodes one of the subunits of GABA-A receptors and is located on human chromosome 5q34-q35, which is one of the regions reported to be linked to mood disorders. We examined the GABRA1 gene as a candidate for mood disorders. We performed mutation screening of the GABRA1 in 24 Japanese bipolar patients and evaluated associations in Japanese case-control subjects consisting of 125 bipolar patients, 147 patients with depressive disorders, and 192 healthy controls. We identified 13 polymorphisms in the GABRA1 gene. Associations of the specific haplotype with affective disorders was suggested in the Japanese case-control population ( $p=0.001$ ) These results indicate that the GABRA1 gene may play a role in the etiology of bipolar disorders.

**Cytogenetic and molecular characterization of a chromosome 3q inversion in a patient with language delay. D.A.**

*Kwasnicka*<sup>1</sup>, *A.M. Summers*<sup>2</sup>, *Y. Qi*<sup>1</sup>, *W. Roberts*<sup>3</sup>, *S. Choufani*<sup>1</sup>, *S.W. Scherer*<sup>1</sup>. 1) Department of Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Genetics, North York General Hospital, Toronto, Ontario, Canada; 3) Department of Pediatrics, The Child Developmental Center, Toronto, Ontario, Canada.

We describe a paracentric inversion of chromosome 3 (inv(3)(q25-29)) in a 5-year-old girl with developmental delay, delayed expressive, and receptive language. Haplotype data on the family suggest that the chromosomal origin of the inversion is inherited from the father, who is also language delayed but socially normal. The aim of the study is to characterize the q25-q29 chromosomal breakpoints in order to identify candidate genes associated with the phenotype. Bacterial artificial chromosome (BAC) clones spanning the breakpoints were identified using fluorescence in situ hybridization (FISH). The proximal and distal breakpoints were found to be located between genetic markers D3S2404/D3S1553 and D3S3642/D3S2305, respectively. Results from a genome scan in a genetically isolated multiplex Finnish families has recently provided evidence for a new autism susceptibility locus (AUTS2) on the chromosome 3q25-27 (Auranen et al., 2002). This might be relevant to our study since speech and language disorder is a common component of the autism phenotype. We are, therefore, working to refine the precise site of the inversion breakpoints to identify candidate genes for testing in additional patients with language disorder, as well as those who fall within the autism-spectrum.

**DNA pooling identifies association of the noradrenergic transporter gene (NET1) with attention deficit hyperactivity disorder (ADHD).** *J. Knight, X. Xu, K. Brookes, J. Mill, P. Sham, E. Taylor, P. Asherson.* SGDP, Institute of Psychiatry, KCL, London, United Kingdom.

This study set out to identify associations between ADHD NET1. The noradrenergic system is known to play a role in attentional mechanisms and is thought to be important in ADHD. Stimulant medications are known to alter the activity of noradrenaline as well as dopamine in the synapse and the highly selective noradrenergic reuptake inhibitor, atomoxetine, is an effective treatment for ADHD symptoms. To date replicated associations have been described with several genes that regulate monoamine neurotransmission (DRD4, DAT1, SNAP-25, DRD5 and 5HT1B). Here we set out to investigate whether common polymorphisms within NET1 are associated with the DSM-IV ADHD combined subtype, using a sample that has previously shown association with genes that regulate synaptic release and reuptake of neurotransmitters (DAT1 and SNAP-25). We identified all SNPs from publicly available databases that have minor allele frequencies 10 % and span the NET1 genomic region (n=35). Heterozygosity rates were validated before association analysis (n=21 in final set). DNA pooling was used to screen for associations (n=180 cases, n=334 controls) and positive findings confirmed by individual genotyping. DNA was quantified for pooling by fluometry and allele frequency estimates obtained using a primer extension method (Snapshot). We identified 6 SNPs that showed significant allele frequency differences between the case and control pools (rs2242447 p=0.002; rs998424 p=0.00004; rs3785157 p=0.0007; rs747107 p=0.037; rs42460 p=0.046; rs2242446 p=0.049). Preliminary analysis of individual genotypes and multi-marker haplotypes support the initial DNA pooling results but do not provide additional evidence of association. Assuming these data reflect a true association, this suggests that a functional variant conferring risk for ADHD is likely to be in strong linkage disequilibrium with, or may indeed be, one of the three markers showing the highest evidence for association. Further work aims to confirm the association using within-family tests, identify likely functional variants and test for functionality.

**Association between nicotine dependence and an A/G polymorphism in the beta-muscular nicotinic acetylcholine receptor (CHRNA1) gene.** *J.Z. Ma<sup>1</sup>, J. Beuten<sup>1</sup>, R.T. Dupont<sup>2</sup>, K.M. Crews<sup>3</sup>, T.J. Payne<sup>3</sup>, M.D. Li<sup>1</sup>.* 1) The University of Texas Health Science Center, San Antonio, TX; 2) The University of Tennessee Health Science Center, Memphis, TN; 3) The University of Mississippi Medical Center, Jackson, MS.

Epidemiological studies have strongly implicated that genetics play a significant role in the determination of smoking behavior and nicotine dependence; however, the susceptibility genes responsible for these phenotypes remain to be characterized. Previously, our genome-wide linkage analysis indicated that the 17p13.1 chromosomal region might harbor candidate gene(s) for nicotine dependence. One of the genes located in this region is the beta-muscular nicotinic acetylcholine receptor gene which represents a potential candidate for influencing smoking behavior and nicotine dependence. Several single nucleotide polymorphisms within the CHRNA1 gene have been identified and two of them were assayed for association with smoking behavior in this study by using the 5' nuclease allelic discrimination technique in both Caucasian and African-American populations. Association analysis using the ASSOC program of the S.A.G.E. package suggested that there exists a strong association between an A/G polymorphism in the CHRNA1 gene and the number of cigarettes smoked per day, as well as and the Fagerstrom Test for Nicotine Dependence (FTND) score, in the African-American population under both the additive and dominance genetic model ( $P < 0.03$ ). However, no significant association was obtained between this A/G polymorphism and both phenotypes under the additive, dominance, or recessive model in the Caucasian population. These results suggest that this A/G polymorphism in the CHRNA1 gene may be related to nicotine dependence in the African-American population (supported by DA-12844).

Program Nr: 2005 from 2003 ASHG Annual Meeting

**Fine-mapping of a Chromosome 7 substance abuse vulnerability locus implicates NrCAM gene regulatory regions.** *H. Ishiguro, Q. Liu, G.R. Uhl.* Dept Molecular Neurobiology, NIDA/NIH, Baltimore, MD.

Classical genetic studies demonstrate substantial heritabilities for alcoholism and drug abuse, with most of the genetic vulnerabilities being shared between these two disorders. COGA consortium studies displayed alcoholism links to a broad chromosome 7 region centered on D7S1793 and D7S1830. Previous studies in our laboratory demonstrated association of SNP markers in this region with polysubstance abuse in each of two samples of NIDA research volunteers. To pursue fine mapping of this locus, I have examined 60 SSLP markers in this region in polysubstance abusers and control individuals. A cluster of chromosome 7 97-103 Mb markers revealed nominally-significant associations with substance abuse. In our lab, a neuronal cell adhesion molecule gene in this region (NrCAM) was previously defined as morphine-regulated, and as expressed in dopaminergic brain regions that are important for the rewarding effects of most if not all abused substances. Cocaine- and amphetamine-induced NrCAM regulation in mice brain are also identified, as well as receptor type protein tyrosine phosphatase beta (RPTPb), one of homologous or heterologous binding partners. Interactions between NrCAM and RPTPbeta could well influence the development or maintenance of brain circuits important for acute drug reward. We thus produced a sequence alignment and haplotype definitions in Caucasian and African-American samples in the human NrCAM genomic region, based on genotypes at SSLPs and SNPs. The genomic region associated with drug abuse and alcoholism contained several blocks of restricted haplotype diversity, and haplotypes that were associated with addiction vulnerability in several different populations. Initial studies of mRNAs from the brains of individuals heterozygous for these haplotypes reveal different levels of expression of NrCAM mRNAs from these two haplotypes. Allelic/haplotypic analysis for the RPTPbeta also suggests association with substance abuse. Convergent data from molecular genetic and neurobiological approaches thus strongly supports NrCAM, and possibly its binding partners, as important genes for human addiction vulnerability.

**7q Candidate Gene screening in Autistic disorder.** *M. Mori<sup>1</sup>, T. Yamagata<sup>1</sup>, H. Li<sup>1</sup>, T. Goto<sup>1</sup>, K. Suwa<sup>1</sup>, A. Yasuhara<sup>2</sup>, M.Y. Momoi<sup>1</sup>.* 1) Department of Pediatrics, Jichi Medical School, Tochigi, Japan; 2) Department of Pediatrics, Kouri Hospital, Kansai Medical University, Osaka, Japan.

Although many candidate gene loci were reported and a strong genetic component was indicated in autistic disorder, only a few diseases related genes were identified. Among these loci, Chromosome 7q is a strong candidate gene locus of autistic disorder. There are some positional-functional candidate genes such as FOXP2, Wnt family gene, small G-protein-coupled receptor genes on chromosome 7q. We previously analyzed and reported some candidate genes such as FOXP2 and HTR5a. This time we analyzed Wnt family genes and small G-protein-coupled receptor genes on chromosome 7q. Patients diagnosed as pervasive developmental disorder or autism according to the criteria of DSM-were enrolled in this study after informed consents by their parents. 70 Japanese patients and 100 American patients (from AGRE) were analyzed. This study was approved by the bioethics committee for human gene analysis at Jichi Medical School. Genomic DNA was extracted from the peripheral blood leukocytes using the standard methods. All exons of each gene were amplified separately by PCR. Mutations were screened by DHPLC analysis with WAVE DNA-fragment analysis system (Transgenomic, Inc., Omaha). And mutations were confirmed by direct sequencing analysis. We found several polymorphisms and two missense mutations in Wnt family gene and small G-protein-coupled receptor gene, respectively. One missense mutation in WNT gene was detected also in his unaffected mother, but not in 134 normal individuals. It seemed that these mutations had a possibility of causing disease, although they were not conclusive. Because these genes were expressed especially in the brain, these mutations would induce some changes in higher brain functions. Further screening of candidate genes in larger sample set and study on the functional change of identified mutation as well as candidate gene knockout animal model analysis is needed to clarify their contribution to the autistic disorder.

**Apolipoprotein E SNP haplotypes: association with hemorrhagic stroke.** R. Kaushal<sup>1</sup>, D. Woo<sup>2</sup>, M. Haverbush<sup>2</sup>, P. Pal<sup>1</sup>, N. Wang<sup>1</sup>, J. Khoury<sup>1</sup>, P. Shekar<sup>2</sup>, B. Kissela<sup>2</sup>, C. Moomaw<sup>2</sup>, L. Sauerbeck<sup>2</sup>, G. Sun<sup>1</sup>, R. Chakraborty<sup>1</sup>, J. Broderick<sup>2</sup>, R. DeKa<sup>1</sup>. 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Dept Neurology, Univ of Cincinnati, Cincinnati, OH.

Stroke is the foremost cause of disability and the third leading cause of death in the western hemisphere. It is one of the most complex diseases with several subtypes as well as secondary risk factors such as hypertension, hyperlipidemia, and diabetes, which in turn have genetic and environmental risk factors of their own. Variations in the apolipoprotein E (*APOE*) gene have been associated with Alzheimers disease which shares a common pathophysiologic mechanism (amyloid deposition) with lobar intracerebral hemorrhage (ICH). The genetic heterogeneity of *APOE* has also been associated with aneurysmal subarachnoid hemorrhage (SAH) as well as outcome following stroke. However, these associations remain inconclusive. To test for association, we genotyped four SNP markers in the *APOE* gene (*rs1160983*, *rs1160984*, *rs1160985* and *rs157581*), spanning a distance of 11 kb, in 98 cases with SAH and 181 age, gender, and race-matched controls and 105 cases of ICH and 179 matched controls. Haplotype analysis revealed significant differences in SAH cases and controls. Further, stratification based on race (Caucasians and African Americans) showed even greater differences between Caucasian cases of SAH and controls (p 0.001). Of the observed 10 haplotypes, three, viz., 1111, 1211, 1212 (1 = wild, 2 = mutant allele), showed significant differences. The ICH group was further sub-divided into lobar versus non-lobar cases. There was a significant difference between cases and controls of lobar ICH for haplotypes 1211 (cases - 28%, controls - 47%; p = 0.03) and 2212 (cases - 6%, controls - 0%; p = 0.04). In the same group, the marker *rs157581* also showed significant differences in allele frequencies between cases and controls (allele 1 = 80% in cases, and 63% in controls; p = 0.024). These results indicate that *APOE* gene plays a significant role in both subarachnoid hemorrhage and lobar intracerebral hemorrhage. Supported by NIH grant NS36695.

**Parkin mutations cause late-onset slowly progressing Parkinson's disease.** *J. Harris<sup>1</sup>, S. Afridi<sup>2</sup>, P. Greene<sup>1</sup>, S. Fahn<sup>1</sup>, K. Marder<sup>1, 2, 3</sup>, L.N. Clark<sup>2, 4</sup>.* 1) Department of Neurology,; 2) Taub Institute for Research on Alzheimer disease and the Aging Brain,; 3) Gertrude H. Sergievsky Center, and; 4) Department of Pathology, Columbia University, New York, NY.

The Parkin gene on chromosome 6q25.2-27 is associated with autosomal recessive, juvenile-onset Parkinson's disease (PD) and sporadic young-onset PD (age of onset <45 years). Slower progression of disease and a good response to levodopa have been reported as characteristic clinical features of young-onset patients with Parkin mutations. More recently, homozygous and heterozygous mutations have been identified in the Parkin gene in familial and sporadic late-onset PD. We hypothesized that late-onset PD patients with clinical symptoms resembling young-onset Parkin-related PD may have a higher prevalence of Parkin mutations. Thus, we selected late-onset PD patients (>45 years), with features of the characteristic Parkin phenotype including slow progression and good response to levodopa. Patients (n=22) were selected who continued to have mild symptoms in the medicated state after years of symptoms. The mean age at onset of our group of patients was 61.4 years (range 48-76 years) and the mean duration of symptoms at time of last evaluation was 12.4 years (range 5-25 years). The patients were selected blind to family history. Sequencing and gene dosage analysis of the Parkin gene in cases and matched controls was performed. We report the frequency of Parkin mutations and polymorphisms in these patients and in a matched control series. There was no significant difference in positive family history between our patients with and without Parkin mutations. We found that a significant percentage of our patients with slow progression, good response to levodopa and onset >45 years have Parkin mutations. This suggests that Parkin mutations may be much more common in late-onset PD than previously reported.

**Investigation of Candidate Genes in Pathological Gambling.** *M.M. Krinsky<sup>1</sup>, P.M. Muglia<sup>1,2</sup>, J.L. Kennedy<sup>1,2</sup>, N.E. Turner<sup>3</sup>.* 1) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 3) Department of Social Health and Policy, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

Pathological gambling (PG), according to the DSM-IV, is an impulse-control disorder that is characterized by persistent and maladaptive gambling behaviors. A recent meta-analysis reported the lifetime prevalence of PG in adults at 1.6%, with an additional 3.9% of adults having a gambling problem (Shaffer, 1999). Family, twin, and genetic association studies have reported that the susceptibility to PG has a relatively large genetic component. Like other psychiatric conditions, PG is considered a complex disorder since it is likely determined by several genes interacting together as well as with environmental factors. Converging lines of evidence have suggested the dopaminergic pathways represent important principal biological components involved in the etiology of PG. We collected DNAs on 145 gambling subjects (55 PG, 31 borderline-PG, and 55 non-PG) who underwent a thorough assessment including DSM-IV criteria and the South Oaks Gambling Screen. We genotyped 5 dopamine-related candidate genes (DRD4, DAT, COMT, DRD5 and TH) and compared the phenotype scores across genotype groups. We were unable to detect a significant association with any of the polymorphisms genotyped (DRD4:  $t=-0.501$ ,  $p=0.617$ ; DAT:  $t=1.251$ ,  $p=0.213$ ; COMT:  $t=-1.639$ ,  $p=0.104$ ; DRD5:  $t=-0.404$ ,  $p=0.687$ ; TH:  $t=0.695$ ,  $p=0.489$ ) however, there was a trend for the biased presence of the associated risk allele in the PG group for DRD4 (7-repeat) 42% and COMT (allele 2) 23%. Furthermore, we observed a higher frequency of the risk allele of the DRD4 (7-repeat), COMT (Allele 2) and DRD5 (148 bp) genes than in previously reported studies. Correlation studies showed that the additive genotypic effects of the candidate genes (excluding TH) accounted for 2.9% of variance in our sample ( $r=0.171$ ,  $p=0.046$ ). These results are preliminary and further analyses are underway using additional candidate genes, larger samples and matched case-control subjects.

**Association of SNPs in Dopaminergic Pathway Genes with young onset and late onset Parkinson's Disease among Indians.** *B.K. Thelma*<sup>1</sup>, *S. Punia*<sup>1</sup>, *M. Behari*<sup>2</sup>, *U. Muthane*<sup>3</sup>, *R.C. Juyal*<sup>4</sup>. 1) Dept Zoology, Univ Delhi, Delhi, India; 2) Dept Neurology, All India Institute of Medical Sciences, New Delhi, India; 3) Dept of Neurology, National Inst. of mental health and neurosciences, Bangalore, India; 4) National Inst. of Immunology, New Delhi, India.

Parkinson's disease is a progressive neurodegenerative disorder characterized by bradykinesia, resting tremor, muscular rigidity, postural instability and has a prevalence of >1% in 55-year old individuals and >3% in those >75 years of age. Among Indian PD patients, ~10% and 20% are accounted for, by young onset and familial PD respectively and a large majority falls under the late onset category. Mutations in genes such as alpha Synuclein, Parkin, DJ-1, UCHL-1, have been observed in some familial forms of PD. However, the genetic basis of a large majority of young onset as well as the late onset PD cases is still not clear. Various candidate genes from the dopaminergic pathway, cytochrome P450 family of genes, oxidative stress genes and mitochondrial genes have been implicated for development of PD by various mechanisms. SNPs have emerged as powerful markers for establishing association of candidate chromosomal region(s) with complex traits. We have, in this study undertaken to establish, association if any, of a large number of SNPs in some candidate genes from the dopaminergic pathway with young onset PD (n=180) and late onset PD (n=345) using a case-control approach. Significant associations of SNP(s) in the tyrosine hydroxylase, dopamine receptor D2, and catechol O-methyltransferase genes have been observed in both young onset and late onset PD in our study.

**Evidence supporting *CENTG2* as an autism susceptibility gene.** *T.H. Wassink<sup>1</sup>, J. Piven<sup>2</sup>, V.J. Vieland<sup>1,3</sup>, L. Jenkins<sup>1</sup>, R. Goedken<sup>3</sup>, M.A. Spence<sup>4</sup>, M. Smith<sup>4</sup>, V.C. Sheffield<sup>5</sup>.* 1) Department of Psychiatry, University of Iowa Carver College of Medicine, Iowa City, IA; 2) Neurodevelopmental Disorders Research Center and Department of Psychiatry, University of North Carolina, Chapel Hill, NC; 3) Department of Biostatistics, University of Iowa College of Public Health, Iowa City, IA; 4) Department of Pediatrics, University of California, Irvine, Irvine, CA; 5) Department of Pediatrics and the Howard Hughes Medical Institute, University of Iowa Carver College of Medicine, Iowa City, IA.

We identified three autistic subjects with 2q37.3 terminal deletions, and refined the deletion breakpoint regions using polymorphism mapping and FISH probes. These breakpoints, and others in the literature, were within or immediately upstream of the gene centaurin gamma-2 (*CENTG2*). While numerous genes are absent in these deletions, *CENTG2* is an attractive candidate autism disease gene. It is expressed in the developing brain and is involved in biomolecular pathways that influence cellular functions such as axon growth and guidance, cellular differentiation, metabolism, and vesicular trafficking. We therefore assessed *CENTG2* for its involvement in autism by 1) screening its exons for variants in 135 unrelated autistic individuals and 160 control subjects, and 2) assessing for linkage and LD 6 intra-genic polymorphisms in 60 autism ASP families. The exon screen revealed a Ser to Gly substitution in one proband, an Arg to Gly substitution in another, both in conserved functional domains; a CT transition in two sibs that significantly diminished the strength of a potential exon splice enhancer, a common Ile to Val substitution, and an intronic AG deletion in one father and his two affected children that may lead to aberrant splicing of exon 12. We also identified an intriguing mini-satellite polymorphism in intron 1 the predominant and secondary alleles are 1110 and 660 nt long, respectively that is in linkage with autism. In addition, strong evidence for linkage emerged with a maximum two-point HLOD value of 4.2 from a polymorphism in intron 10; no evidence for LD was identified at any of the markers tested. We conclude, therefore, that *CENTG2* may contribute to autism susceptibility.

**Association of GSK-3 polymorphisms with Alzheimer's disease and frontotemporal dementia.** *B.A.J. Schaffer<sup>1</sup>, B.L. Miller<sup>2</sup>, K.C. Wilhelmsen<sup>3</sup>, S. Weintraub<sup>4</sup>, N. Johnson<sup>4</sup>, E. Bigio<sup>5</sup>, B. Quinn<sup>4</sup>, M.-M. Mesulam<sup>4</sup>, J.L. Cummings<sup>1</sup>, D. Masterman<sup>1</sup>, D.H. Geschwind<sup>1</sup>.* 1) Dept. of Neurology, David Geffen School of Medicine, UCLA, Los Angeles, CA; 2) Dept. of Neurology, UCSF, San Francisco, CA; 3) Gallo Clinic and Research Ctr., San Francisco, CA; 4) Depts. of Neurology and Psychiatry & Behavioral Sciences, Northwestern Univ. Feinberg School of Medicine, Chicago, IL; 5) Dept. of Pathology, Northwestern Univ. Feinberg School of Medicine, Chicago, IL.

Pathologic phosphorylation of the microtubule associated protein tau is a hallmark of many neurodegenerative diseases, including Alzheimer's disease (AD), frontotemporal dementia (FTD), primary progressive aphasia (PPA) and progressive supranuclear palsy (PSP). Thus, genes that phosphorylate tau are logical candidate genes for these diseases. We have previously shown that GSK-3 induced hyperphosphorylation of tau is an important mediator of neurodegeneration in a drosophila model and here explore its potential association with AD and FTD.

We sequenced the promoter of GSK-3 and all 12 exons including surrounding intronic sequence in a mostly Caucasian population of FTD, AD and aged normal subjects. One new SNP was found in the promoter, one in exon 4, two in exon 9, and 11 in the introns. The rare variants occurring within exons did not change coded amino acids. However, a more common intronic polymorphism occurring with an allele frequency of 5.9% in aged normals (6/102 chromosomes) occurs at more than twice the frequency among FTD subjects (12.0%; 17/142 chromosomes) and AD subjects (13.8%; 13/94 chromosomes). This SNP is located 68 nucleotides upstream of exon 3 within an intronic region of high homology with mouse, suggesting that it plays an as yet unknown functional role. This study provides statistical support for association of polymorphisms within the GSK-3 gene and tau-related neurodegenerative conditions, including AD and FTD. This is the first genetic evidence that sequence variation within genes involved in tau phosphorylation may contribute to human neurodegenerative conditions.

Program Nr: 2013 from 2003 ASHG Annual Meeting

**Molecular genetic analysis of a chromosome 4q31.3-34 deletion associated with autism.** A. Woodroffe, S. Ramanathan, P. Flodman, M. Bocian, L. Mays, C. Modahl, M. Hanouni, M.A. Spence, M. Smith. Pediatrics, University of California- Irvine.

Autism is a developmental disorder characterized by impaired communication and social interactions and stereotypic patterns of interest and activity. This report is a case study of a subject who met ADI-R and ADOS-G diagnostic criteria for autism. He was also found to have significant language impairment, hypotonia, minor congenital anomalies, and an IQ of 59. The anomalies include metatarsus adductus, cryptorchidism, shortened metacarpals and syndactyly of the second and third toes. Through karyotyping, he was shown to have a deletion on one member of his chromosome 4 pair. We used FISH mapping and microsatellites to determine the breakpoints and extent of this deletion. Due to the lack of known polymorphic microsatellites in the region of interest, we developed 4 new polymorphic markers, two are located in the PDGFC gene, one in the glycoprotein M6A (GPM6A) gene, and one in the AMPA glutamate receptor A2 (GLUR2) gene. We found that the deletion extends about 19 Mb from 4q31.3-q34. Analysis revealed that the deletion occurred de novo, on the paternally derived chromosome. The telomeric end of the deletion is within the GPM6A gene, the centromeric end is within the PDGFC gene. 33 genes mapped to the deletion region, 14 of these genes are expressed in the brain. Five genes that are especially interesting are: GLUR2, the glycine receptors GLRA3 and GLRB, carboxypeptidase E (CPE) and GPM6A. The GLUR2 is of interest because glutamate receptor deficiency has been previously reported in autism. Also, Carlsson et al (1998) proposed that autism is a hypoglutamatergic disorder associated with decreased AMPA glutamate receptor response. Hemizygosity for CPE is interesting given its role in processing neuropeptides, including oxytocin, vasopressin, and proopiomelanocortin (POMC). The GPM6A gene encodes a neuronally expressed gene that plays a role in downstream nerve growth factor signaling pathway. The genes mentioned above, and other genes that map within the region corresponding to the deletion, constitute candidate genes for autism. [Supported by Grant NICHD HD35458 MA Spence PI].

**A missense coding polymorphism in the Urokinase-Type Plasminogen Activator gene (*PLAU*) is associated with Alzheimers disease and age-dependent changes in plasma A42 levels.** S.G. Younkin<sup>1</sup>, J. Ronald<sup>1</sup>, H. Asahara<sup>1</sup>, L. Feuk<sup>2</sup>, J. Prince<sup>2</sup>, M. Tucker<sup>3,4</sup>, L. Younkin<sup>1</sup>, M. Hella<sup>1</sup>, S. Jain<sup>1</sup>, L. Hersh<sup>4</sup>, M. Kindy<sup>4</sup>, W. Markesbery<sup>4</sup>, M. Hutton<sup>1</sup>, M. deAndrade<sup>5</sup>, R.C. Petersen<sup>6</sup>, N. Graff-Radford<sup>7</sup>, S. Estus<sup>3,4</sup>, A. Brookes<sup>2</sup>, N. Ertekin-Taner<sup>1,8</sup>. 1) Dept Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Center for Genomics and Bioinformatics, Karolinska Institute, Stockholm, Sweden; 3) Dept Physiology, University of Kentucky, Lexington, KY; 4) Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY; 5) Dept Health Sciences Research, Mayo Clinic, Rochester, MN; 6) Dept Neurology, Mayo Clinic, Rochester, MN; 7) Dept Neurology, Mayo Clinic, Jacksonville, FL, USA; 8) Dept Neuroscience, Mayo Clinic, Rochester, MN.

Plasma amyloid protein (A42) levels and late onset Alzheimers disease (LOAD) have been linked to the same region on chromosome 10q. The *PLAU* gene, which is within this region, encodes urokinase-type plasminogen activator (uPA), which converts plasminogen to plasmin. *PLAU* is an attractive candidate because A aggregates induce *PLAU* expression thereby increasing plasmin, which degrades A. In this study, we analyzed a missense C/T polymorphism in exon 6 of *PLAU* (*PLAU\_1*) in which the minor T allele causes a proline to leucine change (P141L) within the kringle domain of *PLAU*. We analyzed *PLAU\_1* for association with AD in six case-control series by meta-analysis. The C/T and T/T *PLAU\_1* genotypes showed association with an overall estimated OR of 1.2. The C/T and T/T genotypes of *PLAU\_1* were also associated with significant, age-dependent elevation of plasma A42 in twenty-four extended LOAD families that we analyzed ( $p=0.0006$ ). In knockout mice lacking the *PLAU* gene, plasma A was significantly elevated, also in an age-dependent manner. The *PLAU\_1* associations reported here were independent of the associations we found with the genetic variants in the *IDE* or *VR22* regions. These results provide strong evidence that *PLAU* or a nearby gene is involved in the development of LOAD. *PLAU\_1* is a plausible pathogenic mutation that could act by increasing A42, but additional biological experiments are required to show this definitively.

**Association of FGF20 with late-onset Parkinson disease.** *J.M. van der Walt<sup>1,2</sup>, E.R. Martin<sup>1,2</sup>, W.K. Scott<sup>1,2</sup>, F. Zhang<sup>1,2</sup>, K. Fujiwara<sup>1,2</sup>, R. Kittappa<sup>3</sup>, M.A. Nance<sup>2</sup>, J.P. Hubble<sup>2</sup>, W.C. Koller<sup>2</sup>, R. Pahwa<sup>2</sup>, M. Stern<sup>2</sup>, B.C. Hiner<sup>2</sup>, J. Jankovic<sup>2</sup>, C.G. Goetz<sup>2</sup>, G.W. Small<sup>2</sup>, F. Mastaglia<sup>2</sup>, L.T. Middleton<sup>2</sup>, M.A. Pericak-Vance<sup>1,2</sup>, J.M. Vance<sup>1,2</sup>.* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Duke CHG/GlaxoSmithKline PD Genetics Collaboration; 3) National Institute of Health, National Institute of Neurological Disorders and Stroke, Bethesda, MD.

The pathogenic process responsible for the loss of dopaminergic neurons within the substantia nigra of Parkinson disease (PD) patients is poorly understood. However, there is strong evidence to support the involvement of fibroblast growth factor 20 (FGF20) in the survival of dopaminergic cells. FGF20 is a neurotrophic factor that is preferentially expressed within the substantia nigra of rat brain. The human homologue has been mapped to 8p21.3-8p22, which is also an area of PD linkage revealed through our published genomic screen. In order to test whether FGF20 influences risk of PD, we genotyped 3 single nucleotide polymorphisms (SNPs) using TaqMan in a large family based study. We analyzed our sample (N families = 440) using the pedigree disequilibrium test (PDT) and the genotype-PDT that assess association between alleles or genotypes, respectively, and risk. We revealed a highly significant association between an intronic SNP rs1989754 (p-value = 0.0006) and PD in our overall sample with and a weaker association with SNP rs1721100 (p-value = 0.02) located in a regulatory region. The frequency of allele rs1989754G is increased by 5% in the affected family member sibs relative to the unaffected family member sibs. Furthermore, genotype-PDT analysis revealed that genotype rs1989754GG is also positively associated with PD risk (p-value=0.02). We suggest that FGF20 may be a risk factor for late-onset PD. We are currently screening exons of FGF20 for variants that may affect the function of the protein.

**Linkage disequilibrium and haplotype analysis of BDNF gene variations in Parkinson's Disease.** A. Parsian<sup>1</sup>, R. Sinha<sup>1</sup>, B. Racette<sup>2</sup>, J.H. Zhao<sup>3</sup>, J.S. Perlmutter<sup>2</sup>. 1) Birth Defects Ctr, Univ Louisville Hlth Sci Ctr, Louisville, KY; 2) Department of Neurology, Washington University School of Medicine, St. Louis, MO; 3) Department of Epidemiology and Public Health, University College London, London, UK.

Most cases of Idiopathic Parkinson's disease (PD) are sporadic but approximately 20% have a positive family history suggesting a hereditary component. Although most of these genetic factors are unknown, genes coding for nerve growth factors involved in dopamine receptor and cellular regulation such as brain-derived neurotrophic factor (BDNF) are logical candidate genes. The goal of this study was to determine the role of the BDNF gene in the development of familial and sporadic PD. We sequenced the promoter region of the gene using genomic DNA from 45 patients with familial PD. Two single nucleotide polymorphisms (SNPs) at positions C-1331T and C270T were identified. There was no sign of linkage disequilibrium between these two SNPs. We screened our sample of 146 patients with and 212 without a positive family history for PD and 195 matched controls with the SNP at C270T and G196A in exon 5 of the gene. The 270T allele was more common in the familial PD subjects compared to normal controls ( $p=0.0006$ ) but not significantly different between sporadic PD and normal controls. The genotype frequencies were significantly different only between familial PD and normal controls ( $p=0.00001$ ). Both PD groups were categorized based on age of onset of 50 in two groups of  $<50$  and  $>50$  years. There was a highly significant difference in allele and genotype frequency between the familial group with age of onset of  $>50$  years and controls ( $p=0.0002$  and  $p=0.0001$ ). We estimated and compared the haplotype frequencies between C270T and G196A markers in PD and controls that was positive (Heterogeneity statistic was 14.9,  $p=0.0019$ ). Our data indicate the possibility of linkage disequilibrium between the C270T variation and a mutation in coding region of the BDNF gene and suggest that BDNF may play a role in the development of familial PD that warrant further study.

**Chromosome microdeletions as etiological factors in autism: Report of 4 cases and identification of autism candidate genes.** *M. Smith, P. Flodman, A. Woodroffe, M.E. Bocian, M. Hanouni, M.A. Spence.* Dept Pediatrics, Univ California, Irvine, Irvine, CA.

Autism is a complex neurodevelopmental disorder. Identification of autism candidate genes through linkage analysis is hampered because there are many more sporadic cases of autism than familial cases. Autism candidate genes may be identified through molecular genetic analysis of structural chromosome changes that occur in affected subjects. We have identified 4 autistic subjects who each have a different chromosome deletion. The following regions are involved: 15q22-q23, 2q37.3, 13q12-q13, 4q31.3-4q34. We carried out FISH studies and analyses of polymorphic microsatellite markers to define the deletion regions. Marker analysis revealed that each of the deletions arose de novo on a paternal chromosome. In consequence of deletion, patients were hemizygous for one or more brain expressed genes encoding molecules involved in neurodevelopment, signaling molecules or neurotransmitters. The 15q22-q23-deletion patient is hemizygous for Neogenin, a Netrin 1 receptor. Neogenin is expressed in developing forebrain, corpus callosum, hippocampus and dorsal thalamus. In consequence of the 2q37.3 deletion an autistic subject is hemizygous for centaurin gamma 2, a phosphatidyl inositol signaling pathway molecule. She is also hemizygous for neuronal homeobox gene GBX2 and ATSV axonal transporter of synaptic vesicles. The 13q12-q13 deletion leads to hemizyosity for DCAMKL1 that contains doublecortin and Cam kinase domains and plays a role in cortical development. He is also hemizygous for MADH9, a member of the SMAD TGF beta signaling pathway. Smad and Tgf beta mutants in *Drosophila* are associated with defective neuronal pruning. The 4q31.3-q34 deletion patient is hemizygous for 3 neurotransmitter receptor genes: AMPA glutamate receptor GLURA2 and the glycine receptor genes GLRA3, GLRB3. This subject is also hemizygous for carboxypeptidase E (CPE) that cleaves neuronal prepropeptides including oxytocin vasopressin and POMC. Chromosome changes are not uncommon in autism (Yu et al. AJHG 2002) comprehensive screening for them, using FISH, microsatellite and/or microarray analysis, is required.

**Association of a 5HT1B polymorphism with suicidal behavior.** *E.C. Tan<sup>1</sup>, Y.L. Tan<sup>2</sup>, Y.Y. Teo<sup>3</sup>, G. Lau<sup>4</sup>, C.H. Tan<sup>2</sup>.*  
1) Defense Medical Res Inst, Defense Science & Tech Agency, Singapore, Singapore; 2) Faculty of Medicine, National University of Singapore; 3) Department of Statistics, National University of Singapore; 4) Department of Pathology, Health Sciences Authority.

Personality traits which are highly heritable are often predictive of later development of psychiatric disorders and behaviors such as aggression, hostility, impulsivity and other anti-social behavior. Abnormalities in serotonergic neurotransmission have been implicated in suicidal ideation and behavior due to its function in mediating the control of mood, aggression and impulsivity. In particular, 5HT1B receptor knock-out mice showed increased aggression as well as increased alcohol and cocaine consumption. For suicide, a severe consequence of impulsive behavior, studies have found that the levels of some receptors such as the 5HT subtypes may be altered in brains from suicide victims and other disorders involving impulsive behavior. To test the hypothesis that the 5HT1B receptor mediated serotonergic dysfunction might be involved in suicidal behavior through the disinhibition of aggression and impulsivity, we examined the association of a single nucleotide polymorphism in the 5HT1B receptor gene and suicide. Our sample consisted of 333 confirmed suicide cases (mean age 43.6 SD = 19.1) and 110 controls (mean age 43.3 SD = 16.3) recruited from institute and hospital staff with informed consent. The HTR1B 861G>C polymorphism was genotyped by PCR-RFLP. There is statistically significant difference in genotype distribution between the control and suicide group ( $p = 0.02$ ). Subjects with at least one copy of G possess greater suicidal tendencies with the odds ratio at 1.97 (95% CI = 1.22,3.18). Testing for allelic effects with allele C as the baseline, the odds ratio for allele G is 1.41, 95% CI = (1.04,1.92). A gender effect on suicide tendencies is also observed ( $p = 0.01$ ) with our results showing that males are more at risk than females overall (odds ratio = 1.76, 95% CI = 1.14,2.72) although there are more female suicide victims among the young while the trend is reversed for the elderly. We would be expanding the sample size to increase the power of our study.

**DD genotype of the ACE gene is a risk factor for spontaneous intracerebral hemorrhage.** A. Slowik<sup>1</sup>, W. Turaj<sup>1</sup>, T. Dziedzic<sup>1</sup>, A. Haefele<sup>2</sup>, L. Sobanska<sup>1</sup>, P. Szerner<sup>1</sup>, J. Pera<sup>1</sup>, M. Malecki<sup>3</sup>, A. Szczudlik<sup>1</sup>, D.A. Figlewicz<sup>2,4</sup>. 1) Neurology, Jagiellonian University, Krakow, Poland; 2) Neurology, University of Rochester, Rochester, NY; 3) Metabolic Diseases, Jagiellonian University, Poland; 4) Neurology, University of Michigan, Ann Arbor, MI.

The angiotensin converting enzyme (ACE) gene is considered an important candidate gene for stroke involving small cerebral vessels, particularly spontaneous intracerebral hemorrhages (SIH) and ischemic strokes due to small vessel disease (SVD). An insertion/deletion (I/D) polymorphism in intron 16 of the ACE gene has been shown to be associated with plasma ACE levels and activity. It accounts for approximately 45% of the total variability of serum ACE levels, with the highest values in DD allele carriers. The ACE enzyme plays a role in endothelial function, and the regulation of smooth muscle proliferation and tone. In this study we evaluated whether the ACE gene I/D polymorphism was a risk factor for SIH or SVD. 58 patients with SIH (mean age: 58.9 +/-11.6 years), 70 patients with ischemic stroke due to SVD (mean age: 64.4 +/- 10.6 years) and 256 healthy controls matched for age and sex, were genotyped for ACE I/D polymorphism. All patients with SIH underwent computed tomography, angiography, and where needed, MRI or MRA to exclude vascular malformations, hemorrhage to tumor, amyloid angiopathy etc. SVD ischemic stroke was diagnosed according to TOAST criteria. The ACE gene polymorphism was detected by PCR of intron 16 specific I/D fragments, 490kb, and 190kb, respectively. The ACE genotype distribution in patients with SIH (II-17.3%, ID-37.9%, DD-44.8%) differed significantly from controls (II-23.3%, ID-49.2%, DD-27.5%) (p<0.05). ACE genotype distribution in patients with SVD stroke and their controls showed no significant difference. A logistic regression model demonstrated that the DD genotype of ACE gene is independent from hypertension as a risk factor for SIH (OR=2.14, 95%CI: 1.01-4.53). Thus, the DD genotype of ACE gene is a risk factor for SIH, but not for ischemic stroke related to SVD. These two small cerebral vessel diseases differ with respect to this aspect of their genetic predispositions.

**X Chromosome Inactivation and Candidate Gene Studies in Females with Autism.** *Z. Talebizadeh, D.C. Bittel, N. Kibiryeve, M.G. Butler.* Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Autism is a neurodevelopmental disorder with sex ratio of 3-4 times higher in males than in females. It is not clear why autism is more prevalent in males than in females. However, genes on the X chromosome may contribute to the excess number of males, which is further supported by males having only one X chromosome. As a result of X chromosome inactivation, females in the general population are mosaic for X-linked gene expression with one population of cells expressing genes from the maternal X and the other population expressing genes from the paternal X chromosome. X inactivation is generally random with an expected mean inactivation pattern of 50:50. Deviation from the 50:50 ratio (greater than 80:20) is referred to as X chromosome skewing. If a female is heterozygous for a gene predisposing to autism, X chromosome skewing may contribute to autism. We studied X chromosome skewing in females diagnosed with classical autism (N=26; 8 simplex and 18 multiplex) compared with similarly aged unaffected female siblings and/or controls with the use of the androgen receptor (AR) gene as a marker for X chromosome skewing. The age range was 5 to 12 years. The frequency of the methylated (inactive) and unmethylated (active) alleles were determined and skewness pattern characterized by methyl sensitive restriction enzyme (HhaI or HpaII) digestion followed by genotyping and measurement of the ratio of the allele peak heights. A trend for X chromosome skewing was detected (Fisher exact test,  $p=0.071$ ) in our autism group (6 out of 22) compared to unaffected females (1 out of 19). The promoter region of the XIST gene involved in X chromosome inactivation, has been analyzed for the presence of a mutation associated with X chromosome skewness in the relevant subjects but no mutations seen. Additionally, X chromosome candidate genes for autism were evaluated including gastrin-releasing peptide receptor (GRPR) and two X-linked neuroligins (NLGN3 and NLGN4) using quantitative RT-PCR and direct DNA sequencing. To date, no mutations have been found in these candidate genes in our autism subjects.

**Markers associated with the inversion polymorphism on chromosome 8p23 are associated with Panic Disorders.**

*T.E. Thorgeirsson<sup>1</sup>, H. Oskarsson<sup>2</sup>, S. Bjornsdottir<sup>1</sup>, C. Lopez-Correa<sup>1</sup>, N. Desnica<sup>1</sup>, J. Pop Kostic<sup>1</sup>, N. Vidarsdottir<sup>1</sup>, J.G. Stefansson<sup>3</sup>, H. Kolbeinsson<sup>3</sup>, E. Lindal<sup>3</sup>, J. Sainz<sup>1</sup>, N. Gagunashvili<sup>1</sup>, E. Gudfinnsson<sup>1</sup>, M.F. Frigge<sup>1</sup>, A. Kong<sup>1</sup>, J.R. Gulcher<sup>1</sup>, K. Stefansson<sup>1</sup>.* 1) deCODE genetics, Reykjavik, Iceland; 2) Therapeia, Reykjavik, Iceland; 3) Landspítalinn-University Hospital, Reykjavik, Iceland.

We report the association of the less frequent form of the inversion polymorphism on chromosome 8p23 to Panic Disorder (PD). We initially studied the chromosomes of 43 individuals with PD by fluorescence in-situ hybridization (FISH), and found 50% of the chromosomes having the rarer order, but its frequency has been estimated at 26% in European populations (Giglio et al, *Am J Hum Genet*, 68(4):874-83). We subsequently identified surrogates for the inversion status by analyzing allelic association of microsatellite markers and SNPs in the region in a larger group of individuals with known status for the inversion. Several excellent surrogates were identified, alleviating the need for further FISH. The conclusions from the FISH measurements were confirmed in a larger sample using the surrogate markers, with several markers at 8p23 exhibiting association to PD with highly significant p-values. In all cases the alleles associated to PD are the same alleles that are associated to the rarer form of the inversion. Specifically, alleles strongly associated with the inversion have a relative risk of 1.8 for PD compared to the other alleles. Weaker associations and lower risk ratios were detected for bipolar disorder and depression severe enough to require medication. Whether the inverted segment plays an active role casting PD as a genomic disorder, or serves as a background for another genetic variation increasing the risk of psychiatric disorders will be discussed.

**Evidence for the involvement of the BDNF gene in autism and relation to family history of depression.** *A.M. Vicente<sup>1</sup>, S. Silva<sup>1</sup>, A.M. Coutinho<sup>1</sup>, C. Bento<sup>2</sup>, C. Marques<sup>2</sup>, A. Atade<sup>2</sup>, T. Miguel<sup>2</sup>, L. Borges<sup>2</sup>, G. Oliveira<sup>2</sup>.* 1) Instituto Gulbenkian de Ciencia, Oeiras, Portugal; 2) Hospital Pediatrico de Coimbra, Coimbra, Portugal.

The Brain-Derived Neurotrophic Factor (BDNF) plays a fundamental role in the regulation of neural growth, differentiation and function. Abnormal neonatal levels of BDNF in children who were later diagnosed with autism have been reported, and there is growing evidence for an association of the BDNF gene with affective disorders. Particularly relevant to the etiology of autism, BDNF plays an important role in the development, function, and regeneration of serotonergic neurons. A microsatellite marker 1kb upstream of the BDNF start site and a functional SNP in exon 1 of the BDNF gene were tested for association with autism in a sample of 195 nuclear families with one affected child. The TDT for haplotypes of the two markers was significant ( $P=0.029$ ), with a distortion in the transmission of haplotype 2 ( $P=0.0071$ ). In our idiopathic sample, we find that 12% of patients have a family history of depression, a much higher rate than is found in the patients with known etiology and which therefore cannot be explained by the burden of raising a handicapped child. We further investigated the hypothesis of a common underlying genetic defect in autism and depression by restricting our analysis to the 24 patients whose parents reported having suffered episodes of depression. Comparing haplotype frequencies between patients with and without depressed parents we found haplotype 1 significantly more common ( $P=0.005$ ) and haplotype 4 significantly less common ( $P=0.003$ ) in the children of depressed parents. Because BDNF interacts with the serotonin system at multiple levels, and hyperserotonemia is a consistent feature in autism, we tested whether BDNF variants contribute to serotonin level variation in autism patients. QTDT analysis revealed no association of BDNF with serotonin distribution. These results provide evidence for an association of the BDNF gene with autism, in particular in the subgroup of autistic patients with depressed parents, and thus reinforce a role of BDNF in the etiology of autism.

Program Nr: 2023 from 2003 ASHG Annual Meeting

**Williams Syndrome: evidence from atypical deletions links GTF2I and GTF2IRD1, but not FZD9, with posterior cortical structure and neural functions.** *A.F. Simon<sup>1</sup>, G.M. Yao<sup>1</sup>, X.-N. Chen<sup>1</sup>, D. Mills<sup>2</sup>, F.E. Rose<sup>3</sup>, L.S.*

*Salandanan<sup>1</sup>, A. Reiss<sup>4</sup>, U. Bellugi<sup>3</sup>, J.R. Korenberg<sup>1</sup>.* 1) Med Genet, Cedars-Sinai Medical Center, UCLA, Los Angeles, CA; 2) Emory Univ., Atlanta, GA; 3) The Salk Institute, San Diego, CA; 4) Dept of Psychiatry and Behavioral Sciences, Stanford Univ School of Medicine, Stanford, CA.

Williams syndrome (WS) is a neurodevelopmental disorder caused by a deletion of chromosome 7q11.23. Individuals exhibit striking peaks and valleys in neurocognition that include deficits in visuospatial processing along with relatively preserved language and facial processing. These features are associated with distinct variations in neuroanatomy and physiology. In an effort to identify their genetic origins, we have used studies of molecular structure, volumetric magnetic resonance imaging (MRI), neurocognition, and event-related potentials (ERPs) in 71 individuals with WS characteristics. We used multicolor FISH, with a panel of 45 BACS, PACS and cosmids, PCR of somatic cells hybrids and quantitative southern blots to identify 69 adults with typical deletions, and 2 adult males with overlapping atypical deletions (one deleting from FKBP6 through CYLN2, and the second deleting CLDN4 through GTF2I). These individuals' breakpoints provide models with which to test hypotheses linking neural profiles with the deletion effects of 3 regions: FKBP6/FZD9-TBL2, CLDN3/4-CYLN2 and GTF2IRD1-GTF2I. Combining genetic with neural information, we propose that decreased expression of 2 transcriptional regulators, GTF2IRD1 and GTF2I, but not of FZD9, is related to a distinct subset of WS features that includes posterior cerebral variation, visuospatial processing (copy tasks and line orientation), and abnormal neural activity (ERPs) for face processing. The results of this study begin to define pathways linking gene expression with human cognition.

**A scyllatoxin-insensitive isoform of the human SK3 channel.** *O.H. Wittekindt*<sup>1, 2</sup>, *V. Visan*<sup>1</sup>, *H. Tomita*<sup>3, 4</sup>, *F. Imtiaz*<sup>3, 5</sup>, *J.J. Gargus*<sup>3, 6</sup>, *F. Lehmann-Horn*<sup>1</sup>, *S. Grissmer*<sup>1</sup>, *D.J. Morris-Rosendahl*<sup>2</sup>. 1) Department of Applied Physiology, University of Ulm, Ulm, Germany; 2) Institute of Human Genetics and Anthropology, Albert-Ludwigs-University, Freiburg, Germany; 3) Department of Physiology & Biophysics, University of California, Irvine, CA; 4) Department of Psychiatry, University of California, Irvine, CA; 5) King Faisal Medical Center, Riyadh, Saudi Arabia; 6) Division of Human Genetics, University of California, Irvine, CA.

SK ion channels mediate the after hyperpolarisation (AHP) and are shown to modulate the spike frequency of excitable cells. In the rat SK3 channels function as pacemakers in dopaminergic neurons, blockage causing bursts of action potentials and increased dopamine release, providing SK3 a candidate role in dopaminergic transmission, a process hypothesized to be affected in schizophrenia. The *KCNN3/SK3* gene is located on chromosome 1q21.3, a region implicated in schizophrenia. It contains a polymorphic CAG repeat within its first coding exon for which an association with schizophrenia has been extensively studied. We have isolated a novel SK3 isoform from human embryonic cDNA, SK3\_ex4, that contains a 15 amino acid insertion within the S5 to P loop segment. Alternative splicing has been recognized to be important in increasing the functional diversity of ion channels. Transcripts encoding SK3\_ex4 are co-expressed with SK3 but at lower levels in neuronal as well as in non neuronal tissues. In order to investigate the pharmacokinetic properties of SK3\_ex4, we expressed the isoforms SK3 and SK3\_ex4 in tsA cells. The most obvious distinguishing feature of this new isoform was that while SK3 was blocked by scyllatoxin (K<sub>d</sub> = 2.1 nM) and d tubocurarine (K<sub>d</sub> = 5.4 M), hSK3\_ex4 was not affected by either. Both isoforms were similarly activated by cytosolic Ca<sup>2+</sup> and by 1 ethyl 2-benzimidazolinone (1 EBIO), blocked by TEA<sup>+</sup> and Ba<sup>2+</sup>, and showed similar permeabilities relative to K<sup>+</sup> for Cs<sup>+</sup> and Rb<sup>+</sup>. These features are compatible with SK3\_ex4 underlying the recognized toxin-insensitive component of the afterhyperpolarisation in excitable cells and perhaps in disorders of dopamine release.

**Mapping the genetic architecture of Tau H1 in neurodegeneration.** *M. Toft*<sup>1,2</sup>, *L. Skipper*<sup>1</sup>, *K. Wilkes*<sup>1</sup>, *S. Lincoln*<sup>1</sup>, *J. Aasly*<sup>2</sup>, *M. Farrer*<sup>1</sup>. 1) Neuroscience, Mayo Clinic Jacksonville, Jacksonville; 2) Department of Neurology, St. Olav's Hospital, Trondheim, Norway.

The tau H1 haplotype has been associated with 4R tauopathies including progressive supranuclear palsy, corticobasal degeneration and argyrophilic grain disease. More controversially the same haplotype has been associated with Parkinson's disease. Using H1-specific SNPs we demonstrate tau H1 is a misnomer, which consists of a family of recombining H1 alleles. Population genetics, linkage disequilibrium and association analyses have shown that one discrete haplotype is preferentially associated with parkinsonism. Using a sliding scale of H1-specific haplotypes, in age/gender matched Parkinson's disease cases and controls from central Norway, we have refined the association within individuals with global tau H1/H1 genotypes to a ~40kb interval within the tau gene. This haplotype is highly associated with disease ( $p < 2e-6$ ). Hypothesis to explain the enigmatic association of both tauopathy and synucleinopathy with tau H1 are explored. An update on the genetic, genomic and functional analysis of marker variability within this region is presented.

**Identification of ethyl mercury-related genetic determinants that may increase susceptibility towards autism using a yeast deletion based assay.** . A.B. Shah<sup>1</sup>, J. Faustino<sup>1</sup>, R. Zordan<sup>2</sup>, S. Angeli<sup>2</sup>, J. Gitschier<sup>1,2</sup>. 1) Howard Hughes Medical Institute; 2) Departments of Medicine and Pediatrics, University of California at San Francisco, San Francisco, CA.

Thimerosal, a preservative composed of 49.6% ethyl mercury, has been used in several pediatric vaccines distributed around the world. Several studies, illustrating the toxic effects of other forms of mercury on the brain and nervous system, led to the removal in 1999 of thimerosal from vaccines in the United States; however, multidose vials of vaccines containing thimerosal are still being used for childhood immunization in developing countries. This preservative has become a major source of mercury in children who, within their first two years of life, may have received a quantity of mercury exceeding safety guidelines.

The similarities between the characteristic traits defining or associated with autism and the sensory, neurological, motor, and behavioral dysfunctions resulting from toxic mercury exposure suggest that some cases of regressive autism may be induced by early mercury exposure from thimerosal. To investigate the plausibility for a connection between thimerosal and autistic spectrum disorders, we have carried out a large scale screen using a haploid *Saccharomyces cerevisiae* yeast deletion library to identify strains carrying a single null allele exhibiting ethyl mercurial ion sensitivity. We have identified a number of genes involved in several diverse cellular processes, including signal transduction, vesicular trafficking, microtubule formation, proline biosynthesis, chromatin silencing, RNA transcription, and the oxidative stress response. Furthermore, we have discovered genetic players with unknown function, some of which may have a direct role in mercurial export since thus far, no eukaryotic genes involved in mercury homeostasis have been identified. We propose that genetic alterations affecting mRNA levels, gene function, or gene dosage of specific genes may establish a predisposition whereby thimerosal's adverse effects occur only in some children.

**Identification of *COL24A1* as a novel candidate gene for heart failure in mice and humans.** *K.M. Carlson, E.R. Hauser, M.P. Donahue, W.E. Kraus, H.A. Rockman, D.A. Marchuk.* Duke University Medical Center, Durham, NC.

Heart failure (HF) is a complex disease, exhibiting phenotypic variability in outcome related to both environmental and genetic factors. Although biological candidate genes have been investigated as risk factors, identification of novel loci has been largely unsuccessful. We have used a mouse model of HF as a means to identify genetic risk factors. The HF phenotype of a transgenic mouse with cardiac-specific over-expression of the Ca<sup>++</sup> binding protein, calsequestrin (CSQ), shows strong genetic background (strain-specific) effects. We previously described the use of this model to identify a major modifier locus, *Hfm2*, on mouse chromosome 3, affecting both heart function and survival. We now report further analysis of this locus. We screened 412 N2 backcrossed (F1(CSQ)XDBA) progeny for crossovers in the *Hfm2* interval and determined survival for all animals with a crossover within this region. Three proximal and two distal crossovers define a new 1.1 Mb interval, with only two discordant animals. This interval contains 12 annotated genes, 4 of which are not known to be expressed in the heart. DNA sequencing of the remaining 8 genes in DBA and C57Bl/6 strains identified coding polymorphisms (3 SNPs) in only one novel gene. Through the use of mouse/human synteny, we identified the novel gene as collagen type XXIV, alpha 1. We also identified 30 SNPs in the putative promoter region of the gene. RT-PCR analysis indicates that the transcript is up-regulated in this model of HF. These data, as well as the role of collagens in the remodeling that occurs during HF, make *COL24A1* a novel candidate gene for human HF. We sequenced *COL24A1* in 16 human patients with HF, and identified 11 nonsynonymous cSNPs. These were typed in a panel of 243 HF patients. Preliminary data shows a potential association ( $p < 0.06$ ) between V61A(182t->c) and disease severity, as measured by ejection fraction. We are currently collecting additional HF patients and identifying additional SNPs in the gene for further analysis.

**Novel COL6A1 variants and congenital heart defects (CHD) in Down Syndrome (DS).** *U. Fairbrother<sup>1</sup>, M.J. Baptista<sup>2</sup>, G.E. Davies<sup>1</sup>, D. Triikka<sup>1</sup>, A.M. Kessling<sup>1</sup>.* 1) Med & Community Genetics, Imperial College, London, United Kingdom; 2) Laboratory of Neurogenetics, Bethesda, MD, USA.

Free trisomy 21 pathology is unlikely to be due simply to over expression of chromosome 21 genes, since only 40% of individuals with DS have a CHD. Much evidence suggests phenotypic variation is related to specific alleles, and protein products functioning suboptimally in trisomic cells. We identified the COL6A1-A2 gene cluster as a CHD critical region. In individuals with partial trisomy and DS + CHD, COL6A1 has never been excluded from a causal role. We screened 91% of the COL6A1 coding region in 97 families, including individuals with DS +/- CHDs. Of those 19 had complete AV canal defect (AVSD), 11, ventricular septal defect (VSD) and 19 a combination/other CHD. There is a higher than expected level of coding and non-coding variation in COL6A1, with over 30 variable sites identified including mutations in the collagen VI 1 chain C-terminal globular region. We identified novel amino acid changes in the triple-helical (TH) region that may perturb heterotrimer formation with 2 and 3 chains, in native collagen VI monomers. COL6A1 genomic analysis identifies a putative cryptic splice site that may result in alternative splicing and detects an intron conserved more highly than the flanking exons. The next intron has exceptional length and sequence variation suggestive of a recombination hot spot: there may be a similarly polymorphic region in the analogous COL6A2 position. We have evidence that a subset of these haplotypes discriminates between individuals with DS or DS + CHD. Collagen VI tertiary structure may affect complex higher order interactions during heart development. Recent published evidence shows that trisomic 21 fibroblasts have increased adhesive capacity for extracellular collagen VI through 1 integrin interaction. We propose that alterations in higher order structure of collagen VI protein result from combinations of mutations embedded in particular COL6A1 haplotypes. This may lead to altered trisomic cell adhesiveness resulting in a single or several types of CHD.

**An Investigation of the Matrix Metalloproteinase-3 -1612 5A/6A Polymorphism in Ischemic Heart Disease using Family Based Tests of Association.** *P.G. McGlinchey<sup>1</sup>, M.S. Spence<sup>1</sup>, G. Murphy<sup>1</sup>, A.R. Allen<sup>2</sup>, C. Patterson<sup>3</sup>, P.P. McKeown<sup>2</sup>.* 1) Department of Cardiology, Royal Victoria Hospital, Belfast, United Kingdom; 2) Department of Medicine, Queen's University of Belfast, United Kingdom; 3) Department of Epidemiology & Public Health, Queen's University of Belfast, United Kingdom.

**Introduction.** Atherosclerosis is the pathological basis of ischemic heart disease (IHD). Matrix metalloproteinases (MMPs) are enzymes important in vascular remodelling, a feature of atherosclerosis. Increased MMP activity predisposes to atherosclerotic plaque rupture, a feature of acute myocardial infarction and unstable angina. In contrast, reduced MMP activity may cause decreased matrix degradation, leading to increased plaque size. MMP3 has been found in plaques and has the broadest spectrum of activity of all MMPs. A common polymorphism in the promoter region of the MMP3 gene, the -1612 5A/6A polymorphism, has functional importance in vitro, with the 5A allele associated with increased MMP3 expression. Case-control studies have shown conflicting findings of the role of this polymorphism in IHD. We investigated this polymorphism in a well-defined IHD population using two family based tests of association. **Methods.** Families with at least one individual with premature onset IHD (males 55 years, females 60 years) with all grandparents born in Ireland were recruited. Genotyping was performed using a PCR-RFLP method. Analysis was performed using the combined transmission disequilibrium test (TDT)/sib-TDT and the pedigree disequilibrium test (PDT). These tests are unaffected by population admixture. **Results.** 388 families consisting of 1023 individuals (418 affected cases, 110 parents, and 495 unaffected siblings older than the proband was at IHD onset) were recruited and genotyped. The -1612 5A/6A polymorphism was demonstrated to be not associated with IHD by either the combined TDT/sib-TDT ( $p=0.16$ ) or the PDT ( $p=0.06$ ). The study afforded over 80% power to detect a deviation of allele transmission from 50 to 60% ( $p0.05$ ). **Conclusion.** The MMP3 -1612 5A/6A polymorphism is not associated with premature-onset IHD in the Irish population.

**Atrioventricular septal defects in *Creld1*-deficient mice reflect the association of *CRELD1* mutations with heart defects in humans.** *C.L. Maslen, G.T. Fouad, S.W. Robinson.* Dept Molec/Med Genetics, Oregon Health & Science Univ, Portland, OR.

Atrioventricular septal defects (AVSD) are commonly occurring heart malformations, and are the most frequently diagnosed birth defect in the first year of life. The atrioventricular valves and septa form from progenitor cardiac structures called endocardial cushions. AVSD represents a failure of endocardial cushion development, resulting in incomplete septation. *CRELD1* is a novel membrane bound glycoprotein with characteristics of a cell adhesion molecule. The *CRELD1* gene maps to chromosome 3p25.3 in the vicinity of the *AVSD2* locus. Missense mutations in *CRELD1* are associated with AVSD in humans (Robinson, AJHG, 2003). In that study we found that about 6% of individuals with non-Down syndrome related AVSD have a *CRELD1* mutation. There is incomplete penetrance, indicating that *CRELD1* is a genetic risk factor for AVSD. To evaluate the specific role of *CRELD1* in heart development, we created a mouse model that has been genetically altered to eliminate the *Creld1* gene. Examination of *Creld1*<sup>-/-</sup> embryos shows that they die *in utero* at approximately embryonic day E11.0. Histopathologic analysis indicates that *Creld1*<sup>-/-</sup> mice have multiple heart malformations. The atrioventricular endocardial cushions are underdeveloped and have a reduced number of mesenchymal cells migrating into the cushions, as is required for normal development. Mice heterozygous for the disrupted allele (*Creld1*<sup>+/-</sup>) are usually viable and fertile with no obvious signs of abnormalities. However, a small subset of *Creld1*<sup>+/-</sup> embryos has pericardial edema. Those embryos have a deficiency in cellularization of the atrioventricular endocardial cushions similar to that seen in the null embryos, but the heart defects appear to be less severe than those seen in *Creld1*<sup>-/-</sup> embryos. These data demonstrate that *CRELD1* function is required for atrioventricular septal morphogenesis. Haploinsufficiency results in endocardial cushion defects with incomplete penetrance. The failure of endocardial cushion cellularization in *Creld1*-deficient mice is consistent with the association between *CRELD1* mutations and AVSD in humans.

**Involvement of chromosome Xp11.22 region in the human hypertension.** *M.Z. Labuda<sup>1</sup>, J. Uwabo<sup>1</sup>, Y. Sun<sup>1</sup>, D. Gaudet<sup>2</sup>, F. Gossard<sup>1</sup>, T. Kotchen<sup>3</sup>, A.W. Cowley<sup>3</sup>, J. Tremblay<sup>1</sup>, P. Hamet<sup>1</sup>.* 1) Medicine, Res.Center of Hotel Dieu Hosp , Montreal, Quebec, Canada; 2) Complexe Hospitalier de la Sagamie, Chicoutimi-Canada; 3) Medical College of Wisconsin, Milwaukee-USA.

Heat shock proteins (Hsp) play a critical role in maintaining cellular homeostasis as a protective response to different kind of stress. Hsp27 is one of such proteins involved in maintaining structural integrity and contractile function of the cardiac cell. Hsp27lp on human chromosome Xp has high similarity to Hsp27 but its functional status remains to be established. A 3UTR mRNA polymorphism resides in similar position in rat Hsp27 shown to be associated with hypertension. Here we investigated influence of this gene on hypertension status among subjects from French Canadian families from Saguenay-Lac St-Jean in Quebec. Our sample consisted of 774 individuals from 115 families (>250 sibships) selected for the presence of at least two sibs with early onset HT (55y). The analysis was carried out on 359 males and 415 females (66% and 60% hypertensive) and was performed according to gender, age and HT status. Subjects were stratified into the following groups NT<55y, NT>60y, NT 55-59y, HT with the onset 41-55y, HT with the onset >55y, HT with the onset <40y. In males, the frequency of genotype 1 (17.2%, 62/359 overall), increased with age among hypertensive and consequently decreased among NT with age. At 55-59y there was only 6.5% NT (2/31) genotype 1 male carriers, while over 60y none of 20 NT males was a carrier of this genotype. Among females divided into six groups the distribution of genotypes was significantly different ( $p=0.003$ ), in contrast to males, with overrepresentation of genotype 2/2 among HT. In a group by group comparison no significant different was observed but genotype 2 appeared to be a risk for developing early HT. Among females with late HT onset (55y) the frequency of genotype 1/1+1/2 increased to 41% comparing to 16% in whole female sample suggesting an influence of genotype 1 on HT among postmenopausal women. In conclusion: Our data suggests involvement of chromosome Xp11.22 region (possibly Hsp27lp) in human hypertension with a specific impact of age in each gender.

**QTLs for Atherosclerotic Lesions and Aortic Aneurysms in the C57BL/6J and C3H/HeJ Mouse Models. S.**

*Wang<sup>1</sup>, W.-B. Shi<sup>2</sup>, X.-P. Wang<sup>1</sup>, A. Ghazalpour<sup>1</sup>, A.J. Lusis<sup>1</sup>.* 1) Human Genetics, University of California, Los Angeles, CA; 2) Radiology, University of Virginia, Charlottesville, VA.

Inbred mouse strains C57BL/6J and C3H/HeJ differ strikingly in susceptibility to atherosclerosis on an apoE<sup>-/-</sup> background. B6.apoE<sup>-/-</sup> mice develop lesions readily whereas C3H on the same background are resistant. In order to identify the genes responsible for the difference in susceptibility, B6.apoE<sup>-/-</sup> and C3H.apoE<sup>-/-</sup> mice were crossed to generate 135 female F2 progeny for QTL analysis. The mice were fed on chow for 10 weeks, sacrificed, and a genome scan was conducted. The F2s were phenotyped for aortic lesions, calcification, aneurysms, weight, total cholesterol, HDL, LDL, free fatty acids, and glucose levels. QTLs for aortic lesions were found on proximal chromosome 9 (D9mit25) with a LOD score of 6.2, and on proximal chromosome 4 (D4mit111) with a LOD score of 3.0. A QTL for aneurysms was found over the same region of chromosome 4 with a LOD score of 4.8. We suspect the chromosome 4 QTL is caused by Toll-Like Receptor 4, an LPS receptor that is known to be nonfunctional in C3H mice due to a missense mutation. The chromosome 9 QTL is being further investigated through the construction of congenic mice. We hypothesize that genes involved in inflammatory responses are the primary determinants of atherosclerosis susceptibility in this model, as it has been shown in vitro that aortic endothelial cells isolated from B6 exhibit inflammatory response when treated with minimally oxidized LDL, while C3H endothelial cells fail to be induced.

**Genetics of salt sensitive and low renin hypertension.** *S.M. Williams<sup>1</sup>, J. Yatabe<sup>2</sup>, S. Midorikawa<sup>2</sup>, S. Hashimoto<sup>2</sup>, T. Watanabe<sup>2</sup>, J.H. Moore<sup>1</sup>, M.D. Ritchie<sup>1</sup>, P.A. Jose<sup>3</sup>, R.A. Felder<sup>4</sup>, H. Sanada<sup>2</sup>.* 1) Prog Hum Genet, Vanderbilt Univ Med Ctr, Nashville, TN; 2) Fukushima Med Univ, Fukushima, Japan; 3) Georgetown Univ Med Ctr, Washington, DC; 4) Univ of VA Health Sciences Ctr, Charlottesville, VA.

Salt sensitive hypertension is a genetic condition that affects millions of people world-wide. However, clinical diagnosis of salt sensitivity (SS) is difficult. Therefore, low renin (LR) hypertension is usually used as a proxy. We tested the hypothesis that these two conditions have the same underlying genetic basis by determining the best genetic model for each and comparing them. We studied 83 Japanese subjects (35 SS and 48 non-SS hypertensives) for SS and 131 Japanese subjects for renin status (70 LR and 61 normal/high renin hypertensives). For each cohort we studied 12 polymorphisms in 9 loci (3 SNPs in the G protein-coupled receptor kinase type 4 - GRK4; 2 SNPs in angiotensinogen, the indel variant in angiotensin converting enzyme, and 1 SNP in each of the following genes - AT1 receptor, CYP11B2, D1 receptor, alpha-adducin and G-protein beta3 subunit). We analyzed single site associations for the phenotypes and found significant associations for both SS and LR hypertension for all three SNPs in the GRK4 gene, and for LR hypertension for the CYP11B2 and alpha-adducin genes. In addition to single site analysis, we used multifactor dimensionality reduction (MDR) to determine the best genetic model for each phenotype. In the case of SS hypertension a 3 locus model incorporating all three GRK4 variants successfully predicted the phenotype correct 94.4% of the time. However, despite the single locus effects found for LR hypertension with all 3 variants in the GRK4 and the CYP11B2 and alpha-adducin genes, the best MDR model incorporated only one of the GRK4 variants and the SNP in the CYP11B2 (Prediction 84.5%). These results illustrate two important points: 1) the genetic basis of SS and LR hypertension, although having some overlap are not identical, suggesting that these two phenotypes are not the same and 2) interactions among genes may be more important in the genetics of complex phenotypes than marginal effects..

**Association of APOC3 -455T/C genotypes with coronary artery disease risk in Metabolic Syndrome patients.** *E. Trabetti<sup>1</sup>, O. Olivieri<sup>2</sup>, F. Pizzolo<sup>2</sup>, N. Martinelli<sup>2</sup>, D. Girelli<sup>2</sup>, A. Bassi<sup>3</sup>, R. Corrocher<sup>2</sup>, P.F. Pignatti<sup>1</sup>.* 1) Mother-Child & Biol-Genetics, Univ. Verona, Verona, Italy; 2) Dept. Clinical & Experimental Medicine, Univ. Verona, Verona, Italy; 3) Institute of Clinical Chemistry, Univ. Verona, Verona, Italy.

**Background.** We have recently demonstrated (1) that homozygosity for APOC3 -455T/C variant represents an independent susceptibility factor for coronary artery disease (CAD). This variant has a reduced affinity for the nuclear factors mediating the inhibitory insulin effect on the apo CIII gene transcription, so that it is considered the first example of insulin resistance at the gene level. Metabolic Syndrome includes obesity, hypertension, diabetes or glucose intolerance and disorders of lipid metabolism, and it is linked to insulin activity. **Materials and Methods.** We studied a total of 873 patients, 549 of whom had angiographically documented coronary atherosclerosis, whereas 251 had normal coronary arteriograms. Patients were also classified as having the metabolic syndrome (MS, n=270) or not (MS-free, n=603) according the Adult Treatment Panel III (ATP III) criteria. We measured plasma lipids, insulin and apolipoproteins A1, B, E, C-III and assessed APOC3 -455T/C genotype of all patients. **Results.** In CAD patients, 17.7% were homozygous for the -455C variant compared to 10.2% in CAD-free group ( $p < 0.02$ ), whereas there was no difference in genotype frequency between MS and MS-free group (15.2 vs 15.4, NS). However, OR for CAD in MS patients was increased in individuals carrying -455C: OR=5.988 (2.88-12.42) in heterozygotes, and OR=9.276 (2.17-39.6) in CC homozygotes. The -455C variant was also associated with increased apo CIII and TG levels. **Conclusions.** APOC3 -455T/C genotypes contribute to increase the CAD risk associated with the Metabolic Syndrome, and are associated with increased plasma levels of TG-rich lipoproteins and apo CIII. (1) O. Olivieri et al. Apo CIII gene polymorphisms and risk of coronary artery disease. *Journal of Lipid Research*, 43:1450-1457, 2002.

**PON2 Ser311Cys genotype, and its interaction with smoking, increase the risk of myocardial infarction in patients with coronary atherosclerosis.** *P.F. Pignatti<sup>1</sup>, D. Girelli<sup>2</sup>, N. Martinelli<sup>2</sup>, O. Olivieri<sup>2</sup>, F. Pizzolo<sup>2</sup>, S. Friso<sup>2</sup>, I. Tenuti<sup>2</sup>, R. Corrocher<sup>2</sup>, M. Grow<sup>3</sup>, S. Cheng<sup>3</sup>, E. Trabetti<sup>1</sup>.* 1) Dept Mother & Child/Biol & Gen, Univ Verona, Verona, Italy; 2) Dept. Clinical & Experimental Medicine, Univ. Verona, Verona, Italy; 3) Dpt. Hum. Genetics, Roche Molecular Systems, Inc., Alameda, CA, USA.

**Background.** Increased oxidative stress is a major determinant of endothelial dysfunction, involved in the pathogenesis of the atherothrombotic process. Paraoxonases (PON) are a group of enzymes with antioxidant properties. Three common polymorphisms have been described in PON genes (PON1 Leu55Met and Gln192Arg; PON2 Ser311Cys), with possible implications for the risk of coronary atherosclerotic disease (CAD) or its main thrombotic complication, myocardial infarction (MI). **Methods.** 890 subjects were subjected to angiographic documentation of coronary vessels (272=CAD-free; 618=CAD). In the CAD group, 341 subjects had documentation of MI. All the conventional risk factors for CAD and the above mentioned PON1 and PON2 gene polymorphisms were assessed. The interaction of the polymorphisms with smoking, the main environmental factor involved in oxidative damage, was evaluated. **Results.** An increased frequency of heterozygotes and homozygotes for PON2 311Cys were present among CAD subjects with MI than among CAD subjects without MI (35.5% vs 28.8%, and 7% vs 3.6%, respectively; P 0.01). By multivariate logistic regression analysis, the adjusted OR for MI among PON2 311Cys carriers was 1.5 (95% CI, 1.03-2.19). Smoking was associated to an increased risk of MI (OR=1.6; 95% CI, 1.2-2.3). The risk of MI in smokers was related to PON2 Ser311Cys genotypes, being significantly increased in Cys/Cys homozygotes (OR=5.6; 95% CI, 1.7-16.4) and heterozygotes (OR=2.1; 95% CI, 1.3-3.6), but not in Ser/Ser homozygotes (OR=1.2; 95% CI, 0.8-1.8). PON2 Ser311Cys genotype did not influence risk of MI in non-smoker CAD. **Conclusions.** In subjects with CAD, MI risk may be influenced by the interaction between PON2 Ser311Cys genotype and smoking.

**Adrenergic receptor polymorphisms associated with resting heart rate: The HyperGEN Study.** *J.B. Wilk<sup>1</sup>, R.H. Myers<sup>1</sup>, J. Pankow<sup>2</sup>, S.C. Hunt<sup>3</sup>, M.F. Leppert<sup>3</sup>, R.C. Ellison<sup>1</sup>.* 1) Boston University School of Medicine, Boston, MA; 2) University of Minnesota School of Public Health, Minneapolis, MN; 3) University of Utah, Salt Lake City, UT.

Polymorphisms in the adrenergic receptor (AR) genes have been reported to be associated with cardiovascular function, including 1 AR polymorphisms associated with resting heart rate. We evaluated the association of polymorphisms in the 1, 2 and 2B ARs with resting heart rate in groups of participants in the HyperGEN Study: hypertensive and normotensive whites and African-Americans. Because beta-blockers are known to influence heart rate, hypertensives using these medications were evaluated separately. All analyses were adjusted for age, sex, body mass index, alcohol use, smoking status, and measures of daily exercise. The Ser49Gly polymorphism of the 1 AR was significantly associated with resting heart rate in two groups. In hypertensive African-Americans not taking beta-blockers, carriers of the Gly allele had a higher mean resting heart rate by 4.7 beats per minute compared to Ser allele homozygotes ( $p=0.008$ ). In contrast, the Gly homozygotes in the normotensive white sample had a mean resting heart rate 4.1 beats per minute lower than the Ser allele carriers ( $p=0.007$ ). The 2 AR polymorphism Gly16Arg was associated with lower mean heart rate in the sample of white hypertensives taking beta-blockers ( $n=103$ ), where the Arg homozygotes had 5.8 beats per minute lower mean heart rate ( $p=0.03$ ). The 2B C/A polymorphism was associated with heart rate in the small sample ( $n=33$ ) of hypertensive African-Americans taking beta-blockers, where carriers of the A allele had higher mean resting heart rate by 7.8 beats per minute compared to C homozygotes ( $p=0.03$ ). In summary, the Ser49Gly polymorphism of the 1 AR was associated with heart rate, but opposite effects were seen for different racial and hypertension status groups. The increased sympathetic nervous system activation that occurs with hypertension may modify the effect of the Ser49Gly polymorphism on heart rate. Polymorphisms in the 2 and 2B ARs exhibit evidence for association with heart rate among hypertensives treated with beta-blockers.

**Genome-wide scan for conotruncal heart defect loci in a canine model.** *P. Werner<sup>1</sup>, M.G. Raducha<sup>1</sup>, U. Prociuk<sup>1</sup>, E.O. Ostrander<sup>2</sup>, R.S. Spielman<sup>3</sup>, E.F. Kirkness<sup>4</sup>, D.F. Patterson<sup>1</sup>, P.S. Henthorn<sup>1</sup>.* 1) School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA; 2) Clinical Research and Human Biology Divisions, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) The Institute for Genomic Research, Rockville, MD.

Isolated (non-syndromic) congenital heart defects (CHDs) are among the most common birth defects in humans and dogs. In both species, inheritance patterns are usually non-Mendelian and multifactorial inheritance has been assumed. Conotruncal defects (CTDs), a subgroup of CHDs, consist of a spectrum of defects of the conus septum, conal ventricular septal defects, tetralogy of fallot, and persistent truncus arteriosus. We performed a genome-wide scan for CTD linked loci in a keeshond dog F1 backcross pedigree in which 46 of 101 offspring had CTDs. Two-point linkage analysis under a model of autosomal recessive inheritance identified regions of suggestive linkage on three canine chromosomes: CFA2, CFA9, and CFA15. None of these loci by itself accounted for segregation of CTD in the pedigree. Multipoint parametric analysis with GENEHUNTER resulted in a significant LOD score for CFA9 (corrected LOD score of 3.31) and supported linkage to loci on CFA2 and CFA15 (corrected LOD scores of 2.71 and 3.03). GENEHUNTER TWOLOCUS analysis supported the hypothesis that CTD in the keeshond is oligogenic and suggested that, in a given individual, CTD-predisposing alleles for at least two of the three loci are necessary to produce CTD. Two of the CTD-linked canine chromosome regions contain genes that when knocked out in mice produce cardiac malformations similar to keeshond CTD: CX45 on CFA9 and EDNRA on CFA15. The CTD-linked regions in the dog are orthologous to portions of human chromosomes 5, 17, and 4. Genes known to be involved in congenital heart disease or heart development excluded by these studies include HAND1, CSX, TBX5, HAND2, and CSPG2 (Versican).

**The genetics of bleeding after cardiac surgery.** *I.J. Welsby, M. Podgoreanu, J. Mathew, B. Phillips-Bute, M.F. Newman, D.A. Schwinn, M. Stafford-Smith.* Anesthesiology, Duke University Medical Center, Durham, NC.

**Introduction** While some individual prothrombotic polymorphisms have been independently associated with bleeding after cardiac surgery, the joint effects of multiple genetic variant have never been studied. Therefore, we examined the association of 19 prospectively defined candidate prothrombotic polymorphisms with bleeding after coronary artery bypass grafting (CABG) surgery. **Methods** Following informed consent, 890 adult patients undergoing primary elective CABG surgery were enrolled in the study. Renal disease, liver disease and preoperative coagulopathy were exclusion criteria. After confirming Hardy-Weinberg equilibrium, univariate and multivariate analyses were used to identify possible associations between polymorphisms and 12 hour chest tube drainage. Those with a promising univariate association were included in a final multivariate linear regression model, which also examined potential interactions between polymorphisms. Bootstrap analysis was performed to test the validity of the final model; results are expressed as the number of times the association was significant in 100 resamplings. **Results** Upon preliminary analysis, four polymorphisms appear associated with chest tube drainage. The relationships are complex and involve paired 2-way interactive effects. Final results of our analysis will be presented at the meeting. **Discussion** Strengths of our study include that it examines multiple genetic polymorphisms simultaneously, involves a large number of patients, and measures a clinically important outcome. Our study design enables identification of 2-way interactive effects of common polymorphisms, whereas studies focused on a single polymorphism may overlook such interactions. Our findings in this relatively unstudies patient population may prove very clinically important.

Program Nr: 2039 from 2003 ASHG Annual Meeting

**Effect of an *NCCT* mutation on blood pressure in the Amish.** *S. Rutherford, J.O. Green, B.D. Mitchell, A.R. Shuldiner.* Dept Medicine, Univ Maryland, Baltimore, Baltimore, MD.

Hypertension (HT) affecting approximately 20-25% of Caucasian adults is a common multifactorial disorder and a well-known predisposing risk factor for stroke, renal failure and cardiovascular disease. The condition has a genetic basis, although at present the number of genes are unknown. The molecular basis for the Mendelian forms of HT such as glucocorticoid-remediable aldosteronism, Liddles syndrome and the syndrome of apparent mineralocorticoid excess are shown to arise from mutations that increase renal salt. Previous studies have shown mutations in the thiazide-sensitive sodium-chloride cotransporter gene (*NCCT*) reduce renal salt reabsorption and blood pressure in a large Amish kindred with Gitelmans syndrome [Cruz et al., (2001) *Hypertens* 37:1458-1464]. One of the mutations identified in *NCCT* is a single base substitution (CGC->GGC) at codon 642, which substitutes a glycine for the normal arginine located in a conserved region in the cytoplasmic C-terminus of the encoded protein. This mutation results in a loss of *NCCT* function. We therefore tested this mutation in an Old Order Amish population from Lancaster County, Pennsylvania that previously shows evidence for a genetic susceptibility to blood pressure variation [Hsueh et al., (2000) *Circulation* 101:2810-2816]. For this study, we used a PCR assay to genotype the single base substitution in approximately 1400 Amish individuals. Preliminary data from association analysis showed no significant differences between 90 hypertensive individuals who either had blood pressures greater than 140/90mmHg or were currently using antihypertensive medication, and 88 normotensive individuals over 45 years of age with blood pressures less than 120/80 mmHg. We are continuing to genotype more Amish individuals and will present the results from association analysis in the expanded set of Amish individuals.

**Myocardial Ion Channel IKr-alpha-Subunit Genes KCNH2 and KCNE2: Haplotype structure and modulation of the QTc Interval.** A.S. Pfeufer<sup>1</sup>, S. Perz<sup>3</sup>, S. Jalilzadeh<sup>1</sup>, T. Illig<sup>2</sup>, J. Muller<sup>1</sup>, H. Lowel<sup>2</sup>, G. Steinbeck<sup>4</sup>, H.E.

Wichmann<sup>2</sup>, S. Kaab<sup>4</sup>, T. Meitinger<sup>1</sup>. 1) Institute of Human Genetics, TU Munich and GSF Research Center, Munich, Germany; 2) Institute of Epidemiology, TU Munich and GSF Research Center, Munich, Germany; 3) Institute of Medical Informatics, TU Munich and GSF Research Center, Munich, Germany; 4) Medizinische Klinik und Poliklinik I, Klinikum der LMU Munich, Grosshadern, Munich, Germany.

The QT interval in the surface ECG is a sensitive and specific indicator of myocardial repolarization. QT prolongation indicates repolarization disturbances leading to TdP tachycardia and sudden cardiac death. Family and sib-pair studies have identified a 36% to 52% genetic component of QT. We investigated minor gene variants of the myocardial Ion Channel IKr-alpha-Subunit and long QT syndrome disease Genes KCNH2 and KCNE2 for their influence on QT. Surface-ECG recordings from participants of a population based epidemiological survey in the Augsburg region (n=4149) were used. QT correction parameters for heart rate (RR interval, +0.153 ms/ms) age (+0.245 ms/y) and sex (+7,70 ms for female) were determined by linear regression. The combined influence of these three independent variables on QT accounted for 1,59% of its total variance by multivariate regression analysis. For genetic analysis patients on cardiac medication or those showing signs of any disease pathology in their ECGs were excluded (remaining n=1019). Measured QT values were transformed to heart rate-, age- and sex- independent QTc values. Mean QTc was 409 ms (SD +/- 15 ms) when standardized to a 45y old male with a heart rate of 60/min. Genotyping of 45 SNPs revealed strong LD within both genes. Haplotype analysis revealed the 5 major haplotypes (AF>0,05) in KCNH2 and in 2 in KCNE2. Within the KCNH2 gene several consecutive SNPs showed a significant association to QTc. Most significantly associated was KCNH2 I489I (rs740952). In GG carriers QTc was 408,1 +/- 15,4 ms (n=634), in GA heterozygotes it was 410,0 +/- 14,9 ms (n=304) and in AA homozygotes 414,6 +/- 17,3 ms (n=43) (p = 0,004). The effect of the I489I SNP was of the same quality in both males and females but found stronger in males.

**Pank4, A novel pantothenate kinase gene is a Candidate Gene for Type II Diabetes Mellitus.** *Y. Li<sup>1</sup>, L. Liu<sup>1</sup>, J. Zhao<sup>2</sup>, J. Zuo<sup>1</sup>, F. Fang<sup>1</sup>.* 1) National Laboratory of Medical Molecular Biology, Institute of Basic Medical Sciences, Peking Union Medical College, Chinese Academy of Medical Sciences, 5# Dong Dan San Tiao, Beijing, P. R. China 100005; 2) Human Genetics Center, The University of Texas, Health Science Center at Houston, Houston TX 77030, USA.

**Purpose:** To identify the function of a SD rat novel pantothenate kinase gene(pank4).

**Methods:**Pank4 was cloned from SD rat by messenger RNA differential display and its expression has been localized in many tissues by immunohistochemistry. Several proteins concern with regulation of blood glucose have been found to interact with Pank4 protein by yeast two-hybrid. The result has been further analyzed by far-western blotting and immunoprecipitation..

**Result:**A novel pantothenate kinase gene,Pank4, which was cloned from SD rat, is related to blood-glucose regulation and had ever been named Fang-1 (GenBank Accession NO.AF399873), and shared high similarity with its human homologue (GenBank Accession No. AK001644), which was identified as the pantothenate kinase 4 (pank4) gene. Firstly, the pank4 antibody was obtained by immunizing rabbit and purified, then immunohistochemicalized to rat muscle, heart muscle, lung, liver, kidney ,pancreas, hypothyroid, brain and small intestine tissues, the pank4 protein mainly express in some kind of cells which need more energy. So we can concluded that the pank4 may be related to energy producing. Secondly, by yeast two-hybrid using the pank4 as bait, we found that pank4 was interacted with 3 beta-hydroxysteroid dehydrogenase isomerase type II, glyceraldehyde- 3-phosphate dehydrogenase, *Rattus norvegicus* pyruvate kinase, *Rattus norvegicus* glycogen Phosphorylase, by in-vivo and in vitro identification, pank4 was interacted with these proteins. The result suggested that pank4 is not only a key regulatory enzyme in the CoA biosynthesis, but also is a key regulatory enzyme in the saccharometabolism. It may play a very important role in the glucoregulation. So we proposed the the pank4 may be a novel candidate gene for type II diabetes mellitus.

**CAG repeat alteration and parental origin of the androgen receptor in Turner syndrome.** *S.M. Zeng, J. Yankowitz.*  
Dept OB/GYN, University of Iowa Roy J. and Lucille A. Carver College of Medicine, Iowa City, IA.

Turner syndrome (TS) is a common cytogenetic abnormality characterized by a female phenotype with short stature, gonadal dysgenesis, and various somatic stigmata. The etiology for these specific features is obscure. Evidence points to a lack of important genes on the missing X-chromosome or segment. Circulating androgen levels are reduced in TS and androgen treatment may improve some problems in TS patients. Thus androgen deficiency maybe involved in the pathophysiology of TS. Androgen acts through its intracellular receptor (AR). Polymorphic trinucleotide repeats of CAG can regulate activity of the AR. Changes in CAG repeat number have been implicated in the pathogenesis of spinal bulbar muscular atrophy, ambiguous genitalia, and cancer. We evaluated CAG repeat length of AR in TS. We also evaluated any relation to parental origin of the X-chromosome.

CAG repeat length and X chromosomal parental origin was analyzed in 60 45,X TS patients by means of genotyping and sequencing techniques. CAG repeats were categorized into two groups by the trinucleotide repeat length; short (CAG < 22) and long (CAG  $\geq$  22) repeat length. The frequencies of short and long repeats are 20% (12/60) and 80% (48/60), while in 96 controls 8.3% (8/96) had the short repeat and 91.7% (88/96) had the long repeat. TS patients have a significantly higher frequency of the short CAG repeat compared with normal controls ( $P=0.034$ ). Parental origin of CAG repeats was determined in 49 of 60 TS cases. In 12 patients with short CAG repeat 5 cases had a paternally derived X and 7 patients had a maternally derived X. In 37 patients with long CAG repeat 11 had a paternally derived X and 26 had a maternally derived X. No significant difference in parental origin of the CAG repeat exists between the patients with short and long repeats ( $P>0.05$ ).

Our results show no association between CAG repeat length and parental source of the X chromosome. TS patients appear to have a greater chance of short CAG repeats than controls. This might contribute to some of the phenotypic features of TS.

**Patterns of Differential Gene Expression In Schizophrenia Overlap In Cortical Regions.** *M.P. Vawter<sup>1</sup>, S.J. Evans<sup>2</sup>, P. Choudary<sup>3</sup>, M. Atz<sup>1</sup>, H. Tomita<sup>1</sup>, B. Bolstad<sup>5</sup>, J. Li<sup>4</sup>, T. Speed<sup>6,7</sup>, R. Myers<sup>4</sup>, S.J. Watson<sup>2</sup>, E.G. Jones<sup>3</sup>, H. Akil<sup>2</sup>, W.E. Bunney<sup>1</sup>, NIMH Conte Center and Pritzker Neuropsychiatric Disorders Research Consortium.* 1) Dept Psychiatry, Univ California, Irvine, Irvine, CA; 2) MHRI, University of Michigan, Ann Arbor, MI; 3) Center for Neuroscience, University of California, Davis, CA; 4) Stanford Human Genome Center, Stanford University, Palo Alto, CA; 5) Group in Biostatistics, University of California, Berkeley, CA; 6) Department of Statistics, University of California, Berkeley, CA; 7) Division of Genetics and Bioinformatics, WEHI, Melbourne, Australia.

This project involves a multi-site collaborative effort to investigate gene expression in neuropsychiatric disorders in multiple brain regions. We have investigated schizophrenia (n = 9) and controls (n = 9) by microarray analysis using Affymetrix U133A and B chips. We report on the microarray comparison of three cortical regions: dorsolateral prefrontal cortex (DLPFC), anterior cingulate, and entorhinal cortex (ERC). We selected the top and bottom differentially expressed genes for schizophrenia from a robust probe level linear model analysis (<http://stat-www.berkeley.edu/users/bolstad/AffyExtensions/AffyExtensions.html>) for each brain region. The top 500 and bottom 500 changed genes were further classified using Gene Ontology and KEGG classifications. There was over-representation of ribosomal genes, heat shock related genes, chaperone genes, and immune genes in cortical regions. The preliminary gene classifications for the ERC, DLPFC and anterior cingulate will be compared to the results from the hippocampus. The preliminary microarray evidence suggests several cortical regions share overlapping expression patterns for genes dysregulated in schizophrenia. This work was supported by NIH Conte Center Grant MH60398-03 and the Pritzker Neuropsychiatric Disorder Research Consortium Fund.

**Effects of Mood Disorders and Suicide on Gene Expression Profiles in Postmortem Brains.** *H. Tomita<sup>1</sup>, M.P. Vawter<sup>1</sup>, S.J. Evans<sup>2</sup>, P. Choudary<sup>3</sup>, J. Li<sup>4</sup>, B. Bolstad<sup>5</sup>, T. Speed<sup>6,7</sup>, R.M. Myers<sup>4</sup>, E.G. Jones<sup>3</sup>, S. Watson<sup>2</sup>, H. Akil<sup>2</sup>, W.E. Bunney<sup>1</sup>, NIMH Conte Center and Pritzker Neuropsychiatric Disorders Research Consortium.* 1) Dept Psychiatry, Univ California, Irvine, Irvine, CA; 2) MHRI, University of Michigan, Ann Arbor, MI; 3) Center for Neuroscience, University of California, Davis, CA; 4) Stanford Human Genome Center, Stanford University, Palo Alto, CA; 5) Group in Biostatistics, University of California, Berkeley, CA; 6) Department of Statistics, University of California, Berkeley, CA; 7) Division of Genetics and Bioinformatics, WEHI, Melbourne, Australia.

To examine gene expression changes in mood disorders, gene transcript abundance was measured by microarray analysis in patients with bipolar disorder type I (BPD, n = 9), major depressive disorder (MD, n=11), and compared to a control group (n=20) matched for age, gender, and post mortem interval (PMI). Also, a subgroup of 4 BPD and 6 MD patients who committed suicide was compared to the remaining mood disorder patients, and controls who died rapidly by accident or acute diseases. Total RNA was extracted from three brain regions, anterior cingulate, dorsolateral prefrontal and cerebellar cortices, and each sample was run in duplicate on Affymetrix U95Av2 chips at 3 laboratories. Signal intensity of each gene was extracted using three independent methods, microarray suite version 5.0, robust multi-array analysis (RMA) and probe level model analysis (PLM). Microarray findings were validated by quantitative RT-PCR. Effects of agonal state, brain pH, age, gender, and PMI on gene expression profile were evaluated along with the disorders. These differences in gene expression profile involving multiple signaling pathways such as MAPK pathway will be discussed in the context of pathogenesis of severe mood disorders involving suicidal behavior. This work was supported by NIH Conte grant MH60398-03 and the Pritzker Neuropsychiatric Disorder Research Consortium Fund. We acknowledge participation of all Consortium members in this work.

**Heterozygous mutations in *BBS1*, *BBS2* and *BBS6* have a potential epistatic effect on Bardet-Biedl patients with two mutations at a second BBS locus.** *J.L. Badano*<sup>1</sup>, *J.C. Kim*<sup>2</sup>, *B.E. Hoskins*<sup>3</sup>, *R.A. Lewis*<sup>4,5,6,7</sup>, *S.J. Ansley*<sup>1</sup>, *D.J. Cutler*<sup>1</sup>, *C. Castellan*<sup>9</sup>, *P.L. Beales*<sup>3</sup>, *M.R. Leroux*<sup>2</sup>, *N. Katsanis*<sup>1,8</sup>. 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD 21287, USA; 2) Department of Molecular Biology and Biochemistry, Simon Fraser University, Burnaby BC, Canada V5A 1S6; 3) Molecular Medicine Unit, Institute of Child Health, University College London, London WC1N 1EH, UK; 4) Departments of Molecular and Human Genetics; 5) Ophthalmology; 6) Pediatrics and; 7) Medicine, Baylor College of Medicine, Houston, TX 77030, USA; 8) Wilmer Eye Institute, Johns Hopkins University; 9) The Clinical Genetics Service, Bolzano General Hospital, Bolzano 39100, Italy.

Bardet-Biedl syndrome (BBS) is a pleiotropic genetic disorder with substantial inter- and intrafamilial variability, that also exhibits remarkable genetic heterogeneity, with seven mapped BBS loci in the human genome. Recent data have demonstrated that BBS may be inherited either as a simple Mendelian recessive or as an oligogenic trait, since mutations at two loci sometimes are required for pathogenesis. This observation suggests that genetic interactions between the different BBS loci may modulate the phenotype, thus contributing to the clinical variability of BBS. We present three families with two mutations in either *BBS1* or *BBS2*, in which some but not all patients carry a third mutation in *BBS1*, *BBS2*, or the putative chaperonin *BBS6*. In each example, the presence of three mutant alleles correlates with a more severe phenotype. For one of the missense alleles, we also demonstrate that the introduction of the mutation in mammalian cells causes a dramatic mislocalization of the protein compared with the wild-type. These data suggest that triallelic mutations are not always necessary for disease manifestation, but might potentiate a phenotype that is caused by two recessive mutations at an independent locus, thus introducing an additional layer of complexity on the genetic modeling of oligogenicity.

**Multiplexed Pyrosequencing Analysis of CARD15 Gene Mutations in Inflammatory Bowel Disease.** *S. Toth*<sup>1</sup>, *O. Palmieri*<sup>2</sup>, *A. Ferraris*<sup>2</sup>, *A. Andriulli*<sup>2</sup>, *A. Latiano*<sup>2</sup>, *V. Annese*<sup>2</sup>, *B. Dallapiccola*<sup>2</sup>, *M. Devoto*<sup>2</sup>, *S. Surrey*<sup>2</sup>, *P. Fortina*<sup>2</sup>.  
1) Pyrosequencing, Inc., Westboro, MA; 2) Thomas Jefferson University, Philadelphia, PA.

Crohn's disease (CD) and Ulcerative colitis (UC), the main types of Inflammatory Bowel Disease (IBD), have a genetic predisposition. Recently, mutations in the Caspase recruitment domain protein 15 (CARD15/NOD2) gene have been identified in patients with Crohn's disease, one of the most frequent causes of gastrointestinal morbidity in Western Europe and North America. A triplex Pyrosequencing protocol was developed for the rapid detection of three common, clinically relevant single-base changes (SNPs) in the NOD2 gene. Pyrosequencing technology was used to detect gene variants: 3020InsC, Arg702Trp, and Gly908Arg in research samples from Italian families and unrelated controls. Three PCR primer pairs were used to amplify the region encompassing each single-base variant interrogated in this study. One primer from each pair contained a 5'-biotin group that was used to purify single-stranded DNA bound to Sepharose beads. Template DNA was annealed with a sequencing primer and the primer strand was elongated by the sequential addition of individual nucleotides to generate sequence information. Following each nucleotide addition and extension step, excess dNTPs were degraded by apyrase. Pyrosequencing technology couples DNA sequencing by synthesis with an enzymatic cascade to generate a light signal whenever pyrophosphate is released following nucleotide incorporation into the DNA template. Research samples from 458 IBD families (with 2+ affected individuals) were analyzed, including 170 CD (affected and non-affected members), 210 UC and 78 Mixed families (members with CD or UC). Genotyping results using Pyrosequencing technology were shown to be concordant with results obtained previously with other genotyping methods. A significant association between NOD2 gene mutations and CD was demonstrated in the Italian population samples. This technology was shown to be a rapid and effective research methodology for genotyping mutations in complex diseases.

**Translocation breakpoint in two unrelated Tourette syndrome cases, within a region previously linked to the disorder.** *F. Crawford*<sup>1,2</sup>, *G. Ait-Ghezala*<sup>1</sup>, *M. Sutcliffe*<sup>3</sup>, *R. Hauser*<sup>4</sup>, *A. Silver*<sup>1</sup>, *M. Mullan*<sup>2,5</sup>. 1) Child Development Center, Department of Psychiatry, Univ South Florida, Tampa, FL; 2) James A Haley Veterans Administration, Tampa, FL; 3) All Childrens Hospital, St. Petersburg, FL; 4) Department of Neurology, University of South Florida, Tampa, FL; 5) Roskamp Institute, 2040 Whitfield Avenue, Sarasota, FL.

We have described two unrelated families wherein balanced t(6;8) chromosomal translocations occur in individuals diagnosed with Tourette Syndrome (TS). In one of these families, the transmission of the translocation is associated with learning and behavioral difficulties; in the other family one parent is unaffected and the other cannot be traced, thus transmission cannot be demonstrated and it is possible that the translocation may have occurred de novo. The breakpoint on chromosome 8 occurs within the q13 band in both families, suggesting that a gene or genes in this region might contribute to the TS phenotype. Existing linkage and cytogenetic data, suggesting involvement of chromosome 8 in TS families and individuals, further support this hypothesis. We have identified two YAC clones mapping distal and proximal to the chromosome 8 translocation site as determined by Fluorescent In Situ Hybridization (FISH). PCR amplification of genetic markers in this region, using isolated chromosomes from one of the patients, followed by BAC screening with the closest flanking genetic markers, has identified a 200Kb BAC which by FISH we have demonstrated encompasses the chromosome 8 breakpoint in both families. The fact that the chromosomal breaks in the TS cases from both families occur within such a small region of chromosome 8 further supports the hypothesis that disruption of a gene or genes in this part of chromosome 8 contributes to the clinical phenotype in these families.

**Functional COMT Polymorphism in a 22q11 Deletion Syndrome adult population.** *M. Gheorghiu<sup>1</sup>, E.W.C. Chow<sup>1,2</sup>, R. Weksberg<sup>2,3</sup>, A.S. Bassett<sup>1,2</sup>, O. Caluseriu<sup>1,3</sup>.* 1) Clinical Genetics Research, CAMH, Toronto, Ontario, Canada; 2) University of Toronto; 3) Hospital for Sick Children.

22q11 Deletion Syndrome (22qDS) is a congenital, autosomal dominant syndrome characterized by variable clinical features including learning disabilities, palatal abnormalities, congenital cardiac defects and psychiatric disorders, mainly schizophrenia. A microdeletion of 1.5-3.0 Mb is detectable by FISH in the majority of 22qDS patients but genetic mechanisms underlying the pathogenesis of 22qDS still remain to be clarified. One of the genes mapped to 22q11.2 is catechol-O-methyltransferase (COMT), an enzyme involved in degradation of dopamine. COMT has been proposed as a candidate for expression of psychiatric disorders including schizophrenia because of the role dopamine is hypothesised to play in schizophrenia pathogenesis. The COMT gene contains in exon 4 a functional polymorphism, Val158/108Met, that determines high or low activity of this enzyme, respectively. This could influence the level of dopamine in the prefrontal lobe which may be involved in the cognitive impairment and other behavioural expression commonly found in schizophrenia. We genotyped 50 adult subjects with 22qDS, 25 with schizophrenia (22qDS-SZ) and 25 non-psychotic (22qDS-NP), in order to investigate the Val158/108Met functional polymorphism in a COMT hemizygous population. There was no significant difference between the 22qDS-SZ and 22qDS-NP groups (n=13 and n=12, respectively, with the Met allele). However, examining symptom expression in the overall sample who had detailed symptom data we found that the 22 subjects (n=12 22qDS-SZ; n=10 22qDS-NP) with the Met allele had significantly more severe ratings on the excitement factor of schizophrenia than the 24 subjects (n=11 22qDS-SZ; n=13 22qDS-NP) with the Val allele ( $p=0.003$ ). Excitement factor items include hostility and impulsivity. These findings are consistent with a minor role of Val158/108Met as a modulator factor involved in schizophrenia pathogenesis in 22qDS patients.

**A balanced translocation t(4;15) associated with severe obesity.** *J. Klar*<sup>1</sup>, *B. Åsling*<sup>2</sup>, *M. Ulvsbäck*<sup>2</sup>, *A. Dellsén*<sup>2</sup>, *C. Ström*<sup>2</sup>, *A. Forslund*<sup>3</sup>, *N. Dahl*<sup>1</sup>. 1) Dept Genetics & Pathology, Uppsala Univ, Uppsala, Sweden; 2) AstraZeneca R&D, Mölndal, Sweden; 3) Department of Medical Sciences, Uppsala University, Sweden.

Obesity is a highly prevalent, multigenic trait that predicts increased morbidity and mortality and contributes to many health problems in the Western society. We have identified a family in which a mother and her two children present with severe obesity. These individuals have a body mass index (BMI) of 43-50 (normal 19-25). Chromosome analysis revealed a balanced reciprocal translocation t(4;15) in affected individuals. Dietary factors behind the phenotype were excluded. Clinical and biochemical investigations did not reveal any associated abnormalities or metabolic disturbances. Here we report the molecular cloning of the breakpoints and the identification of two genes affected by the rearrangement on chromosome 4 and 15 respectively. A novel fusion gene is formed by the translocation and a corresponding fusion transcript with an ORF is detected in adipocytes. This translocation and the identification of genes possibly affected by the breakpoints lead to the identification of yet unknown obesity-related genes and pathways.

**Behavioral characterization of mouse models for Smith-Magenis syndrome and Dup 17 (p11.2 p11.2).** *K. Walz<sup>1</sup>, C. Spencer<sup>1</sup>, K. Kaasik<sup>1</sup>, C.C. Lee<sup>1</sup>, J.R. Lupski<sup>1,2,3</sup>, R. Paylor<sup>1,4</sup>*. 1) Molecular & Human Gen, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Childrens Hospital, Houston, Texas; 4) Division of Neurosciences, Baylor College of Medicine.

Contiguous gene syndromes (CGS) refer to a group of disorders associated with chromosomal rearrangements in which the phenotype is thought to result from altered copy number of physically linked dosage sensitive genes. Smith Magenis Syndrome and [dup(17)(p11.2p11.2)] are CGS associated with a deletion or a duplication of band p11.2 of chromosome 17 respectively. Previously we reported the creation, by chromosomal engineering, of rearranged chromosomes carrying a deletion/deficiency (Df(11)17) or a duplication (Dp(11)17) of the syntenic region on mouse chromosome 11 that spans the genomic interval commonly rearranged in these patients. Here we present an exhaustive behavioral analysis of these models indicating that heterozygous animals carrying the engineered deletion (Df(11)17/+) or the duplication (Dp(11)17/+) are hypoactive or hyperactive respectively and both have learning disabilities. In addition period length differences were found for (Df(11)17/+) mice compared with wt littermates. These results indicate that a dosage sensitive gene present in this region is responsible for behavioral abnormalities in the mouse as has been shown for the human syntenic interval.

**Identification of Chromosome 7 Breakpoints in an Autistic Family Indicates Candidate Genes for Autism**

**Susceptibility.** *D.A. Skaar<sup>1</sup>, L. Christ<sup>2</sup>, M.L. Cucarro<sup>1</sup>, J.R. Gilbert<sup>1</sup>, S. Schwartz<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Dept. of Genetics, Case Western Reserve University, Cleveland, OH.

During ascertainment of multiplex families for linkage analysis of autism, a paracentric inversion in Chromosome 7 ((inv(7)(q22-q31.2)) was identified in Family 7543. Two of three children were affected with autism, and the third, while not meeting criteria for autism, exhibits expressive language disorder. All three sibs carry the paracentric inversion, which they inherited from their mother. Analysis of microsatellite markers on 7q showed support for linkage to autism in multiple studies over the ~30cM region which includes this inversion. The evidence for involvement of this inversion in autism is strong, given its occurrence in multiple autistic siblings, and the linkage analysis on this area of 7q. Therefore, the breakpoints of this inversion should identify genes involved in autism.

We report here the identification of the breakpoints. The first identification, to regions of BAC inserts by FISH, identified a 194kb region for the proximal, and a 175kb region for the distal breakpoint. The proximal breakpoint region contains a number of genes and pseudo-genes for Cytochrome P450 polypeptides (CYP3A5, CYP3A5P1, CYP3A7, CYP3A5P2, and CYP3A4) as well as the uncharacterized FLJ32468. The distal breakpoint region contains no known genes, but does contain several transcribed regions, indicated by ESTs, and one exon of a predicted novel gene. In order to identify the genes directly affected, the location of breakpoints is being narrowed down by southern blotting of restriction fragments, which will be presented.

**Serum cholesterol and suicidality in Smith-Lemli-Opitz syndrome heterozygotes.** A. Lalovic<sup>1</sup>, L. Merkens<sup>2</sup>, G. Arsenault-Lapierre<sup>1</sup>, M. Nowaczyk<sup>3</sup>, F.D. Porter<sup>4</sup>, L. Russell<sup>5</sup>, R. Steiner<sup>2</sup>, G. Turecki<sup>1</sup>. 1) McGill Group for Suicide Studies, Douglas Hospital Research Centre, Verdun, QC, Canada; 2) Oregon Health Sciences University, Portland, OR, USA; 3) McMaster University, Hamilton, ON, Canada; 4) Heritable Disorders Branch, NICHD, NIH, Bethesda, MD, USA; 5) Montreal Children's Hospital, Montreal, QC, Canada.

It is well established that family history of suicidal behavior represents an increased risk of suicide for an individual, and this combined with consistent evidence from twin and adoption studies suggests that there is a genetic component to suicidal behavior. Interest in cholesterol as a biological marker of suicide risk has been sparked by a large number of studies demonstrating an association between low serum cholesterol and suicidal behavior. Smith-Lemli-Opitz syndrome (SLOS) heterozygotes may serve as an interesting model in which to examine the relationship between natively lower levels of cholesterol and suicidal behavior, while concurrently investigating the genetic aspects of suicide. Smith-Lemli-Opitz syndrome is a developmental disorder caused by recessively inherited mutations in the gene for the enzyme 7-dehydrocholesterol reductase involved in cholesterol biosynthesis. Parents of SLOS children are obligate heterozygotes and are clinically normal, but due to the partial enzymatic defect have cholesterol levels that fall in the lower range. We examined suicidal behavior, impulsivity, aggression and depression in SLOS heterozygotes (n = 51) and controls (n = 54). Controls, like SLOS heterozygotes, were parents of children with a chronic debilitating disorder, thus controlling for important effects of care-giver stress. SLOS heterozygotes reported a positive family history of attempted and completed suicide significantly more frequently than controls (30.6% SLOS heterozygotes, 9.3% controls;  $p < 0.05$ ), while family history of psychiatric disorders did not significantly differ between the groups. History of attempted suicide tended to be more common among SLOS heterozygotes (6.0% SLOS heterozygotes, 1.9% controls;  $p > 0.05$ ). Behavioral measures are discussed in the context of these findings.

**Mutations in PTCH maybe rare causes of non-syndromic cleft lip and palate.** *M. Mansilla*<sup>1</sup>, *E. Castilla*<sup>2,3</sup>, *J. Lopez Camelo*<sup>4</sup>, *J. Murray*<sup>1</sup>. 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept of Genetics, Fiocruz, Brazil; 3) CONICET, Argentina; 4) IMBICE, Buenos Aires, Argentina.

Patched (PTCH) is the proposed receptor for sonic hedgehog (SHH) in a complex with smoothened (SMO) and regulates the expression of WNT and TGF beta. Mutations in PTCH cause the nevoid basal cell carcinoma syndrome (NBCCS) which include rib and craniofacial abnormalities and multiple tumor types. Cleft palate is found in 4% of the cases. To determine if mutations in PTCH might cause non-syndromic forms of cleft, we sequenced the complete coding sequence and exon/intron boundaries in the 23 exons of PTCH in DNA samples from 180 probands with non-syndromic cleft lip and palate. We detected 3 new missense mutations and for these exons we sequenced all family members available, an additional 180 cleft cases and 90 normal controls from the same region. In exon 6 (extracellular domain) we found a P295S change. It was present in an affected Filipino female and also in her two non-affected brothers and father. This residue is conserved in mouse, zebrafish and chicken. For exon 9 a D436N change was located in the transmembrane domain and is conserved in chicken, zebrafish and mouse. We found this variation in a case from Iowa and in his unaffected mother, neither of whom on repeat clinical exam had any features of NBCCS. Another change was found in an affected male from the Philippines, with his normal mother showing the same variation. This S827G change was found in exon 15, an extracellular domain. None of the changes were found in 180 controls and there was no history or physical evidence for features of Gorlin Syndrome in any of these 3 affected or in the family members. We propose that mutations in PTCH in the extracellular domain (that is proposed to interact with SHH) and the intracellular domain (proposed to interact with SMO) may interfere with this pathway decreasing SHH activity contributing to clefting. Since the SHH path also includes interactions with cholesterol metabolism, which also results in defects that cause cleft palate, this phenotypic feature may arise from complex interactions of genes and environmental influences.

**Variants in SKI, IRF6, and RFC1 are associated with cleft lip/palate in a South American population. A.R.**

*Vieira*<sup>1</sup>, *I.M. Orioli*<sup>2</sup>, *E.E. Castilla*<sup>3</sup>, *M.E. Cooper*<sup>4</sup>, *M.L. Marazita*<sup>4</sup>, *J.C. Murray*<sup>1</sup>. 1) Pediatrics, The University of Iowa, Iowa City, IA; 2) ECLAMC at Department of Genetics, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil; 3) ECLAMC at Department of Genetics, Oswaldo Cruz Institute, Rio de Janeiro Brazil and CEMIC, Buenos Aires, Argentina; 4) Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA.

ECLAMC (Estudio Colaborativo Latino Americano de Malformaciones Congenitas or Latin American Collaborative Study of Congenital Malformations) is a program which has investigated the causes of congenital malformations and their frequencies in Latin American hospitals since 1967. Beginning in January 1998, ECLAMC has collected biological samples from children with nonsyndromic oral-facial clefts (NSOFC) and their mothers for molecular analysis. NSOFC are common congenital malformations known to occur in approximately 1/1,000 live births in ECLAMC hospitals. The present study used the likelihood ratio test (LRT)-based analysis to detect non-Mendelian transmission of DNA sequence variants in IF6, SKI, RFC1, MTHFR, TGFA, and TGFB3 to 233 South American children from their respective mothers. The results show association between NS cleft lip (CL) and SKI ( $p=0.004$ ) and weaker association with NS cleft lip with or without cleft palate (CL/P) ( $p=0.042$ ). Previous studies have shown that the frequency of mitochondrial haplotype D (HapD) among these clefting cases is higher than the general population. When the analysis was divided by children with HapD versus any other haplotype group, a borderline difference between these two groups were seen for SKI ( $p=0.09$ ), but significant differences were seen for IRF6 and RFC1 ( $p=0.003$ ). An association between CL/P and IRF6 ( $p=0.023$ ), and CL and RFC1 ( $p=0.017$ ) was seen only for the non HapD group. These results support previous linkage and linkage disequilibrium findings with 1p36, 1q32, and 4p in humans and suggest that SKI, IRF6, and RFC1 mutations make a contribution to clefts in South American populations, however these contributions will depend on the type of Amerindian ancestry.

**Molecular and cytogenetic analyses in Brazilian patients affected by autism spectrum disorders.** *E.S. Moreira<sup>1</sup>, G.M. Orabona<sup>1</sup>, L.O. Avelar<sup>1</sup>, E. Vadasz<sup>2</sup>, L.M. Biason<sup>2</sup>, V.N.O. Takahashi<sup>1</sup>, K. Abe<sup>1</sup>, A.M. Vianna-Morgante<sup>1</sup>, M.R. Passos-Bueno<sup>1</sup>.* 1) Centro de Estudos do Genoma Humano/Departamento de Biologia/ Instituto de Biociências, Universidade de São Paulo, São Paulo, SP, Brazil; 2) SEPIA, Instituto de Psiquiatria, Hospital das Clínicas, Faculdade de Medicina, Universidade de São Paulo, São Paulo, SP, Brazil.

Autism spectrum disorders (ASDs) comprise a group of neurodevelopmental conditions characterized by impairments in reciprocal communication and social interaction, as well as by unusually restricted and stereotyped patterns of behaviors and interests. The symptoms are usually apparent in the first three years of life and the population prevalence has been estimated in 1/1000, with a sex ratio of 4:1 male to female. Although most cases of ASDs seem to be caused by complex genetic mechanisms, 10 to 15% appear in association with chromosomal abnormalities or monogenic conditions. Chromosomal abnormalities among autistic individuals have been reported with frequencies from 5 to 12%. The FMR1 (CGG)<sub>n</sub> expansion typical of the fragile X syndrome has been found in up to 13% ASD patients. Two recent papers described the identification of pathogenic mutations in the gene MECP2 in three girls with autism. In our study, we selected 126 Brazilian families with ASDs, using the diagnostic criteria outlined in DSM-IV, to search for chromosomal abnormalities and/or mutations in the FMR1 and MECP2 genes. These 28 female and 108 male patients are grouped in 116 sporadic and 10 familial cases. No chromosomal alterations were detected in 80 individuals after G-banding analysis. Among the 100 male cases tested for the FMR1 (CGG)<sub>n</sub> expansion through PCR, only one was found to carry the full mutation. This result was further confirmed through Southern blotting. No mutations were detected in the 90 individuals screened for the exons 2 and 3 of the MECP2 gene through denaturing high-performance liquid chromatography (dHPLC). We are currently analyzing exon 4 of MECP2. Although preliminary, these data suggest that chromosomal alterations and FMR1 mutations are not a significant factor in the etiology of ASDs in Brazil. **Identification of a celiac disease gene on chromosome 19.** *M. van Belzen*<sup>1,2</sup>, *A. Zhernakova*<sup>1</sup>, *A. Bardoel*<sup>1</sup>, *R. Houwen*<sup>2</sup>, *C. Mulder*<sup>3</sup>, *C. Wijmenga*<sup>1</sup>. 1) Biomedical Genetics, UMCU, Utrecht, Netherlands; 2) Pediatric Gastroenterology, UMCU, Utrecht, Netherlands; 3) Department of Gastroenterology, VU University Medical Center, Amsterdam, Netherlands.

Celiac disease is a common autoimmune disorder and is strongly associated to HLA-DQ2 and DQ8. However, the contribution of the HLA-region has been estimated at approximately 40%, so non-HLA genes must also be involved in the etiology of celiac disease. We have recently performed a genomewide screen in 101 affected sibpairs to localize these genes, and we identified significant linkage to 19p13.1 (MMLS 4.31; nominal  $p = 6.2 \times 10^{-6}$ ). The size of the maximum LOD-1 candidate region was only 3 Mb, but this region is very gene-rich and contained 92 genes and ESTs. Therefore we performed fine-mapping of the region in a case-control cohort of 216 celiac disease patients and 216 matched controls to identify the celiac disease susceptibility gene. Firstly, the region was saturated with microsatellite markers and one marker was significantly associated with celiac disease ( $p = 0.0013$ ). Secondly, 50 single nucleotide polymorphisms (SNPs) were typed using a DNA-pooling strategy, and four SNPs in a 30 kb region showed significant association. Single typing of these SNPs confirmed these findings (individual  $p < 0.01$ ). The four associated SNPs combine into a single haplotype that is more frequent in cases versus controls ( $p = 0.012$ ). Although this gene has no obvious role in intestinal or autoimmune processes, its expression pattern is consistent with intestinal function. Implication of this gene in the etiology of celiac disease may lead to the identification of a pathway not previously implicated in celiac disease pathogenesis.

**The MAOA promoter polymorphism and disruptive behavior disorders: Gene-environment interaction.** *M.M. Vanyukov*<sup>1,2,3,5</sup>, *B.S. Maher*<sup>1,4,5</sup>, *B. Devlin*<sup>1,3,5</sup>, *R.E. Tarter*<sup>1,3,5</sup>, *L. Kirisci*<sup>1,3,5</sup>, *G.P. Kirillova*<sup>1,5</sup>, *R.E. Ferrell*<sup>1,2,5</sup>. 1) Center for Education and Drug Abuse Research (CEDAR), Dept. of Pharmaceutical Sciences; 2) Dept. of Human Genetics; 3) Dept. of Psychiatry; 4) School of Dental Medicine; 5) University of Pittsburgh, Pittsburgh, PA.

Monoamine oxidase A (MAO-A) is a primary candidate for testing its contribution to variation in the risk for behavior disorders because of its important role in the metabolism of neurotransmitters, including dopamine and serotonin. A point nonsense mutation inactivating the *MAOA* gene results in a behavioral syndrome including high aggression (Brunner et al., *Science*, 262:578-580, 1993). Our findings (Vanyukov et al., *Am J Hum Genet*, 60:122-126, 1995), since supported by others, have suggested an association of the *MAOA* gene with the risk for early onset substance use disorders (SUD). Caspi et al. (*Science*, 297:851-854, 2002) reported that a functional *MAOA* promoter polymorphism moderated the relationship between indices of maltreatment in children and their later antisocial behavior. To extend these findings, we tested the relationship between the *MAOA* promoter polymorphism, indices of paternal and maternal neglect and the risk for disruptive behavior (conduct, oppositional defiant, and attention deficit hyperactivity) disorders in a longitudinal study of a sample of European-American males, using regression, correlation and survival analyses. Similar to the Caspi et al. results, the strength of association between neglect and behavioral disorders (CD and ADHD) depended on the *MAOA* alleles. Their role, however, was reverse to that observed by Caspi et al. for maltreatment. Significant relationships, both with the risk of the disorder and the rate of its development, were detected only in the group with 3.5- and 4-repeat ("high activity") alleles. These findings support involvement of variation in the *MAOA* gene in the development of behavioral deviation.

**Single nucleotide polymorphisms of the human GFPT1 gene are associated with type 2 diabetes and diabetic nephropathy.** *Y. Jia<sup>1</sup>, H. Zhang<sup>1</sup>, Z. Zhang<sup>1</sup>, T. Hale<sup>1</sup>, J. Cooper<sup>1</sup>, S.C. Elbein<sup>1,2</sup>.* 1) Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR 72205.

Considerable data support a role of increased glucose flux through the hexosamine pathway in insulin resistance, defective insulin secretion, and diabetes complications including diabetic nephropathy. Glucose flux into this pathway is controlled by the enzyme glutamine:fructose-6-phosphate amidotransferase (GFPT), which is encoded by separate genes from unlinked genetic loci, GFPT1 and GFPT2. To examine the role of GFPT1 variants in the susceptibility to type 2 diabetes (T2DM) and diabetic nephropathy (DN), we screened a total of 7170 bp of sequence, including 1 kb of 5' flanking sequence, 5' and 3' untranslated regions, all 19 exons, and 100 bp to 200 bp of sequence flanking each exon for mutations by DHPLC in 24 Caucasian (C) and 24 African American (AA) individuals. We identified 9 single nucleotide polymorphisms (SNPs), of which 7 were found in both populations, and 2 were found only in the African American population. One SNP was in the putative promoter region, 2 SNPs were in the 3'UTR and the remaining SNPs were either intronic or flanking. We typed the 6 common SNPs in 192 Caucasian individuals with diabetes and 192 control individuals. One SNP in intron 9 is associated with diabetes in Caucasians ( $p=0.0435$ ). Seven SNPs were typed in 149 AA with DN, 113 AA T2DM without DN, and 88 AA controls. One SNP in intron 1 and one SNP in 3' UTR were associated with DN ( $p=0.0102$  and  $p=0.0141$ ), but no SNP was associated with T2DM. Real time RT-PCR analysis showed a 30% increase in mRNA levels in transformed lymphocytes from T2DM individuals and a 2-fold increase in DN individuals in Caucasian population. No significant differences were found in AA T2DM and DN individuals, and no difference in allele-specific expression was seen for the 3' untranslated SNP. SNPs in GFPT 1 were associated with T2DM and DN. Our data suggest that increased GFPT1 expression resulting from common SNPs may cause increased glucose flux through the hexosamine pathway and contribute to T2DM and diabetic nephropathy.

**Susceptibility to polycystic ovary syndrome (PCOS) is associated with variation in the region of the insulin receptor gene.** *D. Stewart*<sup>1</sup>, *M. Urbanek*<sup>2</sup>, *T. Smith*<sup>1</sup>, *W. Ankener*<sup>1</sup>, *K. Ewens*<sup>1</sup>, *R. Legro*<sup>3</sup>, *J. Strauss*<sup>1</sup>, *A. Dunai*<sup>2</sup>, *R. Spielman*<sup>1</sup>. 1) U of Pennsylvania Sch of Medicine, Phila. PA; 2) Feinberg Sch of Medicine, Northwestern U, Chicago, IL; 3) Penn State U Sch of Medicine, Hershey, PA.

Polycystic ovary syndrome (PCOS) is the most common cause of anovulatory infertility. Although familial aggregation is observed, inheritance is non-Mendelian and PCOS is considered a complex trait. In previous studies of markers at or near 37 candidate genes, we found evidence for both linkage and association at only one marker: D19S884, located approximately 1 Mb centromeric to the insulin receptor (*INSR*) on chromosome 19. The mean sharing for this marker in 98 affected sib pairs was 63% ( $p=0.004$ ), and the transmission/disequilibrium test (TDT) chi-square for allele 8 is 11.85 ( $p=0.0006$ ) (all  $p$ -values are nominal). *INSR* is of special interest because insulin resistance is a hallmark of PCOS and PCOS-like features (hirsutism, hyperandrogenemia and polycystic ovaries) are seen in some individuals with the syndromes of extreme insulin resistance secondary to mutations in *INSR*. We have now analyzed data for SNPs in this region from approximately 400 families. For 11 SNPs (10 intronic and one exonic) distributed throughout *INSR*, we found no TDT values greater than 1.2 ( $p > 0.5$ ). We have studied two intronic SNPs located close to D19S884; for one (1.9 kb from D19S884), the TDT was 4.7 (marginally significant:  $p=0.03$ ). At the other SNP (6.2 kb from D19S884 in the opposite direction), the TDT was 0.198 (NS). Comparison of DNA sequence in this intronic region as provided by the UCSC Genome Browser shows homology between mouse and human; this finding is consistent with a possible regulatory role in gene expression. The lack of evidence for association among 11 SNPs in *INSR* makes it unlikely that variation in *INSR* itself accounts for susceptibility to PCOS. The presence of a SNP with modest association 1.9 kb from D19S884 strengthens the evidence that genetic variation in that immediate region is associated with PCOS. The evidence for conserved non-coding sequence supports the possibility of functional elements in this region that affect susceptibility to PCOS.

**Polymorphism in the androgen receptor and mammographic density in women taking and not taking estrogen and progestin therapy.** *E.O. Lillie<sup>1,2</sup>, L. Bernstein<sup>1</sup>, S.A. Ingles<sup>1</sup>, W.J. Gauderman<sup>1</sup>, G. Rivas<sup>2</sup>, V. Gagalang<sup>2</sup>, T. Krontiris<sup>2</sup>, G. Ursin<sup>1,2,3</sup>.* 1) Keck School of Medicine, University of Southern California, Los Angeles, CA 90089; 2) City of Hope/Beckman Research Institute, Duarte, CA 91010; 3) University of Oslo, Norway.

Some evidence exists indicating that women with the less active form of the androgen receptor (*AR*) genotype, characterized by a higher number of CAG repeat lengths, have increased breast cancer risk. Mammographic density is a strong breast cancer risk factor that probably reflects hormone induced cell proliferation in the breast. We evaluated the association between *AR*-CAG repeat length and mammographic density. We genotyped blood samples and obtained mammographic density information from 404 African-American and Caucasian breast cancer patients in Los Angeles County who participated in a population-based case-control study. We used the median *AR*-CAG length as the cut-point between short (S) and long (L) CAG repeat length. To model the dependence of percent mammographic density on *AR* genotype, we fit linear and ordinal logistic regression models. We observed no association between *AR*-CAG length and mammographic density among all women combined, among premenopausal women, or among postmenopausal women with no estrogen-progestin therapy (EPT) use. In postmenopausal EPT users, carriers of the less active *AR*-CAG (L/L genotype) had statistically significantly higher mean percent density (36.8%) than carriers of the more active *AR*-CAG (S/S genotype) (16.9%,  $p=0.01$ ). In this group, the odds ratio (OR) for a single quartile increase in percent mammographic density per long allele was 4.73; (95% confidence interval (CI): 1.89-11.79,  $p$  trend $<0.0001$ ). Our results suggest that while the *AR* gene itself is not a strong predictor of mammographic density, it is associated with increased mammographic density in women on EPT. The *AR* gene may therefore play a key role in determining whether EPT causes breast cancer in women.

**Genotypic variation of specific SNPs in the Calpain 10 gene within a cohort of the Black South African**

**population.** *A. Olckers*<sup>1,2</sup>, *G.W. Towers*<sup>1</sup>, *M.N. Wessels*<sup>1</sup>, *P. Rheeder*<sup>3</sup>, *P. Schwarz*<sup>4</sup>. 1) Centre for Genome Research, Potchefstroom University, Pretoria, South Africa; 2) DNAbiotec (Pty) Ltd, Pretoria, South Africa; 3) Dept of Clinical Epidemiology, University of Pretoria, South Africa; 4) Department of Endocrinopathies and Metabolic Diseases, Medical Faculty Carl-Gustav-Carus, Technical University Dresden, Germany.

Type 2 diabetes mellitus (T2D) is a term utilised to describe a large group of phenotypically heterogenous metabolic disorders having numerous aetiologies characterised by chronic hyperglycaemia and disturbances in the metabolism of fat, protein and carbohydrates due to insulin loss, insulin insensitivity or both. A major T2D susceptibility locus namely NIDDM1 was localised to chromosome 2 in the Mexican American and Northern European populations. The gene expressing the protein calpain 10 (CAPN10) is located at this specific locus and is an ubiquitously expressed non lysosomal cysteine protease. Various single nucleotide polymorphisms (SNPs) found in the intronic regions of this gene have been associated with T2D in the Mexican American and Northern European populations. Blood samples were collected from 200 clinically well-characterised adult Black South African diabetic patients and 100 Black controls. These individuals underwent molecular screening via real time PCR utilising hybridisation probe technology. The results were utilised in determining the allele and haplotype frequencies of the aforementioned SNPs. Upon comparison to various reported non-African populations it was elucidated that this group of individuals presented with a great amount of variation. The alteration UCSNP-63 was determined not to be in Hardy Weinberg equilibrium within this population, which may be an indication of it being in linkage disequilibrium with T2D. Haplotype analysis detected the absence of various non-African at-risk haplotypes, which may be indicative that the role of this gene in T2D susceptibility is different in the African and non-African populations. The investigation underscores a genetically heterogenous aetiology of T2D susceptibility within the Black South African population.

**Association between TaqI polymorphism of gap junction beta 5 gene (GJB5) and psychotic symptoms in bipolar disorder.** X. Ni<sup>1</sup>, J. Kennedy<sup>1, 2</sup>. 1) Neurogenetics Section, Ctr Addiction & Mental Health, Toronto, ON, Canada; 2) Department of Psychiatry, University of Toronto.

Using differential screening of gene initiation sequences, we found one of the differential DNA signals in the probands with schizophrenia and bipolar disorder compared with their parents in pooled DNAs. The sequence of this DNA fragment showed high homology with the gap junction beta 5 gene (GJB5). Therefore, we selected GJB5 as a candidate gene for major psychotic disorders. Recently, we presented a positive association between the TaqI polymorphism of GJB5 and schizophrenia in 2003 International Conference on Schizophrenia Research. To test for the presence of association between GJB5 and psychotic symptoms in bipolar patients, we analyzed the TaqI polymorphism of GJB5 in 145 BP probands with psychotic symptoms, 133 BP patients without psychosis, and 231 unrelated healthy controls. All cases and controls were collected in Toronto and central Canada. Case-control analysis was performed on the genotype data. The distributions of GJB5 TaqI genotypes in all three groups we tested were in Hardy-Weinberg Equilibrium (HWE). Though there was no significant difference of genotype frequencies between BP probands without psychosis and healthy controls ( $\chi^2=1.3748$ ,  $df=2$ ,  $p=0.5029$ ), we detected a trend to significance between BP probands with and without psychotic symptoms ( $\chi^2=5.0854$ ,  $df=2$ ,  $p=0.0787$ ), and a significant association between the TaqI polymorphism of GJB5 and bipolar psychotic symptoms compared with controls ( $\chi^2=8.118$ ,  $df=2$ ,  $p=0.0173$ ). These results indicate that GJB5 may play a role in the etiology of psychotic symptoms in bipolar disorder. Keywords: bipolar disorder, psychotic symptom, genetics, association analysis, gap junction beta 5 gene. This research was supported by CIHR/CPRF Partnered Fellowships.

Program Nr: 2063 from 2003 ASHG Annual Meeting

**Dopamine System Genes and Human Motor Activity.** *B.S. Maher, M.M. Vanyukov, M.L. Marazita, R.E. Ferrell.*  
Univ Pittsburgh, Pittsburgh, PA.

The dopamine system is hypothesized to play a major role in variation in human activity levels. We applied a measured-genotype approach to investigate the association of polymorphisms at several dopamine system genes with measured motor activity in a population of 103 10-12 year old Caucasian males. Motor activity was measured using an acceleration sensitive wrist-worn monitor worn by each subject during a standardized two-day research protocol. A VNTR polymorphism in the 3' UTR region of the dopamine transporter (DAT1) was significantly associated, without Bonferroni correction, with motor activity. Polymorphisms in the dopamine receptors D1, D2, D4 and D5 were not associated with motor activity.

**Stability of polymorphic trinucleotide repeats of the androgen receptor in uterine leiomyoma.** *J. Yankowitz, S.M. Zeng.* Dept OB/GYN, University of Iowa Roy J. and Lucille A. College of Medicine, Iowa City, IA.

The human androgen receptor gene (AR) contains three polymorphic trinucleotide repeats: CAG, GGN and ACG. These repeats may regulate transactivation activity of the AR. The expansions or reduction of the former two repeats have been implicated in the pathogenesis of several diseases such as spinal bulbar muscular atrophy, ambiguous genitalia, and prostate, breast and colon cancer. Instability of microsatellite repeats have been seen in some neoplasms compared to normal tissue. Uterine leiomyoma are the most common benign uterine tumor occurring in about 25% of women during their lifetime. Little is known about the etiology and pathogenesis of this neoplasia. We evaluated whether the stability and length of these three trinucleotide repeats is associated with uterine leiomyoma. We used PCR and 6% polyacrylamide gel electrophoresis to evaluate the number of triplet repeats in 38 leiomyoma tissues and 20 surrounding normal myometrium. The stability of the trinucleotide repeat was confirmed through the comparison of the genotypes between the tumor and its surrounding normal tissues, and the repeat length of these polymorphisms was determined by directly sequencing. No change in copy number of these three repeats was found in 20 patients with tumor and the corresponding surrounding normal tissue. This indicated that instability of AR trinucleotide repeats may not be involved in the pathogenesis of uterine leiomyoma.

**Screening of an Azorean population with major psychoses at the triplet repeat expansion associated loci SCA8, SCA17 and SCA1.** *T. Fortune*<sup>1</sup>, *C.N. Pato*<sup>2</sup>, *M.T. Pato*<sup>2</sup>, *M.H. Azevedo*<sup>3</sup>, *J.L. Kennedy*<sup>1</sup>, *J.B. Vincent*<sup>1</sup>. 1) Clarke Division, CAMH, Toronto; 2) Center for Psychiatric and Molecular Genetics, SUNY, Syracuse, NY, USA; 3) (3) Department of Psychiatry, University of Coimbra Hospital, Coimbra, Portugal.

The molecular mechanism associated with the anticipation observed in neurodegenerative disorders was identified in 1991 as a triplet repeat expansion (TRE). This has led to the study of polymorphic triplet repeat loci in the context of major psychoses. SCA8 is unusual among the expanded repeat neurodegenerative disorders because not all persons with the TRE develop ataxia. Investigation of unrelated psychosis cases versus controls has found that twice as many expansions (100-1300 repeats) occur at SCA8 in major psychosis cases (1.25%) as unaffected controls (0.7%). We have yet to identify ataxia among psychosis patients with large SCA8 repeat alleles. The SCA8 associated TRE is located in its most 3'exon. This TRE could also influence the expression of Kelch-like 1, KLHL1, which is expressed brain specifically. The most 5' exon of SCA8 overlaps the first exon of KLHL1 which is transcribed in the opposite orientation. Recent studies of ataxic patients with expansions at other known TRE loci has revealed a subgroup of individuals who also have an expansion at SCA8, leading to the speculation that TRE at SCA8 may have a trans acting role in repeat instability. We have previously screened 32 SCZ and BPAD families from the Azores Islands at the SCA8 locus, we have now added a further 70 families. Among the newly examined families we have identified 7 expanded repeats in 6 families. We have screened the same population at the CAG polymorphism at SCA1 and SCA17 loci. All of the SCA17 alleles fell within the normal range, 25-42 CAG repeats and only 2.5% fell outside the most common allele range reported in the normal population, 32-39 CAG repeats. The repeats found at the SCA1 locus were also found to fall within the expected normal range, 6-39 repeats, in fact they were between 10-24 repeats in size. We are screening further members of these families for the SCA8 TRE in order to investigate links between TRE and psychoses.

**Association of SNPs in the ADH gene cluster with alcoholism.** *T. Foroud<sup>1</sup>, D. Dick<sup>1</sup>, X. Xuei<sup>1</sup>, A. Goate<sup>2</sup>, B. Porjesz<sup>3</sup>, H. Begleiter<sup>3</sup>, T. Reich<sup>2</sup>, H.J. Edenberg<sup>1</sup>, COGA collaborators.* 1) Indiana Univ Sch Medicine, Indianapolis, IN; 2) Washington University, St. Louis, MO; 3) SUNY Downstate Medical CenterBrooklyn, NY.

Polymorphisms in the alcohol metabolizing enzymes, alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), have been consistently found to protect against alcoholism susceptibility in studies of East Asian populations. Linkage analyses in the primarily Caucasian, multiplex alcoholic families recruited in the Collaborative Study on the Genetics of Alcoholism (COGA) found evidence for a protective locus on chromosome 4, in the region containing the ADH gene cluster. To further evaluate the role of the 7 genes in the ADH gene cluster, 58 single nucleotide polymorphisms (SNPs) were genotyped in a sample of more than 2,200 individuals from alcoholic families. Analyses defining alcoholism based on the DSM-IV criteria detected strong evidence of association ( $p < 0.05$ ) using the pedigree disequilibrium test with eight of the nine SNPs in the ADH4 gene. The sliding window method, employed to form haplotypes using three adjacent SNPs, were all highly significant ( $p < 0.01$ ). These analyses suggest that the role of the ADH genes in affecting risk for alcoholism is not limited to the protective effects found in individuals of East Asian descent. This work was supported by the NIH grant U10AA08403 from the National Institute on Alcohol Abuse and Alcoholism (NIAAA). These analyses were also supported by AA13358 and AA00285.

**Joint analysis of chromosome 6p markers and antibodies to infectious agents in schizophrenia.** *J.J. Kim<sup>1</sup>, K.V. Chowdari<sup>1</sup>, J. Wood<sup>1</sup>, R. Yolken<sup>2</sup>, S. Bacanu<sup>1,3</sup>, B. Devlin<sup>1,3</sup>, V.L. Nimgaonkar<sup>1,3</sup>.* 1) Departments of Psychiatry, University of Pittsburgh, School of Medicine, WPIC, Pittsburgh, PA; 2) Stanley Laboratory of Developmental Neurovirology, Johns Hopkins School of Medicine, Baltimore, MD; 3) Departments of Human Genetics, University of Pittsburgh, School of Medicine and Graduate School of Public Health, WPIC, Pittsburgh, PA.

**OBJECTIVE:** Numerous studies have suggested linkage and associations of schizophrenia with polymorphisms localized on chromosome 6p, but they have been inconsistent. To resolve these inconsistencies, we have conducted multi-staged linkage and association analyses. We have also combined the genetic information with serological data relating to exposure to a range of infectious agents.

**METHODS:** Our sample included 100 affected sib-pairs, 158 case-parent trios and 161 unrelated controls. The cases were diagnosed as schizophrenia or schizoaffective disorder with DSM IV. Twenty two microsatellite markers, localized to a 21.5Mb region flanking the HLA region, were analyzed. We also assayed antibodies to cytomegalovirus (CMV), toxoplasma gondii, herpes simplex virus 1 and 2 (HSV-1 and HSV-2) among the patients and their parents.

**RESULTS:** TDT analysis revealed transmission distortion across the HLA region. These analyses attained nominal significance using the MCETDT program for D6S1663, D6S1545 and M6S230. A significant case-control difference, corrected for multiple comparisons, was detected at M6S125 using the CLUMP program. Significant transmission distortion was also observed at M6S125, when the sample was stratified on the basis of elevated titers of antibody to CMV among the patients and mothers.

**CONCLUSION AND FUTURE STUDIES:** Our analyses continue to provide evidence suggestive of linkage and association with schizophrenia in the HLA region. The results related to CMV exposure are intriguing, as they suggest a specific interaction between genetic variation and exposure to CMV, a putative pathogen for schizophrenia. We aim to analyze SNPs of candidate genes around the markers that showed significance in this study.

**Mutation screening of the apolipoprotein-L (APOL) genes and its association with schizophrenia.** *T. Ohtsuki<sup>1</sup>, T. Kojima<sup>2</sup>, YC. Shen<sup>3</sup>, YH. Han<sup>3</sup>, T. Arinami<sup>1</sup>.* 1) Department of Medical Genetics, University of Tsukuba, Tsukuba, Japan; 2) Department of Neuropsychiatry, Nihon University, Tokyo, Japan; 3) Institute of Mental Health, Beijing Medical University, Beijing, China.

Schizophrenia is a complex genetic disorder. However, the etiology of schizophrenia is poorly understood. Several genome-wide scans and meta-analysis of genome scans identified that 22q11-q13 is one of the susceptibility locus for schizophrenia. D22S683 on 22q12.3 showed significant association with schizophrenia in Japanese, European-American, and Chinese populations.

Recently, gene expression analysis by Mimmack et al (2002) identified that apolipoprotein - L1, L2, and L4 are significantly up-regulated in the prefrontal cortex of patients with schizophrenia. An apolipoprotein gene family (APOL1-6) is located near D22S683 on 22q12.3, and APOL1-4 are clustered as a result of tandem gene duplication and are highly homologous to each other.

In this study, we searched for mutations in all exons and exon-intron junctions of the APOL1-4 gene by direct sequencing in 48 Japanese patients with schizophrenia. We evaluated associations between schizophrenia and polymorphisms detected with a high frequency. We also evaluated associations in microsatellite markers located near the APOL gene. We performed a TDT (Transmission disequilibrium test) in 68 families with schizophrenia (16 Japanese families and 52 Chinese families). None of these polymorphic alleles were significantly associated with schizophrenia. However, two microsatellite markers were significantly associated with schizophrenia. In conclusion, we did not detect any evidence that the genomic variations in the APOL1-4 gene contribute to genetic susceptibility to schizophrenia in the Japanese and Chinese populations. However, we can not exclude the possibility that this genomic region is associated with expression of apolipoprotein-L genes in patients with schizophrenia.

Written informed consent was obtained from all subjects. This study was approved by Ethics Committee of each authors affiliation.

Allelic variants of SNPs of the CARD15 gene, located on chromosome 16q, cause susceptibility to Crohn disease (CD), but not ulcerative colitis (UC). We previously found linkage to chromosome 16q in both CD and UC Italian families. In this study, we tested 90 Italian inflammatory bowel disease (IBD) families for the three most common CARD15 SNPs known to affect risk of CD (R702W, G908R and L1007fsinsC) and compared their frequencies in probands against 108 normal controls. Allele and phenotype frequencies at all three SNPs were significantly different between CD probands and controls, but not between UC probands and controls. When all three SNPs were combined into a single CARD15 phenotype, the relative risk of CD for carriers of two variants (either homozygotes or compound heterozygotes) compared to non-carriers was highly significant (OR=41.41, 95% CI=(4.86, 352.95), p=0.00001) whereas the relative risk for heterozygotes at only one SNP was not (OR=1.63, 95% CI=(0.57, 4.69), p=0.39). After removing 26 CARD15 positive families, we performed a GENEHUNTER model-free linkage analysis with 18 microsatellites spanning 28 cM around CARD15. In the CD group, there was no significant evidence of linkage after the CARD15 positive families were removed (all p-values > 0.05). In contrast, significant linkage to D16S408, located 12 cM away from CARD15, was found in 37 CARD15 negative UC families (p = 0.003). Our results suggest that additional genes in the pericentromeric region of chromosome 16 may affect risk of inflammatory bowel disease. We are currently testing SNPs in candidate genes near D16S408 for association to IBD in our families' probands.

**Three novel SCN1A missense mutations in generalized epilepsy with febrile seizures plus.** G. Annesi<sup>1</sup>, S. Carrideo<sup>1</sup>, G. Incorpora<sup>3</sup>, D. Civitelli<sup>1</sup>, A. Polizzi<sup>3</sup>, F. Annesi<sup>1</sup>, P. Tarantino<sup>1</sup>, I.C. Cirò Candiano<sup>1</sup>, P. Spadafora<sup>1</sup>, E.V. De Marco<sup>1</sup>, U. Aguglia<sup>4</sup>, A. Labate<sup>1</sup>, L. Pavone<sup>3</sup>, A. Quattrone<sup>1,2</sup>, A. Gambardella<sup>1,2</sup>. 1) Inst Neurological Sci, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia Catanzaro, Italy; 3) Institute of Pediatrics, University of Catania, Italy; 4) Regional Epilepsy Centre, Hospital of Reggio Calabria, Italy.

**Summary.** Purpose: to screen 13 Italian families with generalized epilepsy with febrile seizures plus (GEFS+) for mutations in SCN1A, SCN1B and GABRG2 genes. Patients and methods. We selected 13 unrelated families with GEFS+. There were 37 affected members, and most of them had febrile seizures (FS) or FS plus. Genomic DNA was extracted by standard methods. The 26 exons of SCN1A, five exons of SCN1B and nine exons of GABRG2 were individually amplified using primers based on an intronic sequence. PCR products were analyzed by single strand conformation polymorphism and sequence. Results. In three GEFS+ families, we identified three novel missense mutations of the SCN1A gene, which co-segregated with the disorder and never occurred in 100 unrelated controls. The first Tyr779Cys mutation was located in the DII/S1 segment, the second Met1841Thr and the third Ile1944Thr were located within the intracellular C terminal region. The latter mutation was associated with severe myoclonic epilepsy at infancy (SMEI). There were no variants of SCN1B or GABRG2 genes that co-segregated with the GEFS+ phenotype. Conclusions. The results of our study further support the role of the SCN1A gene in the etiology of GEFS+. Our findings also reinforce the belief that SMEI represents the very severe end of the spectrum within GEFS+ phenotype. Reference Annesi G., Gambardella A. et al. (2003). Two novel SCN1A missense mutations in Generalized Epilepsy with febrile seizures plus. *Epilepsia* (in press).

**A possible role of gamma-aminobutyric acid A receptor-associated protein (GABARAP) in nicotine dependence.**

*J. Beuten*<sup>1</sup>, *J. Ma*<sup>1</sup>, *R. Dupont*<sup>2</sup>, *K. Crews*<sup>3</sup>, *T. Payne*<sup>3</sup>, *M. Li*<sup>1</sup>. 1) Department of Psychiatry, University of Texas Health Science Center, San Antonio, TX; 2) Departments of Psychiatry and Allied Health, The University of Tennessee Health Science Center, Memphis, TN; 3) Departments of Diagnostic Sciences and Medicine, The University of Mississippi Medical Center, Jackson, MS.

Nicotine dependence is a complex trait with strong genetic and environmental influences. Twin and adoption studies have demonstrated that the heritability for smoking initiation and smoking persistence is at least 50%. Based on the results from our genome-wide linkage analysis on the Framingham Heart study population, 13 genomic loci located on 12 different chromosomes are likely to harbor susceptibility genes for smoking behavior. During the past several years, we have been collecting phenotypic information and blood samples from both smoker and non-smoker members of predominantly Caucasian and African-American families. Currently more than 1,400 subjects have been recruited and their DNA samples are available for genetic analysis. To determine possible association between candidate genes and nicotine dependence, we genotyped these DNA samples by the TaqMan assay with SNPs selected from candidate genes located within the linked regions, and known to play a role in drug abuse and/or dopamine metabolism pathways. One of the genes of interest in this study is gamma-aminobutyric acid A receptor-associated protein (GABARAP), which promotes clustering of the GABA(A) neurotransmitter receptors and is located on chromosome 17p13.2. Association analysis using the ASSOC program of S.A.G.E. indicated that a significant association exists between the G/T polymorphism at amino acid position 164 in the GABARAP gene and nicotine dependence in the Caucasian population under both the additive and dominance genetic model ( $P < 0.04$ ). In the African-American population, however, no significant association between this G/T polymorphism of the GABARAP gene and nicotine dependence was found. These findings support a possible role of GABARAP in nicotine dependence in the Caucasian population (Supported by DA-12844).

**A mixed epigenetic-genetic model for autism with the ubiquitin ligase *UBE3A* as a candidate principal gene.** *T. Sahoo*<sup>1</sup>, *Y. Jiang*<sup>1</sup>, *M. Shinawi*<sup>1</sup>, *R.C. Michaelis*<sup>2</sup>, *I. Buyse*<sup>1</sup>, *C.D. Kashork*<sup>1</sup>, *R.J. Schroer*<sup>2</sup>, *B.B. Roa*<sup>1</sup>, *D.W. Stockton*<sup>1</sup>, *R.S. Spielman*<sup>3</sup>, *R.E. Stevenson*<sup>2</sup>, *L.G. Shaffer*<sup>1</sup>, *A.L. Beaudet*<sup>1</sup>. 1) Human & Molec Gen, Baylor Col Medicine, Houston, TX; 2) Greenwood Genetic Center, S. Carolina; 3) Univ. of Pennsylvania, Philadelphia, Pennsylvania.

We propose a mixed epigenetic-genetic model for autism with a principal imprinted gene in chromosome 15q. The Angelman gene (E6-AP ubiquitin-protein ligase; *UBE3A*) maps in this region, is imprinted with paternal silencing in brain, and affects neurological function and learning. We hypothesize that over-expression of an imprinted gene in 15q11-q13 is the major cause of autism, and *UBE3A* is the strongest candidate with brain-specific failure of paternal silencing as a major mechanism. Using a subset of AGRE and NIMH autism sib-pairs a small number of families with maternal duplications of 15q11-q13 were identified. Genotyping of affected sib pairs showed increased sharing of paternal alleles in 15q11-q13, with the greatest sharing centromeric to the imprinting center at D15S817 with a  $X^2$  of 5.48 ( $P=0.02$ ). We propose that autism may be caused in the majority of cases by imprinting defects arising on normal or susceptible paternal chromosome 15 during spermatogenesis or after fertilization prior to MZ twinning, leading to brain-specific over-expression of *UBE3A*. We are testing the hypothesis that autism etiology involves a gene-nutrient interaction analogous to but opposite from the finding in neural tube defects (NTDs), such that increased folate intake for the maternal-fetal unit will increase rather than decrease risk for autism; in addition the hypomorphic allele for MTHFR would be protective and be under-represented in autism. Testing for the frequency of MTHFR genotypes (222A->V) shows a lower frequency of V/V allele in autistic cases compared to controls but the difference may not be statistically significant. A transmission disequilibrium test (TDT) to test for parent-of-origin bias in the transmission of the hypomorphic allele revealed a statistically significant increase in paternal transmission of the A allele to autistic offsprings ( $X^2=4.403$ ;  $p<0.05$ ) suggesting that V would be a protective allele.

**Case-control, TDT and gene-gene interaction analysis of MTHFR, BCL3 and TGF $\alpha$  genes in nonsyndromic clefting Brazilian families.** *D.A. Gaspar<sup>1,2</sup>, S.R. Matioli<sup>2</sup>, R.C. Pavanello<sup>1,2</sup>, B.C. Araújo<sup>3</sup>, M. André<sup>4</sup>, S. Steman<sup>5</sup>, N. Alonso<sup>5</sup>, M.R. Passos-Bueno<sup>1,2</sup>.* 1) CEGH, IBUSP, Univ de São Paulo; 2) Depto Biologia, IB-USP, Univ de São Paulo; 3) Hospital Menino Jesus; 4) FOU SP, Univ de São Paulo; 5) Depto de Cirurgia Plástica, FMUSP; São Paulo, Brazil.

Nonsyndromic cleft lip with or without cleft palate (CL/P), one of the most common birth defects in humans, is a complex disorder in which both genetic and environmental factors influence risk. The 677 CT polymorphism at the MTHFR gene has been associated with CL/P in some populations and some authors, including a previous report by our own group, found that the maternal MTHFR genotype might also be a risk factor for CL/P to their descendants. However, this issue is still controversial. In order to elucidate the role of the 677 CT/MTHFR polymorphism to the predisposition to CL/P, we performed a case-control study of this functional SNP in a large sample of individuals ascertained in two different regions of Brazil (São Paulo and Ceará): 424 CL/P patients, 336 mothers of CL/P patients and 634 controls matched by ethnic and social background to patients. TDT was also carried out in 105 CL/P patients and their parents. This polymorphic system is in Hardy-Weinberg equilibrium in all subgroups ( $P > 0.05$ ). We also observed that T allele and the TT genotype frequencies did not differ among CL/P patients (9% and 30%), mothers of CL/P patients (9% and 29%) and controls (8% and 29%) ( $P > 0.05$ ). The lack of association between the 677T allele and CL/P was further confirmed through the TDT strategy ( $\chi^2 = 3.7468$ , 1df;  $P = 0.05$ ). We have also evaluated a possible interaction between the 677 CT/MTHFR polymorphism and the at risk-alleles for CL/P at BCL3 (allele 135bp;  $n = 85$ ) or TGF $\alpha$  (allele C2/TaqI;  $n = 162$ ) genes. We did not observe any indication of gene-gene interaction between MTHFR and either BCL3 or TGF $\alpha$ . In conclusion, maternal or patients genotypes harboring the 677T/MTHFR allele do not increase the risk of CL/P; in addition, this locus does not seem to interact with TGF $\alpha$  and BCL3 in the susceptibility to this malformation, although the sample sizes available for the various genotypic combinations may limit statistic power.

**A Study of DR-DQ Matched T1D Cases and Controls in a Continental Italian Population Reveals Susceptibility Effects of DPB1 and HLA-A Alleles.** *J.A. Noble<sup>1</sup>, A.M. Valdes<sup>2</sup>, Q. McGrue<sup>1</sup>, A. Galgani<sup>2</sup>, A. Petrone<sup>2</sup>, S. Di Cola<sup>2</sup>, H.A. Erlich<sup>3</sup>, P. Pozzilli<sup>2</sup>, R. Buzzetti<sup>2</sup>.* 1) Childrens Hosp Oakland Res Ins, Oakland, CA; 2) University of Rome, Rome, Italy; 3) Roche Molecular Systems, Alameda, CA.

T1D patients from the Lazio region of central Italy with HLA DR-DQ genotypes classified as high-risk (DR3/DR4, DR3/DR3, and DR4/DR4) were compared to controls with the same set of genotypes in an effort to identify risk factors for T1D in addition to the HLA DR- and DQ-encoding loci. The HLA class II locus DPB1 and the HLA class I locus A were genotyped and analyzed in an initial set of 42 patients and 147 controls. Consistent with previous reports, the frequencies of DPB1\*0301, DPB1\*0202, and A\*2402 were higher in patients than in controls, while frequencies of DPB1\*0402 and A\*0101 were lower in patients than in controls, although these differences did not reach statistical significance in the combined data. However, analyses of the subset of DR3/DR3 patients and controls revealed statistically significant differences in some allele frequencies. Significantly more DR3/DR3 patients had at least one copy of the DPB1\*0301 allele than did the DR3/DR3 controls ( $p = 0.035$ ), consistent with several previous reports of a predisposing effect for this allele. For HLA-A, analysis of only the DR3/DR3 patients and controls revealed a significant excess of A\*0301 in patients ( $p = 0.021$ ). This possible predisposing effect of A\*0301 has not been previously observed. A\*0301 is in strong linkage disequilibrium with the highly protective DR2 haplotype (DRB1\*1501-DQB1\*0602), such that the allele appears somewhat protective in other studies not matched for DR and DQ-encoding loci. Results from examining the allele in the context of DR-DQ-matched samples may be more representative of its true effect on T1D susceptibility. Collection and genotyping of additional samples is in progress. The larger sample set will be utilized not only to increase the power of the DPB1 and HLA-A analyses but also to examine other candidate T1D susceptibility loci in this DR-DQ matched case-control study.

**Epistasis in Polygenic Disorders: The Effect of Age of the Mother at the Birth of her First Child.** *D.E. Comings*<sup>1</sup>, *J.P. MacMurray*<sup>2</sup>. 1) Medical Genetics, City of Hope Medical Center, Duarte, CA; 2) Carlsbad Science Foundation, Monrovia, CA.

**Purpose:** Epistasis refers to a situation in which the effect of one unit is not predictable unless the value of the other unit is known. This includes gene gene interactions and gene non-gene interactions.<sup>1</sup> We previously identified maternal age as an epistatic factor for the interaction of a LEP gene microsatellite polymorphism with age of onset of menarche.<sup>2</sup> When the maternal age was 25 years of age, an early age of menarche was associated with the LEP short alleles. By contrast, when the maternal age was 26 years, an early age of menarche was associated with the LEP long alleles. The purpose of this study was to investigate two questions: a) was maternal age an epistatic factor for other gene trait interactions? and b) was maternal age or maternal age at the birth of the first child (Maternal age 1st) more important?

**Methods:** We examined the association of the DRD1 gene (Dde I polymorphism) with four phenotypes in a database of Tourette syndrome probands: OCD, stuttering, conduct disorder and ADHD. **Summary:** Both maternal age and maternal age 1st born were epistatic factors for the interaction of the DRD1 gene with OCD and stuttering. Maternal age 1st born was consistently a stronger epistatic factor than maternal age. This may reflect a different genetic background in individuals who have children early versus those who have them late. We observed a special type of epistasis in which the association of the 11 and 22 homozygotes was in opposite direction for the two epistatic conditions. We have termed this *genostasis* (geno = genotype, stasis = reversal). Since the two effects neutralize each other, significant gene trait associations could be missed if genostatic factors were not included in the analysis. Maternal age 1st may prove to be an important genostatic factor for many other gene-trait interactions.

1. Brodie, & M. J. Wade Epistasis and the Evolutionary Process New York, N.Y.: Oxford. pp. 3-19. 2. Comings, D.E. et al. Molecular Genetics and Metabolism 2001; 73: 204-210.

**Search for association with *Klotho* allele variation and atherosclerosis in the Baltimore Longitudinal Study on Aging.** A. Bektas, D. Taub, S. Najjar, D. Muller, L. Ferrucci, C.A. Francomano. National Institute on Aging/NIH, Baltimore, MD.

Numerous studies on the *klotho* mutant mouse have demonstrated that the *klotho* gene is involved in the suppression of several aging phenotypes, including atherosclerosis. Arking et al (2002, 2003) showed that the KL-VS allele of the *klotho* gene might be as a functional variant that influences longevity and an independent risk factor for coronary artery disease (CAD). We looked for an association between the KL-VS allele and the phenotype of atherosclerosis in the Baltimore Longitudinal Study on Aging (BLSA) population. Our initial analysis included Caucasian participants, ages (66) to (92) with and without atherosclerotic disease (coronary artery disease and/or stroke). We screened a healthy control group for the previously described KL-VS allele, containing six sequence variants in complete linkage disequilibrium. The presence of the KL-FC and KL-VS alleles of the *klotho* gene were determined by sequencing healthy control subjects (N=148). In patients with coronary artery disease-atherosclerosis-stroke (CSAD) (N=83) the alleles were detected by restriction fragment length polymorphism (RFLP) analysis. We found that the frequency of KL-FC allele was (0.83) in the healthy control group and (0.86) in CSAD group ( $P>.05$ ). The frequency of KL-VS allele was (0.17) in healthy control group and (0.14) in CSAD group ( $P>.05$ ). Therefore, these data did not support an association between KL-VS allele of *klotho* gene and CSAD disease in BLSA white population. Inclusion of additional black healthy control subjects and CSAD patients resulted in allele frequencies of 0.84 for the KL-FC allele in the healthy control group, and 0.84 in the CSAD group ( $P>.05$ ). The KL-VS allele frequency was 0.16 in the healthy control group, and 0.16 in the CSAD group ( $P>.05$ ). Thus, the data do not support an association between atherosclerotic disease and the *klotho* KL-VS allele in the BLSA population. Further work in additional populations and with age stratification is required.

Program Nr: 2077 from 2003 ASHG Annual Meeting

**Investigation of the CHRNA4 gene for a possible role in tobacco use and addiction.** *M.A. Ehringer, S. Young, R. Corley, M. Stallings, A.C. Collins, J.K. Hewitt.* Institute Behavioral Genetics, Univ Colorado, Boulder, CO.

That genetic factors contribute to tobacco use and nicotine dependence has been well established through adoption, twin, and family studies. However, the specific genes contributing to an individual's risk of becoming addicted to nicotine remain unknown. Recent studies using mouse models have identified a polymorphism in the gene for the 4 subunit of the neuronal nicotinic receptor (Chrna4) which is linked to increased sensitivity to nicotine. This project involves utilizing the genomics resources developed through the human genome project to examine SNPs in the human CHRNA4 gene. Genotyping assays for six selected SNPs have been developed using a modification of the ABI PRISM SNaPshot ddNTP Primer Extension Kit. 333 late adolescents/young adults aged 17 to 21, representing a Colorado community sample, have been previously assessed for tobacco-related phenotypes. Genotypes for the six CHRNA4 SNPs are being determined for these individuals. Preliminary data indicate that five of the six SNPs are present with minor allele frequencies between 0.04 and 0.38; however, one of the SNPs is not polymorphic in this sample. Calculations to determine the D measure of linkage disequilibrium suggest that D between the SNPs varies from 0.11 to 0.77. Upon completion of genotyping of all SNPs for all subjects, we will test for a possible association between the variants and two tobacco-related phenotypes. Evaluating a quantitative measure of typical pattern of use, we will use linear regression to test for a possible association between frequency of use and genotype. Similarly, approximately half of the subjects display at least one DSM-IV dependence symptom for nicotine, while the other half do not. A chi-square test will be used to test whether a particular genotype for one or more of the SNPs is associated with dependence symptoms. The identification of particular SNPs that may be associated with tobacco use and addiction should facilitate greater understanding of the underlying genetic and biological mechanisms contributing to this disease. This work has been supported by the Colorado Tobacco Research Program (IDEA grant #21-034) and NIH/NIDA P60 DA 11015-05.

**MECP2 variants in psychiatric diseases: possible association with autism.** *J. Feng<sup>1</sup>, A. Shibayama<sup>1</sup>, C. Glanzmann<sup>1</sup>, J. Yan<sup>1</sup>, E. Cook Jr.<sup>2</sup>, N. Craddock<sup>3</sup>, I. Jones<sup>3</sup>, D. Goldman<sup>4</sup>, L. Heston<sup>5</sup>, S. Sommer<sup>1</sup>.* 1) Dept Molecular Genetics, City Hope Natl Medical Ctr, Duarte, CA; 2) University of Chicago, Dept. of Psychiatry, Chicago, IL; 3) University of Birmingham, Division of Neuroscience, Queen Elizabeth Psychiatric Hospital, Birmingham, UK; 4) NIAAA, NIH, Dept. of Psychiatry, Bethesda, MD; 5) University of Washington, Dept. of Psychiatry, Seattle, WA.

Mutations in the gene coding methyl-CpG-binding protein 2 (MECP2) cause Rett syndrome (RTT) and have also been reported in a number of X-linked mental retardation syndromes. Putative mutations have recently been described in a few autistic patients and a boy with language disorder and schizophrenia. In this study, DNA samples from individuals with schizophrenia and other psychiatric diseases were scanned in order to explore whether phenotypic spectrum of mutations in the MECP2 gene extends beyond the traditional diagnosis of RTT and X-linked mental retardation syndromes. The coding regions, adjacent splicing junctions and highly conserved segments of the 3'-untranslated region (3'-UTR) were examined in 214 patients including 106 with schizophrenia, 24 with autism and 84 patients with other psychiatric diseases by DOVAM-S. To our knowledge, this is the first analysis of variants in highly conserved regions of the 3' UTR of this gene. A total of 1.5 megabases was scanned (5.2 kb per haploid gene). Higher frequencies of missense and 3-UTR variants were found in autism. One missense and two 3-UTR variants were found in 24 patients with autism versus one patient with a missense change and one patient with a 3-UTR variant in 144 ethnically similar patients without autism ( $p=0.02$ ). These mutations suggest a possible association between the MECP2 gene and autism, warranting further study.

**Mutation analysis of *CYP11B1* and *CYP11B2* in patients with increased 18-hydroxycortisol production.** *J. Nicod, B. Dick, F.J. Frey, P. Ferrari.* Division of Nephrology and Hypertension, University Hospital, Berne, Switzerland.

In patients with glucocorticoid remediable aldosteronism (GRA), a rare hypertensive disorder caused by the presence of a chimeric aldosterone synthase (*CYP11B2*) and 11-hydroxylase (*CYP11B1*) gene, high level of urinary 18-hydroxycortisol (18OHF) excretion are observed. In some patients with hypertension increased urinary 18OHF secretion is also found in the absence of the hybrid *CYP11B1/CYP11B2* gene. We hypothesised that gene variants of *CYP11B1* or *CYP11B2* may be linked to this abnormal glucocorticoid production.

The urinary steroid profile was analysed by gas chromatography/mass spectrometry in 429 hypertensive patients and 98 (23%) thereof tested positive for increased 18OHF excretion. After correction for total cortisol excretion, 12 subjects showed an abnormally high 18OHF excretion. For genotyping DNA was obtained from 6 of these patients. All tested negative for the hybrid *CYP11B1/CYP11B2* gene and were further analysed for mutations in all exons and promoter regions of both *CYP11B1* and *CYP11B2* by single strand conformation polymorphism (SSCP) and sequencing when appropriate.

The genetic analysis of the two genes revealed the presence of 9 variants in *CYP11B2* and 3 in *CYP11B1*. In addition to published polymorphic sites, we identified 2 new variants in *CYP11B2* but no new variants in *CYP11B1*. The newly identified *CYP11B2* mutations are a C/T single nucleotide exchange located in the first intron and a double nucleotide exchange at the 5 splice site of exon 8. The mutated sequence corresponds to the sequence of *CYP11B1* indicating a gene conversion. This suggests that the mutant is not likely to affect splicing. Thus, none of the genetic variants identified explains the high urinary excretion of 18OHF.

We present here a complete method for the genetic analysis of the *CYP11B1* and *CYP11B2* genes. By this method we could not identify genetic variants responsible for a GRA-like phenotype. The presence of high levels of 18OHF should not be used alone as a diagnosis tool for GRA.

***FOXC2* variation in breast cancer survivors with secondary lymphedema.** *R.L. Miller<sup>1</sup>, E. Feingold<sup>1</sup>, K. Lorenzo<sup>1</sup>, K.L. Levinson<sup>1</sup>, J.W. Dunlap<sup>1</sup>, M.A. Kimak<sup>1</sup>, E.C. Lawrence<sup>1</sup>, A. Soran<sup>4</sup>, V.G. Vogel<sup>2</sup>, J.H. Esman<sup>3</sup>, R.E. Ferrell<sup>1</sup>, D.N. Finegold<sup>5</sup>*. 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Magee-Womens Hospital and UPCI, Pittsburgh, PA; 3) Div. of Physical Medicine and Rehabilitation, UPMC-S, Pittsburgh, PA; 4) NSABP Center, Pittsburgh, PA; 5) Dept Pediatrics, Children's Hospital of Pittsburgh, Pittsburgh, PA.

Secondary lymphedema following treatment of breast cancer develops in 15-20% of breast cancer survivors (Rockson, 2001). There are no well defined differences between surgical technique, grade of tumor, or environmental risk factors that accurately predict who is at the highest risk for developing secondary lymphedema. We hypothesized that genetic variation may predispose a woman to a greater risk for developing secondary lymphedema following breast cancer surgery. Hereditary primary lymphedema is caused by at least two genes, forkhead box C-2 (*FOXC2*) and vascular endothelial growth-factor receptor-3 (*VEGFR3*), which when mutated, alter the development and function of the lymphatic system. We performed detailed sequence analysis of *VEGFR3* and *FOXC2* for 45 cases with secondary lymphedema and 48 controls without secondary lymphedema in our study population of breast cancer survivors. A single non-conservative amino acid substitution, G460E, in *FOXC2* was identified in 2 cases, and no controls. This variation did not occur in 282 alleles genotyped in an unselected mixed Caucasian population. This substitution, outside of the fork-head domain, may provide an increased risk for secondary lymphedema when combined with environmental factors.

**The Dopamine-4 Receptor Gene Associated with Increased Body Mass: A Behavioural Model of Obesity in Two Female Psychiatric Populations.** *R.D. Levitan<sup>1</sup>, M. Masellis<sup>2</sup>, A.S. Kaplan<sup>3</sup>, R.W. Lam<sup>4</sup>, V.S. Basile<sup>2</sup>, C. Davis<sup>3</sup>, P. Muglia<sup>2</sup>, S. Tharlamangam<sup>2</sup>, S.H. Kennedy<sup>5</sup>, J.L. Kennedy<sup>2</sup>.* 1) CAMH, University of Toronto, Department of Psychiatry; 2) Neurogenetics Section, CAMH, University of Toronto, Department of Psychiatry; 3) Eating Disorders Program, University Health Network, University of Toronto; 4) University of British Columbia, Department of Psychiatry; 5) University Health Network, University of Toronto, Department of Psychiatry.

**Background:** There is growing interest in delineating behavioural risk factors for increased body mass. Brain dopamine activity mediates the rewarding properties of food and plays a role in obesity. In the current study we examined whether variation in the dopamine-4 receptor gene (DRD4) was associated with maximal lifetime body mass and obesity in two female psychiatric conditions characterized by overeating. **Methods:** The study sample consisted of 132 women with winter seasonal affective disorder who reported increased intake of high carbohydrate/high fat foods when depressed, and 115 women with binge eating and purging in the context of bulimia nervosa. Maximal lifetime body mass and rates of obesity were compared across the two genotypic groups defined by the presence or absence of the 7-repeat allele of the DRD4 exon III VNTR polymorphism. **Results:** In the overall sample, there was a significant association between the 7-repeat allele and both continuous and categorical measures of increased body mass. The lifetime rates of obesity for individuals with and without the 7-repeat allele were 28.2 % and 13.6 % respectively ( $p=0.0047$ ). This pattern held true in both the SAD group and in the BN group considered separately, with the smaller group of non-depressed bulimics showing a particularly marked effect. Further analysis revealed an association between the 7-repeat allele and binge eating in the SAD group, further supporting a link between DRD4 and increased eating behaviour per se. **Interpretation:** Pending replication in other samples, these results point to a genetic vulnerability factor that could help in the early identification and treatment of females at higher risk for obesity due to pathologically increased eating behaviour.

**TGF1 - SNP Discovery and Evaluation as a Candidate Gene for Asthma in Puerto Rican and Mexican**

**Asthmatics.** *D.L. Lind<sup>1</sup>, S. Choudhry<sup>2</sup>, A. Reinhart<sup>1</sup>, E. Ziv<sup>3</sup>, P.C. Avila<sup>3</sup>, S. Nazario<sup>4</sup>, J. Casal<sup>4</sup>, A. Torres<sup>4</sup>, J.R. Rodriguez-Santana<sup>5</sup>, J. Salas<sup>6</sup>, M. Selman<sup>6</sup>, R. Chapela<sup>6</sup>, W. Rodriguez-Cintron<sup>4</sup>, S.T. Weiss<sup>7</sup>, E.K. Silverman<sup>7</sup>, J.G. Ford<sup>8</sup>, D. Sheppard<sup>2,3</sup>, P.-Y. Kwok<sup>1</sup>, E.G. Burchard<sup>2,3</sup>.* 1) Cardiovascular Research Inst., UCSF, San Francisco, CA; 2) Lung Biology Center, SFGH, San Francisco, CA; 3) Dept of Medicine, UCSF, San Francisco, CA; 4) San Juan VAMC, Univ of Puerto Rico School of Medicine, San Juan, PR; 5) Pediatric Pulmonary Program of Puerto Rico, San Juan, PR; 6) INER, Mexico City, MX; 7) Brigham and Women's Hospital, Boston, MA; 8) The Harlem Lung Center, Harlem Hospital and Columbia Univ, New York, NY.

Transforming growth factor-1 is a multifunctional cytokine that acts as a growth inhibitor in many cell types and also mediates inflammatory responses. We began our investigation of TGF1 as a candidate gene for asthma by performing SNP discovery in 72 asthmatic individuals (24 Mexicans, Puerto Ricans and African Americans) as well as in 120 normal individuals (40 African Americans, Asians and Caucasians). We sequenced the exons and 300 bp flanking each exon as well as 400 bp upstream of the transcription start, covering a total of 4.4 kb. We found 19 SNPs in this region, 5 of which had allele frequencies 5% in the asthmatic or normal individuals. 4 of the 19 SNPs caused amino acid changes, and 2 of these were present at 5% allele frequency in both asthmatics and at least one population of normal individuals. The common SNPs and coding SNPs will be genotyped, making use of the haplotype structure to limit redundancy. The study population will be 583 Puerto Rican and Mexican trios (asthmatic proband and both biological parents) from the Genetics of Asthma in Latino Americans (GALA) study. We chose to study these two populations because in the U.S., Puerto Ricans have the highest asthma prevalence, morbidity and mortality, and Mexicans have the lowest. Genotype data from the trios will allow us to perform TDT analyses. We also have 400 matched control samples, which will allow us to perform case-control analyses. These results will allow us to evaluate TGF1 as a candidate gene for asthma in Puerto Ricans and Mexicans.

**Association Analysis of Genetic Polymorphisms in Sac, Pank4, Casp9, and Cdc212 genes with Type 2 Diabetes in Han People of Northern China.** G. Wu<sup>1</sup>, J. Zhao<sup>2</sup>, C. Yang<sup>1</sup>, H. Wang<sup>4</sup>, J. Zuo<sup>1</sup>, Y. Wang<sup>3</sup>, Z. Liu<sup>1</sup>, Y. Zhang<sup>1</sup>, Y. Shen<sup>5</sup>, B. Qiang<sup>5</sup>, Z. Yao<sup>5</sup>, W. Huang<sup>3</sup>, C. Zhu<sup>3</sup>, F. Fang<sup>1</sup>. 1) National Laboratory of Medical, Institute of Basic Medical Sci, Beijing; 2) Human Genetics Ctr, Univ Texas, Houston; 3) Chinese National Human Genome Center at Shanghai, Shanghai; 4) Peking Union Medical College Hospital, Beijing; 5) Chinese National Human Genome Center at Beijing, Beijing, China.

In our previous genome-wide screen, we have localized the susceptible loci to chromosome 1. 3 regions: 1p36.23~1p36.33, 1q24.3~25.1 and 1q42.12~42.13, were showed evidence of linkage with type 2 diabetes. Sequencing was applied to detect single nucleotide polymorphisms (SNPs) on the promoters and complete coding regions of 34 candidate genes within above three regions in Chinese population, and a case-control study was performed to explore these SNPs correlations with type 2 diabetes mellitus in Han people of Northern China. The 34 genes chosen were sequenced to detect SNPs in 11 cases and 8 controls of Chinese population. Among the detected SNPs, 124 SNPs were chosen to perform case-control study in 147 normal Han people of Northern China and 222 type 2 diabetes patients. 4 SNPs in SAC (Soluble Adenylyl Cyclase) gene were showed significantly statistical difference. One genetic variation (GGT~GGC)(p=0.003) occurred at the 385th amino acid. It does not change the amino acid. But the variant is 15 nucleotides away from the splicing sites of exon11 that is alternatively spliced. SAC represents a novel mammalian adenylyl cyclase structurally, molecularly, and biochemically distinct from the G protein-regulated, transmembrane adenylyl cyclases (tmACs). The sac protein is an evolutionarily conserved bicarbonate sensor. A new mutation in gene Pank4 (Pantothenate Kinase 4) changed the 547th amino acid (V547A), and showed significantly statistical difference (P=0.028). Pank4 gene encodes a key regulatory enzyme in the biosynthesis of coenzyme A (CoA) in mammalian cells. The mutation maybe changes the function of the protein directly. Also SNPs in the introns in gene Casp9 and Cdc212 showed association (P=0.041,P=0.043) between these SNPs and type 2 diabetes.

**Alcohol Dehydrogenase 4 polymorphisms as a risk factor for alcoholism in Brazilian patients.** *M. Zatz<sup>1</sup>, C. Guindalini<sup>1,3</sup>, S. Scivoletto<sup>2</sup>, R.G.M. Ferreira<sup>1</sup>, G. Breen<sup>3</sup>, M. Zilberman<sup>2</sup>, M.A. Peluso<sup>2</sup>, E. Quedas<sup>1</sup>, A. Nishimura<sup>1</sup>.* 1) Human Genome Research Center, Department of Biology, Institute of Biosciences - University of Sao Paulo; 2) GREA Interdisciplinary Group of Studies on Alcohol and Drugs - Institute and Department of Psychiatry, Medicine Faculty - University of Sao Paulo; 3) Section of Genetics, Division of Psychological Medicine, Institute of Psychiatry-Kings College London.

There is much evidence that the variability in alcohol absorption, distribution and metabolism is a result of both genetic and environmental factors. To date the genes with the strongest associations with alcoholism are those that encode the enzymes involved in alcohol metabolism, the alcohol dehydrogenase (ADH2 and ADH3) and the aldehyde dehydrogenase (ALDH2). The aim of this study was to test the influence of three polymorphisms found in the promoter region of the ADH4 gene, comparing a group of Brazilian alcohol dependent patients (n=92) and normal controls (n=92). We found that the allele C at -75bp position and the allele A at -159bp position were significantly over-represented in the patient group. The haplotype analyze showed that the combination of both risk alleles increases the risk of developing alcoholism by 3 times (OR=2.9, 95%CI: 1.47-5.89). These results suggest that ADH4 may play a role in the etiology of alcoholism, since the association is functionally plausible and has a large effect size, although these promising results require further confirmation. FAPESP/CEPID and CNPq supported this work.

**IL1RN variants are associated also in the general population with asthma and IgE levels.** *M. Wjst<sup>1</sup>, H. Gohlke<sup>1</sup>, N. Herbon<sup>1</sup>, C. Braig<sup>1</sup>, M. Bahnweg<sup>1</sup>, J. Heinrich<sup>1</sup>, K. Richter<sup>2</sup>, J. Altmueller<sup>3</sup>, G. Malerba<sup>4</sup>, P. Pignatti<sup>4</sup>.* 1) Institute of Epidemiology, GSF National Research Center for Environment and Health, Munich-Neuherberg, Germany; 2) Pulmonary Research Institute at Grosshansdorf Hospital, Center for Pneumology and Thoracic Surgery, Grosshansdorf, Germany; 3) Genome Mapping Center, Max-Dellbrueck-Zentrum, Berlin-Buch, Germany; 4) Department of Mother and Child, Biology and Genetics, University of Verona, Italy.

Following a genomewide screen in German/Swedish affected sib pair families we previously found linkage with asthma at the 400 kB interleukin-1 gene cluster on chromosome 2q12-2q14. A further screening of more than 150 tightly-spaced SNPs showed significant association on a restricted LD area around the interleukin 1 receptor antagonist IL1RN which could be confirmed in an Italian family study. IL1RN encodes IL-1r, an anti-inflammatory cytokine. We have now further tested 13 SNPs in IL1RN (2234678, 878972, 315936, 392503, 439154, 442710, 447713, 128964, 434792, 454078, 440286, 3087271, 895496) in a population based survey of 590 adult individuals who were participating in the European Community Respiratory Health Survey ECRHS II. 9% had asthma, 18% were bronchial hyperreactive after methacholine provocation and 26% had IgE levels greater than 100 kU/l. 2 of 13 SNPs were also here significantly associated with asthma (315936,  $P=0.024$ ; 454078  $P=0.036$ ). Haplotype-trait associations were even stronger (A-A-A-C-T-C-A-G-G-A-A-A-G,  $P=0.002$ ; A-A-A-C-T-C-G-G-G-A-A-A-A,  $P=0.004$ , G-G-C-T-C-G-A-T-A-G-T-C-G,  $P<.0001$ ). 7 of the tested 13 SNPs showed an association with total IgE levels (again 315936 with  $P=0.016$  and 454078 with  $P=0.006$ ) while BHR was not associated with any SNP. Resequencing of the two IL1RN promoters, association studies with IL-1r serum level, as well as functional studies are underway. We speculate that one of the IL1RN associated SNPs antagonizes the environmental induced IL1-r production leading to inflammation and sensitization of the bronchial system.

**Searching for working memory genes: preliminary data on COMT genotypes.** *H. Xu<sup>1, 2</sup>, G. Bruder<sup>3</sup>, J. Keilp<sup>3</sup>, M. Shihkman<sup>3</sup>, E. Schori<sup>3</sup>, J. Gorman<sup>4</sup>, T.C. Gilliam<sup>1, 2</sup>.* 1) Department of Genetics and Development, Columbia Univ, New York, NY; 2) Columbia Genome Ctr, Columbia Univ, New York, NY; 3) New York State Psychiatric Institute, New York, NY; 4) Mt. Sinai School of Medicine, New York, NY.

Working memory (WM) deficit is a primary cognitive impairment in schizophrenia. In recent studies (Weinberger et al. 2001, Egan et al. 2001), a functional polymorphism in catechol-O-methyl transferase (COMT) gene was suggested as a strong genetic candidate for individual variance in WM ability, as COMT genotype discriminates performance on the Wisconsin Card Sorting Test (WCST). Because the WCST involves many cognitive components in addition to WM ability, more specific WM tests are required to evaluate the above hypothesis. Here we report results from an ongoing study to identify genes affecting WM ability. Healthy adults were tested on several standard WM tests, including spatial delayed response test, word serial position test, n-back test, and letter-number sequencing test. Wais-III vocabulary test and questionnaires were used to control for IQ impact and psychopathology. Saliva swabs provide a source of genomic DNA for genetic analyses. Preliminary analyses were conducted with the first 274 samples to examine the relation between COMT genotype and WM ability. With the exception of the letter-number sequencing test (ANOVA  $p=0.002$ ), no other significant relation was found between performance scores and COMT genotype. The letter-number sequencing test requires more mental manipulation than other WM tests, and consequently may involve greater executive cognitive processing demands. This result suggests that COMT genotype may be related to other components of executive function in letter-number sequencing test and WCST, besides WM ability. To test this hypothesis, additional subjects are being tested on WCST together with the WM tests. Additional candidate genes for WM will be tested as we simultaneously expand sample size. Subjects with extreme scores will be sequenced to identify new genetic candidates for WM function. Genes implicated in WM function will then be evaluated for disease-related genetic variation in a large schizophrenia sample.

**A High Throughput Genetic Association Study of Tractable Genes in Asthma.** *S.G. Pillai<sup>1</sup>, P.L. St. Jean<sup>1</sup>, D.P. Yarnall<sup>1</sup>, M.J. Wagner<sup>1</sup>, S.S. Sundseth<sup>1</sup>, R.M. DeMent<sup>1</sup>, J.H. Riley<sup>1</sup>, S.X. Seghal<sup>1</sup>, T.K. Fleming<sup>1</sup>, S.N. Hill<sup>1</sup>, G.C. Bennett<sup>2</sup>, S.R. Brewster<sup>1</sup>, E.C. Meldrum<sup>3</sup>, I.J. Purvis<sup>1</sup>, L.T. Middleton<sup>1</sup>, D.K. Burns<sup>1</sup>, N.K. Spurr<sup>1</sup>, A.D. Roses<sup>1</sup>, D.A. Hosford<sup>1</sup>, S.L. Chissoe<sup>1</sup>.* 1) Genetics Research, Glaxo SmithKline, RTP, NC, 27709; 2) GSK Corporate Intellectual Property, RTP, NC, 27709; 3) GSK Center for Excellence in Drug Discovery, Stevenage, UK.

Asthma is the most common chronic childhood disease and it affects a substantial adult population. Hence asthma carries significant direct and indirect economic cost. Several studies have reported linkage or association of asthma to various loci and candidate genes using traditional linkage and candidate gene approaches, but none of these discoveries have yet resulted in new therapeutics for asthma. The pharmaceutical industry focuses on a few gene families -tractable genes- which have a track record of supporting development of successful small molecules into therapeutics. Tractable genes relevant to human disease are the keys to the discovery of new effective medicines for diseases with unmet medical needs. With recent advances in the understanding of the human genome sequence and introduction of high throughput genotyping technologies, it is now possible to undertake large-scale association studies using specific genes. We conducted an association study of 5 asthma phenotypes using SNPs in >1200 tractable genes, carefully selected using bioinformatics approaches. Samples from 294 asthma families with at least one asthmatic child, collected from Denmark and Minnesota were genotyped for 2599 single nucleotide polymorphisms (SNPs) from 1200 tractable genes using a high throughput genotyping platform. A total of 3.5 million genotypes were generated and the data were analyzed using transmission disequilibrium test. Preliminary analysis demonstrated 350, 75, 40 and 8 SNPs with a p value of 0.05, 0.01, 0.005 and 0.001 from 259, 59, 33 and 8 genes with significant association with any of the 5 asthma phenotypes respectively. We are following up positive associations using an independent collection of ~500 families from the Genetics of Asthma International Network (GAIN).

**Transcobalamin II polymorphisms influence plasma levels of vitamin B12 but are not major risk factors for neural tube defects.** *F. Pangilinan<sup>1</sup>, D. Swanson<sup>1</sup>, A. Weiler<sup>1</sup>, V. O'Leary<sup>2</sup>, A. Parle-McDermott<sup>2</sup>, M. Conley<sup>3</sup>, C. Cox<sup>3</sup>, T. Frey<sup>1</sup>, A. Molloy<sup>2</sup>, P. Kirke<sup>4</sup>, J. Mills<sup>3</sup>, J. Scott<sup>2</sup>, L. Brody<sup>1</sup>.* 1) National Human Genome Research Institute; 2) Dept. of Biochemistry, Trinity College-Dublin; 3) National Institute of Child Health and Human Development; 4) Health Research Board, Dublin.

Genetic and environmental factors contribute to the etiology of neural tube defects (NTDs). Lower than average maternal plasma levels of cobalamin (vitamin B12) have been associated with NTDs. Bio-available vitamin B12 is carried in plasma by transcobalamin II (TCII). Amniotic fluid levels of TCII are altered in pregnancies affected by NTDs and in unaffected pregnancies in women who have previously given birth to a child with an NTD. Afman and colleagues reported reduced vitamin B12 binding by TCII as a risk factor for NTDs, and Miller and colleagues reported altered levels of holo-TCII due to the TCII P259R polymorphism.

To evaluate the role of TCII polymorphisms in NTD risk, we genotyped two promoter SNPs and four nonsynonymous coding SNPs in 407 NTD cases, their parents and population matched controls. No significant associations between NTD risk and SNP genotypes were observed. To test whether TCII genotype influences plasma vitamin B12 levels we genotyped 236 normal pregnant women for each of the six TCII SNPs. Mean plasma B12 levels were correlated with TCII P259R genotype (TCII 259PP 289.1 87.7 pg/ml, TCII 259PR 315.1 109.8 pg/ml, TCII 259RR 371.6 142.2 pg/ml, ANOVA  $p = 0.0006$ ). Plasma B12 levels were consistent with an allele dosage effect (test for linear trend  $p = 0.0001$ ). An independent, pooled group ( $n = 868$ ) was similarly analyzed and again a correlation between mean plasma B12 levels and TCII P259R genotype was observed ( $p = 0.037$ ). We conclude that although the examined TCII variants do not appear to contribute to NTD risk, the TCII P259R polymorphism may have a significant impact on other aspects of human health through its affect on plasma vitamin B12 levels.

**SNP, cSNP and Indel Associations with Kawasaki Disease(KD) Susceptibility and Outcomes.** *R.M. Cantor-Chiu<sup>1</sup>, J. Yuan<sup>1</sup>, C. Shimizu<sup>2</sup>, S. Cheng<sup>3</sup>, L. Steiner<sup>3</sup>, H. Shike<sup>2</sup>, S.L. Napier<sup>1</sup>, J.W. Newburger<sup>4</sup>, J.C. Burns<sup>2</sup>.* 1) Human Genetics, UCLA Schl of Med, LA, CA; 2) Pediatrics, UCSD Schl of Med, La Jolla, CA; 3) Roche Mol Sys, Alameda, CA; 4) Pediatrics, Boston Childrens Hosp, MA.

KD is an acute childhood vasculitis that causes potentially life-threatening coronary artery aneurysms (CAA) in 25% of untreated patients. It is likely triggered by infectious agents, but a 5-fold increased incidence in Asians (A) vs. Caucasians (C) (.001 vs. .0002), and a sibling relative risk of 10 in C, strongly suggest the effects of genes. However, the low KD incidence coupled with a low sibling recurrence risk (.002) makes the multiplex families, necessary for a powerful linkage study, rare. Thus, a family-based KD association study is in progress. 105 SNPs, cSNPs and indels in 66 genes, previously implicated in inflammation and/or cardiovascular disease, were genotyped with multi-locus assays (Roche Mol Sys) in a 15% A and 85% C sample of trios (a KD child and both parents). Analyses of the current 130 trios found preliminary evidence of : 1)12 polymorphisms more frequent in A than C ( $p < .007$ ), indicating possible KD genes, 2) no detectable HW disequilibrium of polymorphisms in C, 3)preferential transmission of chemokine receptor 5 (CCR5) ( $p = .02$ ), glycoprotein IIIa ( $p = .02$ ), complement component 5 ( $p = .05$ ), apolipoprotein(a) (LPA) ( $p = .05$ ) and hepatic lipase ( $p = .05$ ) polymorphisms to KD patients by exact transmission disequilibrium tests (TDT), 4) preferential transmission of CCR5 ( $p < .005$ ), LPA ( $p < .007$ ), tumor necrosis factor( $p < .03$ ), and interleukin 6 (IL6) ( $p < .05$ ) haplotypes to KD patients by exact multi-allelic TDT analyses, 5)preferential transmission of polymorphisms in the beta-2-adrenergic receptor ( $p < .02$ ), and IL6 ( $p < .03$ ) to 58 KD patients with CAA. These preliminary findings are not corrected for multiple testing. However, they provide specific hypotheses for analysis in this expanding sample of KD trios. More generally, they demonstrate the value of this family-based association design for identifying genetic contributions to infectious disorders having a low incidence coupled with a low sibling recurrence risk.

Program Nr: 2090 from 2003 ASHG Annual Meeting

**Comparative Analysis of Genome-wide Association Studies Targeting Various Complex Human Diseases and Phenotypic Traits.** *A. Braun, M. Longdown, R. Roth, S. Mah, C.R. Hoyal, G. Marnellos, R. Reneland, M.R. Nelson, S. Kammerer.* Sequenom, Inc., San Diego, CA.

Whole genome association studies using single nucleotide polymorphisms (SNPs), the most abundant variations of the genome, were proposed to identify genes that underlie complex traits. We have developed assays and tested over 220,000 public domain SNPs, with a focus on gene-based regions. Of these, over 130,000 SNPs were confirmed as detectably polymorphic (minor allele frequency > 2%) in at least one population. Approximately 105,000 of these are predicted to have unique map positions in the genome. As a large proof-of-concept study, we employed up to 80,000 of these validated SNP reagent sets in a high-throughput approach using case and control DNA pools. More than 800 associations were identified for 12 common diseases or disease-related traits (breast cancer, prostate cancer, lung cancer, melanoma, diabetes type 2, osteoarthritis, schizophrenia, hypertension, HDL-c, bone mineral density, central fat, and general morbidity). We employ a follow-up strategy that is crucial for distinguishing real and reproducible genetic effects from non-reproducible minor effects and false positives. This includes replication of associations in independent samples, analysis of densely spaced SNPs in the regions of interest, re-sequencing to identify potential causal variants, the development of gene-to-disease hypotheses, which lead to functional experiments. Among the discoveries were several genes previously known to be involved in these traits (e.g. PPAR, CETP, AGC1, CD44). Replicable results and the demonstration of functional changes in these new disease targets represent entry points for the development of novel prognostics, clinical diagnostics and potentially treatment interventions.

**Regulatory genes of NFB and their effect on IBD.** *N.P.S. Crawford, M.R. Eichenberger, T.M. McAuliffe, S. Galandiuk.* Digestive Surgery Research Lab, University of Louisville, Louisville, KY.

Inflammatory bowel disease (IBD) encompasses several chronic inflammatory disorders, and is commonly subdivided into ulcerative colitis (UC), Crohns disease (CD), and indeterminate colitis (IC). Nuclear factor (kappa)B (NFB), a transcription factor that is abnormally active in IBD, up-regulates production of pro-inflammatory molecules in response to a variety of stimuli. The Toll-like receptor (TLR) pathway is a prominent NFB activation pathway and is involved in the innate immune response to many pathogens. We hypothesize that mutations in the genes of critical regulatory proteins within these pathways will play a key role in the pathogenesis of IBD. Mutations of these genes will cause abnormal protein function or expression, which in turn will lead to excessive NFB activity and the chronic inflammation characteristic of IBD. We have initially focused on identifying polymorphisms in the regulatory and amino acid coding regions of the *IB* and *IRAK-M* genes, which are near or within IBD susceptibility loci 4 and 2 respectively.

To date, we have found and characterized polymorphisms in both the *IB* and the *IRAK-M* genes. 387 individuals were genotyped (80 controls, 146 CD, 115 UC and 46 IC) for a C/T polymorphism located 29bp upstream of *IB* exon 4. All three sub-groups of IBD had a higher frequency of the C allele (82%CD, 79% UC and 88%IC) as compared to controls (75%). The comparison between controls and the IC group was significant ( $\chi^2 = 5.4$ ,  $p = 0.02$ ). Within *IRAK-M* we identified the G14339A SNP which is responsible for a valine to isoleucine amino acid substitution. No significant differences between the allele frequencies were found.

These findings suggest that *IB* is involved in the pathogenesis of IBD. We will further analyze other genetic polymorphisms of not only *IB* but *IB* and *IB* as well. Further characterization of polymorphisms within *IRAK-M* will be needed to determine if it is involved in IBD susceptibility.

**Identification of molecular variants at the promoter region of the human alpha7 neuronal nicotinic acetylcholine receptor subunit gene but lack of association with schizophrenia.** *C.-H. Chen<sup>1, 2</sup>, H.-M. Liao<sup>1, 2</sup>, C.-H. Li<sup>1, 2</sup>*. 1) Dept Psychiatry, Tzu-Chi General Hosp, Hualien City, Taiwan; 2) Institute of Human Genetics, Tzu-Chi University, Hualien City, Taiwan.

The human alpha7 neuronal nicotinic receptor subunit gene is considered as a candidate gene for P50 sensory gating deficit in schizophrenic patients. Because P50 sensory gating deficit is a common neurophysiological dysfunction in subjects with schizophrenia spectrum disorders, it is conceivable to hypothesize that the human alpha7 neuronal nicotinic receptor subunit gene might be a susceptible gene for schizophrenia. We searched for mutations at the promoter region of the human alpha7 neuronal nicotinic receptor subunit gene and performed genetic association study in 249 unrelated Han Chinese schizophrenic patients and 273 nonpsychotic subjects from Taiwan. Two molecular variants were identified, designated g.213G>A and g.324A>G, respectively. The g.-213G>A variant was found to obliterate a putative NF-1 transcription factor binding site using computer analysis. One out of 249 patients was detected to be a heterozygote of this variant, but none from 273 controls. The g.-324A>G variant was also very rare in both patients and controls, only one heterozygote of this variant was identified in 249 patients and 273 controls, respectively. Our data do not support the human alpha7 neuronal nicotinic receptor subunit gene as a susceptible gene for schizophrenia in our population.

**Association of ARVCF gene on chromosome 22q11 with schizophrenia.** *H.-Y. Chen*<sup>1</sup>, *J.-I. Yeh*<sup>2</sup>, *M.-Y. Li*<sup>1</sup>, *C.-H. Chen*<sup>1, 3</sup>. 1) Institute of Human Genetics, Tzu-Chi University, Hualien City, Taiwan; 2) Department of Family Medicine, Tzu-Chi University, Hualien City, Taiwan; 3) Department of Psychiatry, Tzu-Chi University, Hualien City, Taiwan.

Patients with chromosome 22q11 microdeletion have increased liability to schizophrenia, suggesting that 22q11 locus may harbor schizophrenia susceptible gene(s). ARVCF is a new catenin family gene mapped to 22q11, which has potential function of mediating cell-to-cell communication and intracellular signal transduction. To test if ARVCF gene is a schizophrenic susceptible gene, we systematically screened the ARVCF gene for mutations in Han Chinese schizophrenic patients from Taiwan. Ten single nucleotide polymorphisms (SNPs) were identified, including four nonsynonymous SNPs, V175A, R196Q, P220L, and R915Q. Genetic association study of these 4 missense SNPs with schizophrenia showed excessive homozygosity of P220 in 102 patients compared to 103 controls (odds ratio = 2.38, 95% confidence interval = 1.30-4.35,  $\chi^2 = 8.01$ ,  $p = 0.0046$ ). The association was replicated by increasing the sample size to 319 patients and 316 controls (odds ratio = 1.5, 95% confidence interval = 1.08-2.07,  $\chi^2 = 6.02$ ,  $p = 0.014$ ). Our data suggest that P220 allele of ARVCF is modestly associated with schizophrenia, which may play a modifying role in the pathogenesis of schizophrenia.

**Positional cloning of a novel gene associated with persistent Hepatitis B Virus Infection.** *A.J. Frodsham<sup>1</sup>, S. Best<sup>1</sup>, S. Lobello<sup>2</sup>, C. Venturi-Pasini<sup>2</sup>, H. Thomas<sup>3</sup>, M. Chiaramonte<sup>2</sup>, M.R. Thursz<sup>3</sup>, A.V.S. Hill<sup>1</sup>.* 1) The Wellcome Trust Centre for Human Genetics, University of Oxford, U.K; 2) Istituto di Medicina Interna, Università di Padova, Italy; 3) Imperial College School of Medicine, St Mary's Hospital, London, UK.

Persistent HBV carriage affects over 350 million people in the world and the end stage sequelae of infection account for 1 million deaths each year. The major global health burden is located where rates of HBV persistence are at their highest in regions such as South East Asia and sub-Saharan Africa. Evidence of the involvement of host genetics has been provided by twin studies and association studies with both HLA and non-HLA genes.

A whole genome scan using families from Italy was completed. A locus on chromosome 6q27 was identified that shows strong evidence of linkage to outcome of infection. Fine mapping and further analysis identified several polymorphic markers within a region of less than 150kb that show evidence of association with persistent infection ( $P < 0.05$ ). Examination of the haplotypes in this region also showed a highly significant association with outcome of infection ( $P < 0.001$ ). Analysis of the extent of LD in this region suggests that significant LD extends over at least 250kb.

A strategy of sequencing and SNP genotyping was used to investigate and exclude the closest known gene to this region. LD analysis also confirmed that SNPs in this gene are in different haplotype blocks than the associated markers. Examination of the genomic sequence in the region containing the markers revealed no previously identified genes. However several ESTs (expressed sequence tags) map into this region. Via cDNA amplification and sequencing of liver tissue samples, we have identified a large open reading frame in this region corresponding to an 895 amino acid protein and further analysis is underway to elucidate the role this protein plays in determining the outcome of HBV infection.

**Familial and sporadic endometriosis are genotypically different: The role of liver detoxification genes in the pathophysiology of endometriosis.** *I. Flores<sup>1</sup>, E. Rivera<sup>1</sup>, S. Abac<sup>1</sup>, S. Abreu<sup>2</sup>, C. Rios-Bedoya<sup>2</sup>, A. Santiago-Cornier<sup>3</sup>.*  
1) Department of Microbiology, Ponce School of Medicine, Ponce, PR; 2) Epidemiology and Biostatistics Core Program, Ponce School of Medicine, Ponce, PR; 3) Department of Biochemistry, Ponce School of Medicine, Ponce, PR.

Endometriosis is a multifactorial disease characterized by dysmenorrhea, dyspareunia, and infertility. The cause of this common gynecologic condition remains elusive, although increasing evidence supports the role of genetic susceptibility in disease etiology. Endometriosis has been shown to be associated with polymorphisms in liver detoxification enzymes, including glutathione S transferase (GST), N-acetyl transferase 2 (NAT-2) and cytochrome P450 (CYP). This study was conducted to determine whether associations in these three genes are also found in a Puerto Rican population of endometriosis patients. Cases of endometriosis (n=112) and controls (n=59; females who had no endometriosis as shown by surgery and male volunteers) were genotyped according to standard protocols using either PCR amplification alone or PCR-RFLP. No statistically significant differences were observed between cases and controls in any of the genes studied. However, when endometriosis patients were grouped into familial and sporadic patients, patients with a family history were significantly more likely to have the GST-T1 null mutation than either sporadic patients (p=.002) and controls (p=.035). Moreover, only familial endometriosis was significantly associated with the slow acetylator phenotype of NAT-2 (p=.018; OR=6.6). This study provides evidence for the differentiation of familial and sporadic endometriosis as two different diseases at the genetic level, and supports a role of environmental toxicant exposure in the development of this disease.

**Association of the serotonin receptor 5-HT<sub>5A</sub> with autism.** A.M. Coutinho<sup>1</sup>, G. Oliveira<sup>2</sup>, C. Fesel<sup>1</sup>, C. Marques<sup>2</sup>, A. Ataíde<sup>2</sup>, T. Miguel<sup>2</sup>, L. Borges<sup>2</sup>, A.M. Vicente<sup>1</sup>. 1) Instituto Gulbenkian Ciencia, Oeiras, Portugal; 2) Hospital Pediatrico de Coimbra, Coimbra, Portugal.

Autism is a neurodevelopmental disorder with a complex genetic etiology. Consistent linkage has been found to chromosome 7q, at 7q31 and at 7q35-36 where loci involved in language impairment and restrictive-repetitive behaviors are located. The serotonin receptor 5A (5-HT<sub>5A</sub>), which is expressed only in the central nervous system and thus likely mediates the central effects of serotonin, is located on 7q36.1. Association of the *HTR5A* gene with affective disorders has been reported, and knockout mice for this gene show behavior alterations. We tested the involvement of *HTR5A* in autism susceptibility and in the specific autism-associated phenotype indexed by the total scores for algorithm items of the area of Restricted, Repetitive Behavior and Interests of the Autism Diagnostic Interview-Revised (ADI-R) (D total score). Three SNPs were tested (-19G/C and -18C/T in 5' UTR, and 12A/T in exon 1) in 194 nuclear families (including 202 probands). Using the Transmission Disequilibrium Test an association with the marker -18C/T was found ( $P=0.012$ ), with allele -18C more often transmitted than -18T ( $\chi^2=6.1$ , 1 df,  $P=0.0136$ ), and a preferential paternal transmission ( $\chi^2=7.2$ , 1 df,  $P=0.0073$ ) suggestive of maternal imprinting. Haplotypes of the three markers were also associated with autism ( $P=0.033$ ). Kruskal-Wallis one-way ANOVA was used to test the association of *HTR5A* genotypes with the Restricted, Repetitive Behavior and Interests scores (D total score). The exon 1 marker 12A/T was found to be associated with the D total score distribution, with higher mean scores, which reflect an increased severity of the abnormal behavior, associated with genotype 12A/12A ( $H=6.26$ , 1 df,  $P=0.0124$ ) and lower mean scores associated with genotype 12A/12T ( $H=11.3$ , 1 df,  $P=0.0008$ ). Our data suggest a role of *HTR5A* variants in the susceptibility to autism and in the determination of repetitive and stereotyped behaviors, likely including complex interactions with other molecules of the 5-HT system.

**Human variants of SCN1, a modifier gene on chromosome 1q21.** *D.A. Buchner, M. Trudeau, M.H. Meisler.*  
Human Genetics, University of Michigan, Ann Arbor, MI.

The severity of many Mendelian disorders is influenced by genetic background. We recently identified a modifier gene in the mouse, *Scnm1*, that converts a chronic movement disorder into a lethal disease. The primary mutation (*med<sup>J</sup>*) changes a splice donor site of the mouse sodium channel gene *Scn8a* (*Na<sub>v</sub>1.6*) and results in a mixture of wildtype transcripts (10%) and exon-skipped mutant transcripts (90%). The modifier mutation was identified using sequence databases to compare resistant and susceptible inbred strains. A premature stop codon was identified in the nuclear zinc finger protein, *SCNM1*. The effect of the modifier mutation is to reduce the proportion of correctly spliced sodium channel transcript to 5% of total, which is below the threshold for survival. The identity of the modifier gene was confirmed by transgenic rescue of the *C57BL/6J-med<sup>J</sup>/med<sup>J</sup>* lethal phenotype. A survey of 36 inbred strains demonstrated that the R187X allele was present only in the closely related C57 and C58 related strains, indicating that the mutation arose in a common ancestor approximately 80 years ago. The *SCNM1* protein contains a bipartite nuclear localization signal, a U1C-like zinc finger domain, and a C-terminal acidic domain, and is predicted to function in 5' splice site selection.

The naturally occurring variant of *Scnm1* in strain *C57BL/6J* was phenotypically unrecognized until it was combined with the second-site mutation in *Scn8a*. The human ortholog, *SCNM1*, is located on chromosome 1q21. To determine whether variants of *SCNM1* are present in the human population, we have screened 179 genomic DNA samples by exon amplification and conformation sensitive gel electrophoresis. Nine individuals (4%) were heterozygous for four different coding variants. Two variants are nonconservative substitutions in evolutionarily conserved residues. By analogy with the *C57BL/6J* mouse, we suggest that functionally compromised variants of *Scnm1* may contribute to the severity of human disorders caused by splice site mutations in unlinked genes.

**Association of *IL4R* haplotypes with Multiple Sclerosis.** *D.B. Mirel*<sup>1</sup>, *J. Wang*<sup>1</sup>, *H.A. Erlich*<sup>1</sup>, *S.L. Hauser*<sup>2</sup>, *L.F. Barcellos*<sup>2</sup>, *J.R. Oksenberg*<sup>2</sup>. 1) Dept. of Human Genetics, Roche Molecular Systems, Inc, Alameda, CA; 2) Dept. of Neurology, University of California, San Francisco; San Francisco CA.

We have investigated, in 332 single-case families, the association of multiple sclerosis (MS) with ten SNPs in the *IL4R* gene. *IL4R* encodes a subunit of the interleukin-4 receptor, a molecule important to cytokine signaling and T-helper cell development. We have genotyped all individuals at eight SNPs within the *IL4R* coding region: I50V, N142N, E375A, L389L, C406R, S478P, Q551R, and S761P, and at two promoter SNPs: C(-3223)T and T(-1914)C. We restricted our study to families where the subject was affected with either the Relapsing Remitting (RR) or Secondary Progressive (SP) course of MS, and stratified families according to presence of the MS-predisposing *HLA*-DR2 haplotype (DRB1\*1501-DQB1\*0602).

The association of individual *IL4R* SNPs with MS was examined using the Transmission-Disequilibrium Test. None of the ten SNPs individually showed an association, even after *HLA*-DR2 stratification. However, as there is strong linkage disequilibrium among these SNPs we could infer the transmission of ten-locus haplotypes in families using the TRANSMIT program of Clayton (1999). By identifying haplotypes (complex alleles) in the MS families, stratified for *HLA* genotype, we have observed significant evidence of association of the *IL4R* gene to MS. In particular, we have identified a specific susceptibility haplotype, and observe that this complex allele confers MS risk in individuals not carrying the *HLA* DR2 genotype (odds ratio = 1.4, adjusted P = 0.026). The MS susceptibility *IL4R* haplotype identified here is distinct from the type-1 diabetes protective haplotype we have previously described (Mirel et al. 2002; Bugawan et al. 2003). These findings further support an important role for the *IL4R* gene and its alleles in immune-related disease susceptibility, and illustrate the value of utilizing multi-SNP haplotype information in association studies.

**Differential gene expression in central human retina by a comparative microarray approach.** *D. Hornan<sup>1</sup>, S. Peirson<sup>2</sup>, A. Hardcastle<sup>1</sup>, A. Bird<sup>1</sup>, S. Bhattacharya<sup>1</sup>, R. Foster<sup>2</sup>, R. Molday<sup>3</sup>, A. Webster<sup>1</sup>.* 1) Department of Molecular Genetics, Institute of Ophthalmology, London, UK; 2) Department of Integrative and Molecular Neuroscience, Imperial College London, UK; 3) Department of Biochemistry and Molecular Biology, University of British Columbia, Vancouver, Canada.

The central human retina contains many more cone photoreceptors than the peripheral retina. Cones are essential for precise vision and are known to express specific opsins and other proteins that form part of the phototransduction cascade. However, much more is known about gene expression in the rod-rich peripheral than the cone-rich central retina.

We used human 2mm foveo-macular and 4mm macular punches, and sections of mid-peripheral retina to study differential gene expression. By combining multiple microarray experiments with quantitative PCR and cutting-edge statistical and bioinformatic analyses, we identified both known and unknown retinal genes.

Two novel retinal genes are expressed at levels approaching that of red/green cone opsin in the central human retina. Two other genes, also found to be over-expressed in central human retina, are involved in the cellular response to stress.

The genes uncovered in this study will provide insight into the role of the central retina in precise vision. They are also likely to be involved in diseases of the macula and fovea such as age-related macular degeneration.

Program Nr: 2100 from 2003 ASHG Annual Meeting

**-sarcoglycan, a gene in which variants cause Myoclonus-Dystonia Syndrome, may also contain Schizophrenia vulnerability variants.** *M. Mineta*<sup>1</sup>, *H. Ishiguro*<sup>2</sup>, *M. Egan*<sup>3</sup>, *J. Taubman*<sup>1</sup>, *B. Kolachana*<sup>3</sup>, *T. Rowe*<sup>1</sup>, *R. Lipsky*<sup>1</sup>, *G.R. Uhl*<sup>2</sup>, *D.R. Weinberger*<sup>3</sup>, *D. Goldman*<sup>1</sup>. 1) Laboratory of Neurogenetics, NIAAA / NIH, Rockville, MD; 2) Molecular Neurobiology Branch, NIDA / NIH, Baltimore, MD; 3) Clinical Brain Disorders Branch, NIMH / NIH, Bethesda MD.

The -sarcoglycan (SGCE) gene encodes transmembrane components of the dystrophin-glycoprotein complex. SGCE loss-of-function mutations cause a myoclonus-dystonia syndrome (MDS) that often includes prominent psychiatric abnormalities. Since the SGCE gene is localized to the Chr 7q21-q22 region that has been implicated in schizophrenia in previous genome scans, SGCE variants are candidates to play roles in schizophrenia. Imprinting at this locus is supported by findings that include MDS transmission through predominantly paternally-inherited alleles. We now report that sixteen-locus transmission disequilibrium testing (TDT) in 114 Caucasian schizophrenia trios provides evidence for significant linkage and association ( $p < 0.005$ ) with a ca. 100kb conserved haplotype block that includes SGCE. We are evaluating the effects of SGCE haplotypes on expression to determine whether this gene or surrounding genes in this haplotype block harbor variants that contribute to susceptibility to schizophrenia.

**A complete map of sequence variation in the DTNBP1 high-risk haplotype from schizophrenics in the Irish Study of High Density Schizophrenia Families.** *B. Riley<sup>1</sup>, D. Thiselton<sup>1</sup>, B. Wormley<sup>1</sup>, R. Ribble<sup>1</sup>, G. Frank<sup>1</sup>, E.J.C.G. van den Oord<sup>1</sup>, D. Walsh<sup>2</sup>, F.A. O'Neill<sup>3</sup>, K.S. Kendler<sup>1</sup>.* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Depts. of Psychiatry and Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) The Health Research Board, Dublin, Ireland; 3) Department of Psychiatry, Queens University, Belfast, Northern Ireland.

We have previously shown association of markers in the dystrobrevin binding protein 1 (DTNBP1) gene with schizophrenia, identified a haplotype block of 30.1 Kb covering exons 1 to 5 of this gene, and identified one high risk haplotype from the six common haplotype structures within this block in the Irish Study of High Density Schizophrenia Families (ISHDSF). Another of the six common haplotypes has been identified as high risk in a sample of German families and trios. We have selected all genetically independent, narrowly-defined ISHDSF cases with the Irish high risk haplotype and controls with the most closely related haplotype for sequence analysis to identify variation that maps specifically to the high-risk haplotype and that may account for the increased risk, as well as to catalogue the complete range of sequence variation within this region. At the time of submission, with >90% of the sequence complete, we have identified 37 SNPs, with average SNP density across the region of 1.6/Kb. Although higher than the genome-wide average, this is likely a result of inclusion of the numerous repeat motifs occurring in this gene in our analyses, rather than an indication of higher than normal variation in this gene. We have also identified 6 additional polymorphisms, three ins/del polymorphisms of 4, 6 and 10 bp, a mononucleotide T-repeat, a dinucleotide A/C repeat and a complex 31 bp sequence variant. Of these, two (5.4%) of the SNPs and one allele of the T-repeat map specifically to our high-risk haplotype. All three of these polymorphisms map to a 3 Kb segment of intron 3. Polymorphisms from the map of haplotype-specific variation in the ISHDSF provide candidate are being tested in family, case-control and triads samples from Ireland at the time of submission.

**Gene Expression Changes in Suicides with and without Major Depression.** *G. Turecki*<sup>1</sup>, *A. Sequeira*<sup>1</sup>, *F. Gwadry*<sup>2</sup>, *L. Canetti*<sup>1</sup>, *Y. Gingras*<sup>1</sup>, *J. Ffrench-Mullen*<sup>2</sup>. 1) Dept Psychiatry, Douglas Hosp, McGill Univ, Montreal, PQ, Canada; 2) Gene Logic Inc, Gaithersburg, MD.

Classical binding and biochemical approaches have pointed out to a large number of possible biological markers for suicide. However, these classical approaches have produced conflicting results. Gene expression profiling at the level of mRNA by means of cDNA microarrays offers the possibility to study the expression patterns of thousand of genes in parallel. The purpose of this study was to test the hypothesis that brain gene expression profiles are associated specifically with suicide and with major depression. Total mRNA was isolated from 7 selected brain cortical areas from 20 suicide cases (10 with and 10 without major depression) and 10 matched controls using the Affymetrix HG-U133 chip set. At the  $p < 0.001$  level, the number of fragments differentially expressed was of 685 between controls and suicides with major depression, 106 between controls and suicides and 233 between suicides with major depression and suicides without major depression. Two biologically relevant genes were selected for further investigation based on expression patterns that were significantly and consistently different between groups. These were Spermine/Spermidine N1-acetyltransferase (SAT) gene and the insulin-like growth factor binding protein (IGFBP 7) gene. SAT is the rate-limiting enzyme in the biosynthesis of polyamines, which play a key role in protein synthesis, cell proliferation, and neuronal plasticity and is implicated in the cellular response to stress. Insulin-like growth factor binding proteins are soluble proteins that regulate IGF (insulin growth factor) availability in body fluids and tissues and that modulate IGF binding to its receptors. SAT and IGFBP7 genes alterations were confirmed by means of RT-PCR and immunohistochemistry in the same brain samples. In conclusion, gene alterations investigation in post-mortem human brains by means of microarray analysis have produced consistent results and showed specific differences associated with suicide and major depression.

**Characterization of a Translocation Breakpoint on Chromosome 20 in a Pair of Autistic Twins.** *R. Sultana*<sup>1</sup>, *W.H. Raskind*<sup>2,5</sup>, *C.M. Disteché*<sup>3</sup>, *F. Cortes*<sup>7</sup>, *F. de la Barra*<sup>8</sup>, *G.D. Schellenberg*<sup>2,4,6</sup>, *E.C. Villacres*<sup>1</sup>. 1) Psychiatry & Behavioral Sciences; 2) Medicine; 3) Pathology; 4) and Neurology, Univ Washington; 5) MIRECC; 6) and GRECC at SVAMC Seattle, WA; 7) Genetic and Metabolic Diseases Unit, INTA; 8) and Psychiatry and Mental Health Department, Univ Chile.

A pair of autistic twins with a t(7;20) (q11.2; p11.2) was analyzed to identify the chromosome 20 gene disrupted by the translocation. Previously a novel gene (AUTS2) that spans this 7q11.2 breakpoint in these twins was cloned. To determine the position of chromosome 20 breakpoint we generated somatic cell hybrids between a lymphoblastoid cell line from one of the twins and Chinese Hamster Ovary (CHO) cells. Two hybrids, one with the derivative chromosome 7 and the other with derivative chromosome 20, were used to narrow the region of this breakpoint. STS markers from BAC clones that had been mapped to 20p11.2 by FISH were selected for STS content mapping of the two hybrid cell lines. Initial STS content mapping of the hybrids mapped the 20p11.2 breakpoint to a 27 Mb region of NT\_001387. Additional primer pairs were designed to further narrow the breakpoint to a 61 Kb chromosome 20 region. To amplify a fragment spanning this breakpoint five chromosome 20 primers from the 61 Kb region were used in long-range PCR, each paired with a chromosome 7 primer within 500 bp of the breakpoint. The PCR fragment amplified in this manner was sequenced and the location of the breakpoints determined on chromosomes 7 and 20 sequences by BLAST analysis. The breakpoint maps to position +/- 26008190 and +/- 25685711 of the chromosome 20 sequence in a duplicated segment of chromosome 20. Which one of these two chromosome 20 sites is disrupted by this breakpoint has yet to be determined. Sequencing of a larger DNA fragment across the breakpoint and analysis of single nucleotide polymorphic sites present in the two duplications will give information about the exact location of this breakpoint within this segmental duplication of chromosome 20. The effect of this translocation on chromosome 20 genes in the vicinity of the breakpoint will be analyzed. Analysis of these patients can lead to the identification of gene defects that cause autism.

**A meta-analysis of association and linkage between the dopamine transporter gene (DAT1) and childhood ADHD.** *I.D. Waldman.* Psychology, Emory University, Atlanta, GA.

Recently, a number of studies have examined association and linkage between candidate genes in the dopaminergic neurotransmitter system and childhood attention-deficit hyperactivity disorder (ADHD). Several studies have demonstrated association and linkage between ADHD and a number of these genes, specifically the dopamine receptor D4 and D5 genes (i.e., DRD4 and DRD5) and the dopamine transporter gene (i.e., DAT1), whereas some studies have failed to replicate these relations. In this study, we examine linkage and association between ADHD and a functional polymorphism in the 3' untranslated region of DAT1 via a meta-analysis of effect sizes derived from transmission disequilibrium test results from 18 independent samples. We tested for association and linkage between DAT1 and ADHD (i.e., whether the relative risk [RR] was significantly greater than 1) across studies, as well as whether there was significant heterogeneity in the effect sizes. We also conducted similar analyses for DRD4 and ADHD to compare the magnitude of effect sizes to that for DAT1. Results from meta-analyses of data from 18 samples suggest association and linkage of both DAT1 and DRD4 with ADHD (RR = 1.14,  $p = .073$  and RR = 1.4,  $p = .004$ , respectively). Despite the similar relative risks for these two genes, their level of significance differed markedly. This is due to the fact that there was little heterogeneity in the effect sizes for DRD4, but substantial heterogeneity in the effect sizes for DAT1, suggesting that systematic differences in the samples and / or methods of these studies may be contributing to differences in the relation of DAT1 and ADHD. In an attempt to explain the heterogeneity in the DAT1 effect sizes, we are testing for the potential moderating role of several variables, including the magnitude of DRD4 effect size, the location of the study (i.e., US / Canada versus UK / Europe / Asia), the proportion of ADHD subtype diagnoses (i.e., Combined versus Inattentive type), the rates of overlapping diagnoses (e.g., of Oppositional Defiant and Conduct Disorder), the proportion of male participants, and the assessment method used (i.e., interview versus questionnaire).

**Identification of autism susceptibility genes on 7q31 using cytogenetic abnormalities.** *J.B. Vincent<sup>1,2</sup>, S. Choufani<sup>2</sup>, D. Kwasnicka<sup>2</sup>, J. Skaug<sup>2</sup>, S.W. Scherer<sup>2</sup>.* 1) Neurogenetics Sect, R30, Ctr Add/Mental Hlth, Toronto, ON, Canada; 2) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto.

We have attempted to identify candidate autism susceptibility genes by combining evidence from genetic linkage studies of autism, and cytogenetic abnormalities in patients with autism to search for susceptibility genes for autism on chromosome 7. Evidence for a gene or genes for autistic disorder on chromosome 7q has been documented by a number of genome-wide linkage studies. Supporting evidence for an autism susceptibility locus on 7q has come from cytogenetic studies of autism patients with chromosomal abnormalities on 7q. We have now identified four autism patients with chromosomal aberrations mapping to 7q, within the region implicated by the linkage studies: HSC1: t(7;13)(q31.2;q21); HSC2: t(5;7)(q14;q31); HSC3: t(6;7)(p12;q22); HSC4: t(7;11)(q31;q25). Using fluorescence in situ hybridization we have mapped the breakpoints for the patients abnormal chromosomes, and have identified and cloned several novel genes (RAY1/ST7 and TCAG\_4133353, HSC1 and HSC2 respectively) and identified several other known genes (KCND2, NPTX2, FOXP2, for HSC2, HSC3 and HSC4 respectively) that are either disrupted by or are adjacent to the breakpoints. The breakpoints for HSC1, HSC2 and HSC4 are all within 5Mb of each other on 7q31. Using denaturing high performance liquid chromatography and DNA sequence analysis, we have screened a number of the candidate genes for mutations among over 90 multiplex autism families, and have identified a number of rare DNA variants. For KCND2, a gene encoding a brain-specific potassium voltage-gated channel, several amino acid sequence variants were identified in exon 5, including N490D variant present in both affected and one unaffected sibling in one family, and N544S, present in both affected siblings of a second family. We have identified a number of variants within exons of the putative non-coding gene, TCAG\_4133353, which spans the HSC2 breakpoint, including a polymorphic 300bp insertion/deletion. Using RT-PCR we are currently studying expression of genes near the breakpoints to determine whether transcription is being disrupted via a position effect.

Program Nr: 2106 from 2003 ASHG Annual Meeting

**Large-Scale SNP Typing Of Candidate Genes For Susceptibility To Malaria.** *A.J. Walley, C. Aucan, A.V.S. Hill.*  
Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, United Kingdom OX3 7BN.
